114.11 Advanced Examples

These examples are intended to demonstrate basic programming in MAGMA using the functions of this chapter together with a few from Chapter 112. There is little or no explanation of the geometry behind the examples. We assume here that you are familiar with that and are really interested in the problem of realising it in MAGMA.

114.11.1 Trigonal Curves

We discuss a particular example covered by Petri's theorem. In fact, we write down a curve C of genus 8 which is trigonal. We discover this easily since its canonical embedding is not cut out by quadrics. It would be nice to have automatic functions to recognise the equations of the surface scroll cut out by the quadrics, but at the moment they don't exist so we have to make that calculation by hand.

Example H114E37

First we make the curve and compute its canonical model.

```
> k := Rationals();
> P<X,Y,Z> := ProjectiveSpace(k,2);
> C := Curve(P,X^8 + X^4*Y^3*Z + Z^8);
> Genus(C);
8
> phi := CanonicalMap(C);
> P7<a,b,c,d,e,f,g,h> := Codomain(phi);
> CC := phi(C);
> CC;
a^3*e + d^4 + d^2*h^2
a^3*f + d^3*e + d*e*h^2
a^3*g + d^3*f + d*f*h^2
a^3*h + d^3*g + d*g*h^2
a^2*b + d^3 + d*h^2
a^2*c + d^2*e + e*h^2
a*b*c + d^2*f + f*h^2
a*c^2 + d^2*g + g*h^2
b*c^2 + d^2*h + h^3
-a*c + b^2  -a*e + b*d  -a*f + c*d  -a*f + b*e
-a*g + c*e  -d*f + e^2  -a*g + b*f  -a*h + c*f
-d*g + e*f  -d*h + f^2  -a*h + b*g  -b*h + c*g
-d*h + e*g  -e*h + f*g  -f*h + g^2
```

In this example, we can see all the quadrics which cut out the canonical model CC. But even if we could not, or if computing the full canonical ideal was too difficult, we can compute the conics in the canonical ideal separately using only linear algebra.

```
> SC := Image(phi,C,2);
> SC;
a*c - b^2  a*e - b*d  a*f - c*d  a*g - c*e
```

```
a*h - c*f  b*e - c*d  b*f - c*e  b*g - c*f
b*h - c*g  d*f - e^2  d*g - e*f  d*h - f^2
e*g - f^2  e*h - f*g  f*h - g^2
> Dimension(SC);
2
```

We would like to identify the scroll SC. Even better, we would like to find a map from a ruled surface to this scroll and pull the image curve CC back to this ruled surface. Then the fibres of the ruling will cut out the g^1_3 on C giving its trigonal structure. We will also see the Maroni invariant of C directly. In this case one immediately recognises the equations of the scroll so can write down the ruled surface and choose the bidegree of linear system which gives the map to the scroll.

```
> F<r,s,u,v> := RuledSurface(k,2,4);
> psi := map< F -> P7 | [ m : m in MonomialsOfWeightedDegree(F,[0,1]) ] >;
> SF := psi(F);
> DefiningIdeal(SF) eq DefiningIdeal(SC);
true
```

To realise the curve's trigonal structure, we need to create a divisor by intersecting it with a fibre of the ruling. The natural way would be to pull the curve back to F via psi and work there. However, MAGMA currently cannot create divisors that lie on curves on scrolls.
Luckily, we *can* work with the image `CC` in `P7` and obtain the divisor `D` of the image of a fibre under `psi` intersected with `CC` for our g^1_3. This is then used to define a $3-1$ map to the projective line.

```
> fib := psi(Scheme(F,r));
> Dimension(fib);
1
> D := Divisor(CC,fib);
> Degree(D);
3
> #Basis(D);
2
```

So `D` really does give us a g^1_3. To get the map to P^1, we can pull it back to `C`, but it is faster to compose the divisor map on `CC` with `phi`. Proceeding this way, it is then a good idea to use the function field of `C` to simplify the map description.

```
> phiD := DivisorMap(D);
> mpD := Expand(Restriction(phi,C,CC)*phiD);
> FC := FunctionField(C);
> rat := FC!(p1/p2) where p1,p2 := Explode(DefiningPolynomials(mpD));
> mpD := map<C->Codomain(mpD)|[rat,1]>; mpD;
Mapping from: CrvPln: C to Projective Space of dimension 1
Variables : $.1, $.2
with equations :
X^7 + X^3*Y^3*Z
Z^7
```

114.11.2 Algebraic Geometric Codes

MAGMA includes functions for working with codes which arise from algebraic geometry. Discussion of these functions is left to the chapter on error-correcting linear codes, Chapter 152. As is well known, these codes are often created using Riemann–Roch spaces of divisors on curves. Here we demonstrate the creation of such a code taken from the book of van Lint and van der Geer [vLvdG88]. This is a famous example which arises many times in that book, as Example II (3.12) for instance.

Example H114E38

This code is based on the Klein quartic over the finite field $F8$ of 8 elements, a curve that we define immediately. Notice that we start by defining a curve C over the field of 2 elements. This is so that we can investigate C over small fields while still being able to work over $F8$ later.

```
> F2 := FiniteField(2);
> F4<t4> := FiniteField(4);
> F8<t8> := FiniteField(8);
> P<x,y,z> := ProjectiveSpace(F2,2);
> C := Curve(P,x^3*y + y^3*z + z^3*x);
> C8<a,b,c> := BaseChange(C,F8);
> C8;
Curve over GF(2^3) defined by
a^3*b + a*c^3 + b^3*c
```

The code will have length 24, corresponding to the 24 rational points of C.

```
> #RationalPoints(C8);
24
```

In constructing such codes, one must have a collection of points, in this case the 24 rational points we have just found, and a divisor whose support is disjoint from these points. As the divisor, we take some multiple of a conjugate pair of points defined over the finite field of 4 elements. In MAGMA, it is convenient to use the function field machinery to describe this as a place of degree 2. It is constructed as the intersection of C with one of its bitangents.

```
> L := Curve(P,x+y+z);
> IntersectionPoints(C,L);
{@ @}
> C4 := BaseChange(C,FiniteField(4));
> P4 := Ambient(C4);
> L4 := BaseChange(L,P4);
> IntersectionPoints(C4,L4);
{@ (t4 : t4^2 : 1), (t4^2 : t4 : 1) @}
> [ IntersectionNumber(C4,L4,p) : p in $1 ];
[ 2, 2 ]
```

So we see that L is indeed a bitangent of C and that the two points of intersection are defined properly over the finite field of 4 elements. In order to be able to compute the Riemann-Roch

space of a divisor, we compute this intersection as a place on $C8$. Notice how the support of the divisor D is not used in its display until it has been explicitly computed.

```
> FP8<X,Y> := FunctionField(Ambient(C8));
> Div := DivisorGroup(C8);
> D := Divisor(Div,X + Y + 1);
> D;
Divisor on Curve over GF(2^3) defined by
a^3*b + a*c^3 + b^3*c
> Decomposition(D);
[
    <Place at (0 : 1 : 0), -3>,
    <Place at (1 : 0 : 0), -1>,
    <Place at ($.1 + 1 : $.1 : 1), 2>
]
> D;
Divisor -3*Place at (0 : 1 : 0) + 2*Place at ($.1 + 1 : $.1 : 1) -
1*Place at (1 : 0 : 0)
```

This divisor contains the place we require with multiplicity 2 and some negative contributions at infinity. We extract the degree 2 place we need.

```
> p := Support(D)[2];
> Degree(p);
2
```

Now we can make the code. Rather than using the rational points of $C8$, the code creation intrinsic takes a sequence of degree 1 places. But they are also easily retrieved. The divisor we use will be $3p$.

```
> G := 3*p;
> S := Places(C8,1);
> #S;
24
> AGC := AlgebraicGeometricCode(S,G);
> Dimension(AGC);
4
```

In fact, it is the dual code that is really wanted, but this is easy.

```
> Dual(AGC);

114.12 Curves over Global Fields

114.12.1 Finding Rational Points

There are also various point search routines for more general schemes.

`PointsCubicModel(C, B :` *parameters*`)`

`OnlyOne`	BoolElt	*Default :* `false`
`ExactBound`	BoolElt	*Default :* `false`
Verbose	`CubicModelSearch`	*Maximum :* 1

Given a plane cubic over the rationals, this function searches, by a reasonably efficient method due to Elkies [Elk00], for a point on C of naïve height up to B — the asymptotic running time is $O(B)$.

If `OnlyOne` is set to `true`, the search stops as soon as it finds one point; however, the algorithm is p-adic and there is no guarantee that points with small co-ordinates in $\mathbf{Z}$ will be found first. If `ExactBound` is set to `true`, then points that are found with height larger than B will be ignored.

Example H114E39

```
> P<x,y,z>:=ProjectiveSpace(Rationals(),2);
> C:=Curve(P,x^3+9*y^3+73*z^3);
> time PointsCubicModel(C,10^4);
[ (31/2 : -15/2 : 1), (-353/824 : -1655/824 : 1), (-463/106 : 111/106
: 1), (-1 : -2 : 1), (-2347/526 : 635/526 : 1), (-206/5 : 99/5 : 1),
(22/5 : -13/5 : 1), (-43/16 : -29/16 : 1), (-25 : 12 : 1), (-4493/1076
: -299/1076 : 1), (-215/47 : 64/47 : 1), (-631/151 : -22/151 : 1), (-4
: -1 : 1), (278/193 : -393/193 : 1), (-328/55 : 137/55 : 1), (311/88 :
-207/88 : 1), (145/71 : -148/71 : 1) ]
Time: 2.790
```

114.12.2 Regular Models of Arithmetic Surfaces

Let F be a global field (the rationals, a number field or a function field) with ring of integers O_F. Given a curve C over F with integral defining equations, the associated *arithmetic surface* is the scheme of relative dimension 1 over SpecO_F defined by the same equations. In MAGMA, one can compute a regular model of the arithmetic surface locally at a given prime of O_F, and extract information from it. The 'model' is a data structure which contains several affine patches with maps between them, as well as the components of the special fibre, and other data. This raw data is quite bulky; the interesting information is accessed via the functions described in this section. This functionality may be expanded (on request) in later versions.

The MAGMA category for these data structures is `CrvRegModel`.

Caveat: in the initial implementation there are some restrictions on which curves, and which fields, can be handled. These restrictions are not documented here, and may be lifted in the near future.

114.12.2.1 Creation of Regular Models

`RegularModel(C, P)`

Verbose `RegularModel` *Maximum :* 2

This computes a regular model of the curve C at the prime P. Here C is a curve over a field F (the rationals, a number field or a univariate rational function field), and P is a prime of the maximal order O_F of F (given as an element or as an ideal). The defining equations of C must have integral coefficients, and the reduction of C modulo P must have dimension 1.

The function returns a model of C: this consists of several affine patches, given by integral equations, which together describe a scheme over O_F whose generic fibre is isomorphic to C. (The gluing maps, and the isomorphism to C, are part of the stored data). The model is regular on the special fibre above P. However it is not necessarily a minimal model.

In some cases, the function may replace F by a finite extension L/F in which P is unramified, and return a regular model for the base change C_L. (This occurs when there is a non-regular point or component in the special fibre that is not geometrically irreducible over the residue field.) When this occurs, a warning message is printed.

114.12.2.2 Using Regular Models

`IntersectionMatrix(M)`

Given a regular model, this returns a matrix whose entries are the intersection multiplicities of the (reduced, irreducible) components of the special fibre. Secondly, it returns a sequence giving the multiplicities of the components. (The components of the model always come in the same order.)

`ComponentGroup(M)`

Given a regular model of a curve C at a prime P, this returns (as an abstract abelian group) the group of components of the Neron model of the Jacobian of C over the completion at P. (This is computed from the `IntersectionMatrix` of the model.)

`PointOnRegularModel(M, x)`

Given a regular model of a curve C over a global field F, and a point $x \in C(F)$, this lifts x to a point on the regular model. More precisely, it finds a patch of the model, and a point on the generic fibre of that patch which maps to x (under the isomorphism between the generic fibres of M and C).

Three objects are returned: a sequence giving coordinates of the point, a sequence containing the equations of the relevant patch, and (for internal use) the 'index' of the patch.

114.12.3 Minimization and Reduction

Minimization and reduction is a search for a linear transformation, that leads to nice equations. The general strategy is described in Section 116.4.4.

Here, we describe the routines for the minimization of plane quartic curves and the reduction for plane curves of degree at least 3. The reduction is done by constructing a cluster of special points on the curve. Thus, we start with this.

`ReduceCluster(X)`

`eps`	FldReElt	*Default :* 1e-6
`c`	FldReElt	*Default :* 1
Verbose	`ClusterReduction`	*Maximum :* 3

Here X is a sequence of n-dimensional vectors of complex numbers. The routine returns the cluster in a better embedded form, the transformation matrix applied and its inverse.

Optional arguments: `eps` is the bound used to decide whether a floating point number is zero, and `c` is the initial value of the acceleration factor.

The algorithm is due to Stoll (see [Sto11]).

This routine can be used for reduction of any variety that has a finite and stable set of special points, by using the transformation that reduces the point set.

`ReducePlaneCurve(f)`

Here f is a homogeneous polynomial in 3 variables of degree > 2 with integral or rational coefficients. A new polynomial and the transformation matrix applied are retured.

The routine computes the intersection points of f with its hessian. Then the cluster reduction is applied to this point set.

114.12.3.1 Minimization and Reduction for Plane Quartics

`MinimizePlaneQuartic(f,p)`

Verbose `PlaneQuartic` *Maximum :* 1

Given a plane quartic defined by the polynomial f with integer coefficients this routine computes an at p minimized model of the quartic. The new quartic and the transformation used are returned.

`MinimizeReducePlaneQuartic(f)`

Verbose `PlaneQuartic` *Maximum :* 1

Given a smooth plane quartic curve defined by the polynomial f with integer coefficients this routine computes a minimized and reduced model of the curve. The transformation matrix returned applied to f will evaluate to a scalar multiple of the returned polynomial.

For the reduction step, `ReducePlaneCurve` is used.

Example H114E40

Here we test the code by taking a bad embedding and a of curve.

```
> _<x,y,z> := PolynomialRing(Integers(), 3);
> C := -3*x^4 + 7*x^3*y - 2*x^3*z + 6*x^2*y^2 + 9*x^2*y*z - 9*x^2*z^2
>       + 10*x*y^3 - 7*x*y^2*z + 5*x*y*z^2 - 6*x*z^3 - 3*y^4 + 5*y^3*z
>       - 3*y^2*z^2 + 4*y*z^3 + 6*z^4;
> C2 := Evaluate(C,[45*x+346*y,74*y+43*z,62324*z+3462*x]);
> C2;
850482855369981*x^4 - 77028319604430*x^3*y + 61459466820119559*x^3*z -
11625449190228*x^2*y^2 - 4102113209795298*x^2*y*z + 16654003843623327 72*x^2*z^2
- 62468022936*x*y^3 - 417499281622764*x*y^2*z - 72808467360772908*x*y*z^2 +
2005588071197635933 2*x*z^3 - 16293798512*y^4 - 875035770696*y^3*z -
3749491014537304*y^2*z^2 - 430694749052979580*y*z^3 + 905674491172905110 49*z^4
> MinimizeReducePlaneQuartic(C2);
6*x^4 - 6*x^3*y + 4*x^3*z - 9*x^2*y^2 + 5*x^2*y*z - 3*x^2*z^2 - 2*x*y^3 +
9*x*y^2*z - 7*x*y*z^2 + 5*x*z^3 - 3*y^4 + 7*y^3*z + 6*y^2*z^2 + 10*y*z^3 - 3*z^4
[    14878   4611976 -21564104]
[    -1935    148866   2804580]
[     3330   -256188   1197852]
```

We do not get the initial curve, but we get a curve with coefficients of the same size.

114.13 Minimal Degree Functions and Plane Models

This section contains functionality to compute smallest degree covering maps from a curve to the projective line $\mathbf{P}^1$, which are equivalent to smallest degree functions on the curve. We refer to such maps as *gonal* maps (the degree of such a map is usually referred to as the *gonality* of the curve). There are intrinsics for all general type (genus ≥ 2) curves of genus less than seven and for all trigonal (gonality 3) curves. The trigonal cases use the Lie algebra method to construct degree 3 maps following the algorithm in [SS]. The 4-gonal cases for genus 5 and 6 curves use the algorithms in [Hara]. Hyperelliptic cases (gonality 2) are dealt with directly using the canonical map and parametrisation of rational curves.

Gonal maps may not exist over the base field and the intrinsics here will return a gonal map over a finite extension in such cases. In some cases, the degree of a minimal extension over which a gonal map may be constructed is determined exactly. In others, this may involve difficult arithmetic problems (e.g., finding a point of minimal degree on a plane sextic over $\mathbf{Q}$) and the extension used may not be of minimal degree. This is discussed further in the descriptions of the intrinsics. The intrinsics are designed for input curves defined over number fields or finite fields.

There are also some intrinsics to compute minimal degree plane models of curves of genus 5 and 6. In the genus 6 case, these birational models may be defined over a small extension field of the base field (an exact minimal degree extension is found here). In the genus 5 case, the intrinsic computes models over the base field given a rational point or divisor of degree 2 in the generic case that may be input by the user. The functionality here is incomplete and doesn't currently cover every type of genus 5 or 6 curve or lower genus curves. We plan to extend this in later releases.

114.13.1 General Functions and Clifford Index One

The algorithm of Schicho and Sevilla used for trigonal curves actually covers the slightly more general case of Clifford index one. An algebraic curve has Clifford index one iff it is trigonal or it is of genus 6 and isomorphic to a non-singular plane quintic. In the latter case, the curve has gonality 4. Classical theory (e.g. Petri's theorem) tells us that a curve of genus greater than one has Clifford index 1 precisely when its canonical image is not defined by quadrics alone. For genus > 3, a minimal basis for the ideal defining the canonical image will then consist of quadrics and cubics. A non-hyperelliptic genus 3 curve is always trigonal and it's canonical image is defined by a smooth quartic in the projective plane.

This gives a simple computational test for Clifford index 1. There is an intrinsic described below that may be called directly by the user for Clifford index 1 canonical curves that returns a gonal map to $\mathbf{P}^1$ in the trigonal case or gives a birational map to a smooth plane quintic.

`GenusAndCanonicalMap(C)`

Convenience function for the user. Returns the genus g of the curve C, a Boolean value which is `true` iff $g \leq 1$ or C is hyperelliptic, and the canonical map from C to its canonical image if $g > 1$.

`CliffordIndexOne(C)`

`CliffordIndexOne(C,X)`

The curve C should be a (non-singular) canonical model of a curve of Clifford index 1 (this condition may be tested as described in the introduction). Computes and returns a degree 3 map to the projective line $\mathbf{P}^1$ or a birational map onto a smooth plane quintic, depending on whether C is trigonal or not. In the trigonal case, the map may be defined over a quadratic extension of the base field for curves of even genus. This will occur only if no such map exists over the base field. In the plane quintic case, the map is always defined over the base field. The trigonal case requires that the characteristic of the base field is not 2.

The algorithm used is that of Schicho and Sevilla that applies the Lie algebra method to explicitly compute the fibration map to $\mathbf{P}^1$ of the rational scroll surface X that is defined by the quadrics in the defining ideal of the canonical curve C. The second version of the intrinsic also takes X as an argument in case the user has already computed it.

Example H114E41

```
> P5<x,y,z,s,t,u> := ProjectiveSpace(Rationals(),5);
> C := Curve(P5,[
> -y*z+x*s-y*s+z*t-4*s*t+t^2+2*s*u-3*t*u+2*u^2,
> -z^2+s^2+x*t+2*z*t-2*t^2-4*s*u-2*t*u+4*u^2,
> -z*s-s^2+z*t+t^2+x*u-2*s*u-7*t*u+6*u^2,
> -z*s+s^2+y*t+2*s*t-t^2-2*s*u+t*u,
> -s^2+s*t+y*u-s*u-t*u+u^2,
> -s*t+t^2+z*u-s*u-3*t*u+2*u^2,
> x^3-3*x^2*y+7*x*y^2+3*y^3+x*y*z-y*z^2+9*z^3+3*y^2*s-3*y*z*s-7*z^2*s-7*y*s^2+
> 17*z*s^2-86*s^3-4*z*s*t-16*s^2*t-185*z*t^2+807*s*t^2-406*t^3+17*s^2*u-
> 666*s*t*u+1391*t^2*u+228*s*u^2-1378*t*u^2+393*u^3,
> x^2*z-2*x*y*z+5*y^2*z+y*z^2+3*z^3+8*y^2*s+y*z*s-7*z^2*s+3*y*s^2+17*z*s^2-
> 47*s^3+6*z^2*t+9*z*s*t+s^2*t+32*z*t^2+11*s*t^2-103*t^3-51*s^2*u-171*s*t*u+
> 433*t^2*u+89*s*u^2-577*t*u^2+246*u^3,
> x*z^2-y*z^2-z^3+4*y*z*s+z^2*s+8*y*s^2-3*z*s^2-5*s^3+7*z^2*t-3*z*s*t+17*s^2*t+
> 8*z*t^2-2*s*t^2+62*t^3-41*s^2*u-34*s*t*u-28*t^2*u+14*s*u^2-127*t*u^2+92*u^3
> ]);
> // C a genus 6 canonical curve of gonality 3
> mp3 := CliffordIndexOne(C);
> mp3;
Mapping from: Crv: C to Curve over Rational Field defined by
0
with equations :
x - 2*z + 10*s - 7*t + 10*u
-2/5*x - 24/5*s + 26/5*t - 44/5*u
```

We can check that `mp3` gives a degree 3 map by seeing that the degree 10 linear pencil of divisors generated by D_1 and D_2, the hyperplane sections of C given by the two defining equations of the

map, has a common degree 7 factor.

```
> defs := DefiningPolynomials(mp3);
> D1 := Scheme(C,defs[1]);
> D2 := Scheme(C,defs[2]);
> D12 := Scheme(C,defs);
> Degree(D1); Degree(D2);
10
10
> Dimension(D12); Degree(D12);
0
7
```

114.13.2 Small Genus Functions

This section contains intrinsics to compute gonal maps for curves with genus greater than one and less than seven.

`Genus2GonalMap(C)`

Returns a degree 2 map from genus 2 curve C to the projective line. The map is defined over a quadratic extension of the base field k iff no such map exists over k. The map is just the canonical map followed by an inverse parametrisation of its image.

`Genus3GonalMap(C)`

`IsCanonical` BoolElt *Default :* `false`

For a genus 3 curve C, returns the gonality (2 or 3) and a gonal map to $\mathbf{P}^1$. C is trigonal precisely when it is non-hyperelliptic, when its canonical image is a plane quartic Q. Gonal maps are given by the canonical map onto Q followed by projection from a point on Q. Constructing one requires finding a point on Q. If Q is defined over the rationals, a point search up to a small height is applied, and if Q is defined over a finite field a point enumeration is applied to try to find a point over the base field. If this fails to locate a point or if the base field is a number field, a point of Q over an extension of degree ≤ 4 of the base field is used. Thus the map returned may be over an extension of the base field and this extension may not be of minimal degree.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

`Genus4GonalMap(C)`

`IsCanonical`	BoolElt	*Default :* `false`

For a genus 4 curve C, returns the gonality (2 or 3) and a gonal map to $\mathbf{P}^1$. C is trigonal precisely when it is non-hyperelliptic. In the trigonal case, a gonal map is computed using the `CliffordIndexOne` intrinsic. This involves computing a fibration map for a quadric surface in $\mathbf{P}^3$ containing the canonical image of C, which may be defined over a biquadratic extension of the base field in bad cases. So the map returned may be defined over an extension of degree 4, whereas the map on C should always be defined over an extension of degree at most 2. We will try to fix this in later releases.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

`Genus5GonalMap(C)`

`DataOnly`	BoolElt	*Default :* `false`
`IsCanonical`	BoolElt	*Default :* `false`

For a genus 5 curve C, returns the gonality (2, 3 or 4) and a gonal map to $\mathbf{P}^1$. In the gonality 4 case, it also returns some extra data that gives the parametrisation of the set of degree 4 linear pencils (g^1_4s) which give the gonal maps.

The hyperelliptic case (gonality 2) is handled as usual by parametrising the canonical image which gives a gonal map that may be defined over a quadratic extension of the base field.

The trigonal case is easy to deal with here since the rational scroll X that contains the canonical image of C is of codimension 2 in its ambient. We directly compute the fibration map of X from the minimal free polynomial resolution of the canonical coordinate ring of C. This gives a gonal map on C that is always defined over the base field.

In the general (4-gonal case), there are infinitely many equivalence classes of gonal maps which are parametrised by a plane quintic curve F. This along with a function f which takes a point in $F(K)$ as an argument are returned as third and fourth return values. f evaluated at $p \in F(K)$ will return the corresponding gonal map on C which is defined over K or a quadratic extension of it. The actual gonal map returned as the second return value is given by searching for a point on F over a small extesnion of the base field. We use a point search as for `Genus3GonalMap` if the base field is the rationals or a finite field. Otherwise or if this fails, we find a point over an extension field by decomposing a random hyperplane section of F. We try to use singular points on F, if they exist, which correspond to g^1_4s whose associated rational scroll is defined by a rank 3 rather than a rank 4 quadric.

If the parameter `DataOnly` is set to `true` (the default is `false`), then only the gonality is returned when it is less than 4, and only the gonality, F and f are computed and returned in the 4-gonal case.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

`Genus6GonalMap(C)`

`DataOnly`	BoolElt	*Default :* `false`
`IsCanonical`	BoolElt	*Default :* `false`

For a genus 6 curve C, returns the gonality (2, 3 or 4), a second type identifer and a gonal map to $\mathbf{P}^1$. The second type number is irrelevant in the gonality 2 and 3 cases, when it is always 1. It is 1,2 or 3 in the 4-gonal case.

For 4-gonal curves of secondary type 2, C is a double cover of a genus 1 curve E through which all gonal maps factor. In this case, the map giving this double covering is returned as a fourth return value. Secondary type 3 curves are isomorphic to (smooth) plane quintics and an isomorphism to such a quintic is returned as the fourth return value. These maps are defined over the base field.

The hyperelliptic case (gonality 2) is handled as for `Genus5GonalMap`.

The trigonal case requires the characteristic of the base field to not be 2. It uses the `CliffordIndexOne` intrinsic and constructs a gonal map that is defined over a quadratic extension of the base field k if no such map exists over k.

There are 3 distinct subcases of the 4-gonal case, which are distinguished by the second return number.

Type 2 curves are double covers of a genus 1 curve E and there are infinitely many 4-gonal maps which are given by composing this double cover with a degree 2 map of E to $\mathbf{P}^1$. E is constructed as a projective normal curve of degree 5 in $\mathbf{P}^4$. The gonal map returned is found by looking for k-rational points on E by general point search methods and, if this fails, taking a point on E defined over a finite extension of k lying in a random hyperplane section of E.

Type 3 curves are (birationally) isomorphic to a plane quintic C_5. The infinitely many 4-gonal maps are given by projection from a point on C_5. The gonal map returned is constructed by finding a k-rational point on C_5 or one over a finite extension as for type 2.

Type 1 (general type) curves have only finitely many gonal maps up to equivalence (5 at most, in fact). The algorithm explicitly finds algebraic data defining these map classes. It chooses one defined over k if possible. Otherwise, we take one over a minimal degree extension of k. The gonal map returned is thus defined over a minimal degree extension of k for such maps.

If the parameter `DataOnly` is set to `true` (the default is `false`), then only the gonality (and secondary type 1) is returned when it is less than 4, and only the gonality, secondary type t and fourth return value when $t = 2$ or 3 are computed and returned in the 4-gonal case.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

Example H114E42

We give some examples with 4-gonal curves of genus 5 and 6. Firstly, we take a random canonical curve of genus 5 given by the intersection of 3 quadrics in $\mathbf{P}^4$.

```
> P4<x,y,z,t,u> := ProjectiveSpace(Rationals(),4);
> C := Curve(P4,[
> -x^2-x*y-y*z+z^2-x*t-y*t-z*t+t^2-x*u+y*u-t*u,
> -x*y+y^2+y*z+x*t+y*t-z*t+z*u+t*u+u^2,
> -x^2-x*y-y*z+z^2+x*t-y*t+t^2-x*u+y*u+z*u+t*u+u^2]);
> g,mp4,F,f := Genus5GonalMap(C);
> g;
4
> mp4;

114.13.3 Small Genus Plane Models

This section contains intrinsics to compute minimal degree birational plane models for curves of genus 5 or 6.

`Genus6PlaneCurveModel(C)`

`IsCanonical` BoolElt *Default :* `false`

For a genus 6 curve C of gonality 4 which isn't the double cover of a genus 1 curve (i.e. subtype 2 for `Genus6GonalMap`), returns a birational map to a plane curve of minimal degree (5 or 6). This map may be defined over a finite extension of the base field k, but it will always be a minimal degree extension for the existence of minimal degree plane models. The first return value is a boolean, which is `true` only if C is of gonality 4 and not of subtype 2. If so, the second return value is the map to the curve.

When C is birationally isomorphic to a plane quintic C_5, (subtype 3 for `Genus6GonalMap`), C_5 is a minimal degree plane model and it and the birational map to it are defined over k. This is a Clifford index 1 case, and the computation is performed via the `CliffordIndexOne` intrinsic.

In the general case, (subtype 1 for `Genus6GonalMap`), the smallest degree plane models are of degree 6, there are only finitely many birational maps from C to degree 6 plane curves up to linear equivalence and these are in 1-1 correspondence with the finitely many equivalence classes of gonal maps. The birational maps to plane models are computed by a slight variant of the same algorithm used to compute the gonal maps (see [Hara]). The return value is over the base field k, if possible, and otherwise over a smallest degree (at most 5) possible field extension.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

`Genus5PlaneCurveModel(C)`

`Genus5PlaneCurveModel(C,P)`

`Genus5PlaneCurveModel(C,Z)`

`IsCanonical` BoolElt *Default :* `false`

For a genus 5 curve C, tries to compute a birational map over the base field k to a plane curve of minimal degree (5 or 6) for plane curve models over $\bar{k}$. The first

return value is a boolean which is `true` if the construction succeeds and, if so, the second return value is the birational map to the plane curve.

If C is hyperelliptic, the return value is always `false`. Gonality 3 curves are always birational over k to a plane curve of degree 5 with a single singular point and the computation always succeeds. The map to $\mathbf{P}^2$ on a canonical model C_c of C lying in $\mathbf{P}^4$ is given by projection from a line lying in the rational scroll surface X that contains C_c.

If C is 4-gonal and isn't a double cover of a genus 1 curve, the minimal degree plane model is of degree 6 and there are infinitely many of these (up to linear equivalence) that are given by projection from a secant line or tangent line of the canonical model C_c.

To find a birational map to such a model over k, we need a secant or tangent line defined over k, which will correspond to a k-rational point on C_c or a k-rational reduced divisor of degree 2 (i.e. 2 distinct points that are k-rational or conjugate over a quadratic extension of k).

The second and third versions of the function have a second argument that should be a k-rational *non-singular* point on C or a reduced subscheme of C of dimension 0 and degree 2, whose points (over $\bar{k}$) lie in the non-singular locus of C. These are used to define the k-rational tangent line or secant line on the canonical model and the intrinsic will always succeed and return the map to a degree 6 model if they are provided by the user.

In the version with only the curve C as input, the intrinsic attempts to find a (non-singular) k-rational point on C using `PointSearch` if the base field is the rationals or using point enumeration if the base field is a finite field. If this search fails, or k is a field of a different type, the intrinsic will fail and return `false`.

If the input C is already a canonical model, parameter `IsCanonical` may be set to `true`. This will simplify the internal processing. **NB** The defining equations of C must be a minimal basis for its defining ideal.

Example H114E43

We use the intrinsic for genus 6 curves to get a degree 6 plane model for the modular curve $X_0(58)$, starting from its canonical model.

```
> X := X0NQuotient(58,[]);
> X;
Curve over Rational Field defined by
x[1]^2-x[1]*x[3]+x[2]*x[4]+x[2]*x[5]-x[1]*x[6]+x[4]*x[6]+x[5]*x[6],
x[1]^2-x[1]*x[2]-x[2]^2-x[1]*x[3]-x[1]*x[4]+x[3]*x[4]+x[2]*x[5]+x[3]*x[5],
-x[1]^2+x[1]*x[2]+x[2]^2+x[4]^2+x[4]*x[5]-x[2]*x[6],
-x[1]^2-x[1]*x[2]+x[2]^2+x[2]*x[3]-x[1]*x[4]+x[2]*x[4]+x[3]*x[4]+x[4]^2-x[5]*x[6],
x[2]^2-x[1]*x[3]+x[2]*x[3]+x[3]^2-x[1]*x[4]+x[3]*x[4]+x[2]*x[6]+x[3]*x[6],
x[1]*x[2]-x[2]*x[3]-x[1]*x[4]+x[3]*x[4]+x[2]*x[5]+x[3]*x[5]+x[4]*x[5]-x[1]*x[6]+
x[2]*x[6]+x[3]*x[6]+x[4]*x[6]
> boo,mp := Genus6PlaneCurveModel(X : IsCanonical := true);
> boo;
```

```
true
> C<x,y,z> := Codomain(mp); //the plane model
> C;
Curve over Rational Field defined by
x^6-3*x^5*y+x^4*y^2+3*x^3*y^3-7/4*x^2*y^4-1/4*x*y^5-1/4*y^6+3/2*x^5*z-x^4*y*z-
9/2*x^3*y^2*z+7/2*x^2*y^3*z+5/8*x*y^4*z+3/4*y^5*z+5/4*x^4*z^2+1/4*x^3*y*z^2-

115 RESOLUTION GRAPHS AND SPLICE DIAGRAMS

Chapter 115
RESOLUTION GRAPHS AND SPLICE DIAGRAMS

115.1 Introduction

Both resolution graphs and splice diagrams are labelled graph-like diagrams used to encode geometric data closely related to some resolution of singularities procedure in algebraic geometry. They are commonly used to visualise this data. Of course, there are other tools in MAGMA, Puiseux expansions for instance, which can be used if preferred. A typical example is when a configuration of curves on a surface is the given data. In this case, *dual graph* of the configuration has vertices corresponding to the individual curves and edges corresponding to their intersections. The vertices may be labelled with the selfintersections of the corresponding curves and possibly also with the multiplicities with which the curves appear in the configuration.

This chapter discusses two different enhanced graph types: `GrphRes` for resolution graphs and `GrphSpl` for splice diagrams. Neither of them is literally a graph in MAGMA; in particular, functions taking graphs as argument cannot be applied directly to objects defined here. Instead they work by having a directed graph, referred to as the *underlying graph*, as a primary attribute and by caching other data (which is typically associated to particular vertices and edges of the graph) in sequences as secondary attributes. There are also vertex types which allow the convenient idiom of MAGMA's graph package to be used. Note, however, that unlike other graph types, these do not have edge types.

Graph surgery routines cannot be used directly since they must manage both the underlying graph and the associated data. A collection of appropriate surgery functions, those used in resolution routines, have been provided in this context; they are usually brief, simply concatenating attribute data whenever it is present on both sides.

Functions to recover data related to the graph, whether globally or at a particular vertex or edge, are also provided. Thus the user does not access labels of the graph but rather uses the intrinsics listed later in this chapter. Of course, usually these do no more than unload an attribute.

115.2 Resolution Graphs

A resolution graph g is a graph with data associated to its vertices. The underlying graph is the dual graph of a blowup process. The vertices correspond to rational curves E, "exceptional curves", on some surface S which are contracted by some map $f : S \to P^2$, where P^2 is the projective plane. Such maps arise during the resolution process by blowups of a curve singularity, say $p \in C$ where C is a curve in P^2. In that context, C can be

pulled back to S using f and the pullback can be decomposed (as an effective divisor on S) as

$$f^*C = \widetilde{C} + E_C$$

where $\widetilde{C}$ is the *birational transform* of C and E_C is an effective divisor supported on the union of the exceptional curves. The surface S is never realised as a geometric object.

For a vertex v of g, the corresponding rational curve is often denoted E_v. The edges of g correspond to the intersections between different E: vertices v and w are joined by edges corresponding in some way to the points of intersection of the curves E_v and E_w. In the contexts used below, any two curves will meet at most in one point and that will be a transverse intersection. So the intersection number E_vE_w on S will be the number of edges between v and w, either zero or one, if they are distinct vertices and a selfintersection number associated to v otherwise. Thus the graph enables basic intersection calculations to be carried out implicitly on S.

The data associated to each vertex v is the following where $E = E_v$: the selfintersection E^2; the coefficient of E in some pullback divisor, often E_C but this depends on the context; the coefficient of E in a representative of the canonical class of S locally supported on the exceptional curves; the number of transverse intersections of the birational transform $\widetilde{C}$ of C with E. At each vertex v, this data is often denoted s_v, m_v, k_v, t_v respectively. This is the coarsest kind data one could want. It enables basic intersection theory calculations (including calculating the contribution of a singularity p of a curve C to the genus of C). For more detailed calculations, the map f and the equation of the birational transform of C are held on patches along each E. In each case, the patch is an affine xy-plane with E as the line $y = 0$ in it (although it is actually the closure of this patch and map that is recorded).

Resolution graphs are usually created implicitly by some geometrical algorithm like the resolution of a plane curve singularity. The first creation methods below are of this nature. But graphs can also be created explicitly by providing the required data. How much data is required varies according to the purpose of the graph; some common alternatives are included here.

115.2.1 Graphs, Vertices and Printing

Resolution graphs are less complicated as a type than the other graphs in MAGMA. They do not have associated vertex and edge sets. However, there is a resolution graph vertex type so that vertices can be passed between intrinsics.

Graph printing is similar to that of the underlying directed graph. An example is

```
The resolution graph on the Digraph
Vertex  Neighbours
1 ([ -2, 9, 1, 0 ])     2 ;
2 ([ -4, 18, 2, 0 ])    3 ;
3 ([ -2, 63, 9, 0 ])    4 6 ;
4 ([ -2, 42, 6, 0 ])    5 ;
5 ([ -2, 21, 3, 0 ])    ;
```

```
6 ([ -1, 66, 10, 3 ])   ;
```

This is a graph on 6 vertices — they are listed as one of the integers $1, \ldots, 6$ down the left. The integer corresponding to a vertex is called the *index* of the vertex. In brackets by each vertex v is a label of the form $[s, m, k, t]$ where s is the selfintersection, m is the multiplicity (the interpretation of which is dependent on the context), k is the canonical multiplicity and t is the number of transverse intersections at v as described in the introduction. Next comes a space-separated list of the vertices at the far end of edges directed away from v. Until one is used to reading graphs in this way, and also even then, drawing the graph by hand is recommended.

The vertex labels can be shorter if some data is missing. The alternatives are $[s]$, $[s, t]$ and $[s, m, t]$ in the previous notation. The most data consistent with what has been calculated for the graph will be displayed.

Notice that, although these really are printed as graph labels, the data in them should not be accessed as such. These labels are often unassigned, or assigned in an unexpected way. They are only intended for printing. There are dedicated functions below for retrieving data associated to a graph.

`g eq h`

Returns `true` if and only if the resolution graphs g and h are the same object in MAGMA.

`ResolutionGraphVertex(g,i)`

`g ! i`

The vertex of the resolution graph g with index i.

`Vertex(v)`

The underlying directed graph vertex of the resolution graph vertex v.

`ResolutionGraph(v)`

The resolution graph of which v is a vertex.

`IsVertex(g,v)`

Returns `true` if and only if v is a vertex of the resolution graph g.

`Index(v)`

The index of the underlying graph vertex of the resolution graph vertex v; this is the integer appearing as the vertex identifier when the graph is printed.

`v eq w`

Returns `true` if and only if the resolution graph vertices v and w are the same object in MAGMA.

115.2.2 Creation from Curve Singularities

Let C be a reduced plane curve, either affine or projective. See Chapter 114 for details of how to create such a curve. Let p be a singular point of C. The intrinsic below calculates the dual graph of the resolution of p on C together with some auxiliary data. As in the introduction, the sequence of blowups required in the resolution is thought of as a morphism $f : S \to P^2$ of projective surfaces; P^2 is the projective plane (which is the closure of the ambient plane of C if it is affine) while S is a surface not realised explicitly in MAGMA.

The target resolution is the minimum transverse resolution, sometimes called the log resolution, a resolution in which the birational transform $\widetilde{C}$ of C on S is nonsingular and transverse to the exceptional locus. However, there are circumstances under which a larger resolution will be calculated. This makes no difference to the geometric data arising from the resolution.

```
ResolutionGraph(C, p)
```

M	RNGINTELT	*Default :* 1
K	RNGINTELT	*Default :* 1

```
ResolutionGraph(C, p)
```

Calculate a transverse resolution graph of the plane curve singularity of C at the point p. If the point argument is missing and C is affine, the resolution is calculated at the origin, but in that case parameters cannot be assigned and take the default values.

The numerical parameters determine whether additional data is calculated: value 1, the default, enables the calculation while value 0 omits it.

The parameter `M` refers to the pullback multiplicities of C. It returns a sequence $[m_v]$ of rational numbers (although always integral in the current algorithms) corresponding to the vertices of the graph. These numbers have the following meaning: on the blownup surface S, as divisors,

$$f^*C = \widetilde{C} + \sum m_v E_v$$

where the sum is taken over the vertices v of the graph and E_v is the corresponding exceptional curve.

The parameter `K` refers to the canonical multiplicities along g. It returns a sequence $[k_v]$ of rational numbers (although again always integral) corresponding to the vertices of the graph. On the blownup surface S in a neighbourhood of the union of exceptional curves E the canonical class K_S has a representative

$$K_S = \sum k_v E_v$$

where the sum is taken over the vertices of the graph.

The surface S is covered by affine plane patches. The map f to the projective plane can be calculated when restricted to these patches. In fact, the closure of

these maps is calculated as a birational automorphism of the projective plane. All blowup algorithms arrange that the exceptional curve E_v corresponding to a vertex v is (a patch on) L_y, the second coordinate line "$y = 0$", in the projective plane. So pulling C back to the plane using the patch map at v will produce a curve having $m_v L_y$ as a component.

The calculation of maps and pullbacks is expensive so some precautions are taken. First, the maps are only calculated at significant vertices of the graph: significant here means that the blowup procedure branches at that vertex, or that $\widetilde{C}$ meets the exceptional locus there. Second, the maps are calculated as a sequence of maps: the map required is the composition of these. The composition will be carried out automatically if needed. (In the current code, this can only be carried out if no field extensions have been made. This will be updated in due course.)

The calculation is carried out by tying together strings of blowups (done recursively in one go using a standard Newton polygon argument). The Newton polygon argument used automatically makes a curve transverse to all axes, not just to exceptional curves. These extra blowups do not invalidate numerical calculations made with the resolution graph (since minimality is never a condition) and they are essential when resolving irregular fibres of pencils.

Example H115E1

First make a curve with a singularity. The following curve demonstrates the typical way singularities with more than one Puiseux pair — those which need the Newton algorithm to be repeated when calculating a resolution or local parametrisation — arise.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,(x^2 - y^3)^2 + x*y^6);
```

The interesting singularity is at the origin. The next two lines calculate the resolution graph of this singularity and display it.

```
> g := ResolutionGraph(C,Origin(A));
> g;
The resolution graph on the Digraph
Vertex  Neighbours
1 ([ -3, 4, 1, 0 ])     2 ;
2 ([ -2, 12, 4, 0 ])    3 4 ;
3 ([ -2, 6, 2, 0 ])     ;
4 ([ -3, 14, 5, 0 ])    5 ;
5 ([ -1, 30, 12, 1 ])   6 ;
6 ([ -2, 15, 6, 0 ])    ;
```

The resulting graph has 6 vertices. So the transverse resolution of this singularity is achieved by 6 blowups. The order of blowup can be determined by the third column, the canonical class: this number strictly increases throughout the process, so curve E_1 is the first exceptional curve, E_3 is the second and so on until finally E_5 is extracted. This could also be deduced from the sequence of selfintersections, the first column. See how the birational image of C after blowing up only intersects E_5, and then only in a single transverse point. In other words, C has a single place at the origin.

115.2.3 Creation from Pencils

Let P be a jacobian pencil in the affine plane A^2, that is, a pencil of the form $f(x, y) = c$ as c varies. See Chapter 112 for details of how to create jacobian pencils. The resolution graph which can be created automatically is the regular resolution graph: that is, the minimal sequence of transverse blowups which resolve the rational map determined by P from the projective plane (the closure of A^2) to the projective line. However, other resolution graphs can be constructed using more explicit creation functions.

`ResolutionGraph(P)`

The resolution at infinity of the jacobian pencil $P : f = c$ of some polynomial f as the value c varies defined on some affine space A. This resolution graph is thought of as being rooted with root vertex corresponding to the line at infinity of A. The multiplicities are those of the fibre of f at infinity.

`ResolutionGraph(P,a,b)`

The resolution graph at infinity of the union of the two fibres of P above a and b. The multiplicities and canonical class are not calculated automatically for this graph.

Example H115E2

The following is a simple example of a pencil exhibiting interesting behaviour at infinity. It is taken from [Neu99].
First a pencil in some affine plane is made.

```
> A<x,y> := AffineSpace(Rationals(),2);
> f := x^2*y - x;
> P := Pencil(A,f);
> P;
The pencil defined by x^2*y - x
```

Then the regular resolution graph at infinity is calculated.

```
> ResolutionGraph(P);
The resolution graph on the Digraph
Vertex  Neighbours
1 ([ -1, 3, -3, 0 ])    2 5 ;
2 ([ -3, 1, -2, 0 ])    3 ;
3 ([ -1, 0, -2, 1 ])    4 ;
4 ([ -2, 0, -1, 0 ])    ;
5 ([ -2, 2, -2, 0 ])    6 ;
6 ([ -2, 1, -1, 0 ])    7 ;
7 ([ -1, 0, 0, 1 ])     ;
```

The resulting graph has 7 vertices. Vertex 1 corresponds to the line at infinity of the plane, or more properly to its birational image after blowing up. The pencil meets this line at two points,

each of which have undergone three blowups in the resolution process. The vertex labels carry auxiliary data. The first column lists the selfintersections of the curves E_v corresponding to the vertices v. The general fibre of the pencil meets a single exceptional curve above each of the points as shown by the fourth column. The fibre at infinity is $3E_1 + E_2 + 2E_5 + E_6$ as shown in the second column. The third column gives the multiplicities of a canonical divisor on the blownup surface: K_S can be represented by the divisor $-3E_1 - 2E_2 - 2E_3 - E_4 - 2E_5 - E_6$.
It is known that the pencil P is irregular at infinity above 0. This can be seen by calculating the explicit resolution of the union of two fibres, $f = 0$ and a general one, say $f = 1$.

```
> ResolutionGraph(P,0,1);
The resolution graph on the Digraph
Vertex  Neighbours
1 ([ -1, 0 ])   2 5 ;
2 ([ -3, 0 ])   3 ;
3 ([ -1, 1 ])   4 ;
4 ([ -2, 2 ])   ;
5 ([ -2, 0 ])   6 ;
6 ([ -2, 0 ])   7 ;
7 ([ -1, 2 ])   ;
```

The multiplicities and canonical class have not been calculated by this function. Later in this chapter there are functions which will do this, although the multiplicities require some interpretation. The selfintersections have been calculated as before (and notice that the blowups at least appear to be exactly those of the previous resolution procedure; in fact they are indeed the same). The number of transverse intersections are now those of the union of the two fibres. Since the fibre above 1 is general it contributes one intersection at vertex 3 and one at vertex 7. So the intersections of the irregular fibre can be deduced, namely two at vertex 4 and one at vertex 7.

115.2.4 Creation by Hand

A resolution graph can be created by hand. This can be fiddly if the underlying graph is complicated. See Chapter 149 for details on how to create a directed graph.

`MakeResolutionGraph(g,s,t)`

`MakeResolutionGraph(g,s)`

The resolution graph on underlying directed graph g. Although it is not checked, the graph g should usually be a directed tree otherwise some reduction algorithms which might be invoked later might not work. In that case, moreover, its root must be the vertex of index 1.

The selfintersections of vertices correspond to the integer entries of the sequence s. If used, the number of transverse intersections of the putative resolved curve with each vertex correspond to the integer entries of the sequence t.

`MakeResolutionGraph(N)`

The resolution graph corresponding to the Newton polygon N.

`UnderlyingGraph(g)`

The underlying directed graph of the resolution graph g.

115.2.5 Modifying Resolution Graphs

Any resolution graph, whether created by hand or not, can have its numerical data calculated or modified. There are also some functions for performing surgery on the underlying graph.

There are also functions which do the linear algebra calculations typical of the numerical calculations associated with resolution graphs. But beware: they each base their calculation on some part of the data of the graph but make no check that all numerical data is consistent at the end of calculation.

`Connect(v,w)`

If v and w are vertices of distinct resolution graphs, return the graph comprising the union of these graphs joined by an edge from v to w. Selfintersections are inherited by the graph from its two components. Multiplicities, canonical class and transverse intersections will be inherited if calculated on both components.

`CalculateCanonicalClass(~g)`

Calculate the canonical class supported on the resolution graph g using the selfintersections of the E_v and the assumption that the E_v are nonsingular rational curves meeting transversely. Note that this calculation uses only the selfintersections already associated to g.

`Disconnect(v,w)`

If v and w are vertices of a resolution graph g, return the resolution graph with any edge joining them removed. The resulting graph may well be disconnected. The only data preserved is the selfintersections and transverse intersections.

`Component(v)`

The connected component of the resolution graph containing vertex v.

`CalculateMultiplicities(~g)`

Calculate the pullback multiplicities of the resolution graph g using the selfintersections of the E_v, the assumption that the E_v are nonsingular rational curves meeting transversely, and the number of transverse intersections of $\widetilde{C}$ with the E_v. It is assumed that g is the resolution graph of a curve singularity during this calculation, although that need not be the case. In general there will be some choice of multiplicities. If g is the resolution of a curve singularity, and if the multiplicity of that singularity is cached, then the correct multiplicities can be identified: the multiplicity along the first blownup curve is the same as that of the singularity; the curve which was blown up first can be identified since it alone has canonical multiplicity 1.

However, if g arose as the resolution at infinity of two fibres of a pencil, for instance, the multiplicities calculated here would depend on which two fibres were used. The result would be the unique divisor supported on g which when added to the birational transform of the two affine fibre patches was linearly equivalent to the zero divisor. In particular, if the two fibres were general, the calculation here would return -2 times the fibre at infinity. Otherwise the calculation will return a combination of that and the exceptional components of irregular finite fibres. The intrinsic which calculates the regular resolution graph of a pencil already takes this into account.

`CalculateTransverseIntersections(~g)`

Calculate the number of transverse intersections of $\widetilde{C}$ with each E_v on the basis of their selfintersection numbers and multiplicities in the resolution graph g.

`ModifySelfintersection(~v,n)`

Change the selfintersection at vertex v of a resolution graph to n.

`ModifyTransverseIntersection(~v,n)`

Change the number of transverse intersections at vertex v of a resolution graph to n.

115.2.6 Numerical Data Associated to a Graph

The meaning of the data given here depends on the context in which the graph was created. The case already discussed of a configuration of rational curves arising from the resolution of a curve singularity is the prototype.

Many of these functions can also be applied to a single vertex of a graph: `Selfintersection`, `CanonicalMultiplicity` and so on.

`Size(g)`

The number of vertices of the underlying graph of the resolution graph g. Typically, this is the number of exceptional curves in the resolution.

`SelfIntersections(g)`

The selfintersections of the vertices of the resolution graph g.

`Multiplicities(g)`

The multiplicities of the vertices of the resolution graph g in some divisor.

`CanonicalClass(g)`

The multiplicities of the vertices of the resolution graph g in a local representative of the canonical class.

`TransverseIntersections(g)`

The number of transverse intersections of some curve (usually used to create g) with the vertices of the resolution graph g.

`GenusContribution(g)`

The contribution to the genus of a plane curve of a singularity having g as its resolution graph.

`CartanMatrix(g)`

The incidence matrix of the (undirected) graph underlying the resolution graph g with selfintersections on the diagonal.

`Determinant(g)`

The determinant of the Cartan matrix of the resolution graph g.

115.3 Splice Diagrams

Splice diagrams are graphs decorated with integer labels at each end of each edge and a number of arrows, often none at all, attached to each vertex. They are fully described in [EN85]. No description of the meaning of splice diagrams will be given here, only the functions that MAGMA has for manipulating them. (There are two common features of splice diagrams that cannot yet be realised. First, omitting edge labels which are 1 is common but is not allowed. Second, and less trivially, arrow weights are not allowed.

Other data that is also stored with the diagram are vertex multiplicities, canonical multiplicities, and total linking numbers of vertices. The distinction between a splice diagram and its underlying directed graph, as well as that between a splice diagram vertex and its underlying vertex, is often left implicit.

115.3.1 Creation of Splice Diagrams

Splice diagrams are usually created from geometric objects like plane curve singularities or jacobian pencils. They can also be built explicitly by hand. The section on translations between graphs describes functions which create splice diagrams associated to resolution graphs.

`SpliceDiagram(C,p)`

The splice diagram of the plane curve singularity of C at the point p.

`RegularSpliceDiagram(P)`

The regular splice diagram at infinity of the jacobian pencil P. This diagram is considered to be rooted at vertex 1 corresponding to the line at infinity of the ambient plane of P. Its underlying graph is directed away from this root.

`MakeSpliceDiagram(g,e,a)`

A splice diagram on directed graph g. The edge labels are taken from the sequence e. The elements of this sequence are sequences of pairs of integers $[a, b]$. The i-th element of e will be assigned to the i-th edge of g (in the order returned by `Edges(g)`) with a as the near label and b as the far label (with respect to the directions of the edges of g). The number of arrows at each vertex are taken from the sequence of integers a.

`MakeSpliceDiagram(e,l,a)`

The splice diagram described by the data in the sequences e, l, a. The first two contain sequences of two integers: e is interpreted as a set of directed edges, the integers appearing in it being the vertex indices of the resulting graph. Edge labels are determined by the sequence l as in the previous function. The number of arrows at each vertex are taken from the sequence of integers a.

`SpliceDiagramVertex(s,i)`

The vertex of the splice diagram s having index i.

`SpliceDiagram(v)`

The splice diagram containing the vertex v.

`UnderlyingGraph(s)`

The underlying directed graph of the splice diagram s.

`UnderlyingVertex(v)`

`Vertex(v)`

The vertex of the underlying graph corresponding to the vertex v of a splice diagram.

`Vertices(s)`

The vertices of the splice diagram s.

`RootVertex(s)`

The root vertex of the splice diagram s as a rooted tree directed away from its root by the directions on the edges.

`Index(v)`

The index of the vertex v of a splice diagram.

`s eq t`

`v eq w`

Returns `true` if and only if the splice diagrams s and t are the same object in MAGMA. This can also be applied to a pair of vertices of a splice diagram.

115.3.2 Numerical Functions of Splice Diagrams

The raw numerical data of a splice diagram is the collection of labels on its edges and vertices together with data recovered from the underlying graph. First we list functions to get hold of this data, and then some more substantial functions which derive many of the natural conclusions of this data, linking number, euler characteristic and so on.

`EdgeLabels(s)`

The integer labels on the edges of the splice diagram s.

`VertexLabels(s)`

The integer labels on the vertices of the splice diagram s.

`TotalLinking(v)`

The total linking number of the vertex v of a splice diagram.

`LinkingNumbers(s)`

The total linking numbers of the vertices of the splice diagram s.

`Linking(u,v)`

The linking number of vertices u and v of a splice diagram.

`EdgeDeterminant(u,v)`

The edge determinant of the edge joining the vertex u to the vertex v of a splice diagram.

`Valency(v)`

The splice valency of the vertex v of a splice diagram. This is the valency of v in the underlying graph plus the number of arrows at v.

`IsRegular(s)`

Returns `true` if and only if the splice diagram s is regular.

`IsReduced(s)`

Returns `true` if and only if the splice diagram s is reduced, that is, it has no valency 2 nodes and no weight 1 leaves.

`HasIrregularFibres(s)`

Returns `true` if and only if the splice diagram s has a vertex with zero linking number.

`Degree(s)`

The linking number of the first vertex of the splice diagram s.

`EulerCharacteristic(s)`

The Euler characteristic of the splice diagram s.

`Size(s)`

The number of vertices of the splice diagram s.

`Arrows(s)`

A sequence of integers containing the number of arrows of the splice diagram s: the i-th sequence entry is the number of arrows at the vertex of index i. This function can also be applied to a single vertex returning a single integer.

`VertexPath(u,v)`

A sequence of vertices on the path from the vertex u to the vertex v of a splice diagram. The second return value is the sequence of products of off-path weights at each vertex.

115.4 Translation Between Graphs

Splice diagrams arise from resolution graphs by a reduction procedure and conversely resolution graphs arise from splice diagrams by a continued fraction calculation. At present, MAGMA only incorporates the former calculation. However, when a splice diagram s has been constructed using a curve singularity, the corresponding resolution graph g is calculated and can be recovered using the function `CorrespondingResolutionGraph`. The vertices of s correspond to a subset of those of g. The correspondence can be recovered with the function `CorrespondingVertices`.

115.4.1 Splice Diagrams from Resolution Graphs

By default MAGMA always makes the reduced splice diagram since otherwise many determinants would be calculated unnecessarily.

The translation of resolution graph g to splice diagram is done in two steps. First the underlying graph of g is reduced by the removal of all vertices of valency 2 (including arrows in the valency calculation). Then the edge labels are calculated using determinants of subgraphs.

`SpliceDiagram(g)`

`L`	RNGINTELT	*Default :* 0
`K`	RNGINTELT	*Default :* 0
`Reduced`	RNGINTELT	*Default :* 1

A splice diagram of the resolution graph g. All parameters can take the value 0 or 1. If `Reduced` is 1 then the splice diagram will be reduced, otherwise it will be the splice diagram on the underlying graph of g.

The parameter `L` refers to the total linking numbers of the vertices of the resulting splice diagram. The parameter `K` refers to the canonical class of the vertices of the resulting splice diagram. Each quantity will be calculated when the corresponding parameter is 1.

`SpliceDiagram(g,v)`

The splice diagram of the resolution graph g with the condition that the vertex v will not be removed by a reduction.

116 ALGEBRAIC SURFACES

Chapter 116
ALGEBRAIC SURFACES

116.1 Introduction

This chapter contains MAGMA geometric functionality for working specifically with algebraic surfaces and specialised subtypes. We hope to greatly expand this area in upcoming years. The general surface type `Srfc` is for 2-dimensional algebraic varieties over a field (i.e. schemes that are geometrically reduced and irreducible).

The current functionality is largely split between that for (singular) hypersurfaces in ordinary projective 3-space, which is older and relies heavily on the formal desingularisation package of Tobias Beck, and that for ordinary projective surfaces in arbitrary dimensional ambients that are "almost non-singular". The latter relies more on MAGMA's coherent sheaf package. Here, almost non-singular means that only simple (A-D-E) singularities are allowed. These are terminal singularities which don't affect computations involving the pluri-canonical sheaves. It is useful to allow simple singularities as they naturally occur in a number of models (anticanonically-embedded degenerate Del Pezzo surfaces; minimal models for surfaces of general type).

The surface type `Srfc` is a subtype of the scheme type `Sch` so the general functionality for schemes (see Chapter 112) and coherent sheaves (see Chapter 113) is of course also available.

The first section of the chapter deals with functions for surfaces in general ambients although, as noted above, there are singularity assumptions and the restriction to ordinary projective surfaces for many of the intrinsics.

The next section deals with surfaces in $\mathbf{P}^3$ with no singularity assumptions. this contains functions to compute formal desingularizations, general adjoint linear systems, classification and reduction of rational surfaces to special type and a general parametrization routine.

The final section deals with specific code for Del Pezzo surfaces, the specialised subtype for which we currently have the most functionality. There are parametrization routines over the rationals (or number fields in some cases) for Del Pezzos by degree and constructions for degree 6 Del Pezzos associated to different twisted torus type. There are also minimisation and reduction routines for degree 3 and 4 Del Pezzos and construction, point-counting and computation of invariants for degree 3.

116.2 General Surfaces

116.2.1 Introduction

We describe here the newer functionality for surfaces (two-dimensional, geometrically integral schemes over a field) in arbitrary dimensional ambients. However, the reader should be aware that there are major restrictions for many of the intrinsics.

The biggest problems are the singularity assumptions (either non-singular or with at worst simple singularities) and restrictions to ordinary projective space which means that large dimensional ambients are unavoidable at times. These are the general issues most in need of address in future development. Since the time (and memory) for singularity checks can often vastly outweigh the time for the main processing, singularity checks are usually *only* performed when the user explicitly asks for them by setting a parameter value to `true`.

The main functionality is for the computation of fundamental invariants (irregularity, geometric genus etc.), checks for different type of 'non-singularity' (e.g. Gorenstein, only simple singularities), Kodaira-Enriques classification, computation of minimal models (including the full canonical model for a surface of general type) and construction of random surfaces from certain families in $\mathbf{P}^4$.

116.2.2 Creation Functions

As for general schemes and curves, surfaces may be created in any of MAGMA's ambient spaces. However, nearly all of the current specialised surface functionality only applies to surfaces in ordinary projective space.

The requirement for a scheme to be a surface is that it is defined over a field, is of dimension 2 and is geometrically integral (reduced and irreducible when base extended to the algebraic closure of the ground field). Due to the difficulty in checking for *geometric* integrality, at present we only test for integrality (reduced and irreducible over the base field).

See Section 116.4.2 for some specific creation intrinsics for Del Pezzo surfaces and Section 116.4.3 for some additional degree 6 Del Pezzo constructors. Additionally, see Section 116.2.7 for intrinsics to create a range of surfaces in $\mathbf{P}^4$ belonging to special families.

`Surface(A,I)`

`Surface(A,f)`

`Surface(A,S)`

`Nonsingular`	BOOLELT	*Default :* `false`
`Check`	BOOLELT	*Default :* `true`
`Saturated`	BOOLELT	*Default :* `false`

Let A be an ambient or a scheme which already has some defining equations. The function returns the surface defined by the ideal I, the single polynomial f or the sequence of polynomials S within the scheme A.

If I or the set of new defining equations added to those of A generate an ideal that is known to be saturated (*c.f.* Section 112.3), `Saturated` can be set to `true`. If the surface is known to be non-singular or singular, much subsequent calculation

can be avoided by setting `Nonsingular` to `true` or `false`. The parameter `Check` is `true` by default and forces the function to check that the surface is integral (reduced and irreducible) by testing primality of the (saturated) defining ideal. This can be an expensive computation in high-dimensional ambients, so it is best to set `Check` to `false` if it is known in advance that the surface is integral. As stated above, our actual requirement is that surfaces are geometrically integral (equivalently, the surface is integral and the base field is integrally closed in the coordinate ring) because many of the surface intrinsics only really make sense for such varieties. However, this is a more difficult property to test. In practice, integrality should usually imply geometric integrality.

`RationalRuledSurface(P,n)`

Returns a rational, ruled surface X in the ordinary, projective ambient $P = \mathbf{P}^m$ with parameters $n, m-1-n$ where n is the second argument. Such a surface is a rational scroll that can be defined in a number of equivalent ways (see Appendix A2H, [Eis05]).

Let $\mathbf{P}^n$ and $\mathbf{P}^{m-1-n}$ be the linear subspaces of P corresponding to the first $n+1$ coordinates and the last $m-n$ coordinates respectively. Then X is given geometrically as the union of the lines L_{QR} joining a point Q on a rational normal curve in $\mathbf{P}^n$ to a point R on a rational normal curve in $\mathbf{P}^{m-1-n}$, where Q and R correspond under a fixed isomorphism of the first rational normal curve to the second. In the cases $n = 0$ and $n = m-1$, the first or second rational normal curve degenerates to a single point and X is the cone of all lines from a rational normal curve in a hyperplane of P to a point (the apex) outside of the hyperplane. The apex is the only singular point of the surface X (and is not a simple singularity in general). In the non-degenerate cases, X is non-singular. n must always be between 0 and $m-1$ (inclusive).

Following the notation of Section 2, Chapter 5 of [Har77], the rational ruled surface with parameters r, s can also be defined as follows. If e is $\mathrm{Max}(r,s)$-$\mathrm{Min}(r,s)$ and v is $\mathrm{Max}(r,s)$, then X is the Hirzebruch surface X_e (Thm. 2.17, *ibid*) mapped into P via the linear system $|C_0 + v * f|$, which gives an embedding precisely in the non-degenerate cases.

The second return value is a scheme map f from X to $\mathbf{P}^1$ which defines the ruling on X: the fibres of f are all lines in P.

`RandomCompleteIntersection(P,ds)`

`Nonsingular`	BoolElt	*Default :* `true`
`RndP`	RngIntElt	*Default :* 1

This is the same as the general scheme intrinsic to generate a random complete intersection scheme in ordinary projective space $P = \mathbf{P}^m$ over a finite field or the rationals. *ds* should be a sequence of positive integers of length $m-2$. The intrinsic will generate random homogeneous polynomials $F_1, \ldots, F_{m-2}$ of degrees $ds[1], \ldots, ds[m-2]$ in the coordinate ring of P and return the subscheme X of P

with the F_i as defining equations. It is checked that X has dimension 2 (in which case all irreducible components have dimension 2). If parameter `Nonsingular` is set to the default value of `true`, the non-singularity (actually smoothness) is also checked. This guarantees that X is geometrically integral and the result is returned as a surface type `Srfc`. If the check is not performed, X is constructed as a plain `Sch`. If X fails the dimension or non-singularity check, a new set of random polynomials is generated.

If the rationals are the base field, the parameter `RndP` is a positive integer used as an upper absolute bound for random coefficients of polynomials. That is, the algorithm uses random integers between $-RndP$ and $+RndP$ inclusive. The default value here is 1.

`KummerSurfaceScheme(C)`

Returns the Kummer surface of the Jacobian J of the genus 2 hyperelliptic curve C. This is a singular model of the surface: a quartic hypersurface in $\mathbf{P}^3$ with 16 simple "A1" singularities corresponding to the 16 points of order 1 or 2 on J. Its desingularisation is a K3 surface.

Example H116E1

We illustrate the basic creation functions with some simple examples. Firstly, we create a degree 3 (Del Pezzo) and a degree 4 (K3) surface in $\mathbf{P}^3$ directly by giving a defining equation.

```
> P3<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> X := Surface(P3,x^3+y^3+z^3+t^3);
> X;
Surface over Rational Field defined by
x^3 + y^3 + z^3 + t^3
> X := Surface(P3,x^4+y^4+z^4+t^4);
> X;
Surface over Rational Field defined by
x^4 + y^4 + z^4 + t^4
```

We can create a degree 5 Del Pezzo surface in $\mathbf{P}^5$ by specifying it as the projective plane blown up in 4 points (and anti-canonically embedded).

```
> P2<x,y,z> := ProjectiveSpace(Rationals(),2);
> pts := [* P2![1,0,0],P2![0,1,0],P2![0,0,1],P2![1,1,1] *];
> X := DelPezzoSurface(P2,pts);
> P5<x,y,z,s,t,u> := Ambient(X);
> X;
Del Pezzo Surface of degree 5 over Rational Field defined by
-y*z + x*s + s^2 - s*t - s*u + t*u,
-y*s + s^2 + x*t - s*t,
-z*s + s^2 + x*u - s*u,
-s^2 + s*t + y*u - t*u,
```

```
-s^2 + z*t + s*u - t*u
```

The next example is a random surface in $\mathbf{P}^5$ which is the complete intersection of hypersurfaces of degrees 2, 2 and 3

```
> P5<x,y,z,s,t,u> := ProjectiveSpace(Rationals(),5);
> X := RandomCompleteIntersection(P5,[2,2,3]);
> X;
Surface over Rational Field defined by
-y*z-z^2-x*s+y*s+z*s-s^2-x*t-y*t-z*t+s*t+t^2-x*u-y*u-z*u-t*u,
-x^2+z^2-y*s+s^2+x*t+y*t-z*t+s*t+z*u-s*u+t*u-u^2,
-x^3-x^2*y+y^2*z-x*z^2+y*z^2-x^2*s+x*z*s+y*z*s+z^2*s+x*s^2-y*s^2+z*s^2+s^3-x^2*t+
x*z*t-z^2*t-x*s*t-x*t^2+y*t^2+z*t^2+s*t^2-t^3+x*y*u-y^2*u+x*z*u+y*z*u+y*s*u+z*s*u
-s^2*u-x*t*u+y*t*u-z*t*u+s*t*u+t^2*u+x*u^2-y*u^2+t*u^2-u^3
```

The next example is a rational ruled surface in $\mathbf{P}^4$ with parameters $2, 1$. This is a nonsingular surface scroll that is abstractly isomorphic to the Hirzebruch surface X_1 (the plane blown up at one point).

```
> P4<x,y,z,s,t> := ProjectiveSpace(Rationals(),4);
> X := RationalRuledSurface(P4,2);
> X;
Surface over Rational Field defined by
-z*s + y*t,
-y*s + x*t,
-y^2 + x*z
```

Finally, we call one of the intrinsics from the section on surfaces in $\mathbf{P}^4$ to get an Abelian surface (2-dimensional Abelian variety) which is the zero locus of a random global section of the famous Horrocks-Mumford vector bundle. There are 18 defining equations of degrees 5 and 6 that we do not list.

```
> P4<x,y,z,s,t> := ProjectiveSpace(Rationals(),4);
> X := RandomAbelianSurface_d10g6(P4);
> #DefiningPolynomials(X);
18
> [TotalDegree(f) : f in DefiningPolynomials(X)];
[ 5, 5, 5, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6, 6 ]
```

116.2.3 Invariants

The following functions give standard invariants for projective surfaces with only A-D-E singularities (or slightly weaker assumptions). Due to the current limitations of the cohomology and sheaf machinery, most are only available for ordinary projective surfaces. For corresponding functions that give invariants of the desingularization of hypersurfaces with more general singularities, see Section 116.3.4. Key invariants are stored when computed.

`GeometricGenus(S)`

`CheckGor`	BoolElt	*Default :* `false`
`UseCohom`	BoolElt	*Default :* `false`

The surface S should be an ordinary projective surface which is Gorenstein (this guarantees that a canonical sheaf K exists as a dualising sheaf and is invertible). Returns the geometric genus of S, defined as the dimension of the space of global sections of K, $h^0(K)$.

The boolean parameter `CheckGor` (default `false`) can be set to true to force a check that S is Gorenstein if this isn't already known and stored. By default, the computation computes (and stores) K and then does a direct computation of its global sections. The alternative method is to compute the genus via cohomology since the dimension of H^2 of the structure sheaf is equal to the genus. Set `UseCohom` to `true` to apply the second method. The advantage of the first method is that it is currently faster (in general) and also that K is used in many other intrinsics. Note that unless S is non-singular or has only A-D-E singularities, the genus computed here will generally be larger than the geometric genus of a desingularization of S.

`Plurigenus(S,n)`

`CheckGor`	BoolElt	*Default :* `false`

The surface S and parameter `CheckGor` are as in `GeometricGenus` above. The integer n should be non-negative. Returns the dimension of the space of global sections of the nth tensor power of the canonical sheaf K of S. Again this will generally be larger than the nth plurigenus of a desingularization of S unless S has at worst simple singularities.

`ArithmeticGenus(S)`

Given a scheme S, this function returns the arithmetic genus. It is, in fact, the general scheme intrinsic.

`Irregularity(S)`

`CheckGor`	BoolElt	*Default :* `false`
`UseCohom`	BoolElt	*Default :* `false`

The irregularity q of S, an ordinary projective surface, defined as the dimension of the cohomology group $H^1(S, O_S)$, where O_S is the structure sheaf of S.

If S is known to be Gorenstein or the geometric genus has already been computed and stored, this is computed from the geometric genus p_g and arithmetic genus p_a using the formula $q = p_g - p_a$. Note that S will be known Gorenstein if it is known to be non-singular or to only have simple singularities (All of these properties will have been stored if already tested for. See next section.).

If `CheckGor` is set to `true` (the default is `false`), and the above conditions arent satisfied, Gorensteinness will be checked and, if S is Gorenstein, the above procedure will be followed. Otherwise, the cohomology machinery is used directly.

Setting `UseCohom` to `true` (the default is again `false`) will force the cohomology machinery to be used, unless the value of q has already been computed and stored.

`ChernNumber(S,n)`

`CheckADE` BoolElt *Default :* `false`

The surface S should be ordinary projective with at most simple (A-D-E) singularities. The integer n should be 1 or 2. The singularity condition, if not already known, will only be tested for if `CheckADE` is set to `true` (default is `false`). The function returns the nth Chern number of S_1, the *minimal* desingularization of S. For $n = 1$, this is just the intersection product $K.K$, where K is the canonical sheaf of S_1. Thanks to the singularity condition, this can just be computed on S. For $n = 2$, the Chern number $c_2(S)$ is computed from the relation $c_2(S) + K.K = 12 * (1 + p_a)$, where p_a is the arithmetic genus of S.

`MinimalChernNumber(S,n)`

`CheckADE` BoolElt *Default :* `false`

The surface S should be ordinary projective with at most simple (A-D-E) singularities. The integer n should be 1 or 2. The singularity condition, if not already known, will only be tested for if `CheckADE` is set to `true` (default is `false`). The function computes and returns the relevant Chern number for a minimal model S_2 of a desingularisation S_1 of S. As above, these numbers follow from knowing $K_m.K_m$ where K_m is the canonical sheaf of S_2. If k is the base-field and S is not rational or birationally ruled (i.e. of Kodaira dimension -1), then S_2 is defined over k and is unique up to k-isomorphism. In these cases, $K_m.K_m$ is known from the Kodaira dimension and the second plurigenus in the Kodaira dimension 2 (general type) case. For rational and ruled surfaces, the minimal model is not unique up to isomorphism and a geometrically minimal model may not be defined over k. In these cases, we conventionally take for the invariants a minimal model over the algebraic closure of k with maximal $K_m.K_m$, which is therefore 9 for rational S and 8 for non-rational, ruled S.

`HodgeNumber(S,i,j)`

`CheckADE` BoolElt *Default :* `false`

The surface S should be an ordinary projective with at most simple (A-D-E) singularities. The singularity condition, if not already known, will only be tested for if `CheckADE` is set to `true` (default is `false`).

The integers i, j should be such that $0 \leq i, j \leq 2$. The function returns the Hodge number $h^{i,j}$ of the minimal desingularization S_1 of S which is the dimension of the cohomology group $H^j(S_1, D^i)$ where D^i is the ith alternating power of the sheaf of differentials of S_1. These are computed by formula from the fundamental invariants which are the geometric genus, the irregularity and the first Chern number of S (or S_1).

Example H116E2

We take an easy example: the Kummer surface of the Jacobian of a genus 2 hyperelliptic curve, embedded in $\mathbf{P}^3$ as a degree 4 surface with 16 A_1 singularities lying beneath the 16 points of order 2 on the Jacobian. A nonsingular quartic in $\mathbf{P}^3$ is a K3 surface and simple singularities don't affect the quartic being K3. We verify this here for the Kummer surface, finding that the invariants are the standard invariants for a K3 surface.

```
> f := PolynomialRing(Rationals())![-1,0,0,0,0,0,1]; //t^6-1
> X := KummerSurfaceScheme(HyperellipticCurve(f));
> IsSingular(X);
true
> HasOnlySimpleSingularities(X);
true
> GeometricGenus(X);
1
> ArithmeticGenus(X);
1
> Irregularity(X);
0
> [ChernNumber(X,i) : i in [1,2]];
[ 0, 24 ]
> for i in [0..2], j in [0..2] do
>  printf "%o,%o : %o\n",i,j,HodgeNumber(X,i,j);
> end for;
0,0 : 1
0,1 : 0
0,2 : 1
1,0 : 0
1,1 : 20
1,2 : 0
2,0 : 1
2,1 : 0
2,2 : 1
```

116.2.4 Singularity Properties

This section contains intrinsics for testing for various levels of 'singularity' of a surface. There are further intrinsics applying to more general schemes in Chapter 112 for basic singularity/non-singularity as well as tests for whether a scheme is locally/arithmetically Cohen-Macaulay or locally/arithmetically Gorenstein. The tests here that are currently specific to surfaces are for normality and for having only simple (A-D-E) singularities. All of these properties are stored when computed for a surface/scheme and the various implications between them are used to shortcut tests. The intrinsics below rely on being able to compute the singular subscheme of the surface and having each singular point lying in a constructible affine patch, so they apply to surfaces lying in a wide range of ambients.

`IsNormal(S)`

Returns whether the surface S is a normal variety. The normality test used here consists of checking that the singular subscheme of S is empty or has dimension zero and applying a local normality test at each singular point p (over a splitting field). The local test used is simply whether the depth of the local ring is 2. Taking an affine patch at p and translating to the origin, we simply consider the quotient of the coordinate ring by a non-vanishing coordinate variable and check that the maximal homogeneous ideal is not an associated prime by a straightforward saturation computation. We could have also chosen to use our test for being Cohen-Macaulay once it is known that the singular subscheme of S is zero dimensional.

`IsSimpleSurfaceSingularity(p)`

The point p should be a point in the pointset of a surface S. It is referred to as a simple or A-D-E singularity if it is an isolated singularity on S which is analytically of the type A_n, $n \geq 1$, D_n, $n \geq 4$, E_6, E_7 or E_8 as described in Chapter III, Section 7 of [BHPdV04]. For convenience, if p is non-singular on S, we class it as a simple singularity of type A_0. These are all Gorenstein (even l.c.i) singularities. Their significance is that they are the surface singularities that impose no 'adjunction' condition on the canonical sheaf with respect to computing the canonical sheaf of the minimal desingularization S_1 of S. They all resolve to a collection of (-2)-curves on S_1 whose intersection pairing matrix is the negative of that of the root system with which they share a label.

This intrinsic tests whether p is a simple singularity and, if so, returns the type as a string ("A", "D" or "E") along with the index n (e.g. 6, 7 or 8 for type "E"). It requires that the characteristic of the base field of S is not 2. Also, the E_n types can be a little awkward to analyse in characteristic 3. Therefore in char. 3, the intrinsic always returns `false` if p is a possible E type singularity.

The intrinsic first uses `IsHypersurfaceSingularity` to determine whether p is analytically isomorphic to a hypersurface singularity (which is the case for all simple singularities) and then tests for A-D-E type by examining the expansion of the equation that defines the analytically equivalent singularity.

NB: The intrinsic doesn't fully check that p is an isolated singularity (i.e., that it doesn't lie on a curve in the singular locus of S). It may crash or hang in some cases where p is not isolated.

`HasOnlySimpleSingularities(S)`

`ReturnList` BoolElt *Default :* `false`

This intrinsic determines whether the surface S has no singularities worse than isolated simple singularities as described in the previous intrinsic. Again, the characteristic of the base field of S should not be 2. If S has only simple singularities and `ReturnList` is `true` (the default is `false`), a list is also returned containing triples that consist of each singular point of S (in a pointset over an extension of the base field) along with its type, given as a string and index number as described

previously. In some cases, it may be already known (and recorded internally) that there are only simple singularities without their precise type having been computed. For example, if S is a minimal or weighted canonical model of a surface of general type.

Example H116E3

Anticanonically-embedded *degenerate* Del Pezzo surfaces of degree ≥ 3 are singular but have only simple singularities. We verify this for a degree 4 Del Pezzo which has 2 conjugate (over a quadratic extension) A_1 singularities.

```
> P<x,y,z,t,u> := ProjectiveSpace(Rationals(),4);
> X := Surface(P,[x*z-y^2, t^2-2*u^2+x^2-2*z^2]);
> HasOnlySimpleSingularities(X : ReturnList := true);
true [* <(0 : 0 : 0 : r1 : 1), "A", 1>, <(0 : 0 : 0 : r2 : 1), "A", 1> *]
> _,lst := $1;
> Ring(Parent(lst[1][1]));
Algebraically closed field with 2 variables over Rational Field
Defining relations:
[
    r2^2 - 2,
    r1^2 - 2
]
```

As a second example, we consider a singular rational ruled surface (scroll) that is the cone over a rational normal curve. The intrinsics tell us that the surface is normal and Cohen-Macaulay (i.e., the local ring at the singular point at the apex of the cone satisfies these properties) but that it satisfies none of the stronger "non-singularity" properties.

```
> P4<x,y,z,t,u> := ProjectiveSpace(Rationals(),4);
> X := RationalRuledSurface(P4,0);
> // one singular point
> Degree(ReducedSubscheme(SingularSubscheme(X)));
1
> Support(SingularSubscheme(X));
{ (1 : 0 : 0 : 0 : 0) }
> HasOnlySimpleSingularities(X);
false
> IsArithmeticallyGorenstein(X);
false
> IsGorenstein(X);
false
> IsCohenMacaulay(X);
true
> IsNormal(X);
true
```

116.2.5 Kodaira-Enriques Classification

`KodairaEnriquesType(S)`

`CheckADE` BoolElt *Default :* `false`

The argument S is a surface in ordinary projective space having at most simple (A-D-E) singularities. As it may be a very heavy computation, the latter is only checked if the user sets the `CheckADE` parameter is set to `true` (the default is `false`).

The function computes the type of S (or rather, of the non-singular projective surfaces in its birational equivalence class) according to the classification of Kodaira and Enriques.

The first number returned is the *Kodaira dimension* of S, which is -1, 0, 1, or 2. We use -1 here rather than $-\infty$. A second return value further specifies the type within the Kodaira dimension -1 or 0 cases (and is irrelevant in the other two cases).

Kodaira dimension -1 corresponds to birationally ruled surfaces. The second number returned in this case is the irregularity $q \geq 0$ of S. So S is birationally equivalent to a ruled surface over a smooth curve of genus q and is a *rational* surface if and only if q is zero.

Kodaira dimension 0 corresponds to surfaces which are birationally equivalent to a K3 surface, an Enriques surface, a torus or a bi-elliptic surface. In the final case, there is a partial subclassification in that the canonical sheaf of the minimal model is a torsion sheaf of order r, where r is 2, 3, 4, or 6. The second integer return value in the Kodaira dimension zero case codes the subtypes as follows:-

-3	Enriques surface
-2	K3 surface
-1	Torus
r	$r = 2, 3, 4$ or 6. Bielliptic surface of subtype r

A third return value is a string that gives a verbal description of the surface type (e.g. "Rational" or "Bi-elliptic (type 3)"). Kodaira dimension 1 surfaces are labelled as "Elliptic fibration" (which they all are – though there are also surfaces of Kodaira dimension less than 1 which have elliptic fibrations) and Kodaira dimension 2 surfaces are labelled as "General type", as is traditional.

There are no built-in restrictions on the characteristic of the base field, but there are some special cases for surfaces of Kodaira dimension 0 in characteristics 2 and 3 that may not be dealt with properly.

The function works by computing a number of the invariants of S and sometimes also considering the dimension of the image of appropriate pluri-canonical maps. We try to compute the least number of invariants to fully determine the type. A useful by-product is that, after calling this function, a number of the surface invariants (always including the geometric genus and irregularity) will have been computed and stored for later use. The type information is also stored.

`KodairaEnriquesDimension(S)`

`CheckADE` BoolElt *Default :* `false`

The argument S is a surface in ordinary projective space having at most simple (A-D-E) singularities. The later condition will only be checked if the parameter `CheckADE` is set to `true`. The function simply returns the Kodaira dimension (-1,0,1,2) without further type information. In most cases it does the same amount of work as to compute the full Kodaira-Enriques type, unless the result has already been determined and stored.

Example H116E4

We will present further cases of Kodaira-Enriques typing in our minimal model examples. For now, we just give two simple examples: a Veronese surface in $\mathbf{P}^5$ and the Kummer surface in $\mathbf{P}^3$ with simple singularities from our earlier example.

The scheme X is a Veronese surface, isomorphic to P^2:

```
> P<a,b,c,d,e,f> := ProjectiveSpace(Rationals(),5);
> X := Surface(P,[b^2-a*c, a*d-b*f, b*d-c*f, d^2-c*e, a*e-f^2, b*e-d*f]);
> // X is a Veronese surface, isomorphic to P^2
> KodairaEnriquesType(X);
-1 0 Rational
```

The scheme X is a singular K3 surface:

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> X := Surface(P,x^3*t+x^2*z^2-8*x*y^2*z-x*z*t^2+16*y^4+y^2*t^2-z^3*t);
> KodairaEnriquesType(X);
0 -2 K3
```

116.2.6 Minimal Models

In contrast to the curve case, a birational equivalence class of surfaces contains an infinite number of non-isomorphic projective, non-singular surfaces. Any two such surfaces are linked by a birational map that consists of a sequence of blowing up points and blowing down exceptional curves (rational (-1)-curves). For any non-singular, projective surface, a sequence of blow downs of exceptional curves will result in a surface with no more exceptional curves after a finite number of steps. Such a surface is referred to as a *minimal model*. It is also possible to further contract connected cycles of rational (-2)-curves to simple singularities. Sometimes minimal model also refers to a surface on which these contractions have been performed. This is particularly true for surfaces of general type where the pluri-canonical models are minimal in this second sense.

For surfaces of Kodaira dimension greater than or equal to zero, there is a unique minimal model (up to isomorphism) within the birational equivalence class. That is, the minimisation procedure of blowing down exceptional curves will always lead to the same thing starting with any non-singular projective surface within that class. This can be

carried out over an arbitrary base field and the minimal model is a unique representative of the class, which partly explains its importance.

For rational or ruled surfaces, there is not a unique minimal model. Over an algebraically closed field, the minimal models in these cases are the projective plane and the *geometrically ruled surfaces* which are fibrations over a non-singular, projective base curve C, all of whose fibres are irreducible curves isomorphic to the projective line. The rational surfaces are those with C rational (in this case, one of the ruled surfaces is not minimal but is the plane blown up in one point). Over a non-algebraically closed base field k, it may not be possible to blow down all exceptional curves working over k and so there are k-minimal surfaces (certain Del Pezzo surfaces, for example) that are not minimal over the algebraic closure. Models like Del Pezzo surfaces that are close to minimal but may not strictly even be minimal over k are still very important for rational and ruled surfaces because they allow the reduction to a small class of standard isomorphism types. We can think of these as quasi-minimal.

This section describes functions which are designed to construct minimal models or quasi-minimal models of ordinary projective surfaces. The precise meaning of this varies a little depending on the Kodaira dimension of S, so there are distinct functions for the different dimensions. The Kodaira dimension, if unknown, can be determined by use of the intrinsics in the previous section.

More of these intrinsics really should work for surfaces with simple singularities - at least, if the user is happy with a result that also has simple singularities. For the moment, except for surfaces of general type (Kodaira dimension 2), we require S to be non-singular.

The output minimal models are all non-singular except for surfaces of general type where all (-2)-curves are contracted to simple singularities, as is traditional. There is also an intrinsic to compute the full canonical model (which lies in weighted projective space in general) and the canonical coordinate ring of a surface of general type. With the Kodaira dimension 1 minimal models, the user can optionally ask for a map to a smooth projective curve C that presents the minimal model M as an elliptic fibration over C. In this case, M is the global arithmetic minimal model of its generic fibre.

`MinimalModelRationalSurface(S)`

`CheckSing` BoolElt *Default :* `false`

Let S should be a non-singular ordinary projective rational (Kodaira dimension -1 and irregularity 0) surface. Non-singularity is not checked by default so to force a check, set `CheckSing` to `true`. It is also left to the user to check that S is rational (using Section KodairaEnriquesType for example).

The intrinsic does not strictly compute a minimal model M (there may be (-1)-curves that can still be blown down over the base field), but instead it produces a standard model that is terminal for the adjunction process.

This means that M will be a member of a small family of special rational surfaces: the projective plane or its Veronese embedding in $\mathbf{P}^5$, an anticanonically embedded Del Pezzo surface, a rational scroll or a conic bundle. Other functions for special surfaces may then be applied to M – to parametrize it, for example.

The return value is a rational map f from S onto M (M may be recovered as the codomain of f) which will be of type `MapSchGrph` or `MapSch`. The implementation proceeds by simply iterating the adjunction map until simple termination criteria are recognised.

Example H116E5

We take one of the family of non-singular rational surfaces in $\mathbf{P}^4$ that can be generated by the `RandomRationalSurface_d10g9` intrinsic to be described later. These surfaces are very far from minimal. They have exceptional curves of degrees 3, 2 and 1 in the $\mathbf{P}^4$ embedding and the theory tells us that we need 2 adjunction maps to reduce the surface to a degree 5 Del Pezzo in $\mathbf{P}^5$, which is terminal. The degree of non-minimality is measured by the first Chern number $K.K$, with $9 - K.K$ or $8 - K.K$ telling us how many point blowups it takes to get from a geometric minimal model (over $\bar{k}$) to the surface, depending on whether the geometric minimal model is $\mathbf{P}^2$ or a rational ruled surface. Here, we start at -9 and get to 5 for the Del Pezzo, which is $\mathbf{P}^2$ blown up at 4 points over the algebraic closure of the base field. We choose to work over a finite field so that the example completes quickly.

`MinimalModelRuledSurface(S)`

`CheckSing` BoolElt *Default :* `false`

The surface S should be non-singular ordinary projective of Kodaira dimension -1. Non-singularity is not checked by default so to force a check, set `CheckSing` to `true`. It is also left to the user to check that S is of the correct Kodaira dimension (using `KodairaEnriquesType` for example).

If S is rational, the intrinsic `MinimalModelRationalSurface` is applied. For non-rational ruled surfaces, the same adjunction procedure is applied to lead to a terminal model M, which is either a non-rational scroll and genuinely minimal, a conic bundle over a non-rational curve that may not be strictly minimal (it may have degenerate fibres that are the intersecting unions of two (-1)-curves) or a non-split minimal ruled surface over a genus one curve embedded as a degree 9 surface in $\mathbf{P}^6$ in such a way that the fibres of the ruling have degree 3.

The return value is a rational map f from S onto M (M may be recovered as the codomain of f) and will be of type `MapSchGrph` or `MapSch`.

`MinimalModelKodairaDimensionZero(S)`

`CheckSing` BoolElt *Default :* `false`

The surface S should be non-singular ordinary projective of Kodaira dimension 0. Non-singularity is not checked by default so to force a check, set `CheckSing` to `true`. It is also left to the user to check that S is of the correct Kodaira dimension (using `KodairaEnriquesType` for example).

The function computes a minimal model M of S, again by repeatedly applying the adjunction map until minimality occurs (the first Chern number is zero).

The return value is a rational map f from S onto M (M may be recovered as the codomain of f) and will be of type `MapSchGrph` or `MapSch`.

Example H116E6

We start with an example of a non-minimal surface X that is a torus T blown up in one point. Such examples naturally occur when T is the Jacobian J of a genus 2 curve C. The product of the C with itself quotiented by an appropriate involution is such an X. It has a natural embedding in $\mathbf{P}^7$. This turns out to be the projection from the zero point of J embedded in $\mathbf{P}^8$ (by three times the theta divisor).
We work over a finite field for speed (although the example doesn't take too long over the rationals). Our example corresponds to the curve C with Weierstrass equation $y^2 = x^5 - 1$. The

minimal model routine has the effect of *unprojecting* here: it recovers the torus J in its $\mathbf{P}^8$ embedding.

> ChernNumber(Y,1);
0
```

So we have one exceptional line blown down and Y is now minimal.

Example H116E7

For our second example, we take a surface of Enriques type in $\mathbf{P}^4$ which comes from one of the special families of $\mathbf{P}^4$ surfaces to be described later. Such surfaces are non-minimal, but isomorphic to an Enriques surface blown up at one point. As we are choosing a random surface from a family which will be defined by many non-sparse equations, we work over a finite field for speed.

```
> k := GF(37);
> P := ProjectiveSpace(k,4);
> X := RandomEnriquesSurface_d9g6(P);
> #DefiningPolynomials(X);

Variables: y[1], y[2], y[3], y[4], y[5], y[6]
10
> ChernNumber(Y,1);
0
```

`MinimalModelKodairaDimensionOne(S)`

`CheckSing`	BoolElt	*Default :* `false`
`Fibration`	BoolElt	*Default :* `false`

Let S be a non-singular ordinary projective surface of Kodaira dimension 1. Non-singularity is not checked by default and to force a check, set `CheckSing` to `true`. It is also left to the user to check that S is of the correct Kodaira dimension (using `KodairaEnriquesType` for example).

The function computes a minimal model M of S. Such a model always has a connected elliptic fibration to a smooth projective curve C (i.e. there is a morphism g from M onto C such that the general fibre of g is a smooth curve of genus 1). If `Fibration` is set to `true` (the default is `false`), the function also computes g and returns it as a second return value.

The first return value is a rational map f from S onto M (M may be recovered as the codomain of f) and will be of type `MapSchGrph` or `MapSch`.

The computation of f again proceeds by repeating adjunction until the first Chern number is zero. There is a slight speed-up here, though, that we apply when S has positive geometric genus. We use the appropriate modification of the image of an effective canonical divisor to compute a new canonical divisor at each stage of adjunction. Although this doesn't usually speed up the computation of the next adjunction map, it can greatly increase the speed of computation of the new first Chern number, which speeds up testing of the termination criterion.

If required, g may be computed by using an appropriate small multiple of the pluricanonical map on M.

`MinimalModelGeneralType(S)`

`CanonicalWeightedModel(S)`

`CheckADE`	BoolElt	*Default :* `false`

The surface S should be ordinary projective of general type (Kodaira dimension 2) with at worst simple (A-D-E) singularities. The singularity condition is not checked by default and to force a check, set `CheckADE` to `true`. It is also left to the user to check that S is of general type (using `KodairaEnriquesType` for example).

The intrinsics construct a minimal model M for S which is of the canonical type: it has any (-2)-curves contracted to simple singularities.

The first intrinsic produces M as an ordinary projective surface as before, which is an m-canonical embedding with m equal to 3 generally but 4 or 5 when S has certain small invariants. This is implemented simply by computing the m-canonical map on S (this map automatically factors through a non-singular minimal model). The drawback of this is that M is usually defined in a high-dimensional projective space. There is a very simple check to see whether the canonical sheaf or the bi-canonical sheaf is very ample, in which case M is just taken as S.

The second intrinsic actually computes the *full* canonical model of S. This is a (generally weighted) projective model of M equal to *Proj* of the canonical coordinate

ring $\sum_{n=0}^{\infty} H^0(S, K_S^{\otimes n})$, where K_S is the canonical sheaf of K. This is more intrinsic and it generally gives a model in a much lower-dimensional space with the drawback that this space is now weighted. The cases where the canonical or bicanonical image is actually isomorphic to M will show up in this version whereas it will produce an actual ordinary projective model in the first case. Currently, this intrinsic has the small restriction that S cannot have geometric genus (and irregularity) zero. The implementation involves calculating with Riemann-Roch spaces for small multiples of an effective canonical divisor.

For either intrinsic, the first return value is a rational map f from S onto M (M may be recovered as the codomain of f) which will be of type `MapSchGrph` or `MapSch` for the first intrinsic and of type `MapSch` only for the second. A second return value is a boolean with value `true` if and only if the original model X is minimal in the sense of containing no (-1)-curves.

`CanonicalCoordinateIdeal(S)`

`CheckADE` BoolElt *Default :* `false`

The surface S should be ordinary projective of general type (Kodaira dimension 2) with at worst simple (A-D-E) singularities. The singularity condition is not checked by default and to force a check, set `CheckADE` to `true`. It is also left to the user to check that S is of general type (using `KodairaEnriquesType` for example).

This intrinsic constructs the full canonical coordinate ring of S as described for `CanonicalWeightedModel`. What is returned is a homogeneous ideal I in a polynomial ring R with variable weightings over the base field of S such that the canonical coordinate ring is isomorphic to the quotient R/I as a graded ring.

Example H116E8

We give two examples of computing minimal models for some surfaces of general type. We begin with a non-singular type I Horikawa surface with first Chern number K^2 equal to 3. It is already minimal and the bi-canonical map gives an embedding into $\mathbf{P}^6$. We start with a bicanonical model. The first intrinsic luckily recognises that the surface is bi-canonical and just returns it as a minimal model. The second intrinsic finds the well-known weighted-projective embedding for such surfaces as a sextic hypersurface in a $\mathbf{P}(1,1,1,2)$ weighted projective space. (see Section 9, Chapter VII, [BHPdV04] or [Hor76]).

```
> P<x1,x2,x3,x4,x5,x6,x7> := ProjectiveSpace(Rationals(),6);
> X := Surface(P,[
>  -x4*x5 + x2*x6, x1*x5 - x4*x6,
>   x3*x4 - x5*x6, x2*x3 - x5^2,
>   x1*x3 - x6^2, x1*x2 - x4^2,
>   x1^3+x1*x2^2+x2^2*x3-x2*x3^2+x3^3+x2^2*x4+x1*x3*x4-x2*x3*x4+x1*x4^2-
>    x2*x4^2-x3*x4^2-x1*x2*x5-x1*x3*x5+x2*x3*x5+x1*x4*x5-x2*x4*x5+x4^2*x5-
>    x1*x5^2+x2*x5^2-x3*x5^2-x5^3-x1^2*x6+x1*x2*x6-x2*x3*x6-x2*x4*x6+
>    x1*x5*x6-x3*x5*x6-x4*x5*x6+x5^2*x6+x1*x6^2+x2*x6^2-x3*x6^2+x5*x6^2-
>    x1*x2*x7+x1*x3*x7+x2*x3*x7-x3^2*x7+x1*x4*x7-x2*x4*x7-x4^2*x7+x5^2*x7+
>    x2*x6*x7+x3*x6*x7-x4*x6*x7+x5*x6*x7-x6^2*x7+x3*x7^2+x4*x7^2+x5*x7^2-
```

```
>    x6*x7^2-x7^3 ]);
> IsSingular(X);
false
> KodairaEnriquesType(X);
2 0 General type
> mp := MinimalModelGeneralType(X);
> X1 := Codomain(mp); //the minimal model
> X1 eq X;
true
> mp1 := CanonicalWeightedModel(X);
> Y := Codomain(mp1);
> PW<a,b,c,d> := Ambient(Y);
> PW;
Projective Space of dimension 3 over Rational Field
Variables: a, b, c, d
The grading is:
    1, 1, 1, 2
```

The fact that the full weighted canonical model has only weights 1 and 2 also shows that the bi-canonical map is an embedding.

```
> Y;
Surface over Rational Field defined by
a^6 + a^4*b^2 + a*b^5 - a^5*c + 2*a^3*b^2*c - a^2*b^3*c - a*b^4*c + a^4*c^2 +
 2*a^3*b*c^2 - 2*a^2*b^2*c^2 - a*b^3*c^2 + 2*b^4*c^2 - a^2*c^4 - a*b*c^4 -
 2*b^2*c^4 + c^6 + a^3*b*d - 2*a^2*b^2*d - a*b^3*d - a^2*b*c*d + a*b^2*c*d +
 a*b*c^2*d + 2*b^2*c^2*d + a*c^3*d - c^4*d + a*b*d^2 - a*c*d^2 + b*c*d^2 +
 c^2*d^2 - d^3
```

We can also ask for the canonical coordinate ideal that defines the canonical coordinate ring which is the coordinate ring of Y. The call takes no time as the canonical weighted model Y and map `mp1` from X to Y have been stored internally.

```
> time CanonicalCoordinateIdeal(X);
Ideal of Graded Polynomial ring of rank 4 over Rational Field
Order: Grevlex with weights [1, 1, 1, 2]
Variables: a, b, c, d
Variable weights: [1, 1, 1, 2]
Homogeneous, Dimension >0
Groebner basis:
[
a^6 + a^4*b^2 + a*b^5 - a^5*c + 2*a^3*b^2*c - a^2*b^3*c - a*b^4*c + a^4*c^2 +
 2*a^3*b*c^2 - 2*a^2*b^2*c^2 - a*b^3*c^2 + 2*b^4*c^2 - a^2*c^4 - a*b*c^4 -
 2*b^2*c^4 + c^6 + a^3*b*d - 2*a^2*b^2*d - a*b^3*d - a^2*b*c*d + a*b^2*c*d +
 a*b*c^2*d + 2*b^2*c^2*d + a*c^3*d - c^4*d + a*b*d^2 - a*c*d^2 + b*c*d^2 +
 c^2*d^2 - d^3
]
Time: 0.000
```

Example H116E9

This example is a non-singular but non-minimal surface. We start with a degree 5 hypersurface in $\mathbf{P}^3$ and then blow up a point using the standard intrinsic to give a model X of the blow-up as a surface in $\mathbf{P}^8$. The original hypersurface is a (simply-weighted) canonical model of X and `WeightedCanonicalModel` does just return a slight linear transformation of it. The computation takes a little time.

```
> P3<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> Y := Surface(P3,x^5+y^5+z^5+t^5 : Nonsingular := true); //the hypersurface
> X := BlowUp(Y,Y![0,0,-1,1]);
> P<x1,x2,x3,x4,x5,x6,x7,x8,x9> := Ambient(X);
> X;
Surface over Rational Field defined by
-x6*x8+x5*x9, -x3*x8+x2*x9, -x1*x8+x3*x9, -x6*x7+x4*x9, -x5*x7+x4*x8,
-x3*x7+x5*x9+x8*x9, -x2*x7+x5*x8+x8^2, -x1*x7+x6*x9+x9^2,
-x3*x5+x2*x6, -x1*x5+x3*x6, -x3*x4+x5*x6+x6*x8, -x2*x4+x5^2+x5*x8,
-x1*x4+x6^2+x6*x9, -x1*x2+x3^2,
x1^4+x2*x3^3+x4*x6^3-x4*x6^2*x9+x4*x6*x9^2-x4*x9^3+x7*x9^3,
x1^3*x3+x2^2*x3^2+x4*x5*x6^2-x4*x5*x6*x9+x4*x5*x9^2-x4*x8*x9^2+x7*x8*x9^2,
x2*x3^2*x5+x1^3*x6+x4^2*x6^2+x2*x3^2*x8+x1^3*x9-x4^2*x6*x9+x4^2*x9^2-

The last line confirms that there was one exceptional divisor blown down.

116.2.7 Special Surfaces in Projective 4-space

There has been much study of the families of nonsingular surfaces of non-general type that lie in $\mathbf{P}^4$ (a complete intersection of two nonsingular hypersurfaces of degrees d and e – the obvious construction – leads to general-type surfaces unless $d + e \leq 5$). These families are a very useful tool for generating random surfaces of a particular Kodaira-Enriques type with a non-singular ordinary projective model lying in a small-dimensional ambient.

Decker, Ein and Schreyer have given many such families in their paper [DES93]. Their constructions make use of the theory of codimension two schemes and the Beilinson spectral sequence for coherent sheaves. The result is that the defining ideal of a surface in the family is isomorphic as a graded module to the cokernel of a random map between two modules over $k[x_0, \ldots, x_4]$ that are direct sums of twists of the modules representing alternating powers of the sheaf of differentials on $\mathbf{P}^4$ (or something slightly more complex derived from these modules). The ideals constructed give Cohen-Macaulay surfaces and the surface is actually non-singular for a general map. The families are generally described by the degree, sectional genus (arithmetic genus of a hyperplane section) and Kodaira-Enriques type of the surfaces they contain. Given the type, knowing the degree and sectional genus is equivalent to knowing the Hilbert polynomial.

Intrinsics are provided to generate a random surface from a selection of the families described in the paper above, following the implementations in the Macaulay 2 computer algebra package.

`RandomRationalSurface_d10g9(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. The intrinsic generates a random (non-minimal) degree 10 rational surface with sectional genus 9 in P from the family described by Ranestad. If the rationals are the base field, the parameter `RndP` is a positive integer used as an upper absolute bound for random coefficients of polynomials. That is, the algorithm uses random integers between $-RndP$ and $+RndP$m, inclusive. The default value here is 2. Parameter `Check` being `true` (the default) means that the random prospective surfaces generated are tested for irreducibility and non-singularity and rejected if they fail (the process tries 10 surfaces before giving up). The user can set this to `false` for a slight speed-up: it is rare that a singular surface occurs.

`RandomEnriquesSurface_d9g6(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random (non-minimal) degree 9 Enriques surface with sectional genus 6 in P. The parameters have the same meaning as for `RandomRationalSurface_d10g9` and the same defaults.

`RandomAbelianSurface_d10g6(P)`

`RndP`	RngIntElt	*Default :* 5
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random degree 10 torus with sectional genus 6. This is just the zero section of an element of the Horrocks-Mumford bundle. The parameters have the same meaning as for `RandomRationalSurface_d10g9` although the default for `RndP` is now 5.

`RandomEllipticFibration_d7g6(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random (minimal) degree 7 elliptic surface with sectional genus 6 in P. These have Kodaira dimension 1, geometric genus 2 and irregularity 0. The parameters have the same meaning as for `RandomRationalSurface_d10g9` and the same defaults.

`RandomEllipticFibration_d8g7(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random (minimal) degree 8 elliptic surface with sectional genus 7 in P. These have Kodaira dimension 1, geometric genus 2 and irregularity 0. The parameters have the same meaning as for `RandomRationalSurface_d10g9` and the same defaults.

`RandomEllipticFibration_d9g7(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random (minimal) degree 9 elliptic surface with sectional genus 7 in P. These have Kodaira dimension 1, geometric genus 1 and irregularity 0. The parameters have the same meaning as for `RandomRationalSurface_d10g9` and the same defaults.

`RandomEllipticFibration_d10g10(P)`

`RndP`	RngIntElt	*Default :* 2
`Check`	BoolElt	*Default :* `true`

The argument P should be a 4-dimensional ordinary projective space defined over the rational numbers or a finite field. Generates a random (non-minimal) degree 10 elliptic surface with sectional genus 10 in P. These have Kodaira dimension 1, geometric genus 2 and irregularity 0. The parameters have the same meaning as for `RandomRationalSurface_d10g9` and the same defaults.

116.3 Surfaces in $\mathbf{P}^3$

116.3.1 Introduction

This section describes several packages of functionality developed for working with (hyper)surfaces in three-dimensional projective space $\mathbf{P}^3$.

At the core is a package to compute a **formal desingularization** of such a hypersurface X, expressed via a collection of algebraic power series giving the formal completion of the components of *some* desingularization lying over the components of the singular subscheme of the hypersurface. This allows the computation of important birational invariants of *any* desingularization of X like the arithmetic and geometric genera and higher geometric plurigenera. The algorithm is based on the method of Jung and was designed and implemented by Tobias Beck. It is fully described in [Bec07].

An important application of the desingularization data is the computation of *m-adjoint* maps as rational maps on X. A function is provided for this. Theoretical and algorithmic details may be found in [BS08].

There are functions to determine whether X is of Kodaira dimension $-\infty$, *i.e.,* birationally ruled. For the important special case of *rational* surfaces, there is a suite of functions to determine whether a parameterization exists over the base field and to explicitly construct one in the affirmative case. This is based on the work of Josef Schicho described in [Sch98] and [Sch00].

A surface X is mapped to a standard model by applying an appropriate m-adjoint map. These are then parameterized by special case code. The main special cases are Del Pezzo surfaces (including some singular cases) and line and conic bundles. The functions can be called directly by the user. Apart from the previously existing Del Pezzo code (for degrees 6, 8 and 9) and the special singular code for degrees 3 and 4, these functions were implemented by Tobias Beck and Josef Schicho.

116.3.2 Embedded Formal Desingularization of Curves

A formal embedded desingularization of plane curves, as described below, is used in the Jung surface resolution process. The main function is available to the user and provides another alternative to the existing function field and resolution graph curve functionality.

Before describing the function, we introduce some terminology. Let $C \subset P$ be a plane algebraic curve (where $P = \mathbf{A}^2_{\mathbf{E}}$ or $P = \mathbf{P}^2_{\mathbf{E}}$ for some field $\mathbf{E}$ of characteristic zero) and

$\pi : Q \to P$ an *embedded desingularization*, *i.e.*, π is proper birational, Q is regular and $D := \pi^{-1}(C) \subset Q$ is a normal crossing divisor. Further let $\{p_1, \ldots, p_r\} \in Q$ be the generic points of the decomposition of D into irreducible components and $\{q_1, \ldots, q_s\} \in Q$ the closed points of the normal crossings of D.

From π we can construct morphisms Spec $\widehat{\mathcal{O}_{Q,p_i}} \to P$ and Spec $\widehat{\mathcal{O}_{Q,q_i}} \to P$. The set of all these morphisms (up to isomorphism of the domain) is called a *formal embedded desingularization* of $C \subset P$. Each of these morphisms has a centre on P which is defined to be the image of the closed point.

The two classes of morphisms are represented, respectively, by homomorphisms $A \to \widehat{\mathcal{O}_{Q,p_i}}$ and $A \to \widehat{\mathcal{O}_{Q,q_i}}$ (where A is either the normal polynomial ring $\mathbf{E}[x, y]$ or the graded polynomial ring $\mathbf{E}[x, y, w]$ and the inverse image of the maximal ideal of the completion ring is the prime ideal defining the centre), and we are free to choose an isomorphic representation of the codomain. We refer to the homomorphisms as μ_i and ν_i respectively.

`ResolveAffineCurve(p)`

`Factors`	SeqEnum	*Default :* []
`Ps`	RngMPolElt	*Default :* 0
`Focus`	RngMPolElt	*Default :* 0
`ExtName`	MonStgElt	*Default :* "*alpha*"
`ExtCount`	RngIntElt	*Default :* 0
Verbose	`Resolve`	*Maximum :* 1

Given the curve defined by $p \in \mathbf{E}[x, y]$ (a non-zero bivariate polynomial over a number field), this intrinsic essentially computes a formal embedded resolution of the curve using a succession of point blow ups. Only morphisms whose centres vanish on the ideal generated by `Focus` are considered. Note that `Focus` may be a single polynomial or a sequence of polynomials.

The three returned lists contain elements of the form $(b_1, (y, m_{11}), (p_1, m_{12}))$, $(b_2, (y, m_2))$ and $(b_2, (p_3, m_3))$ respectively. Here b_1, b_2 and b_3 are homomorphisms $\mathbf{E}[x, y] \to \mathbf{E}'[x, y]$ to some bivariate polynomial ring over an algebraic field extension $\mathbf{E}'$ over $\mathbf{E}$.

The first list gathers normal crossings. Precisely, the extended homomorphism $b_1 : \mathbf{E}[x, y] \to \mathbf{E}'[[x, y]]$ corresponds to a ν_i from above. Moreover we have $\langle b_1(p) \rangle = \langle y^{m_{11}} p_1^{m_{12}} \rangle$ where $y = 0$ and $p_1 = 0$ have a normal crossing.

The second list gathers exceptional divisors. The extended homomorphism $b_2 : \mathbf{E}[x, y] \to \mathbf{E}'(x)[[y]]$ corresponds to a μ_i from above. Moreover we have $\langle b_2(p) \rangle = \langle y^{m_2} \rangle$ and $y = 0$ corresponds to an exceptional divisor.

Finally, the last list corresponds to the components of the original curve. The extended homomorphism $b_3 : \mathbf{E}[x, y] \to \mathbf{E}'\widehat{[x, y]_{\langle p_3 \rangle}}$ (where $\mathbf{E}' = \mathbf{E}$ in this case) corresponds to another μ_i from above. Moreover we have that $b_3(p)$ has multiplicity m_3 in $\mathbf{E}'\widehat{[x, y]_{\langle p_3 \rangle}}$ and corresponds to an original curve component.

If known, a factorization of p (as returned by the `Factorization` command) can be passed using the parameter `Factors` and the squarefree part of p (as returned by the `SquarefreePart` command) using `Ps`.

If the ground field has to be extended, the algebraic elements will be displayed as `ExtName_i` where `i` starts from `ExtCount`. The last return value is the value of `ExtCount` plus the number of field extensions that have been introduced, which can be useful for consecutive naming when making a series of resolution calls.

Example H116E10

We compute an embedded resolution of an affine plane curve.

```
> Q := Rationals();
> Qxy<x,y> := PolynomialRing(Q, 2, "glex");
> f := (y^2-x^3)*(x^2-y^2-y^3);
> NCs, EXs, DCs := ResolveAffineCurve(f : Factors := Factorization(f));
> #NCs, #EXs, #DCs;
7 4 2
> NCs[2]; EXs[3]; DCs[1];
[*
    Mapping from: RngMPol: Qxy to RngMPol: Qxy,
    <y, 4>,
    <-x^2 + 2*x + y, 1>
*]
[*
    Mapping from: RngMPol: Qxy to RngMPol: Qxy,
    <y, 10>
*]
[*
    Mapping from: RngMPol: Qxy to RngMPol: Qxy,
    <y^3 - x^2 + y^2, 1>
*]
> NCs[2][1](x), NCs[2][1](y);
x*y - y
y
```

Here we have passed the factorization of f only for illustrative purposes. The curve is the union of a cusp and a node at the origin. It has two singular points over $\mathbf{Q}$, the origin and another intersection point of the two curves which has a residue field of degree 5 over $\mathbf{Q}$.
We have computed the local information of a (not necessarily minimal) embedded resolution and find that it contains the 2 components of the strict transform, further 4 exceptional divisors and 7 normal crossings. For example, the pushforward of f under the chart map $x \mapsto xy - y, y \mapsto y$ is equal to $y^4(-x^2 + 2x + y)$ up to a local unit. The corresponding germ is isomorphic to a normal crossing in the embedded desingularization. We also see that one of the exceptional divisors has multiplicity 10.
If we were only interested in a local resolution, we would do the following:

```
> NCs, EXs, DCs := ResolveAffineCurve(f : Focus := [x,y]);
> #NCs, #EXs, #DCs;
```

```
5 3 0
```

We focus on the origin, hence, any curve components are not considered . We have 1 less exceptional divisor and 2 less normal crossings. This is because the second intersection point of the above two curve components was already a normal crossing, but our algorithm has nevertheless blown it up in the previous example.

`ResolveProjectiveCurve(p)`

`Focus`	RngMPolElt	*Default :* 0
`ExtName`	MonStgElt	*Default :* "*alpha*"
`ExtCount`	RngIntElt	*Default :* 0
Verbose	`Resolve`	*Maximum :* 1

Given the curve defined by $p \in \mathbf{E}[x, y, z]$ (a non-zero trivariate homogeneous polynomial over a number field), this intrinsic essentially computes a formal embedded resolution of the curve using a succession of point blow ups. This is the same as `ResolveAffineCurve` above, but now p is a homogeneous polynomial in three variables that defines a projective curve. Accordingly, the b_j map from the respective homogeneous coordinate ring to some $\mathbf{E}'[x, y]$.

Example H116E11

We can also desingularize the projectivisation of the above curve.

```
> Q := RationalField();
> QXYZ<X,Y,Z> := PolynomialRing(Q, 3);
> F := (Y^2*Z-X^3)*(X^2*Z-Y^2*Z-Y^3);
> NCs, EXs, DCs := ResolveProjectiveCurve(F); #NCs, #EXs, #DCs;
7 4 2
> NCs[3];
[*
    Mapping from: RngMPol: QXYZ to Polynomial ring of rank 2 over
    Rational Field ...,
    <y, 4>,
    <x^2 + 2*x - y, 1>
*]
> NCs[3][1](X);
x*y + y
> NCs[3][1](Y);
y
> NCs[3][1](Z);
1
```

The homomorphisms take a slightly different shape (because they have now $\mathbf{Q}[X, Y, Z]$ as domain), but otherwise they are the same. This is because the curve has no singularities at infinity.

116.3.3 Formal Desingularization of Surfaces

For curves we have described embedded formal desingularization. For surfaces instead we produce only *formal desingularizations*. Let $S \subset P$ be a hypersurface (where $P = \mathbf{A}^3_{\mathbf{E}}$ or $P = \mathbf{P}^3_{\mathbf{E}}$) and $C \subset S$ a closed subset (which typically contains the singular locus). Further let $\pi : T \to S$ be a *desingularization*, *i.e.*, π is proper birational and T is regular. By $\{p_1, \ldots, p_r\} \in T$ we denote the generic points of the curve components of the decomposition of $D := \pi^{-1}(C)$ into irreducibles.

From π we can construct morphisms Spec $\widehat{\mathcal{O}_{T,p_i}} \to S$. The set of all these morphisms (up to isomorphism of the domain) is called a *formal desingularization* of S over $C \subset S$. Such a morphism has a centre on S which is defined as the image of the closed point (and actually is contained in C).

The morphisms are represented by homomorphisms $A \to \widehat{\mathcal{O}_{T,p_i}}$ (where A is either the algebra $\mathbf{E}[x,y,z]/\langle p\rangle$ or the graded algebra $\mathbf{E}[x,y,z,w]/\langle p\rangle$ with p a defining polynomial), and we are free to choose an isomorphic representation of the codomain. We refer to such a homomorphisms as μ_i.

In the actual algorithm, C is the ramification locus of a finite projection, pr, to an affine or projective plane (C contains the singular subscheme of S). The underlying desingularization T (which is not computed explicitly) is a Jung resolution which is constructed in two stages. Firstly, an embedded resolution of the image of C in the plane is performed by blow-ups and T_1 is taken as the normalization of the pullback of this by pr. So T_1 then has only point singularities of a simple type (*toric singularities*), lying over the (normal-crossing) intersections of components of the embedded resolution. These are resolved by a finite succession of blow-ups on T_1 to give T.

The algorithm computes the formal desingularization, as described above, corresponding to T, using the embedded formal desingularization for curves followed by algebraic power series operations for the normalization and final resolution of the toric singularities. This is described fully in [Bec07]. The μ_i homomorphisms are defined by algebraic power series images of the variables of P.

It is important to note that the Jung desingularization T is not a minimal desingularization and, in any case, the set of morphisms returned for the formal desingularization generally contain some elements whose centre on S is already non-singular (because, for example, components of C are often generically non-singular). However, there is an parameter option with the main function `ResolveProjectiveSurface`, which removes "non-singular" morphisms and possibly others that have no effect on the computation of birational invariants and m-adjoint maps.

`ResolveAffineMonicSurface(s)`

`Focus`	RngMPolElt	*Default :* 0
`ExtName`	MonStgElt	*Default :* "*alpha*"
`ExtCount`	RngIntElt	*Default :* 0
Verbose	`Resolve`	*Maximum :* 1

The main user resolution function `ResolveProjectiveSurface` is for projective hypersurfaces. This affine version, however, may be useful in some circumstances.

The input is a monic, squarefree polynomial $s \in \mathbf{E}[x,y][z]$ where $\mathbf{E}$ is a number field (*i.e.*, s is univariate over a bivariate polynomial ring). Let $S \subset \mathbf{A}^3_{\mathbf{E}}$ denote the surface defined by it and $C \subset S$ the closed subset defined by $\mathrm{disc}_z(s)$ (*i.e.*, the intersection of S with the cylinder over the discriminant curve when considering the projection $S \to \mathbf{A}^2_{\mathbf{E}}$ in z-direction). The function computes a formal desingularization of S over C (see above).

The first return value is a list of elements of the form $((X,Y,Z),o)$ where $X,Y,Z \in \mathbf{F}[[t]]$ are univariate power series (over some field extension $\mathbf{F}$ of transcendence degree 1 over $\mathbf{E}$) s.t. $s(X,Y,Z) = 0$ and o is an integer. The induced homomorphism $\mathbf{E}[x,y][z]/(s) \to \mathbf{F}[[t]]$ corresponds to a μ_i from above and o is its *adjoint order*, *i.e.*, the negation of the order of a special differential form (see Section 116.3.4).

One can specify a focus ideal $F \subset \mathbf{E}[x,y]$ by passing a single generator or sequence of generators in `Focus` (as for `ResolveAffineCurve`). In this case C is taken to be the intersection of S and the cylinder over the zero set of $F + \langle \mathrm{disc}_z(s) \rangle$.

If the ground field has to be extended, the algebraic elements will be displayed as `ExtName_i` where `i` starts from `ExtCount`. The last return value is the value of `ExtCount` plus the number of field extensions that have been introduced, which can be useful for consecutive naming when making a series of resolution calls. A transcendental element will always be displayed as `s`.

Example H116E12

We compute a formal desingularization for the affine surface $z^2 - xy = 0$.

```
> Q := Rationals();
> Qxy<x,y> := PolynomialRing(Q, 2, "glex");
> Qxyz<z> := PolynomialRing(Qxy);
> f := z^2 - x*y;
> desing := ResolveAffineMonicSurface(f); #desing;
3
```

We have computed 3 morphisms. Two of them are centred over the coordinate axes $x = 0$ and $y = 0$. But they might not be of interest, because the surface is normal and has an isolated singularity over the origin.

```
> #ResolveAffineMonicSurface(f : Focus := [x,y]);
1
```

The only remaining morphism corresponds to the exceptional divisor obtained by blowing up the singularity.
Elements in the returned list which define the morphisms of the formal desingularization are examined more closely in the projective surface example below.

`ResolveProjectiveSurface(S)`

`AdjComp`	BoolElt	*Default :* `false`
`ExtName`	MonStgElt	*Default :* "*gamma*"
`ExtCount`	RngIntElt	*Default :* 0
Verbose	`Resolve`	*Maximum :* 1

The principal function for hypersurface desingularization, similar in description to `ResolveAffineMonicSurface` above. The argument is either a projective surface $S \subset \mathbf{P}^3_{\mathbf{E}}$ or an irreducible, homogeneous polynomial $s \in \mathbf{E}[x, y, z, w]$ which defines such a surface S. Computes a formal desingularization (see above) of S. It will be a formal desingularization over an automatically chosen subset $C \subset S$ (using again the cylinder over the discriminant curve w.r.t. a nice projection onto some $\mathbf{P}^2_{\mathbf{E}}$). Accordingly the elements of the return list of formal desingularization data are now of the form $((X, Y, Z, W), o)$.

If `AdjComp` is `true`, then only a sublist is returned that is still sufficient for the computation of birational invariants and adjoint spaces (see Section 116.3.4). The parameters `ExtName` and `ExtCount` and the second return value have the same meaning as in the affine case.

As stated above, the algorithm is based on formally computing a Jung resolution and is described in [Bec07].

Example H116E13

Computing a formal desingularization is easy.

```
> P<x,y,z,w> := PolynomialRing(Rationals(), 4);
> F := w^3*y^2*z+(x*z+w^2)^3;
> desing := ResolveProjectiveSurface(F); #desing;
26
```

Hence, the formal desingularization of the projective surface defined by `F` contains 26 morphisms. They are represented by tuples of power series that vanish on `F`. We have a closer look at the first morphism.

```
> prm, ord := Explode(desing[1]);
> IsZero(AlgComb(F, prm)); ord;
true
4
> X, Y, Z, W := Explode(prm);
> Expand(X, 6); Expand(Y, 6); Expand(Z, 6); Expand(W, 6);
true 1
true -s*t^2
true -t^2
true -1/64*s^2*gamma_0*t^5 + 1/2*gamma_0^2*t^3 + gamma_0*t^2 + t
> Domain(W);
Polynomial ring of rank 1 over Algebraic function field defined
over Univariate rational function field over Rational Field
```

```
by $.1^3 - 1/8*s^2
Graded Lexicographical Order
Variables: t
```

One of the morphisms is of type Spec$\mathbf{Q}(s)[\texttt{gamma_0}][[t]] \to \text{Proj}\mathbf{Q}[x,y,z,w]/\langle F\rangle$ where $\texttt{gamma\_0}^3 - 1/8s^2 = 0$. In particular, $\mathbf{Q}(s)[\texttt{gamma\_0}]$ is isomorphic to the residue field of the corresponding prime divisor on the desingularization. From this one can for example deduce that it is a rational curve. The morphism is given by the ring homomorphism $x \mapsto 1$, $y \mapsto -st^2$, $z \mapsto -t^2$ and $w \mapsto t + \texttt{gamma\_0}t^2 + 1/2\texttt{gamma\_0}^2t^3 - 1/64s^2\texttt{gamma\_0}t^5 + \ldots$.
The adjoint order for this morphism is 4. Consider the chart $x \neq 0$. The special differential form (see Section 116.3.4) in this chart obtained by dehomogenizing is

$$\frac{x^5}{(\partial F/\partial w)(x,y,z,w)}\mathrm{d}y/x \wedge \mathrm{d}z/x.$$

Substituting the values `X`, `Y`, `Z` and `W` we see that it is mapped to

$$\frac{\texttt{X}^5}{(\partial F/\partial w)(\texttt{X},\texttt{Y},\texttt{Z},\texttt{W})}\mathrm{d}\texttt{Y}/\texttt{X} \wedge \mathrm{d}\texttt{Z}/\texttt{X}$$

$$= \frac{1}{(\partial F/\partial w)(\texttt{X},\texttt{Y},\texttt{Z},\texttt{W})}\mathrm{d}(-st^2) \wedge \mathrm{d}(-t^2)$$

$$= \frac{1}{(\partial F/\partial w)(\texttt{X},\texttt{Y},\texttt{Z},\texttt{W})}(2st\mathrm{d}t + t^2\mathrm{d}s) \wedge 2t\mathrm{d}t$$

$$= \frac{1}{(\partial F/\partial w)(\texttt{X},\texttt{Y},\texttt{Z},\texttt{W})}2t^3\mathrm{d}s \wedge \mathrm{d}t$$

The adjoint order is minus the overall order of this expression, hence, -3 plus the order of $(\partial F/\partial w)(\texttt{X},\texttt{Y},\texttt{Z},\texttt{W})$. We check the computation.

```
> Order(AlgComb(Derivative(F,w), prm));
7
```

If we needed the formal desingularization only in order to compute birational invariants or adjoint spaces we could set the parameter `AdjComp` and forget about some morphisms.

116.3.4 Adjoint Systems and Birational Invariants

In this section we describe computation of adjoint spaces. Let $S \subset \mathbf{P}^3_{\mathbf{E}}$ be a surface defined by a homogeneous irreducible polynomial $F \in \mathbf{E}[x_0, x_1, x_2, x_3]$ of degree d and $\Omega_{\mathbf{E}(S)|\mathbf{E}}$ the vector space of rational differential forms of the function field (over the ground field $\mathbf{E}$ of characteristic zero). We can consider $\Omega_{\mathbf{E}(S)|\mathbf{E}}$ a constant sheaf of $\mathcal{O}_S$-modules. Let $U_i \subset S$ be the affine open subsets of the standard covering w.r.t. this choice of variables.

Let $\omega^0_S \subset \Omega^{\wedge 2}_{\mathbf{E}(S)|\mathbf{E}}$ be the subsheaf which is locally generated on U_i by

$$\left(\frac{\partial F/\partial x_j}{x_i^{d-1}}\right)^{-1} \bigwedge_{k\in\{0,\ldots,3\}\setminus\{i,j\}} \mathrm{d}\frac{x_k}{x_i}$$

(for an arbitrary choice of $j \neq i$). By sending this generator to x_i^{d-4} one finds that $\omega^0_S \cong \mathcal{O}_S(d-4)$. Further let $F_{S,m} \subset (\Omega^{\wedge 2}_{\mathbf{E}(S)|\mathbf{E}})^{\otimes m}$ be the subsheaf of those forms whose pullbacks are regular on some desingularization of S. It is called the *sheaf of m-adjoints*. It is in fact well-defined, *i.e.*, doesn't depend on any specific desingularization, and one can show $F_{S,m} \subseteq (\omega^0_S)^{\otimes m}$. For more details we refer to [BS08].

Now since $F_{S,m}$ is a coherent sheaf on the projective scheme $S \subset \mathbf{P}^3_{\mathbf{E}}$ it can be defined by its associated graded module $M_{S,m}$ and by the above discussion $F_{S,m}$ is isomorphic to a subsheaf of $\mathcal{O}_S(m(d-4))$. The module $M_{S,m}$ is thus naturally a graded submodule of $(\mathbf{E}[x_0, x_1, x_2, x_3]/\langle F\rangle)(m(d-4))$. The n-th graded piece of $M_{S,m}$, a linear subsytem of the standard linear system of degree $n+m(d-4)$ homogeneous polynomials on S, corresponds to global sections of the Serre twist $F_{S,m}(n)$. This, under pullback, corresponds to the space of global sections of the twisted m-adjoint sheaf $(\omega_X)^{\otimes m}(n)$ for any desingularization X of S, where (n) now signifies twisting by the n-th tensor power of $\mathcal{L}$, the invertible sheaf on X which gives the map into projective space projecting X down onto S.

These adjoint linear systems immediately give the plurigenera of any desingularization X as well as an explicit representation of the important twisted m-adjoint maps into projective space as rational maps from S (defined by the sequence of homogeneous polynomials forming a basis of the adjoint system). These maps are used to take any rational hypersurface to a standard model, as described in the next section.

All functions in this section (and several in the following sections) allow the user to enter precomputed formal desingularization data. It is a good idea to do this if performing several operations on the same hypersurface to avoid repeated computation of this desingularization.

`HomAdjoints(m,n,S)`

`FormalDesing`	SeqEnum	*Default :* 0
Verbose	`Classify`	*Maximum :* 1

Given a surface S of degree d in $\mathbf{P}^3$ defined over a number field $\mathbf{E}$ together with integers m and n, the intrinsic returns a basis for the vector space of the degree-n graded summand of the graded ring associated to $F_{S,m}$ (*i.e.*, $\Gamma(S, \mathcal{O}_S(n) \otimes F_{S,m})$) as a subspace of the homogeneous forms in $\mathbf{E}[x_0, x_1, x_2, x_3]$ (the coordinate ring of the $\mathbf{P}^3$ ambient) of degree $n + m(d-4)$ (see above).

The parameter FormalDesing may be set to a precomputed formal desingularization (as returned by ResolveProjectiveSurface). The desingularization passed in can be computed with the AdjComp parameter set to true. The default value for FormalDesing is the integer 0, in which case a formal desingularization needs to be computed during function execution.

The function computes the adjoint space as a linear subspace of homogeneous polynomials of the appropriate degree by using the formal divisor morphisms of the formal desingularization to give additional linear conditions at the singular places of S. This is explained fully in [BS08].

GeometricGenusOfDesingularization(S)

FormalDesing SeqEnum *Default :* 0

Given a hypersurface S in $\mathbf{P}^3$, the intrinsic returns the geometric genus of (any) desingularization of S. The function just computes the dimension of the $(1,0)$ adjoint space.

As in the case of HomAdjoints, a precomputed desingularization (of S or its defining polynomial) can be passed in via the FormalDesing parameter.

PlurigenusOfDesingularization(S,m)

FormalDesing SeqEnum *Default :* 0

Given a hypersurface S in $\mathbf{P}^3$, the intrinsic returns the m-th plurigenus of (any) desingularization, X, of S. This is the dimension of the global sections of the sheaf $(\omega_X)^{\otimes m}$ and is just computed as the dimension of the $(m,0)$ adjoint space.

As for HomAdjoints, a precomputed desingularization (of S or its defining polynomial) can be passed in via the FormalDesing parameter.

ArithmeticGenusOfDesingularization(S)

FormalDesing SeqEnum *Default :* 0

Given a hypersurface S in $\mathbf{P}^3$, the intrinsic returns the arithmetic genus of (any) desingularization of S. This is computed from a simple formula involving the dimensions of the (1,1)- and (1,2)-adjoints coming from the Riemann-Roch theorem.

As for HomAdjoints, a precomputed desingularization (of S or its defining polynomial) can be passed in via the FormalDesing parameter.

Example H116E14

We compute several adjoint spaces of a surface. We precompute a formal desingularization and pass it to the calls to HomAdjoints.

```
> P<x,y,z,w> := ProjectiveSpace(Rationals(), 3);
> F := w^3*y^2*z+(x*z+w^2)^3;
> S := Surface(P,F);
> desing := ResolveProjectiveSurface(S : AdjComp := true);
> HomAdjoints(1, 0, S : FormalDesing := desing);
[]
```

```
> HomAdjoints(1, 1, S : FormalDesing := desing);
[
    x*z*w + w^3
]
> HomAdjoints(1, 2, S : FormalDesing := desing);
[
    x^2*z^2 - w^4, x^2*z*w + x*w^3, x*y*z*w, x*z^2*w + z*w^3,
    x*z*w^2 + w^4, y*z*w^2, y*w^3
]
> HomAdjoints(1, 3, S : FormalDesing := desing);
[
    x^3*z^2 - x*w^4, x^2*y*z^2, x^2*z^3 - z*w^4,
    x^3*z*w + x^2*w^3, x^2*y*z*w, x*y^2*z*w, x^2*z^2*w - w^5,
    x*y*z^2*w, x*z^3*w + z^2*w^3, x^2*z*w^2 + x*w^4, x*y*z*w^2,
    y^2*z*w^2, x*z^2*w^2 + z*w^4, y*z^2*w^2, x*y*w^3, y^2*w^3,
    x*z*w^3 + w^5, y*z*w^3, y*w^4
]
>
> HomAdjoints(2, 0, S : FormalDesing := desing);
[]
> HomAdjoints(2, 1, S : FormalDesing := desing);
[]
> HomAdjoints(2, 2, S : FormalDesing := desing);
[
    x^2*z^2*w^2 + 2*x*z*w^4 + w^6
]
> HomAdjoints(2, 3, S : FormalDesing := desing);
[
    x^3*z^2*w^2 + 2*x^2*z*w^4 + x*w^6, x^2*y*z^2*w^2 - y*w^6,
    x^2*z^3*w^2 + 2*x*z^2*w^4 + z*w^6,
    x^2*z^2*w^3 + 2*x*z*w^5 + w^7, x*y*z^2*w^3 + y*z*w^5,
    x*y*z*w^4 + y*w^6, y^2*z*w^4
]
```

116.3.5 Classification and Parameterization of Rational Surfaces

This section contains functions for the recognition of rational surfaces in $\mathbf{P}^3$, the classification and transformation to standard models using appropriate m-adjunction maps and, finally, special case code for these standard models, to determine a parametrization of the original hypersurface.

A *non-singular* surface in $\mathbf{P}^r$ with $r \geq 4$ may be transformed to a standard model using the intrinsic `MinimalModelRationalSurface` (see Section 116.2.6).

`IsRational(X)`

`FormalDesing`	SeqEnum	*Default :* 0
`CheckADE`	BoolElt	*Default :* `false`

Returns `true` if the ordinary projective surface X is (geometrically) rational, i.e. birationally isomorphic to the projective plane over the algebraic closure of its base field. This simply uses the Castelnuevo criterion that X is rational if and only if both the arithmetic genus and second plurigenus of any desingularization are zero.

If the ambient of X is $\mathbf{P}^3$ over a number field, there is no assumption about the singularity of X and a formal desingularization will be used to compute plurigenera. Otherwise, X should have at worst simple (A-D-E) singularities and the algorithms of early sections are used for the computations. In this latter case, the singularity status is assumed by default. To force a check for only A-D-E singularities, the user should set the parameter `CheckADE` to `true`. This can be a very heavy verification in higher dimensional ambients.

The computation in the former case uses a formal desingularization of X. To avoid recalculation, a precomputed formal desingularization can be supplied using `FormalDesing` parameter, as with the `HomAdjoints` intrinsic.

116.3.6 Reduction to Special Models

In this section, we describe the function for the birational transformation over the base field of a rational hypersurface in $\mathbf{P}^3$ into a special model of one of the types in the standard classification as listed by Josef Schicho in [Sch98]. He enumerates 5 basic cases [Sch98, p. 17 and Lem. 5.2-5.7] and splits the last case in two, choosing labels "1", "2", "3", "4", "5A" and "5B". The lemmas describing cases 3 and 5A involve a further case distinction. Also, a label "0" is useful for the non-rational case. From this, we get the label set

$$\mathcal{L} := \{\text{"0"}, \text{"1"}, \text{"2"}, \text{"3a"}, \text{"3b"}, \text{"4"}, \text{"5Aa"}, \text{"5Ab"}, \text{"5Ac"}, \text{"5B"}\}$$

Let S be a surface in $\mathbf{P}^3$. In each of the above cases the author specifies a set of adjoint spaces defining interesting maps, either birationally to a special surface or to a rational normal curve (giving a pencil of rational curves on the surface). More precisely, the maps can be computed using $V_{n,m} :=$ `HomAdjoints` (m, n, S) for certain choices of m and n. Let μ to be the smallest integer s.t. $V_{1,\mu+1} \neq [\ ]$. Then the important $V_{n,m}$ for the different cases are as follows:

0	1	2	3a	3b	4
$[\ ]$	$[V_{1,\mu}]$	$[V_{1,\mu}]$	$[V_{2,2\mu+1}, V_{1,\mu}]$	$[V_{2,2\mu+1}]$	$[V_{1,\mu}, V_{2,2\mu-1}]$

5Aa	5Ab	5Ac	5B
$[V_{1,\mu-1}]$	$[V_{1,\mu-1}, V_{2,2\mu-2}]$	$[V_{1,\mu-1}, V_{2,2\mu-2}, V_{3,3\mu-3}]$	$[V_{2,1}]$

The function to find a parameterization of a rational hypersurface, which uses the reduction function below as a first stage, is described in the next section.

`ClassifyRationalSurface(S)`

`FormalDesing`	SeqEnum	*Default :* 0
Verbose	`Classify`	*Maximum :* 1

Given an ordinary projective surface S in $\mathbf{P}^3$ over a number field, the intrinsic returns the special rational surface type to which S is birationally equivalent and associated data. If S is not (geometrically) rational, the return values are S itself, a list containing only the identity map on S and the string "Not rational".

If S is rational and Schicho's algorithm reduces it to a standard surface Y over the base field k, Y is the first return value. The second return value is a list of one or two scheme maps. The first is always a birational map from S to Y. There is a second map if and only if Y is a rational scroll or conic bundle. Then S (and Y) have fibration maps to a rational normal curve such that the general fibre is a rational curve (and a line or conic for Y). The fibration map on S is the second return value. Note that, if the base field is $\mathbf{Q}$, in these cases, S can be parameterized by calling `ParametrizePencil` with the fibration map as argument.

The third return value is a string describing the type of Y. It is "P2" (for the projective plane!), "Quadric surface" (for a degree 2 surface in $\mathbf{P}^3$), "Rational scroll", "Conic bundle" or "Del Pezzo of degree d" where $1 \leq d \leq 9$. The Del Pezzos might be degenerate (with simple singularities) and are anticanonically embedded in $\mathbf{P}^d$ except for degrees 1 and 2 when they have their standard weighted-projective embeddings.

As usual, to avoid recalculation, a precomputed formal desingularization can be given using the `FormalDesing` parameter, as in the case of the `HomAdjoints` intrinsic.

Example H116E15

Here are a few examples.

```
> P<x,y,z,w> := ProjectiveSpace(Rationals(),3);
```

The first surface:

```
> p1 := x^4 + y^4 - z^2*w^2;
> _,_,typ := ClassifyRationalSurface(Surface(P,p1));
> typ;
Not rational
```

The second surface:

```
> p2 := 2*x + y + 8*z + 5*w;
> Y,_,typ := ClassifyRationalSurface(Surface(P,p2));
> typ; Y;
P^2
Surface over Rational Field defined by
0
```

The third surface:

```
> p3 := x^2 - 4*x*z + 3*x*w + y*z - y*w + 2*z^2 - 3*z*w + w^2;
```

```
> _,_,typ := ClassifyRationalSurface(Surface(P,p3));
> typ;
Quadric surface
```

The fourth surface:

```
> p4 := (y^2 - w*z)*(w^2 - y*x) + (x*z - y*w)^2;
> S := Surface(P,p4);
> Y,mps,typ := ClassifyRationalSurface(S);
> typ;
Rational scroll
> mps[2]; // the fibration map
Mapping from: Srfc: S to Scheme over Rational Field defined by
$.1*$.2 - $.3^2
with equations :
x*y - w^2
y^2 - z*w
x*z - y*w
```

The fifth surface:

```
> p5 := x^3*y - 4*x^3*z - 6*x^3*w - 3*x^2*y^2 - 2*x^2*y*z
>     - 3*x^2*y*w + 50*x^2*z^2 + 146*x^2*z*w + 108*x^2*w^2
>     - 11*x*y^2*z + 2*x*y^2*w + 61*x*y*z^2 + 149*x*y*z*w
>     + 65*x*y*w^2 + 68*x*z^3 + 228*x*z^2*w + 260*x*z*w^2
>     + 112*x*w^3 + 4*y^4 - 13*y^3*z - 19*y^3*w + 20*y^2*z^2
>     + 77*y^2*z*w + 55*y^2*w^2 + 40*y*z^3 + 106*y*z^2*w
>     + 58*y*z*w^2 - 2*y*w^3 + 22*z^4 + 84*z^3*w + 130*z^2*w^2

```

116.3.7 Parametrization of Rational Surfaces

The package also includes functions to directly parametrize rational surfaces (over $\mathbf{Q}$). These use the reduction to special type, described in the last section, followed by specialised algorithms for the special cases, which are described in the following sections and the section on Del Pezzo surfaces. There is a version for hypersurfaces in $\mathbf{P}^3$ and one for more general rational surfaces which are first birationally projected to a hypersurface. Note, however, that the projection method can be very inefficient because it often introduces nasty singularities that cause the resolution process to hang. If it is known that the surface S is non-singular, it is usually much better to use MinimalModelRationalSurface to get a birational map from S to a standard model Y and call the relevant special case parametrization routine for Y directly.

```
ParametrizeProjectiveHypersurface(X, P2)
```

FormalDesing	SeqEnum	*Default :* 0
Verbose	Classify	*Maximum :* 1

Given a surface X in $\mathbf{P}^3_{\mathbf{Q}}$ and a projective plane $P2$ over $\mathbf{Q}$, the intrinsic returns false if the surface is not rational over $\mathbf{Q}$, otherwise returns true and a birational parameterization $P2 \to X$.

The function begins by mapping X, as in ClassifyRationalSurface, to a surface of special type. As for that function, if a formal desingularization (for the defining polynomial p of X) is already known, it can be passed as parameter FormalDesing.

It is assumed that X is defined over $\mathbf{Q}$ because some of the special type routines assume this, partly for simplicity. This will probably be generalised in future releases.

```
ParametrizeProjectiveSurface(X, P2)
```

Verbose	Classify	*Maximum :* 1

Given an ordinary projective surface X in $\mathbf{P}^n_{\mathbf{Q}}$ for some $n \geq 2$ and a projective plane $P2$ over $\mathbf{Q}$, returns false if the surface is not rational over $\mathbf{Q}$, otherwise return true and a birational parametrization $P2 \to X$.

The function finds a birational projection to a hypersurface in $\mathbf{P}^3$ and then calls ParametrizeProjectiveHypersurface.

It should be noted that the birational projection may produce a very singular hypersurface defined by a polynomial with large coefficients. Then, the desingularisation, classification and special parameterization routines may each be very slow. As noted above, it may be better to try to use MinimalModelRationalSurface followed by one of the specialised parametrization routines for a non-singular rational X for larger n.

Example H116E16

We try to parameterize the hypersurfaces given by polynomials p1 - p8 from the previous example.

The surface defined by $p1$:

```
> P2<X,Y,W> := ProjectiveSpace(Rationals(), 2);
> ParametrizeProjectiveHypersurface(Surface(P, p1), P2);
false
```

The surface defined by $p2$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p2), P2);
true Mapping from: Prj: P2 to Surface over Rational Field
defined by 2*x + y + 8*z + 5*w
with equations :
-1/2*X - 4*Y - 5/2*W
X
Y
W
```

The surface defined by $p3$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p3), P2);
true Mapping from: Prj: P2 to Surface over Rational Field
defined by x^2 - 4*x*z + 3*x*w + y*z - y*w + 2*z^2 - 3*z*w + w^2
with equations :
X^2 - 2*X*W
X^2 + X*Y - 4*X*W - Y*W + 2*W^2
X^2 - 3*X*W + Y*W
X^2 - 4*X*W + Y*W + 2*W^2
```

The surface defined by $p4$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p4), P2);
true Mapping from: Prj: P2 to Surface over Rational Field
defined by x^2*z^2 - x*y^3 - x*y*z*w + 2*y^2*w^2 - z*w^3
with equations :
2*X^2*Y^2*W^2 - Y*W^5
X^4*Y^2 - X^2*Y*W^3
X^3*Y*W^2
X^3*Y^2*W
```

The surface defined by $p5$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p5), P2);
true Mapping from: Prj: P2 to Surface over Rational Field
defined by ...
with equations :
-1/4*X^2 + 9/2*X*Y + 1/2*X*W - 69/4*Y^2 - 87/8*Y*W + 1/2*W^2
1/2*X*Y + 11/4*X*W - 5/8*Y^2 - 131/8*Y*W - 63/8*W^2
-11/8*X*Y + 7/8*X*W + 13/4*Y^2 - 11/2*W^2
X*Y - 1/8*X*W - 23/8*Y^2 + 4*W^2
```

The surface defined by $p6$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p6), P2);
```

```
true Mapping from: Prj: P2 to Surface over Rational Field
defined by 4*x^4 + 8*x^3*y + x^2*y^2 - x^2*z^2 + 8*x^2*w^2
           + x*y*z^2 - 7*x*y*w^2 - y^2*w^2
with equations :
-3/8*X^2*Y^2*W - 2*X^2*Y*W^2 - 8/3*X^2*W^3 - 59/24*X*Y^2*W^2
    - 38/3*X*Y*W^3 - 16*X*W^4 + 17/6*Y^2*W^3 + 44/3*Y*W^4
    + 56/3*W^5
-3/8*X^3*Y^2 - 2*X^3*Y*W - 8/3*X^3*W^2 - 59/24*X^2*Y^2*W
    - 38/3*X^2*Y*W^2 - 16*X^2*W^3 + 17/6*X*Y^2*W^2
    + 44/3*X*Y*W^3 + 56/3*X*W^4
-1/8*X^2*Y^2*W - 4/3*X^2*Y*W^2 - 8/3*X^2*W^3 - 1/12*X*Y^2*W^2
    - 16/3*X*Y*W^3 - 40/3*X*W^4 + 19/3*Y^2*W^3 + 104/3*Y*W^4
    + 48*W^5
-3/8*X^2*Y^2*W - 2*X^2*Y*W^2 - 8/3*X^2*W^3 - 8/3*X*Y^2*W^2
    - 14*X*Y*W^3 - 56/3*X*W^4 + Y^2*W^3 + 20/3*Y*W^4 + 32/3*W^5
```

The surface defined by $p7$:

```
> ParametrizeProjectiveHypersurface(Surface(P, p7), P2);
true Mapping from: Prj: P2 to Surface over Rational Field defined by
z^5 + y^3*w^2 + x^2*w^3
with equations :
-X^362*Y^144*W^79 - 9*X^363*Y^141*W^81 - 36*X^364*Y^138*W^83 -

```

`Solve(p, F)`

For convenience, this intrinsic provides a purely algebraic version of parameterization of an affine hypersurface.

Given a polynomial $p \in \mathbf{Q}[x, y, z]$, the equation of a (not necessarily irreducible affine hypersurface S) and a two-variable rational function field $F = \mathbf{Q}(u, v)$, the function finds birational parameterizations of the irreducible components of S (that are parametrizable over $\mathbf{Q}$).

A sequence of triples $(X, Y, Z) \in F^3$ is returned such that $p(X, Y, Z) = 0$ and each triple gives an isomorphism of F to the function field of a component of S.

The routine may again result in a runtime error if it involves parameterizations of special surface types that are not yet implemented, as for the preceding functions.

Example H116E17

The following affine hypersurface has three irreducible factors: one not rational and two that are rational and parameterizable over $\mathbf{Q}$.

```
> Q := RationalField();
> P<x,y,z> := PolynomialRing(Q, 3);
> F<s,t> := RationalFunctionField(Q, 2);
> p := (x^4+y^4-z^2)*(2*x + y + 8*z + 5)
>       *(x^2 - 4*x*z + 3*x + y*z - y + 2*z^2 - 3*z + 1);
> Solve(p, F);
[
    [ -1/2*s - 4*t - 5/2, s, t ],
    [
        (s^2 - 2*s)/(s^2 - 4*s + t + 2),
        (s^2 + s*t - 4*s - t + 2)/(s^2 - 4*s + t + 2),
        (s^2 - 3*s + t)/(s^2 - 4*s + t + 2)
    ]
]
```

116.3.8 Parametrization of Special Surfaces

In this section we describe routines for the explicit parameterization of the special classes of rational surfaces that arise from the reduction of the general case via m-adjoint maps. The algorithms are the work of Josef Schicho, in collaboration with others in some cases. The functions are used in the general parameterization routines but can also be called directly by the user.

`ParametrizeQuadric(X,P2)`

Suppose the scheme $X \subset \mathbf{P}^3_{\mathbf{Q}}$ is a geometrically irreducible quadric (degree 2) projective hypersurface and $P2$ is a projective plane. The intrinsic returns `false` if X is not parametrizable over the rationals, otherwise it returns `true` together with a birational parameterization $P2 \to X$.

Given a rational point p on X, the intrinsic is based on a simple, well-known algorithm (see [Sch98, Sec. 3.1]). Finding the point p is equivalent to finding a non-trivial isotropic vector for F, the quadric form in four variables defining X. This is achieved by a reduction to the solution of two quadrics in three variables, which is performed using standard lattice methods. The solubility routines here assume that the quadric is defined over $\mathbf{Q}$.

Example H116E18

We give a few simple examples.

```
> Q := Rationals();
> P2<X,Y,W> := ProjectiveSpace(Q, 2);
> P3<x,y,z,w> := ProjectiveSpace(Q, 3);
> X1 := Scheme(P3, x^2 + y^2 + z^2 + w^2);
> X2 := Scheme(P3, x^2 + y^2 + z^2 - w^2);
> X3 := Scheme(P3, x^2 + y^2 + z^2);
> X4 := Scheme(P3, x^2 + y^2 - z^2);
> X5 := Scheme(P3, x^2 - 4*x*z + 3*x*w + y*z - y*w + 2*z^2
>                    - 3*z*w + w^2);
> ParametrizeQuadric(X1, P2);
false
> ParametrizeQuadric(X2, P2);
true Mapping from: Prj: P2 to Sch: X2
with equations :
2*X*W
2*Y*W
-X^2 - Y^2 + W^2
X^2 + Y^2 + W^2
> ParametrizeQuadric(X3, P2);
false
> ParametrizeQuadric(X4, P2);
true Mapping from: Prj: P2 to Sch: X4
with equations :
X*Y
-1/2*X^2 + 1/2*Y^2
1/2*X^2 + 1/2*Y^2
Y*W
> ParametrizeQuadric(X5, P2);
true Mapping from: Prj: P2 to Sch: X5
with equations :
X^2 - 2*X*W
X^2 + X*Y - 4*X*W - Y*W + 2*W^2
X^2 - 3*X*W + Y*W
X^2 - 4*X*W + Y*W + 2*W^2
```

`ParametrizePencil(phi, P2)`

Let X be an ordinary projective birationally ruled surface, given as the domain of a rational pencil ϕ defined over $\mathbf{Q}$ (*i.e.*, a rational map $X \to \mathbf{P}^n_{\mathbf{Q}}$ for some n with image a rational normal curve) and $P2$ is a projective plane over $\mathbf{Q}$. The intrinsic returns `false` if X is not parameterizable over the rationals. Otherwise, it returns `true` and a birational parameterization $P2 \to X$.

These intrinsics take care of rational scrolls and conic bundles in the classification of special surfaces. The algorithm is described in [Sch00]. The scheme X is not assumed to be non-singular.

Example H116E19

We start with a (singular) degree 4 hypersurface X in P^3 and construct a pencil from P^2 to X.

```
> Q := Rationals();
> P3<x,y,z,w> := ProjectiveSpace(Q, 3);
> P2<X,Y,Z> := ProjectiveSpace(Q, 2);
> X := Scheme(P3, x^2*z^2 - x*y^3 - x*y*z*w + 2*y^2*w^2 - z*w^3);
> pencil := map<X -> P2 | [x*y - w^2, y^2 - z*w, x*z - y*w]>;
> DefiningPolynomial(Image(pencil));
X*Y - Z^2
> ParametrizePencil(pencil, P2);
true Mapping from: Prj: P2 to Sch: X
with equations :
-X^4*Y + 2*X^2*Z^3
-X^2*Y*Z^2 + Z^5
X*Y*Z^3
X*Z^4
```

`ParametrizeDelPezzo(X, P2)`

The argument X should be a (anticanonically-embedded) Del Pezzo surface (of type `Sch` or `Srfc` and $P2$ a projective plane both defined over $\mathbf{Q}$. The function returns `false` if X is not parametrizable over the rationals and returns `true` and a birational parameterization $P2 \to X$ otherwise.

This intrinsic is the main interface to a suite of functions parameterizing Del Pezzo surfaces (over $\mathbf{Q}$). These include the anticanonically Del Pezzos of degrees 1 and 2, which lie in non-trivially weighted projective spaces. A degree d Del Pezzo surface refers to a rational surface that is embedded in projective space by its anticanonical divisor. For degrees 1 and 2 this means an *ample* embedding into weighted projective space. For $3 <= d <= 9$, this is a very-ample embedding giving X as a degree d surface in ordinary projective space of dimension d.

It should be noted that not only do the routines handle the usual non-singular cases, but they also deal with degenerate singular cases (arising in degrees $d >= 3$. In the latter case, rather than blowing up $9 - d$ *distinct* points in the plane, some

of the blown-up points are "infinitely near" points: lying on the exceptional curves corresponding to already blown-up points). This is important as these degenerate cases can arise in the general parameterization of hypersurfaces in $\mathbf{P}^3$.

The package contains routines to find and blow down sets (defined over $\mathbf{Q}$) of exceptional curves, reducing to a DelPezzo of degree d, $5 <= d <= 9$. After this reduction, these cases are handled by the MAGMA routines described in Section 116.4.3 (which now also handle singular Del Pezzos). There is an exception to the above rule. For *singular* degree 3 and degree 4 Del Pezzo surfaces, it is more efficient to apply special case code directly rather than trying to blow down lines to get to higher degree. Starting in V2.17, special functions are provided do this that can be called directly for a singular anti-canonical degree 3 or 4 surface and are described in the next section.

The routines are not yet fully documented. For the location of exceptional curves and the blowing-down, some details may be found in [Sch98, Sec. 3.5] while [Man86] contains the general theory. There are also implementation notes in the appendix of the software documentation report [Bec08] from which this documentation has been adapted. For the nonsingular degrees 6, 8 and 9 cases, which use the Lie algebra method and the degree 5 case, see the references in Section 116.4.3.

116.4 Del Pezzo Surfaces

116.4.1 Introduction

This section contains a collection of geometric and arithmetic routines for Del Pezzo surfaces in their anti-canonical embeddings (the full weighted projective anticanonical embedding for degrees 1 and 2).

There are routines for creation, parametrization, minimisation and reduction, construction, computation of invariants for degree 3, and point-counting for degree 3 surfaces over a finite field.

There is a specialised type for Del Pezzos, `SrfDelPezzo`, which is a subtype of type `Srfc`. Some intrinsics use this type for arguments while some use the more general `Srfc` (or even `Sch`).

116.4.2 Creation of General Del Pezzos

`DelPezzoSurface(P,L)`

`DelPezzoSurface(S)`

`DelPezzoSurface(Z)`

The Del Pezzo surface of degree $9-d$, embedded by its anticanonical system, which arises by blowing up the projective plane P in the d points. The arguments are either plane P and a list of points L, the set of points Q, or the length d zero-dimensional scheme Z defining the points. If the points are not in sufficiently general position (so that the anticanonical image is not smooth) then an error is reported.

`DelPezzoSurface(f)`

The argument f should be a degree three homogeneous polynomial in a 4-variable polynomial ring P (with grevlex ordering). Creates the degree 3 Del Pezzo surface with defining polynomial f inside $\mathbf{P}^3 = Proj(P)$. If this surface is not smooth an error is reported.

`IsDelPezzo(Y)`

Returns `true` if and only if scheme Y in ordinary projective space is an abstract Del Pezzo surface. If so, it also returns the image X of the standard (pluri-)anticanonical embedding of Y, and the map $Y \to X$. Note that this can be a computationally very heavy function if Y is in a reasonably high-dimensional ambient.

116.4.3 Parametrization of Del Pezzo Surfaces

Del Pezzo surfaces are a special type of non-singular projective surface. A good reference for their general properties is [Man86]. A Del Pezzo surface X has a degree $1 \leq d \leq 9$. For $d \geq 3$, the standard representation is as a degree d surface in $\mathbf{P}^d$ for which a hyperplane section is an anti-canonical divisor. When we talk about Del Pezzos in this section, we mean a surface in that anti-canonical form.

Del Pezzo surfaces are birationally equivalent to the projective plane $\mathbf{P}^2$ over an algebraically-closed field. That is, there exists an invertible scheme map from $\mathbf{P}^2$ to X : a *parametrization*. Most of the functions in this section are concerned with the existence of parametrizations of X over a number field.

The significance of Del Pezzo surfaces comes from *adjunction theory* (see [SvdV87]). The adjunction map for surfaces is a general construct that contracts certain lines, known as exceptional lines, to points. Repeated application of the adjunction map to a rational surface results in a reduction to a surface in one of a small number of families, including the Del Pezzos. For a non-singular ordinary projective surface Y, the intrinsic `MinimalModelRationalSurface` is now available to produce the birational map from Y to one of the special, terminal cases that include the Del Pezzos.

Hence the parametrization problem for general rational surfaces reduces via adjunction (a purely algebraic construction) to parametrization of surfaces in the specific families, which is an arithmetic problem (ie dependent on the ground field). This is the surface analog of the simpler situation for curves. Any rational curve can be algebraically reduced to the projective line or a plane conic and the parametrization of plane conics is also an arithmetic problem.

Thus, the parametrization of Del Pezzo surfaces is an important component in that of general rational surfaces. General parametrization code for rational hypersurfaces in $\mathbf{P}^3$ is described in the previous section and it makes use of the routines described here.

If X is parametrizable with $d \geq 3$, then we can blow down (contract) exceptional lines on it to arrive at a surface with $d = 5$, 6, 8 or 9. The functions described here deal with parametrization in those cases using computational methods based around the Lie algebra of the automorphism group of X. For the theory behind these algorithms, see

[dG06], [dGP], [HS06] and [GSHPBS12]. In one of the examples, we parametrize a cubic hypersurface (degree 3 Del Pezzo) by blowing down to a degree 6 surface.

Although reduction to degree 9 is always possible, for $d = 7$ it is more efficient to work directly using the Lie algebra method. There is now also an intrinsic for $d = 7$ provided by Josef Schicho. Schicho has also written code for the $d = 5$ case, minimal or not, that uses the more geometrical method described in the above reference and a corresponding intrinsic is provided.

Furthermore, the degree $5 - 8$ intrinsics now also cover degenerate cases of singular Del Pezzos in their anticanonical projective embeddings. The additional code for the singular cases is also due to Josef Schicho.

A feature (from V2.17) is the provision of special case code for degree 3 and degree 4 singular Del Pezzos. For some of these, it is not possible to blow down any exceptional lines over the base field but the surface is still parametrizable. Additionally, it is usually much more efficient to handle these cases directly without blowing down curves to get to higher degree.

A general intrinsic `ParametrizeDelPezzo` for parametrizing any Del Pezzo surface of degree $d \geq 1$ in its anticanonical weighted embedding (for $d = 1, 2$ the anticanonical divisor is no longer very ample, but gives an ample embedding into weighted projective space) is described in the previous section. This blows down exceptional lines to reach degree $d \geq 5$ and then invokes one of the intrinsics described in this section. It is more efficient to call the appropriate intrinsic directly if the starting point is either the $d \geq 5$ case or the $d = 3,\ 4$ singular cases.

`SetVerbose("ParamDP", v)`

Set the verbose printing level for the Del Pezzo parametrizing functions. Currently the legal values for v are `true`, `false`, 0, 1 and 2 (`false` is the same as 0, and `true` is the same as 1).

`ParametrizeDegree9DelPezzo(X)`

Let X be a degree 9 Del Pezzo surface anticanonically embedded in 9-dimensional projective space. For this function the base field should be $\mathbf{Q}$. The surface X is defined by 27 degree 2 polynomials. The function performs only basic checks that the input X is valid.

If X is parametrizable over $\mathbf{Q}$ then there is a parametrization $\phi : \mathbf{P}^2 \to X$ which is everywhere-defined and given by cubic polynomials in the variables of $\mathbf{P}^2$. The function returns whether such a ϕ exists and, if so, ϕ also.

`ParametrizeDegree8DelPezzo(X)`

Let X be a degree 8 Del Pezzo surface anticanonically embedded in 8-dimensional projective space over a number field. The surface X is defined by 20 degree 2 polynomials. The function performs only basic checks that the input X is valid.

For degree 8, there are two types of non-singular Del Pezzo surface, the second type splitting into subfamilies:

1) X is isomorphic to $\mathbf{P}^2$ with a single rational point blown up.

2i) X is isomorphic to $T_1 \times T_2$ with T_i Galois twists of $\mathbf{P}^1$.

2ii) X is isomorphic to a Galois twist of $\mathbf{P}^1 \times \mathbf{P}^1$ where Galois acts transitively on the two $\mathbf{P}^1$ factors.

In case 1), X is always parametrizable.
In case 2i), X is parametrizable $\Leftrightarrow$ both T_i are trivial twists of $\mathbf{P}^1 \Leftrightarrow X$ is isomorphic to $\mathbf{P}^1 \times \mathbf{P}^1$.
In case 2ii), there is an infinite family of parametrizable X_a classified by $a \in \mathbf{Q}^*/\mathbf{Q}^{*2}$. The scheme X_a is isomorphic (properly, not just birationally) to the surface in $\mathbf{P}^3$ given by the equation $x_0^2 - ax_1^2 = x_2x_3$.

The main function determines whether X is parametrizable over $\mathbf{Q}$. If so, there is a parametrization $\phi : \mathbf{P}^2 \to X$ (given by cubic polynomials in case 1 and by degree 4 polynomials in case 2) and this is also returned.

The intrinsic also handles the degenerate case of a singular degree 8 Del Pezzo surface. This case is recognised directly from the Lie algebra computation which is part of the main routine and an appropriate adaptation of the general method is used.

Example H116E20

In this example, we parametrize an anticanonical sphere X_2, in the above notation. This is obviously an artificial illustration, as we start with X_2 in the form $F = x_0^2 - 2x_1^2 - x_2x_3 = 0$, which is trivial to parametrize directly! The surface in this form is embedded anticanonically in $\mathbf{P}^8$ by any 9-dimensional vector space complement of $< F >$ in the 10-dimensional linear system of all degree 2 polynomials in $x_0 \ldots x_3$. The parametrizing map is undefined at precisely 2 points of the plane. Geometrically, the map consists of a blowup of these 2 points followed by a blowdown of the line joining them.

`ParametrizeDegree7DelPezzo(X)`

Let X be a degree 7 Del Pezzo surface anticanonically embedded in 7-dimensional projective space over a number field. We allow that X can be a degenerate (singular) Del Pezzo surface here. The scheme X is always parametrizable over the base field and this intrinsic returns such a parametrisation without reduction to degree 8 or 9 but directly from the Lie Algebra method.

`ParametrizeDegree6DelPezzo(X)`

`ExistenceOnly` BoolElt *Default :* `false`

Let X be a degree 6 Del Pezzo surface anticanonically embedded in 6-dimensional projective space. For this function the base field K may be $\mathbf{Q}$ or a number field. The surface X is defined by nine degree 2 polynomials. The function performs only basic checks that the input X is valid. **NB:** This intrinsic only handles the non-singular case. For a singular (degenerate) degree 6 Del Pezzo, use the intrinsic that follows.

The connected component of the automorphism group of X is a 2-dimensional torus over K. For any of the possible tori, there is a family of degree 6 Del Pezzos which correspond to principal homogeneous spaces of the torus up to isomorphism.

The parametrizability of X is equivalent to X corresponding to the trivial homogeneous space of its torus.

The function determines whether a parametrization $\phi : \mathbf{P}^2 \to X$ exists over K and returns one when this is the case. The degree of the polynomials defining a "minimal" ϕ (one which is undefined at the smallest number of points) is 3,4 or 6 depending on the torus type. The parametrization returned is always of this minimal degree.

The surface X is parametrizable if and only if it contains a point over K. Furthermore, it satisfies the local-global principle: it has a point over $K \Leftrightarrow$ it has a point over each p-adic completion of K. (These statements are also true for degree 8 and 9 Del Pezzos)

The `ExistenceOnly` option allows the function to just perform this local solubility check, deciding upon the existence of a parametrization without explicitly constructing one. Depending on the torus type, simultaneous norm equations over a degree 6 field extension of K or a single norm equation over a degree 3 extension of K may have to be solved to construct a parametrization. This is a hard computation, especially if K is not $\mathbf{Q}$, whereas the pure existence check is quite fast.

`Degree6DelPezzoType2_1(K,pt)`

`Degree6DelPezzoType2_2(K,pt)`

`Degree6DelPezzoType2_3(K,pt)`

`Degree6DelPezzoType3(K,pt)`

`Degree6DelPezzoType4(K,K1,pt)`

`Degree6DelPezzoType6(K,pt)`

These functions generate the parametrizable degree 6 Del Pezzo surface X whose (connected) automorphism group is the torus T, which comes from field data K, and which contains point pt.

The point pt must be in 6-dimensional projective space over the base field k of a number field K. Its first projective coordinate may not be 0 and, depending on the torus type, certain of its other coordinates must also be non-zero.

The torus types and corresponding fields K for the various functions are as follows ($pt = [a_0, \ldots, a_6]$):

`Type2_1`. K/k should be a quadratic extension. $T(k) = K^*$ and T acts on $\mathbf{P}^6$ to give an X with degree 3 minimal parametrization. pt satisfies not($a_1 = a_2 = 0$ or $a_3 = a_4 = 0$ or $a_5 = 0$ or $a_6 = 0$).

`Type2_2`. K/k should be a quadratic extension. $T(k) = K^*$ and T acts on $\mathbf{P}^6$ to give an X with degree 4 minimal parametrization. pt satisfies not($a_1 = a_2 = 0$ or $a_3 = a_4 = 0$ or $a_5 = a_6 = 0$).

`Type2_3`. K/k should be a quadratic extension. $T(k) = K^{*N_{K/k}=1} \times K^{*N_{K/k}=1}$. pt satisfies not($a_1 = a_2 = 0$ or $a_3 = a_4 = 0$ or $a_5 = a_6 = 0$).

`Type3`. K/k should be a cubic extension. $T(k) = K^{*N_{K/k}=1}$. *pt* satisfies not($a_1 = a_2 = a_3 = 0$ or $a_4 = a_5 = a_6 = 0$).

`Type4`. K/k and $K1/k$ should be distinct quadratic extensions. $T(k) = L^{*N_{L/K}=1}$ where L is $K.K1$. *pt* satisfies not($a_1 = a_2 = a_3 = a_4 = 0$ or $a_5 = a_6 = 0$).

`Type6`. K/k should be a degree 6 extension which contains cubic and quadratic subextensions K_3 and K_2. For simplicity, the precise condition is that the generator $y = K.1$ must have minimal polynomial of the form $x^6 + 2ax^4 + a^2x^2 - d$ and then $K_3 = k(y^2)$ and $K_2 = k(y^3 + ay)$. $T(k) = K^{*N_{K/K_3}=N_{K/K_2}=1}$. *pt* satisfies not($a_1 = a_2 = a_3 = a_4 = a_5 = a_6 = 0$).

`ParametrizeDelPezzoDeg6(X)`

This variant for parametrizing a degree 6 Del Pezzo also handles the degenerate (singular) case. Note however, that it doesn't recognise singularity from the Lie algebra computation as occurs for degrees 7 and 8. It tests for singularity at the start using the generic non-singularity computation that can be very slow. Therefore for known non-degenerate Del Pezzos of degree 6, it is always better to use the above `ParametrizeDegree6DelPezzo` directly.

That is also used here, if X turns out to be non-singular. Otherwise, projection from a singular point to $\mathbf{P}^5$ reduces the problem to that of parametrizing a rational scroll.

Example H116E21

In the this example, we start with a degree 3 Del Pezzo surface - a non-singular hypersurface in $\mathbf{P}^3$ - which contains the 3 disjoint lines $x = y = 0$, $z = t = 0$ and $x = z, y = t$. These are blown down to give a degree 6 Del Pezzo surface, the parametrisation of which gives a parametrisation of the original surface. As well as demonstrating the degree 6 code, this is a nice example of blowing down exceptional lines on surfaces, something for which more general code will be added at a future date.

```
> R3<x,y,z,t> := PolynomialRing(Rationals(),4,"grevlex");
> P3 := Proj(R3);
> //equation of the degree 3 surface:
> F := -x^2*z + x*z^2 - y*z^2 + x^2*t - y^2*t - y*z*t + x*t^2 + y*t^2;
> X3 := Scheme(P3,F);
> // get the ideal defing the union of the 3 lines:
> I1 := ideal<R3|[x,y]>;
> I2 := ideal<R3|[z,t]>;
> I3 := ideal<R3|[x-z,y-t]>;
> I := I1*I2*I3;
> I := Saturation(I);
```

General surface theory tells us that if H is the hyperplane divisor on X_3, then the blowing down is given by the projective map associated to the divisor $H + L_1 + L_2 + L_3$, where the L_i are our 3 lines. We need the global sections of the sheaf of this: if $L_1 + L_2 + L_3 \sim 2H - D$ (linear equivalence of divisors) for an effective divisor D, then the space of global sections" is" the degree 3 graded

part of the ideal of D (mod the equation of X_3). The ideal I_D of a suitable D is computed by requiring that $ID \cap I = (F, F_2)$ with F_2 a degree 2 polynomial in I.

```
> F2 := Basis(I)[5]; F2;
y*z - x*t
> ID := ColonIdeal(ideal<R3|[F,F2]>,I);
> ideal<R3|[F,F2]> eq (ID meet I);
true
> // get basis of degree 3 graded part of ID
> ID3 := ID meet ideal<R3|Setseq(MonomialsOfDegree(R3,3))>;
> B3 := MinimalBasis(ID3);
> B3;
[
    y*z*t - x*t^2,
    z^3 - z^2*t + t^3,
    y*z^2 - x*z*t,
    x*z^2 - x*z*t + y*t^2,
    y^2*z - x*y*t,
    x*y*z - x^2*t,
    x^2*z - x^2*t + y^2*t,
    x^3 - x^2*y + y^3
]
> // and a complementary subspace of F
> F in ideal<R3|Remove(B3,7)>;
false
> B3 := Remove(B3,7);
> // now map to the degree 6 Del Pezzo
> P6<a,b,c,d,e,f,g> := ProjectiveSpace(Rationals(),6);
> blow_down := map<X3->P6|B3>;
> X6 := blow_down(X3);
> Dimension(X6); Degree(X6);
2
6
```

We also need the inverse of blow down. The general `IsInvertible` function could be used here but again the general theory tells us that the inverse is given by linear equations and it is faster to find them directly by a Grobner basis plus linear algebra computation. We omit this for brevity and just assume the result.

```
> X3toX6 := iso<X3->X6|B3,[f,e,c,a]>;
> // now parametrise X6
> boo,prm := ParametrizeDegree6DelPezzo(X6);
> boo;
true
> p2toX3 := Expand(prm*Inverse(X3toX6));
> p2toX3;

`ParametrizeDegree5DelPezzo(X)`

Let X be a degree 5 Del Pezzo surface anticanonically embedded in 5-dimensional projective space over a number field. We allow that X can be a degenerate (singular) Del Pezzo here. The scheme X is always parametrizable over the base field and this intrinsic returns such a parametrisation without reduction to higher degree.

The scheme X has a finite automorphism group in this case, so the Lie Algebra method cannot be applied. However, there is a more geometric method using projections that works well for degree 5 and that is used here.

`ParametrizeSingularDegree3DelPezzo(X,P2)`

`ParametrizeSingularDegree4DelPezzo(X,P2)`

These two intrinsics compute whether a degree 3 (resp. 4) anticanonically embedded *singular* Del Pezzo X has a parametrization over the base number field k and, if so, return such a parametrization as a scheme map with inverse from $P2$ to X. A projective plane $P2$ over the same base field k is the second argument of the intrinsic and will be used as the domain of the map returned.

The conditions on X mean that is an irreducible degree 3 hypersurface in P^3 in the first case or an irreducible complete intersection of 2 quadrics in P^4 in the second

case, having only a finite number of singularities that are canonical A-D-E type in either case. The condition that there is a finite non-empty set of singularities is checked but whether these singularities are canonical is not checked. In the unlikely event that a degree 3 hypersurface or degree 4 complete intersection has finitely many singularities but one is non-canonical, the functions will fail at some point.

If there is a singular point p defined over the base field, projection from p gives an immediate inverse parametrization of X in the degree 3 case and maps X onto a line or conic bundle in P^3 in the degree 4 case, which is then parameterized by the special routines for those cases. There remain a small number of configurations of conjugate singularities in the contrary case, corresponding to certain special root subsytems of E_6 or D_5. For these, individual methods have been devised and implemented. These include an adaptation of the Lie algebra method for the degree 3 and 4 singular Del Pezzo surfaces that are actually toric.

Example H116E22

The following is an example of a degree 3 hypersurface in P^3 over Q, that is a singular Del Pezzo with 4 conjugate A_1 singularities. It is handled very easily by the special case code.

```
> Q := RationalField();
> P2<a,b,c> := ProjectiveSpace(Q,2);
> P3<x,y,z,t> := ProjectiveSpace(Q,3);
> X := Scheme(P3, -4*x^2*y + 16*x*y^2 - y^3 + 2*x^2*z - 2*x*y*z +
>     7/2*y^2*z - 252*x*z^2 + 16*y*z^2 - 55*z^3 + 10*x^2*t + 14*x*y*t -
>     61/2*y^2*t - 3400*x*z*t + 216*y*z*t - 261*z^2*t - 11468*x*t^2 +
>     728*y*t^2 + 3987*z*t^2 + 21889*t^3);

116.4.4 Minimization and Reduction of Surfaces

Given an algebraic variety defined by several polynomials with integer coefficients, *reduction* asks for another embedding of this **Z**-scheme, such that the defining polynomials have smaller coefficients. *Minimization* asks for an isomorphic **Q**-scheme with minimal invariants. Many constructions of algebraic varieties lead to very bad models and thus it becomes necessary to perform minimization and reduction. Otherwise, subsequent calculations become impractical. The result of the minimization process is usually not unique.

Minimization is done locally for each prime of bad reduction. The local minimization routines and the reduction routines are directly accessible. They may be helpful for local computations or if the computation of all bad primes is too slow. Note that these subroutines do not check for semi-stability (in the sense of Mumford's geometric invariant theory). Unstable varieties may lead to infinite loops. As smooth hypersurfaces are known to be stable the initial computation of the bad primes will fail if an unstable variety is given.

In this section, minimization and reduction routines are described for Del Pezzo surfaces of degrees 3 (cubic surfaces) and 4.

Minimization and reduction is also available for various kinds of genus one curves (see Section 124.6) and plane quartics (see Section 114.12.3).

`MinimizeCubicSurface(f, p)`

Verbose `MinRedCubSurf` *Maximum :* 2

Given a cubic surface f as a homogeneous polynomial with integer coefficients, this routine performs a minimization at the place p. The new equation and the transformation matrix are returned. No checks of stability are done so that an unstable surface will lead to an infinite loop.

`ReduceCubicSurface(f)`

Verbose `MinRedCubSurf` *Maximum :* 2

Given a cubic surface f as a homogeneous polynomial with integral coefficients, this function computes a reduction of the surface. The second returned value is the transformation used.

`MinimizeReduceCubicSurface(f)`

Verbose `MinRedCubSurf` *Maximum :* 2

Given a smooth cubic surface f as a homogeneous polynomial with integer coefficients, this function computes a minimized and reduced model of the surface. The second return value is the transformation matrix. The transformation matrix applied to f will evaluate to a scalar multiple of the returned polynomial.

The algorithm is based on [Els].

`MinimizeDeg4delPezzo(f, p)`

Verbose `MinRedDeg4delPezzo` *Maximum :* 1

Given a degree 4 del Pezzo surface f as a sequence of two quadrics with integer coefficients, this function will compute a partially local minimized model for the place p. The second return value is the transformation matrix.

`MinimizeReduceDeg4delPezzo(f)`

Verbose `MinRedDeg4delPezzo` *Maximum :* 1

Given a degree 4 del Pezzo surface as a sequence of two quadrics with integral coefficients, this function computes a practically minimized and reduced model of the surface. The second return value is the transformation matrix.

The transformation matrix applied to the initial polynomials will evaluate to polynomials defining the same **Q** scheme as that defined by the returned quadrics.

For the reduction step, `ReduceQuadrics` is called.

`MinimizeReduce(S)`

Verbose `MinRedCubSurf` *Maximum :* 2

Verbose `MinRedDeg4delPezzo` *Maximum :* 1

Given a del Pezzo surface S of degree 3 or 4 this function will call the minimization and reduction routines described above and converts the output scheme X to a del Pezzo surface. The second returned value is the matrix hat maps S to the result.

Example H116E23

This example demonstrates minimization and reduction on del Pezzo surfaces of degree 3 and 4 obtained by blowing up rational points.

```
> P2 := ProjectiveSpace(RationalField(),2);
> pts := [P2| [-5,-10,-8], [-4,10,-4], [8,-2,-5], [0,-10,0], [1,5,7], [-7,-8,-6]];
> S := DelPezzoSurface(pts);
> _<W, X, Y, Z> := AmbientSpace(S); // give names to the variables
> S;
Del Pezzo Surface of degree 3 over Rational Field defined by

     - 233411/347200*Z^2
> MinimizeReduce(T);
Del Pezzo Surface of degree 4 over Rational Field defined by
-5*V^2 + 4*V*W + 8*W^2 + V*X - 8*X^2 - 8*V*Y + 3*W*Y + 3*X*Y + 15*Y^2 -
    2*V*Z - 16*X*Z - 10*Y*Z,
-2*V^2 + V*W + 3*W^2 + 2*V*X + 2*W*X - 6*X^2 + 3*V*Y + 3*W*Y - 17*X*Y -
    5*Y^2 + 5*V*Z - 22*X*Z - Y*Z + 13*Z^2
```

116.4.5 Cubic Surfaces over Finite Fields

In this section all cubic surface are represented by a homogeneous polynomial of degree 3 in a rank 4 polynomial ring. The coefficients are elements of a finite field.

`NumberOfPointsOnCubicSurface(f)`

Given a smooth cubic surface f over a finite field this routine computes the Frobenius action on the lines. The return values are the number of points of the surface and the Swinnerton-Dyer number of conjugacy class of the Weil group $W(E_6)$ that contains the Frobenius.

Example H116E24

```
> p := NextPrime(3^100);
> r<x,y,z,w> := PolynomialRing(GF(p),4);
> S := x^3 + 2* y^3 + 7* z^3 + 11 * w^3 - 5 * (-x-y-z-w)^3;
> NumberOfPointsOnCubicSurface(S);
265613988875874769338781322035779626829233452805946242111250315725884985311926\0
    79714208525578202
13
```

So we get a large number of points and the Frobenius has Swinnerton-Dyer number 13.

`IsIsomorphicCubicSurface(f,g)`

`UseLines` BoolElt *Default :* `false`

Given cubic surfaces f and g defined over finite fields, the intrinsic returns `true` if the surfaces are isomorphic. If f and G are isomorphic, there is a second return value comprising a list of matrices such that g^m will evaluate to a scalar multiple of f for each matrix m in the list. In the case where there are several isomorphisms over the algebraic closure of the basefield, one matrix for each isomorphism is returned.

Note that an isomorphism of smooth cubic surfaces is always given by a linear map.

The computation is based on an analysis of a finite set of points associated to the surface. Here we used the singularities of the hessian. If the hessian degenerates, the 135 intersection points of the lines are used. Setting `UseLines` to `true` indicates that the second algorithm is to be used.

As the algorithm involves huge field extensions it is only practical for surfaces over finite fields.

Example H116E25

```
> _<x,y,z,w> := PolynomialRing(GF(101),4);
> S := x^3 + y^3 + z^3 + w^3 - (x+y+z+w)^3;
> time a,b := IsIsomorphicCubicSurface(S, S);
Time: 0.530
> #b;
120
> S := x^3 + 2*y^3 + 7*z^3 + 5*w^3 - y*z*w + x^2*w + 2*y*z^2;
> time a,b := IsIsomorphicCubicSurface(S, S);
Time: 0.480
> #b;
1
> S := x^3 + y^3 + z^3 + w^3;
> time a,b := IsIsomorphicCubicSurface(S, S);
Time: 22.830
> #b;
648
```

Thus the diagonal cubic surface has 648 automorphisms and the Clebsch cubic surface has 120. Both examples are exceptional, a general cubic surface has a trivial automorphism group. The first example is much slower because the hessian degenerates and the 27 lines are used.

116.4.6 Construction of Cubic Surfaces

`CubicSurfaceByHexahedralCoefficients(pol)`

Given a separable polynomial p of degree 6 this intrinsic constructs a cubic surface having the roots of the p as hexahedral coefficients. These surfaces automatically have a Galois invariant set of 12 lines.

See [EJ10] for details.

`CoblesRadicand(p)`

Given a separable polynomial p of degree 6 this routine evaluates the Cobles quartic at the roots of p. Up to a square factor this value is the discriminant of the cubic surface constructed using hexahedral coefficients.

Example H116E26

```
> q<tt> := PolynomialRing(RationalField());
> p6 := tt^6 + 34*tt^4 + 180*tt^3 + 458*tt^2 + 524*tt + 212;
> CoblesRadicand(p6);
-676
> eqn := CubicSurfaceByHexahedralCoefficients(p6);
> Max([AbsoluteValue(c) : c in Coefficients(eqn)]);
13021618703131414093372560000 20
```

We have to use minimization and reduction to make further computations faster.

```
> S := MinimizeReduce(DelPezzoSurface(eqn));
> Equation(S);
6*y[1]^3 - 14*y[1]^2*y[2] + 6*y[1]*y[2]^2 - 6*y[2]^3 - 14*y[1]^2*y[3] +
    9*y[1]*y[2]*y[3] + 11*y[2]^2*y[3] - 21*y[1]*y[3]^2 + 14*y[2]*y[3]^2 +
    3*y[3]^3 - 3*y[1]*y[2]*y[4] + 10*y[2]^2*y[4] + 8*y[1]*y[3]*y[4] -
    53*y[2]*y[3]*y[4] + 40*y[3]^2*y[4] + 9*y[1]*y[4]^2 + 39*y[2]*y[4]^2 -
    23*y[3]*y[4]^2 - 16*y[4]^3
> M := PicardGaloisModule(S);
> Order(Group(M));
72
> CohomologyGroup( CohomologyModule(Group(M),M), 1);
Full Quotient RSpace of degree 2 over Integer Ring
Column moduli:
[ 2, 2 ]
```

Here the hexahedral approach gives us a cubic surface with nontrivial cohomology.

116.4.7 Invariant Theory of Cubic Surfaces

For background on this classical topic we refer to [Hun96, Appendix B] and [Sal58].

In this section a cubic surface is represented by a homogeneous polynomial of degree 3 in a rank 4 polynomial ring.

116.4.7.1 Invariants

By a theorem of Clebsch the ring of invariants of a cubic surface is generated by 5 invariants having degrees 8, 16, 24, 32 and 40. An explicit system of generators was found by Salmon. By Geometric Invariant Theory, stable cubic surfaces are isomorphic if and only if their invariants determine the same point in the weighted projective space $\mathbf{P}(1, 2, 3, 4, 5)$.

`ClebschSalmonInvariants(f)`

Computes a sequence of the numerical values of Salmon's invariants of the cubic surface given by the polynomial f. The second returned value is the discriminant of the surface.

`SkewInvariant100(f)`

Computes the numerical value a degree 100 skew invariant I_{100} of the cubic surface f. The square of I_{100} is an element of Clebsch invariant ring. It vanishes if and only if the cubic surface has an Eckardt point.

`CubicSurfaceFromClebschSalmon(inv)`

Computes a cubic surface whose invariants are equal to the given sequence. The algorithm requires the last invariant to be non-zero.

Example H116E27

```
> r4<x,y,z,w> := PolynomialRing(Rationals(),4);
> surf := r4!CubicSurfaceFromClebschSalmon([1,2,3,4,5]);
> surf := r4!MinimizeReduceCubicSurface(surf);
> surf;
-79*x^3 - 64*x^2*y + 228*x^2*z - 197*x^2*w + 320*x*y^2 - 470*x*y*z + 492*x*y*w
  - 180*x*z^2 - 94*x*z*w - 242*x*w^2 - 125*y^3 + 100*y^2*z + 94*y^2*w + 530*y*z^2
  - 886*y*z*w + 390*y*w^2 - 235*z^3 + 526*z^2*w - 825*z*w^2 +  279*w^3
> inv := ClebschSalmonInvariants(surf);
> inv;
[ 976235771549603375/3, 1906072563306098780753436239622781250/9,

50781250/531441
```

Thus the constructed surface has equivalent invariants (as they are in $\mathbf{P}(1, 2, 3, 4, 5)$) and no Eckardt points.

116.4.7.2 Covariants

A covariant is in the same ambient space as the initial surface. For example the equation itself is a covariant. In the case of a cubic surface this gives a degree 1 order 3 covariant. Products of covariants are again covariants. They form a ring over the ring of invariants.

`LinearCovariants(f)`

The intrinsic constructs a sequence containing Salmon's 4 linear covariants for the cubic surface f.

`ClassicalCovariantsOfCubicSurface(f)`

The intrinsic constructs a sequence containing the 4 classical covariants of the cubic surface f. The first one is the hessian. The next two are classically known as T and Θ. The last one is a degree 9 surface, which intersects f precisely in its 27 lines.

116.4.7.3 Contravariants

A contravariant is in the dual projective space of the initial surface. All contravariants form a ring over the ring of invariants. Contravariants can be constructed from invariants of varieties of the same degree but dimension one less by the Clebsch transfer principle.

`NumericClebschTransfer(f, inv, p)`

Given a form f and a user program `inv` that evaluates an invariant of a form of the same degree but one variable less, this function evaluates the corresponding contravariant of f at the point p. If this is repeated using sufficiently many different knots, it is possible to reconstruct a polynomial representation of the contravariant by interpolation.

`ContravariantsOfCubicSurface(f)`

Computes a sequence of 3 contravariants of the cubic surface f. By Clebsch transfer they correspond to the invariants S, T, and the discriminant of plane cubic curves. Thus the first one describes all hyperplanes such that the intersection with $f = 0$ gives a cubic curve with j-invariant equal to zero. The second gives all hyperplanes intersecting $f = 0$ in a cubic curve with j-invariant 1728 (as long as the intersection is smooth). The last one is $S^2 - 6T$. This is the degree 12 polynomial of the (formal) dual surface. It describes all hyperplanes such that the intersection with $f = 0$ is singular. For smooth surfaces this is equivalent to tangency. If $f = 0$ is singular the result will be reducible or even zero.

Example H116E28

This is the Cayley cubic surface. It has 4 singularities of type A_1 and each results in a linear factor of multiplicity two in the (formal) dual surface.

```
> r4<x,y,z,w> := PolynomialRing(Rationals(),4);
> surf := x*y*z + x*y*w + x*z*w + y*z*w;
> cont := ContravariantsOfCubicSurface(surf);
> Factorization(cont[3]);
```

```
[
    <w, 2>,
    <z, 2>,
    <y, 2>,
    <x, 2>,
    <x^4 - 4*x^3*y - 4*x^3*z - 4*x^3*w + 6*x^2*y^2 + 4*x^2*y*z + 4*x^2*y*w
     + 6*x^2*z^2 + 4*x^2*z*w + 6*x^2*w^2 - 4*x*y^3 + 4*x*y^2*z + 4*x*y^2*w
     + 4*x*y*z^2 - 40*x*y*z*w + 4*x*y*w^2 - 4*x*z^3 + 4*x*z^2*w + 4*x*z*w^2
     - 4*x*w^3 + y^4 - 4*y^3*z - 4*y^3*w + 6*y^2*z^2 + 4*y^2*z*w + 6*y^2*w^2
     - 4*y*z^3 + 4*y*z^2*w + 4*y*z*w^2 - 4*y*w^3 + z^4 - 4*z^3*w + 6*z^2*w^2
     - 4*z*w^3 + w^4, 1>
]
```

116.4.7.4 Interaction of Covariants and Contravariants

One can apply a contravariant to a covariant (or vice versa). The result is a new covariant (resp. contravariant) or an invariant. Its degree is the sum of the degrees of the arguments. The order is the difference of the two orders. If the order of the result is zero, it is an invariant.

One way to define the action is to interpret the contravariant as a differential operator, i.e. x_i^k acts as $\frac{\partial^k}{\partial x_i^k}$. Then one applies this differential operator to the covariant.

`ApplyContravariant(c, d)`

Given a covariant c and a polynomial d, this intrinsic interprets d as a differential operator (i.e., x is replaced by d/dx). It applies this operator to the polynomial c and returns the resulting polynomial.

In invariant theory d is a contravariant and c is a covariant.

Example H116E29

Here we compute Salmon's first invariant by applying a degree 4 order 4 contravariant to the hessian which is a degree 4 order 4 covariant.

```
> r4<x,y,z,w> := PolynomialRing(RationalField(),4);
> surf := x^3 + 2*y^3 + 3*z^3 + 5*w^3 - 2*x*y*(z-w) + (x+y+z+w)^3;
> cont := ContravariantsOfCubicSurface(surf);
> cov := ClassicalCovariantsOfCubicSurface(surf);
> ApplyContravariant(cont[1],cov[1]) / (2^11 * 3^9);
1438753/729
> ClebschSalmonInvariants(surf)[1];
1438753/729
```

116.4.8 The Pentahedron of a Cubic Surface

A general cubic surface can be written as a sum of 5 cubes of linear forms. These are unique up to scaling by third roots of unity and permutation. Thus we can associate 5 points in the dual projective space to a given cubic surface. They are called the faces of its pentahedron. In general the faces of the pentahedron are defined over a larger field.

The algorithm is described in [RS00].

`PentahedronIdeal(f)`

Computes the ideal of the faces of the pentahedron of the cubic surface f.

Example H116E30

The first example is a randomly chosen cubic surface. By construction it has a proper rational pentahedron.

```
> r4<x,y,z,w> := PolynomialRing(Rationals(),4);
> surf := x^3 + (x-y+2*z)^3 + (y-w)^3 + z^3 + (x - 3*y-2*z-7*w)^3;
> p_id := PentahedronIdeal(surf);
> Points(Cluster(ProjectiveSpace(Rationals(),3),Basis(p_id)));
{@ (-1/7 : 3/7 : 2/7 : 1), (0 : -1 : 0 : 1), (0 : 0 : 1 : 0),
   (1/2 : -1/2 : 1 : 0), (1 : 0 : 0 : 0) @}
```

The next example shows that the pentahedron of the diagonal cubic surface degenerates.

```
> diag := x^3 + y^3 + z^3 + w^3;
> p_id2 := PentahedronIdeal(diag);
> Points(Cluster(ProjectiveSpace(Rationals(),3),Basis(p_id2)));
{@ (0 : 0 : 0 : 1), (0 : 0 : 1 : 0), (0 : 1 : 0 : 0), (1 : 0 : 0 : 0) @}
```

The final example is a surface without a pentahedron.

```
> degen := x^3+y^3+z^3 + x*y*z+ w^3;
> p_id3 := PentahedronIdeal(degen);
> Points(Cluster(ProjectiveSpace(Rationals(),3),Basis(p_id3)));
{@ (0 : 0 : 0 : 1) @}
```

117 HILBERT SERIES OF POLARISED VARIETIES

Chapter 117
HILBERT SERIES OF POLARISED VARIETIES

117.1 Introduction

This chapter describes methods of generating graded rings that correspond to polarised algebraic varieties of various types. They can be used to generate examples of subcanonical curves—curves X polarised by a divisor D for which $kD = K_X$, the canonical class, for some integer k—K3 surfaces, Fano 3-folds and Calabi–Yau 3-folds. Of these, K3 surfaces are the best developed, and a database containing several thousand surfaces forms part of MAGMA.

117.1.1 Key Warning and Disclaimer

It is important to be aware of the nature and limitations of the output of the functions and databases described in this chapter. We list five of the issues in numbered points below, of which number 5 is the most important.

A typical example of a graded ring arises from a hyperelliptic curve C of genus g embedded in weighted projective space (wps):

$$C : (y^2 = f) \subset \mathbf{P}(1, 1, g + 1)$$

where the coordinates on $\mathbf{P}(1, 1, g + 1)$ are x_1, x_2, y of weights $1, 1, g + 1$ respectively, and $f = f_{2g+2}(x_1, x_2)$ is a homogeneous polynomial of degree $2g + 2$ in two variables having distinct roots. This embedded variety has homogeneous coordinate ring

$$R(C) = \frac{k[x_1, x_2, y]}{(y^2 - f)}$$

where k is the ground field. As a concise representation of this data, we record only a particular rational representation of the Hilbert series $P_R(t)$ of $R = R(C)$,

$$P_R(t) = 1 + 2t + 3t^2 + \cdots + (g + 1)t^g + (g + 3)t^{g+1} + \cdots = \frac{1 - t^{2g+2}}{(1 - t)(1 - t)(1 - t^{g+1})}$$

from which, as shown in Section 117.2.2, we deduce the fields

Weights = [1, 1, g+1], EquationDegrees = [2g+2].

Even though using this representation involves losing much information about the curve C, it has preserved enough detail so that it is still possible to do such things as create another

curve having the same basic invariants as C, or to recognise the family of hypersurfaces of degree 2 in $\mathbf{P}(1,1,g+1)$ to which C belongs.

This example illustrates several of the points one should keep in mind when interpreting the output of most functions in this chapter.

1. Weighted projective space (wps) The methods used here automatically generate examples of varieties defined by (weighted) homogeneous equations in wps, and so one must be familiar with wps from the outset. See Fletcher [IF00] for an accessible introduction to wps if necessary.

2. Field of definition Since the functions described in this chapter do not return literal equations of varieties, they do not assign a base field k. It is useful to have in mind $k = \mathbf{C}$, the complex numbers, but in many cases the base field is not relevant and one could work over any field. Having said that, there are cases where the base field is a crucial part of the problem.

3. Polarised varieties and their graded rings A *polarised variety* X, A is a variety X together with a divisor A that is ample on X; that is, there is a multiple kA of A which is a hyperplane section of X in some projective embedding $X \subset \mathbf{P}^N$. The homogeneous coordinate ring of X in this embedding is a graded ring which is generated in degree 1. But this embedding is not necessarily the one we want: the graded ring may be very large. Instead, we consider the *total graded ring* of A

$$R(X,A) = \oplus_{n\geq 0} H^0(X, \mathcal{O}_X(nA)),$$

which, with very few exceptions, is a much smaller ring. We do not define the terms precisely here, but suffice it to say that the Proj-correspondence between varieties in wps and the graded rings that are their homogeneous coordinate rings holds in this context between X, A and $R(X,A)$ just as it does for embeddings in ordinary projective space.

Thus we regard the following three pieces of data as being equivalent:

- a polarised variety X, A;
- the total graded ring $R(X,A)$ of a polarised variety X, A;
- the embedding $X \subset \mathbf{P}^N(w_0, \ldots, w_N)$ by all multiples of A, for some weights $w_0, \ldots, w_N$.

And so we use the words 'polarised variety' and 'graded ring' interchangeably. The fact that we also use 'variable', 'coordinate' and 'generator' synonymously is another reflection of this equivalence.

4. Numerical data of families of varieties In fact, we do not consider a single polarised variety X, A. Instead we record weaker information that characterises a family of varieties of which X, A is a particular member. The key piece of information that we work with is the Hilbert series $P_R(t)$ of the graded ring $R = R(X,A)$. This is calculated using the Riemann–Roch formula (RR) once we have decided which class of varieties we are concerned with. In favourable cases, RR takes as ingredients some discrete pieces of geometric data such as genus (which are invariant in flat families of suitably prescribed

varieties) and returns the dimension of the n-th graded piece R_n of the graded ring R. The algorithms work by taking such appropriate data as input, returning a Hilbert series (which is done by applying a formula that is hard-coded) and then analysing that series.

We can often produce extra information such as a prediction of weights $w_0, \ldots, w_N$ in which some suitable X is embedded. Some elementary examples of this are worked out Section 117.2.1.

5. Main problem In most cases, there are no criteria to determine whether a particular set of invariants for RR are actually the invariants of some polarised variety X, A. So even though the data that is then generated by MAGMA purports to be associated to some graded ring $R(X, A)$, there is no reason in any particular case why there really should exist such a polarised variety X, A. Fortunately, in many cases it is clear that there really is a variety that realises the output. In the example of the genus g hyperelliptic curve above, knowing the weights $(1, 1, g+1)$ and the degree of the equation, it is easy to see that there exists a nonsingular variety with these data and one could even write MAGMA routines to present an example using the scheme machinery of Chapter 117.10.2 and then attempt to construct a Weierstrass model of the hyperelliptic curve as described in Chapter 117.10.2 to obtain access to the specialist machinery provided for such curves.

As a rule, any polarised variety X, A that is described by the output of a function—even by the K3 database—cannot be assumed to exist, or if it does exist, it might not take exactly the form described. To prove that such a variety exists as described, it is sufficient to show that there is a quasi-smooth variety in the given wps having the given Hilbert series (or Hilbert numerator).

117.1.2 Overview of the Chapter

Graded ring calculations can be carried out in many different contexts. Included here are functions that work with subcanonical curves, K3 surfaces, Fano 3-folds and Calabi–Yau 3-folds. The latter three have appeared recently as parts of PhD theses, by Altinok [Alt98], Suzuki [Suz] and Buckley [Buc03] respectively. Other references for some of this material are [ABR02], [Rei00], [Pap03], [Bro03].

Section 117.2 gives a sketch of the theory of Hilbert series and describes functions that compute Hilbert series from Hilbert polynomials. It includes worked out examples of the elementary calculations that are behind most of the chapter. It contains the important definition of *Hilbert numerator* with respect to a collection of weights, which turns out to be the key point when we try to describe graded rings as the coordinate rings of polarised varieties.

Singularities are a main ingredient of RR in many applications, and Section 117.3 describes their construction and properties.

Five of the next six sections are devoted to different classes of polarised varieties. In fact, there are four specific classes of polarised variety, and one general class which encompasses them. Section 117.4 contains functions that apply to the general class, and thus are inherited by all classes: when consulting later sections, one should bear in mind that most basic functions will be described in this section. Section 117.5 covers the first

and most elementary application of graded ring methods to studying subcanonical curves, that is, curves polarised by a divisor that divides their canonical class.

K3 surfaces are described in Section 117.6. Although one can construct a single graded ring in isolation, a benefit of the graded ring methods is that they can be used generate large lists in one go. One such application is the amplification of Magma's K3 database from the 391 K3 surfaces in codimension at most 4 to the 24,099 cases in the current version. This is discussed in Section 117.7 which includes a precise statement characterising which K3 surfaces are included in the database and a further severe disclaimer.

There are two classes of 3-fold available: Fano 3-folds and Calabi–Yau 3-folds. The former is covered in Section 117.8, the latter in Section 117.9. Each of these is in a fairly early stage of development, having only basic creation functions and no systematic means for generating the large lists similar to those that exist for K3 surfaces. Nevertheless, one can begin to write lists. Section 117.10 describes how one can assemble such lists into Magma databases, although the process is somewhat technical and has its own limitations. Anyone attempting such lists will be aware that, following results of Kawamata, there are only finitely many deformation families of Fano 3-folds—Suzuki [Suz] classifies those of high Fano index—while it is still unknown whether or not there are finitely many families of Calabi–Yau 3-folds, Kreuzer and Skarke's vast lists [KS00] notwithstanding.

117.2 Hilbert Series and Graded Rings

The theory of Hilbert series is standard so it is only briefly touched on here. See Matsumura [Mat89] Section 13 for more details (or other any standard textbook on algebra such as Zariski–Samuel or Eisenbud.)

117.2.1 Hilbert Series and Hilbert Polynomials

Let $R = \oplus R_n$, the sum taken over $n \geq 0$, be a finitely-generated graded k-algebra with $R_0 = k$ and grading given by n. The *Hilbert polynomial* of R is the numerical polynomial $p(t)$ such that $\dim R_n = p(n)$ for all n sufficiently large. The *Hilbert series* of R is the power series

$$P(R) = \sum_{n \geq 0} (\dim R_n) t^n.$$

For example, let $C \subset \mathbf{P}^3$ be the twisted cubic defined by the three equations

$$xz = y^2, \quad xt = yz, \quad yt = z^2$$

and let

$$R = \frac{k[x, y, z, t]}{xz - y^2, xt - yz, yt - z^2}$$

be the homogeneous polynomial ring of C. Then one computes that

$$P(R) = 1 + 4t + 7t^2 + 10t^3 + \cdots$$

as follows. Certainly $R_0 = k$, and there are no equations of degree 1 so R_1 is the 4-dimensional vector space spanned by x, y, z, t. Now R_2 is spanned by the 10 quadrics $x^2, xy, \dots, t^2$, but these are related by the three equations, so $\dim R_2 = 10 - 3 = 7$. And so on. If you are systematic about it, you will discover quickly that the dimension of R_n is $3n + 1$ for $n \geq 1$. This can be proved by induction. So the Hilbert polynomial of R is $p(t) = 3t + 1$, which determines every coefficient of the Hilbert series $P(R)$ except the constant term.

Consider a bigger example: let $C = C_{10} \subset \mathbf{P}(1, 1, 5)$ be a hyperelliptic curve of genus 4 and degree 2 given by an equation

$$y^2 = f_{10}(x_1, x_2)$$

in coordinates x_1, x_2, y on wps $\mathbf{P}(1, 1, 5)$ where f_{10} is some general polynomial of degree 10. Again one calculates the Hilbert polynomial as $p(t) = 2t - 3$ and Hilbert series as

$$P(t) = 1 + 2t + 3t^2 + 4t^3 + 5t^4 + 7t^5 + 9t^6 + \cdots.$$

This power series can also be described as a rational function

$$P(t) = \frac{1 - t^{10}}{(1 - t)^2(1 - t^5)}$$

from which one can formulate a rule of thumb for relating this expression to the description of the curve as $C_{10} \subset \mathbf{P}(1, 1, 5)$ (or see the answer in Section 117.10.2 or [Rei00], Section 3.2).

Now there are other curves in wps that have the same Hilbert polynomial p as this example, but which have a different Hilbert series. To find one, consider modifying early terms of the series

$$P(t) = 1 + t + 2t^2 + 4t^3 + 5t^4 + 7t^5 + 9t^6 + \dots$$

and attempt to build the curve B in some wps. The coefficient of the term t (which is 1 in this case) implies that there is one linear coordinate x. Then the $2t^2$ demands one degree 2 coordinate y so that the 2-dimensional space of degree 2 homogeneous functions is spanned by x^2, y. In degree 3, x, y generate only a 2-dimensional space $\langle x^3, xy \rangle$, but the graded piece in degree 3 is 4-dimensional, according to the term $4t^3$, so there must be two more generators z_1, z_2. In degree 4 we see $x^4, x^2y, y^2, xz_1, xz_2$ which is just right if we assume that these are linearly independent (which we do). Similarly in degree 5 we hit the right number on the nose. But in degree 6 we see 11 monomials:

$$x^6, x^4y, x^2y^2, y^3, x^3z_1, xyz_1, x^3z_2, xyz_2, z_1^2, z_1z_2, z_2^2.$$

These lie in a 9-dimensional vector space (9 being the coefficient of t^6 in $P(t)$) so there must be two relations between them. We could carry on in this vein, but in fact we have done enough now: it is an exercise in wps to show that the curve

$$B = B_{6,6} \subset \mathbf{P}(1, 2, 3, 3)$$

defined by two general polynomials of degree 6 has genus 4 and degree 2 just as in the first example. We will work this example in MAGMA in the next subsection.

Thus the Hilbert polynomial determines the coefficients of high powers of t in the Hilbert series. So in this case, and more generally for the subcanonical curves of Section 117.5, to determine a Hilbert series P one must produce both the Hilbert polynomial p and a sequence V of the early coefficients that are not determined by p.

There is one extra twist that can happen: it is possible that there is not a single Hilbert polynomial p that determines the higher coefficients, but a sequence of polynomials $p_0, \ldots, p_{r-1}$ so that the nth coefficient is given by $p_i(n)$ where i is the residue of n modulo r. It is easy to generate examples of this using the intrinsics described below. This phenomenon occurs naturally when the RR data includes quotient singularities or fractional divisors, since these tend to make periodic corrections to an otherwise well-determined Hilbert polynomial, and one could rephrase this as above by saying that there is a sequence of Hilbert polynomials. In practice, this is a small distraction that is completely bound up in the main creation intrinsics.

```
HilbertFunction(p,V)
```

```
HilbertFunction(Q,V)
```

The Hilbert function determined by a univariate polynomial p (the Hilbert polynomial), or a sequence Q of univariate polynomials, and a sequence of initial values V. The returned object is a function whose domain is the integers.

```
HilbertSeries(p,V)
```

```
HilbertSeries(Q,V)
```

The Hilbert series determined by a univariate polynomial p (the Hilbert polynomial), or a sequence Q of univariate polynomials, and a sequence of initial values V. The returned object is a rational function in one variable.

117.2.2 Interpreting the Hilbert Numerator

The Hilbert series of a variety $X \subset \mathbf{P}(w_0, \ldots, w_N)$ defined by equations of degrees $d_1, \ldots, d_r$ has the form

$$P(t) = \frac{1 - t^{d_1} - t^{d_2} - \cdots - t^{d_r} + t^e \pm \ldots \pm t^k}{(1 - t^{w_0}) \cdots (1 - t^{w_N})}.$$

We refer to the numerator of this expression as the *Hilbert numerator with respect to the weights* $w_0, \ldots, w_N$, or simply *Hilbert numerator* if the weights are clear.

The aim is to apply a converse statement: if we can manipulate the Hilbert series of a polarised variety into such a form, we guess that it is embedded in $\mathbf{P}(w_0, \ldots, w_N)$ by equations of degrees given by low degree terms with negative coefficients (where the absolute value of the coefficient determines the number of equations of that degree).

This can be taken further: the syzygies, and indeed a free resolution of the ideal of X, are also encoded weakly in the weights and the Hilbert numerator. For more details see [Rei00], Section 3, or [ABR02], Section 4.

`HilbertSeriesMultipliedByMinimalDenominator(p,V)`

`HilbertSeriesMultipliedByMinimalDenominator(Q,V)`

Let h be the Hilbert series determined by a univariate polynomial p, or a sequence Q of univariate polynomials, and a sequence of initial values V. This function produces a rational expression $g(t)/\Pi(1-t^d)$ for h, returning the numerator g as first value and a sequence containing the factors $1-t^d$ of the denominator as second value.

`HilbertNumerator(g, D)`

The product $g \times \Pi(1-t^d)$ taken over all integers $d \in D$, assuming the result is a polynomial. This function is typically used when g is a Hilbert series and D is a proposed collection of weights for a variety realising this series.

Example H117E1

We reproduce the example described in the introduction to this Section 117.2.

```
> T<t> := PolynomialRing(Rationals());
> p := 2*t - 3;
> V := [ 1, 2, 3, 4 ];
> h_fun := HilbertFunction(p,V);
> [ h_fun(n) : n in [0..7]];
[ 1, 2, 3, 4, 5, 7, 9, 11 ]
> h := HilbertSeries(p,V);
> h;
(t^5 + 1)/(t^2 - 2*t + 1)
```

The Hilbert series will be the Hilbert series of a polarised curve C (since the degree of the Hilbert polynomial—the order of growth of the coefficients of the Hilbert series—is one). It is already expressed as a rational function, so we apply a power series ring coercion to see the dimensions of the graded pieces—we could increase the precision if required.

```
> S<s> := PowerSeriesRing(Rationals(),8);
> S ! h;
1 + 2*s + 3*s^2 + 4*s^3 + 5*s^4 + 7*s^5 + 9*s^6 + 11*s^7 + O(s^8)
```

The rule of thumb for interpreting Hilbert series as varieties defined by homogeneous polynomials in wps requires one to write the Hilbert series in the form P/Q for polynomials P, Q, where Q is a product of terms $1-t^a$ (corresponding to the coordinates of weight a). The next line computes the Hilbert series together with the minimal such expression.

```
> HilbertSeriesMultipliedByMinimalDenominator(p,V);
t^5 + 1
[ -t + 1, -t + 1 ]
```

One could interpret this return value as a Noether normalisation of the graded ring of C. Instead, we try some values for a new weight a hoping to stumble on the weights of a wps in which C embeds. We start with $a = 4$, then try $a = 5$.

```
> HilbertNumerator(h,[1,1,4]);
-t^9 + t^5 - t^4 + 1
```

```
> HilbertNumerator(h,[1,1,5]);
-t^10 + 1
```

The first answer made little sense. Having included a generator in degree 4 it demanded an equation of the same degree. That is certainly possible, but assuming the equation involves only the weight 1 variables, it would factorise and the result would not be a variety. However, the final answer is just what we hope for: it suggests that C is realised by a degree 10 curve in $\mathbf{P}(1,1,5)$, which makes perfect sense and is what we expected.
Now consider the modified Hilbert series of the second example of Section 117.2 in which we changed the early coefficients from $V = [1,2,3,4]$ to $[1,1,2,4]$, but kept the Hilbert polynomial p.

```
> h1 := HilbertSeries(p,[1,1,2,4]);
> S ! h1;
1 + s + 2*s^2 + 4*s^3 + 5*s^4 + 7*s^5 + 9*s^6 + 11*s^7 + O(s^8)
> HilbertNumerator(h1,[1,1,5]);
-t^10 + t^9 - t^8 - t^7 + t^6 - t^4 + t^3 + t^2 - t + 1
```

This implies that there is an equation in degree 1. Such an equation immediately eliminates one of the two degree 1 coordinates which would be daft, so we eliminate this redundancy right at the beginning by trying instead

```
> HilbertNumerator(h1,[1,5]);
t^9 + t^7 + 2*t^6 + t^5 + t^4 + 2*t^3 + t^2 + 1
```

In short, this suggests a new variable in degree 2 and two new variables in degree 3: this could be done methodically by considering one generator at a time.

```
> HilbertNumerator(h1,[1,2,3,3,5]);
-t^17 + t^12 + 2*t^11 - 2*t^6 - t^5 + 1
```

Now examining this Hilbert numerator, we see that the first equation is in degree 5. But there is a variable of degree 5. Although that is not a problem, we could try to remove the degree 5 variable, as we would, in practice, if we knew that it appeared linearly in the equation.

```
> HilbertNumerator(h1,[1,2,3,3]);
t^12 - 2*t^6 + 1
```

Finally, this suggests $B_{6,6} \subset \mathbf{P}(1,2,3,3)$, and again it is an easy exercise in wps to confirm that such a curve really does exist with the predicted properties.

`FindFirstGenerators(g)`

This intrinsic function returns a sequence containing the results of a first attempt to deduce plausible weights of generators for the variety with Hilbert series g. The method used proceeds by advancing through the coefficients of g, in order of increasing degree, adding generators of that degree for each positive coefficient. The algorithm stops when it first finds a negative coefficient.

Example H117E2

We first make a Hilbert series which has initial terms $1 + 2t + 3t^2 + 4t^3$.

```
> T<t> := PolynomialRing(Rationals());
> p := 2*t - 3;
> V := [ 1, 2, 3, 4 ];
> h := HilbertSeries(p,V);
> h;
(t^5 + 1)/(t^2 - 2*t + 1)
> S<s> := PowerSeriesRing(Rationals(),4);
> S ! h;
1 + 2*s + 3*s^2 + 4*s^3 + O(s^4)
```

This h is, in fact, the Hilbert series of a graded ring generated by three elements in degrees 1,1,5.

```
> FindFirstGenerators(h);
[ 1, 1, 5 ]
```

There is no guarantee that this intrinsic will always find suitable weights, but it does return a subset of the weights that must occur for any variety that realises the given Hilbert series.

`ApparentCodimension(f)`

`ApparentEquationDegrees(f)`

`ApparentSyzygyDegrees(f)`

If $f = f(t)$ is a polynomial of the form

$$f = 1 - \sum_{i=1}^{N_0} a_{0,i}t^i + \sum_{k=N_0+1}^{N_1} a_{1,i}t^i - \ldots + (-1)^{k-1} \sum_{i=N_{k-2}+1}^{N_{k-1}} a_{k-1,i}t^i + (-1)^k t^{N_k}$$

then the apparent codimension is k, the apparent equation degrees are those i for which $a_{0,i}$ is nonzero (with $a_{0,i}$ equations having that degree i) and the apparent syzygy degrees are those i for which $a_{1,i}$ is nonzero.

117.3 Baskets of Singularities

We describe how to create the various point and curve singularities, together with collections or *baskets* of these singularities that are an ingredient of RR in higher dimensions.

Recall the basic principle of singularity contributions in RR: when we nominate a basket of singularities in the RR formula we do not necessarily expect the corresponding variety to have exactly those singularities associated with it (although that is very commonly the case), but rather to possess singularities which make exactly the same contribution to the RR formula as the singularities of the basket. Thus, we only allow the creation of a restricted class of singularities that (in good cases) allow us to realise all possible contributions.

117.3.1 Point Singularities

The point singularities that are allowed are always finite cyclic quotient singularities. In the surface case (over the complex numbers $\mathbf{C}$) they are always analytically isomorphic to a neighbourhood of the origin in the quotient $\mathbf{C}^2/G$, where G is the group of r-th roots of unity and the action is determined on eigencoordinates x, y of $\mathbf{C}^2$ by the action of a primitive root of unity $\lambda \in G$:

$$\lambda \cdot x = \lambda^a x, \quad \lambda \cdot y = \lambda^b y$$

for some $a, b \in \{0, \ldots, r-1\}$. Such a singularity is denoted by the symbol $\frac{1}{r}(a, b)$.

Similarly, one defines 3-dimensional quotient singularities, where the symbol $\frac{1}{r}(a, b, c)$ denotes a cyclic quotient singularity. Of course, one can go into yet higher dimensions, with symbol $\frac{1}{r}(a_1, \ldots, a_k)$, but although the functions of this chapter can create such singularities, they do not yet calculate RR for singularities of dimension higher than three. By definition, if $p = \frac{1}{r}(a_1, \ldots, a_k)$, the *index of* p is the positive integer r and the *polarisation of* p is the sequence $[a_1, \ldots, a_k]$.

The four main situations in which we use (quotient) point singularities are:

- Gorenstein surface singularities $\frac{1}{r}(a, r-a)$ with r coprime to a (for K3 surfaces)
- terminal 3-fold singularities $\frac{1}{r}(a, r-a, b)$ with r coprime to a, b (for Fano 3-folds)
- isolated canonical 3-fold singularities $\frac{1}{r}(a, b, c)$ with $a+b+c = 0 \bmod r$ and r coprime to each of a, b, c (for Calabi–Yau 3-folds)
- nonisolated canonical 3-fold singularities $\frac{1}{r}(a, b, c)$ with $a+b+c = 0 \bmod r$ and no three of r, a, b, c sharing a nontrivial common factor (for Calabi–Yau 3-folds).

In the final, nonisolated case, the points can be points at the intersection of two branches of the 1-dimensional singular loci, or other points on 1-dimensional singular loci that do not have the generic transverse behaviour. (This case is discussed further in Section 117.10.2 on curve singularities below.)

There is an additional key piece of data. The contribution of a point p to RR for $\chi(X, A)$ depends upon the eigenspace of the G-action in which A lies. In other words, the singularity is also polarised locally by A. This is called the *local polarisation* or the *eigenspace* of the singularity (the latter to distinguish it more clearly from the polarisation), and is another integer n in the range $\{0, \ldots, r-1\}$. When we need to include the eigenspace of A in the singularity, we use the symbol $\frac{1}{r}(a_1, \ldots, a_k)_n$.

Example H117E3

We make a point that can lie on a surface.

```
> p := Point(7,[3,4]);
> p;
1/7(3,4)
> IsGorensteinSurface(p);
true
```

Now we make a point of a 3-fold.

```
> q := Point(5,2,[1,2,3]);
```

```
> q;
1/5(1,2,3)_[2]
> IsTerminalThreefold(q);
true
> Eigenspace(q);
2
> p eq q;
false
```

We did not assign an eigenspace to the point p, so a default value was assigned.

```
> Eigenspace(p);
-1
```

117.3.1.1 Creation of Point Singularities

`Point(r,n,Q)`

`Point(r,Q)`

The point singularity with index a positive integer r, polarisation a sequence of positive integers Q and local polarisation an integer n. The group action should have no quasi-reflections, which means that no integer $k > 1$ is allowed to divide r and all but one of the elements of Q. The local polarisation n modulo r should be a unit modulo r. If it is not given as an argument, the default value is $n = -1$.

117.3.1.2 Accessing the Key Data and Testing Equality

`Dimension(p)`

Dimension of the variety on which the singularity p lies.

`Index(p)`

Index of the singularity p.

`Polarisation(p)`

Polarisation sequence of the singularity p.

`Eigenspace(p)`

Eigenspace of the polarising divisor of the point singularity p.

`p eq q`

Return `true` if and only if the two point singularities p, q have the following attributes equal: dimension, index, polarisation, eigenspace.

117.3.1.3 Identifying Special Types of Point Singularity

`IsIsolated(p)`

Return `true` if and only if the point singularity p is an isolated singularity; that is, if and only if every element of its polarisation is coprime to its index.

`IsGorensteinSurface(p)`

Return `true` if and only if the point singularity p is a Gorenstein surface point; that is, if and only if p is of type $\frac{1}{r}(a, r-a)$ for r, a coprime.

`IsTerminalThreefold(p)`

Return `true` if and only if the point singularity p is a terminal 3-fold point; that is, if and only if it is isolated, dimension 3 and the polarisation is of the form $a, b, r-b$, up to a permutation.

`TerminalIndex(p)`

The integer a when p is a singular point with polarisation sequence of the form $a, b, r-b$, up to a permutation, assuming that p is a terminal 3-fold point singularity.

`TerminalPolarisation(p)`

Polarisation sequence of the singularity p in the order $a, b, r-b$, where r is the index of p, and $b \leq r/2$. There will be an error if p is not a terminal 3-fold point singularity.

`IsCanonical(p)`

Return `true` if and only if the point singularity p is canonical; that is, if and only if the sum of the polarisation is trivial modulo the index.

117.3.2 Curve Singularities

We follow Buckley's analysis of curve singularities in RR [Buc03]. The first thing to note is that curve singularities in MAGMA are always 3-dimensional, that is, they are one-dimensional singular loci $C \subset X$ of polarised 3-folds X, A. The *degree* of C is the intersection number AC. At a general point of a curve singularity C, a transverse section is a Gorenstein surface quotient singularity, that is, a point of type $\frac{1}{r}(a, r-a)$ for coprime integers r, a. This is called the *transverse type* of C and r is called the *transverse index* of C.

There are two further key attributes of a curve singularity C: two integers N, t that carry information about the normal bundle of C and about possible special points on C. We do not discuss the meaning of N here except to say that it encodes the splitting type of the normal bundle (see [Buc03] and [SB] for further information), but in any case note that there are intrinsics described below that can identify appropriate values for N given some other invariants. This pair of invariants occur in RR only in the combination N/t, which itself appears only linearly. So given enough coefficients of the Hilbert series as

input, this value can be recovered. A curve, therefore, does have an attribute 'magic' that records this magic number N/t, and this can be set (and used in RR) even if N, t are not assigned.

We explain the attribute t. The transverse type of C gives a transverse section at any general point along C. But there may be special points, so-called *dissident points*, that do not have such a section. They certainly occur at an intersection point of two curve singularities, but may also be other points in C. They are quotient singularities $\{p_i\}$ whose indices are of the form rt_i for positive integers t_i, where r is the transverse index of C. The invariant t, called the *index* of C, is the GCD of the set of all such t_i.

Example H117E4

We create a curve singularity with given transverse type.

```
> p := Point(3,[1,2]);
> C := Curve(1/3,p,4,3);
> C;
Curve of degree 1/3, N = 4, t = 3 with transverse type 1/3(1,2)
```

We check some of the characteristics of C.

```
> TransverseIndex(C);
3
> IsCanonical(C);
true
> MagicNumber(C);
4/3
```

117.3.2.1 Creation of Curve Singularities

`Curve(d,p,m)`

`Curve(d,p,N)`

`Curve(d,p,N,t)`

The 3-fold curve singularity of degree d, transverse type p (a point surface singularity) and characteristic numbers N, t (which is 1 if not set) or magic number $m = N/t$.

117.3.2.2 Accessing the Key Data and Testing Equality

`Degree(C)`

The degree of the curve singularity C.

`TransverseType(C)`

The transverse type of the curve singularity C, that is, a point surface singularity that is the general transverse section of C.

`TransverseIndex(C)`

The transverse index of the curve singularity C, that is, the index of the point surface singularity that is a general transverse section of C.

`NormalNumber(C)`

The invariant N of the curve singularity C.

`Index(C)`

The invariant t (sometimes called τ) of the curve singularity C that is determined by the indices of dissident points on C.

`MagicNumber(C)`

The number N/t of the curve singularity C, where N is the normal number of C and t is the index of C.

`Dimension(C)`

The dimension of the curve singularity C (currently always 3).

`IsCanonical(C)`

Return `true` if and only if the transverse type of the curve singularity C is a canonical (or Du Val) surface singularity.

`C eq D`

Return `true` if and only if the two curve singularities C, D have the following attributes equal: dimension, degree, transverse type, magic number (or, equivalently, the pair of invariants N, t).

117.3.3 Baskets of Singularities

A *basket of singularities*, or simply *basket*, is a collection of point and curve singularities. One constructs baskets in the hope of finding a variety that has exactly those singularities lying on it as its only singularities, and very often this is indeed the case. It is a marginal issue here, but worth noting that in fact baskets are collections of ideal singularities of a variety X that make exactly the same contributions to RR as the actual singularities of X. So as a matter of principle, one is not primarily seeking varieties with exactly the basket singularities, even though this is what happens in practice.

117.3.3.1 Creation and Modification of Baskets

`Basket(Q)`

`Basket(Q1,Q2)`

The basket of singularities where Q, Q_1, Q_2 are sequences of point or curve singularities.

`EmptyBasket()`

The basket of singularities containing no singularities.

`MakeBasket(Q)`

The basket of singularities containing point singularities that are encoded in the sequence Q. This may occur in different ways. If Q is a sequence of sequences of the form $[r, a]$ (that is, each having length 2) with r, a coprime, then the result will be a basket of points of the form $\frac{1}{r}(a, r-a)$. If Q is a sequence of sequences of some common length $N > 2$, then the result will be a basket of points of the form $\frac{1}{Q[1]}(Q[2], \ldots, Q[N])$. Note that a local polarisation n cannot be included in this constructor: the default value $n = -1$ is always assumed.

`Points(B)`

The sequence of point singularities of the basket B.

`Curves(B)`

The sequence of curve singularities of the basket B.

117.3.3.2 Tests for Baskets

`IsIsolated(B)`

Return `true` if and only if all singularities of the basket B are isolated (so, in particular, there are no curve singularities in B).

`IsGorensteinSurface(B)`

Return `true` if and only if all singularities of the basket B are Du Val singularities, that is, are of the form $\frac{1}{r}(a, r-a)$.

`IsTerminalThreefold(B)`

Return `true` if and only if all singularities of the basket B are terminal 3-fold singularities.

`IsCanonical(B)`

Return `true` if and only if all singularities of the basket B are canonical singularities.

117.3.4 Curves and Dissident Points

Curves of singularities may contain special points not of the typical transverse type; these are the dissident points. The following intrinsics generate sequences of possible dissident points for a particular curve singularity. The point is that some of the invariants of a curve singularity force a curve to have dissident points that together give a certain RR contribution. It is not always easy to see what these points should be, so constructing by hand baskets that include a particular curve singularity can be difficult. These intrinsics all give suggestions for possible sets of dissident points.

`CanonicalDissidentPoints(C)`

A sequence of sequences of points, each of which minimally accounts for the index of the curve singularity C (although further curves may be needed in order for it to make sense).

`SimpleCanonicalDissidentPoints(C)`

A sequence of sequences of points, each of which minimally accounts for the index of the curve singularity C and which does not allow further curves to meet C.

`PossibleCanonicalDissidentPoints(C)`

A sequence of points, each of may appear on the curve singularity C as a dissident point.

`PossibleSimpleCanonicalDissidentPoints(C)`

A sequence of points, each of may appear on the curve singularity C as a dissident point but which is not at the intersection of C with another curve.

117.4 Generic Polarised Varieties

Recall from Section 117.1.1 that, despite some ambiguity, we regard the following as being equivalent: polarised varieties X, A; schemes in wps $X \subset \mathbf{P}^N(w_0, \ldots, w_N)$ where A is a degree 1 hyperplane section; and data about the Hilbert series of the graded ring $R(X, A)$. Thus we constantly refer to a *polarised variety* X, and we expect to be able to retrieve its Hilbert series, its dimension, the codimension of its embedding and other such data.

With one exception, the intrinsics described in this section can be applied to all polarised varieties. The exception is the following little-used intrinsic that creates a polarised variety that is not of a specific type.

`PolarisedVariety(d,W,n)`

The polarised variety of dimension d, with weights given by the sequence W of positive integers and with Hilbert numerator the univariate polynomial n.

117.4.1 Accessing the Data

`Weights(X)`

The weights of the polarised variety X.

`Degree(X)`

The degree of the polarised variety X.

`Basket(X)`

The basket of singularities of the polarised variety X.

`RawBasket(X)`

The basket of singularities of the polarised variety X in sequence format, that is, the basket is a sequence of sequences, in which a singularity $\frac{1}{r}(a, b, c)$ is represented as a sequence $[r, a, b, c]$ of integers. (The Gorenstein surface singularity $\frac{1}{r}(a, r-a)$ admits further abbreviation to $[r, a]$.) Notice that the local polarisation n is not included in this raw basket data; its default value $n = -1$ is assumed.

`Dimension(X)`

The dimension of the polarised variety X.

`Codimension(X)`

The codimension of the polarised variety X.

`HilbertNumerator(X)`
`Numerator(X)`

The numerator $f(t)$ of the Hilbert series $P(t)$ of the polarised variety X when expressed as a rational function $P = f(t)/\&*[1 - t^w : w \in W]$ where the product in the denominator is taken over W, the sequence of weights of X.

`NoetherWeights(X)`

The weights corresponding to a Noether normalisation of the polarised variety X. In other words, these are the weights of polynomials in the graded ring of X that generate a polynomial subring of maximal dimension.

`NoetherNumerator(X)`

The numerator $n(t)$ of the Hilbert series $P(t)$ of the polarised variety X when expressed as a rational function $P = n(t)/\&*[1 - t^w : w \in N]$, where the product in the denominator is taken over N, the sequence of Noether weights of X.

`NoetherNormalisation(X)`

Given a polarised variety X return a pair, the first term of which is the sequence of Noether weights, the second the corresponding numerator.

`HilbertSeries(X)`

The Hilbert series of the polarised variety X expressed as a rational function.

`InitialCoefficients(X)`

The coefficients of the Hilbert series of the polarised variety X expressed as a power series. The number of coefficients returned is equal to the precision of the power series ring in which the Hilbert series was expanded.

`ApparentCodimension(X)`

`ApparentEquationDegrees(X)`

`ApparentSyzygyDegrees(X)`

`BettiNumbers(X)`

If $n(t)$ is the Hilbert numerator of X and is of the form

$$n = 1 - \sum_{i=1}^{N_0} a_{0,i}t^i + \sum_{k=N_0+1}^{N_1} a_{1,i}t^i - \ldots + (-1)^{k-1} \sum_{i=N_{k-2}+1}^{N_{k-1}} a_{k-1,i}t^i + (-1)^k t^{N_k}$$

then the apparent codimension of X is k, the apparent equation degrees are given by those i for which $a_{0,i}$ is nonzero (with $a_{0,i}$ equations of that degree i) and the apparent syzygy degrees are those integers i for which $a_{1,i}$ is nonzero. The Betti numbers are a sequence with first element the sum of all $a_{0,i}$, second element the sum of all $a_{1,i}$, and so on until $a_{k-1,i}$.

117.4.2 Generic Creation, Checking, Changing

Procedural versions of intrinsic functions modify polarised varieties at the generic level because they preserve any subtypes; functional versions exist for special types of polarised variety but not in general.

`X eq Y`

Return `true` if and only if the polarised varieties X and Y have the same dimension, weights, basket and Hilbert numerator. In particular, these conditions imply that X and Y have the same Hilbert series.

`CheckCodimension(X)`

Return `true` if and only if the codimension of X is equal to the apparent codimension of X determined by its Hilbert numerator.

`FirstWeights(X)`

These are weights assigned to the polarised variety X during its construction that carry some relevance; if no such weights were assigned, the usual weights of X will be returned.

`IncludeWeight(~X,w)`

Include the positive integer w among the weights of X, adjusting all other data associated to the embedding of X as required.

`RemoveWeight(~X,w)`

Remove the positive integer w from the weights of X, assuming it appears there and can be removed without destroying the property of the Hilbert numerator being a polynomial. All other data associated to the embedding of X is modified as required.

`MinimiseWeights(~X)`

Remove any weights from X whose presence is not required to keep the Hilbert numerator of X a polynomial.

117.5 Subcanonical Curves

A *subcanonical curve* is a polarised variety C, D where C is a nonsingular curve of genus $g \geq 2$ and D is a divisor on C such that $K_C = kD$ for some positive integer k.

117.5.1 Creation of Subcanonical Curves

`SubcanonicalCurve(g,d,Q)`

The subcanonical curve C, D of genus g, degree d and initial Hilbert series coefficients Q.

`IsSubcanonicalCurve(g,d,Q)`

Return `true` if and only if the data g, d, Q passes some basic checks that there is a subcanonical curve C, D of genus g, degree d and initial Hilbert series coefficients Q. In that case, the second return value is such a curve.

`HilbertPolynomialOfCurve(g,m)`

The Hilbert polynomial $mt + 1 - g$ of a divisor of degree m on a curve of genus g.

`IsEffective(C)`

Return `true` if and only if the polarising divisor of the subcanonical curve C is effective; that is, if and only if the Hilbert series has the form $1 + p_1 t + \cdots$ with $p_1 > 0$.

117.5.2 Catalogue of Subcanonical Curves

This section describes intrinsics that allow the user to generate many examples of Hilbert series of subcanonical curves and attempt to interpret them as curves embedded in wps.

`EffectiveSubcanonicalCurves(g)`

`EffectiveSubcanonicalCurves(g,d)`

A sequence containing data for effective subcanonical curves of genus $g \geq 3$ (polarised by a divisor of degree d if the second argument is given).

`IneffectiveSubcanonicalCurves(g)`

`IneffectiveSubcanonicalCurves(g,d)`

A sequence containing data for ineffective subcanonical curves of genus $g \geq 3$ (polarised by a divisor of degree d if the second argument is given).

117.6 K3 Surfaces

This section describes intrinsics that construct K3 surfaces. It also describes a few intrinsics that can be used to study them, but see Section 117.4 for the general intrinsics that apply to all polarised varieties.

The calculations are based on Altinok's Riemann–Roch formula [Alt98] for polarised K3 surfaces with Du Val singularities.

117.6.1 Creating and Comparing K3 Surfaces

The basic RR data from which a K3 surface can be created comprises an integer, the *genus*, $g \geq -1$ and a basket of (Gorenstein surface) point singularities B. The basket B can be created explicitly as a basket using the functions of Section 117.10.2, but a convenient shortcut is provided whereby the basket argument may be given 'in raw basket format', that is, as a sequence B of length two sequences, each of the form $[r, a]$, denoting the singularity $\frac{1}{r}(a, r-a)$.

`K3Surface(g,B)`

A K3 surface with genus g and basket of singularities B (which may be a basket type or in raw basket format $[[r, a], ...]$).

`K3Copy(X)`

A new K3 surface that carries exactly the same data as the K3 surface X.

117.6.2 Accessing the Key Data

`Genus(X)`

The genus of the K3 surface X; that is, $p_1 - 1$ where p_1 is the coefficient of t in the Hilbert series of X.

`TwoGenus(X)`

The 2-genus of the K3 surface X; that is, $p_2 - 1$ where p_2 is the coefficient of t^2 in the Hilbert series of X.

`SingularRank(X)`

The sum $\sum(r-1)$ taken over the singularities $\frac{1}{r}(a, r-a)$ given in the basket of singularities of the K3 surface X.

`AFRNumber(X)`

The number assigned to the K3 surface X in the low codimension lists of Altinok–Fletcher–Reid.

117.6.3 Modifying K3 Surfaces

Sometimes it is desirable to add or remove weights from a given K3 surface. There are two intrinsics that allow this to be done (and check that a weight really can be removed). These intrinsics are used systematically in the construction of the K3 database.

`IncludeWeight(X,w)`

Return a new K3 surface that is the same as X but with the positive integer w included among the weights and all other data associated to the embedding adjusted as required.

`RemoveWeight(X,w)`

Return a new K3 surface that is the same as X but with the positive integer w removed from the weights, assuming it appears there and can be removed without destroying the property of the Hilbert numerator being a polynomial. All other data associated to the embedding is adjusted as required.

117.7 The K3 Database

The K3 database in MAGMA is a collection of 24,099 K3 surfaces. Recall from Section 117.6 the meaning of K3 surface in this context, and from Section 117.1.1 the relationship between the Hilbert series, the weights and the (Hilbert) numerator.

We describe the set of K3 surfaces selected for inclusion in the database. For $g = -1, 0, 1, 2$, all K3 surfaces of genus g are included, there being 4281, 6479, 6627 and 6628 surfaces, respectively. For higher genus, the data associated to the 6628 K3 surfaces of genus 2 propagates in a predictable way, so only those K3 surfaces with codimension at most 7 and genus in the range 3 to 9 have been included.

Data is held in blocks of surfaces indexed by the first five coefficients of their Hilbert series (excluding the constant term). Note that the t-coefficient of the Hilbert series is one more that the genus, and this defect holds for all genera. To determine the number of surfaces of genus 1, the intrinsics described below may be used. Note the genus argument is a sequence beginning with the integer 2: the sequence is arranged so that the user can ask a more precise question by including other leading genera (up to the first five), and the value 2 is to account for the genus–Hilbert coefficient defect.

```
> D := K3Database();
> NumberOfK3Surfaces(D,[2]);
6627
```

The database is fairly large, so naive searches take time. Specialised tools, described below, support much more efficient searches and should be used wherever possible. We demonstrate this point with timings for a typical search. The first searches the entire database for all K3 surfaces of genus 3 and takes over 2 minutes. It is much more efficient to use a function that looks up curves according to their genus, since this is the primary indexing property used by the database. The second search does this, and takes only a fraction of the time.

```
> time [ X : X in D | Genus(X) eq 3 ];
Time: 139.510
> time [K3SurfaceK(D,[4],i) :i in [1..NumberOfK3Surfaces(D,[4])]];
Time: 0.500
```

117.7.1 Searching the K3 Database

In this section a simple example is presented of extracting a K3 surface with particular properties from the K3 database. Section 117.10.2 provides much greater details and more examples: note, in particular, that only a few hundred of the surfaces that occur in small codimension have been confirmed to exist (even though the vast majority are believed to exist).

Example H117E5

We begin by defining D to be the K3 database.

```
> D := K3Database();
```

```
> D;
The database of K3 surfaces
```

It contains data associated to 24099 (families of) K3 surfaces.

```
> #D;
24099
```

There are several ways to access the K3 surfaces in the database. In the first place, the database is organised into blocks of K3 surfaces that have a common genus. These blocks are then subdivided into K3 surfaces that have a common 2-genus. The blocks having a common 2-genus are further subdivided right down to 5-genus, that is, the coefficient of t^5 in the Hilbert series. These subdivisions are the natural indexing units of the database. One gets the third surface with genus 0 by

```
> X := K3Surface(D,0,3);
> X;
K3 surface no.3, genus 0, in codimension 1 with data
  Weights: [ 1, 6, 8, 9 ]
  Basket: 1/2(1,1), 1/3(1,2), 1/9(1,8)
  Degree: 1/18          Singular rank: 11
  Numerator: -t^24 + 1
  Projection to codim 1 K3 no.2 -- type I from 1/9(1,8)
  Unproj'n from codim 2 K3 no.4 -- type I from 1/10(1,9)
  Unproj'n from codim 2 K3 no.15 -- type IV from 1/5(2,3)
  Unproj'n from codim 3 K3 no.28 -- type II_1 from 1/4(1,3)
  Unproj'n from codim 4 K3 no.84 -- type II_2 from 1/3(1,2)
  Unproj'n from codim 6 K3 no.280 -- type II_5 from 1/2(1,1)
```

This printout displays a lot of information about this surface and its relationship to other surfaces. The minimal printing option may be use to obtain a concise description of this surface alone.

```
> X:Minimal;
K3 surface (g=0, no.3) in P^3(1,6,8,9)
  Basket: 1/2(1,1), 1/3(1,2), 1/9(1,8)
  Numerator: -t^24 + 1
```

When using several genera to access a surface, the genus arguments must be collected together in a sequence. For example, there are 282 K3 surfaces whose first three genera are $p_1 = 0$, $p_2 = 1$, $p_3 = 3$; that is, have weights that are of the form $[2, 3, 3, \ldots]$.

```
> NumberOfK3Surfaces(D,[0,1,3]);
282
```

We get the first of these as follows. The arguments inside the sequence brackets are coefficients of the Hilbert polynomial, while the corresponding genus is one less than the coefficient. N.B. Note the offset by -1 between these arguments and the genera.

```
> K3Surface(D,[0,1,3],1);
K3 surface no.1130, genus -1, in codimension 4 with data
  Weights: [ 2, 3, 3, 3, 4, 4, 5 ]
  Basket: 2 x 1/2(1,1), 5 x 1/3(1,2)
```

```
  Degree: 1/3           Singular rank: 12
  Numerator: t^24 - ... + t^10 - t^9 - 2*t^8 - t^7 - t^6 + 1
  Projection to codim 1 K3 no.820 -- type II_2 from 1/3(1,2)
  Unproj'n from codim 5 K3 no.1131 -- type I from 1/5(2,3)
  Unproj'n from codim 6 K3 no.1145 -- type II_1 from 1/4(1,3)
  Unproj'n from codim 7 K3 no.1412 -- type II_2 from 1/3(1,2)
  Unproj'n from codim 8 K3 no.2176 -- type IV from 1/2(1,1)
```

The genus and number of a K3 surface identifies it uniquely in the database, so the same function may be used to see surface number 1131 which has projection to X.

```
> K3Surface(D,-1,1131) : Minimal;
K3 surface (g=-1, no.1131) in P^7(2,3,3,3,4,4,5,5)
  Basket: 1/2(1,1), 4 x 1/3(1,2), 1/5(2,3)
  Numerator: -t^29 + ... + 6*t^11 - 3*t^9 - 4*t^8 - t^7 - t^6 + 1
```

The projection is from the $\frac{1}{5}(2,3)$ singularity, resulting in the extra $\frac{1}{2}(1,1)$ and $\frac{1}{3}(1,2)$ points. There are also searches that do not use the primary indexing directly. For example, the following variation of `K3Surface` searches for a K3 surface with weights $2,2,3,5,7,9,11$.

```
> K3Surface(D,[2,2,3,5,7,9,11]) : Minimal;
K3 surface (g=-1, no.1615) in P^6(2,2,3,5,7,9,11)
  Basket: 3 x 1/2(1,1), 1/11(2,9)
  Numerator: t^39 - ... + t^16 - t^13 - t^11 - t^9 + 1
```

`K3Database()`

The database of K3 surfaces.

`Number(D,X)`

The integer n such that the K3 surface `Y := K3Surface(D,Genus(X)+1,n)` in the database D has the same Hilbert series as the K3 surface X. The second return value is the K3 surface Y. If there is no such K3 surface, the returned index value is zero.

`Index(D,X)`

The integer i such that the K3 surface `Y := K3Surface(D,i)` in the database D has the same Hilbert series as the K3 surface X. The second return value is the K3 surface Y. If there is no such K3 surface, the returned index value is zero.

Example H117E6

The 'Number' of a K3 surface in the database and its 'Index' may differ: the K3 surfaces of any fixed genus are numbered separately, while the index runs over the whole database.
To illustrate this, consider the following K3 surface.

```
> X := K3Surface(1,[[2,1],[3,1],[4,1],[7,1],[8,1]]);
> X;
K3 surface in codimension 11 with data
  Weights: [ 1, 1, 2, 2, 2, 2, 3, 3, 3, 3, 4, 6, 7, 8 ]
  Basket: 1/2(1,1), 1/3(1,2), 1/4(1,3), 1/7(1,6), 1/8(1,7)
  Degree: 613/168               Singular rank: 19
  Numerator: -t^47 + ... + 38*t^7 - 2*t^6 - 13*t^5 - 7*t^4 + 1
```

This surface has been calculated in isolation. The weights that have been assigned to it are just enough to make sense of the initial terms of the Hilbert series, and to make the singularities. By construction, the K3 database may have added weights to make simple projections work. So we search for X in the database using either 'Index' or 'Number'.

```
> D := K3Database();
> n,Y := Number(D,X);
> i,Y1 := Index(D,X);
> n,i;
1474 12234
```

This result means that X has the same Hilbert series as the 1474-th K3 surface in D of genus 1, which is the same as the 12234-th K3 surface in D.

```
> Y eq Y1;
true
> Y1 eq K3Surface(D,i);
true
```

One can see that Y is in much higher codimension than X, so that extra weights have been assigned to Y.

```
> Codimension(Y);
17
```

117.7.2 Working with the K3 Database

`K3Surface(D,i)`

The ith K3 surface in the K3 database D.

`K3Surface(D,Q,i)`

The ith K3 surface in the K3 database D among those with index suite $Q = [g1 + 1, g2 + 1, ...]$.

`K3Surface(D,g,i)`

The ith K3 surface in the K3 database D among those with genus $g \geq -1$.

`K3Surface(D,g1,g2,i)`

The ith K3 surface in the K3 database D among those with genus $g1 \geq -1$ and 2-genus $g2 \geq -1$.

`K3Surface(D,W)`

The K3 surface in the K3 database D having the weights specified in the sequence W.

`K3Surface(D,g,B)`

The K3 surface in the K3 database D with genus $g \geq -1$ and basket of singularities B (as a basket type or in raw sequence format).

117.8 Fano 3-folds

This section describes intrinsics that construct Fano 3-folds. It also describes a few intrinsics that can be used to study them, but see Section 117.4 for the general intrinsics that apply to all polarised varieties.

The calculations are based on Suzuki's Riemann–Roch formula [Suz] for polarised Fano 3-folds with terminal singularities.

Example H117E7

We make two Fano 3-folds having the same basket but different genus.

```
> X := Fano(2,MakeBasket([[3,1,2,2]]),2);
> X;
Fano 3-fold X,A of Fano index 2, Fano genus 2, in codimension 1 with data
  Weights: [ 1, 1, 2, 3, 5 ]
  Basket: 1/3(1,2,2)
  Degrees: A^3 = 1/3,   (1/12)Ac_2(X) = 8/9
  Numerator: -t^10 + 1
> FanoGenus(X);
2
> FanoBaseGenus(X);
2
> Fano(2,MakeBasket([[3,1,2,2]]),3);
Fano 3-fold X,A of Fano index 2, Fano genus 3, in codimension 2 with data
  Weights: [ 1, 1, 1, 2, 2, 3 ]
  Basket: 1/3(1,2,2)
  Degrees: A^3 = 4/3,   (1/12)Ac_2(X) = 8/9
  Numerator: t^8 - 2*t^4 + 1
```

In this example, the smallest possible genus—the Fano base genus—is 2, and an error will be reported if a smaller value is requested.

Note that the singularities used must be polarised by fA, where f is the Fano index: in practice, this means their index r must be coprime to f and their weights must be of the form $f, a, r-a$.

117.8.1 Creation: $f = 1, 2$ or ≥ 3

`Fano(f,B,g)`

A Fano 3-fold with Fano index $f \geq 1$, Fano genus $g \geq 0$ and basket of singularities B. The singularities must be terminal singularities. The basket can also be presented in raw sequence format: in this case, B is a sequence containing terms such as $[r, a, b, c]$ which denotes the singularity $\frac{1}{r}(a, b, c)$.

`Fano(f,B)`

A Fano 3-fold with Fano index $f \geq 3$ and basket of singularities B. The singularities must be terminal singularities. The basket can also be presented in raw sequence format: in this case, B is a sequence containing terms such as $[r, a, b, c]$ which denotes the singularity $\frac{1}{r}(a, b, c)$.

`FanoIndex(X)`

The Fano index f of the Fano 3-fold X.

`FanoGenus(X)`

The Fano genus of the Fano 3-fold X, an integer ≥ 0 equal to the dimension of the space of sections of the polarising divisor. (The term *genus* often refers to two less that this number).

`FanoBaseGenus(X)`

The smallest possible value for the Fano genus of the Fano 3-fold X.

`BogomolovNumber(X)`

The intersection number $A(c_1(X)^2 - 3c_2(X))$ for the polarised Fano 3-fold X, A.

`IsBogomolovUnstable(X)`

Return `true` if and only if the Bogomolov number $A(c_1(X)^2 - 3c_2(X))$ for the polarised Fano 3-fold X, A is strictly positive.

117.8.2 A Preliminary Fano Database

`FanoDatabase()`

The database of Fano 3-folds.

`Fano(D,i)`

The ith Fano 3-fold in the Fano database D.

`Fano(D,f,i)`

The ith Fano 3-fold in the Fano database D that has Fano index f.

`Fano(D,f,Q,i)`

The ith Fano 3-fold in the Fano database D that has Fano index f and initial plurigenera as specified by the sequence Q (up to the first four plurigenera).

117.9 Calabi–Yau 3-folds

This section describes intrinsics that construct Calabi–Yau 3-folds. It also describes a few intrinsics that can be used to study them, but see Section 117.4 for the general intrinsics that apply to all polarised varieties.

The calculations are based on Buckley's Riemann–Roch formula [Buc03] for polarised Calabi–Yau 3-folds with canonical singularities.

`CalabiYau(p1,p2,B)`

The Calabi–Yau 3-fold X, A with $h^0(X, A) = p_1$, $h^0(X, 2A) = p_2$ and basket of singularities B.

`FindN(X)`

`MaximumN` RngIntElt *Default :* 100

The first nonnegative value, for the Calabi–Yau 3-fold X, of N_{C_i} (where C_i is the ith curve of the basket of X) together with the distance between successive values of N_{C_i}. (The pair $0, 0$ is returned if no solutions below the parameter `MaximumN` are found).

`FindN(p1,p2,B)`

`MaximumN` RngIntElt *Default :* 100

The first nonnegative value of N_{C_i} (where C_i is the ith curve of the basket B of 3-fold points and curves and p_1, p_2 are the first two genera) together with the distance between successive values of N_{C_i}. (The pair $0, 0$ is returned if no solutions below the parameter `MaximumN` are found).

117.10 Building Databases

This section contains a sketch of how databases of examples can be built. This is an aside from the rest of the chapter, and is only of interest if one either wants to understand the construction of the K3 database for its own sake, or wishes to create other similar lists that take too long to be regenerated on demand. Note, however, that the database facility described here is not suitable for very large databases: roughly speaking, it is intended for those containing a few tens of thousands of elements, not millions, and certainly not in the Kreuzer–Skarke [KS00] range.

117.10.1 The K3 Database

This section describes briefly the method of construction used for the K3 database. The K3 database is fully installed in MAGMA—see Section 117.7 for instructions—and there is no need to use the functions described here to rebuild it unless you intend to modify the code to incorporate new information in the database.

The construction is in two steps. First we create all the K3 surfaces we require and write them as abbreviated records to a series of files. Then we load these files one at a time, writing their contents in further abbreviated form to a binary data file, `K3S.dat`. The writing functions keep track of key indexing information and write this to an index file, `K3S.ind`. Functions to read from these files are already installed, so the process is completed by copying these two files to the standard data directory in the MAGMA libraries.

We now go through the process in detail.

117.10.1.1 Creating Many K3 Surfaces

`CreateK3Data(g)`

`CreateK3Data(g,r)`

`CreateK3Data(g,B)`

Create a sequence containing all K3 surfaces of genus $g \geq -1$; restrict to those with singular rank at most r, if given as an argument, or having baskets in the sequence B of baskets, if given as an argument.

The return sequence is ordered according to the natural numerical order on the coefficients of Hilbert series. Analysis of projections of Types I and II is made to modify weights of K3 surfaces, and any inconsistencies between different predictions of weights coming from different projections are reported.

117.10.1.2 K3 Surfaces as Records

`K3SurfaceToRecord(X)`

A record in K3 record format that contains a subset of the data associated to the K3 surface X from which all attributes of X can be computed.

`K3Surface(x)`

The K3 surface with the same data as that of the record x in K3 record format.

117.10.1.3 Writing K3 Surfaces to a File

`WriteK3Data(Q,F)`

Write the K3 surfaces in the sequence Q to the file with name given by the string F. The resulting file F is a text file containing MAGMA code which, when loaded into a MAGMA session, generates a sequence called `data` of records in K3 record format that corresponds to Q.

117.10.1.4 Writing the Data and Index Files

With the data for the K3 database saved as a series of files "k3data-1", "k3data0" and so on, the command `load "writek3db.m";` (or `load "PATH/writek3db.m";`) loads them in turn, writes the two binary files and then deletes the data from the MAGMA session. MAGMA must be running in the directory containing all the data files "k3data...".

117.10.1.5 Reading the Raw Data

In normal MAGMA use, even though the data in the K3 database is in coded form (as a tuple, in fact), when returned to the user it is expressed as a K3 surface. Of course, this final translation step takes a little time, insignificant in most use, but very significant when searching through the whole database. So there are functions to access the raw data, and then to translate it into a K3 surface. The search intrinsics installed in the MAGMA packages use these functions, as should any new searches that need only modest increase in speed.

`K3SurfaceRaw(D,i)`

`K3SurfaceRaw(D,Q,i)`

The i-th element of the K3 database D expressed as a tuple of data (or the i-th element whose Hilbert series has coefficients of t^i given by the integers in the sequence Q, which may have length at most 5).

`K3Surface(x)`

The K3 surface with the same data as that of the tuple x that is in the raw K3 database format.

117.10.2 Making New Databases

Here we explain in general terms how to write new databases of polarised varieties. We give complete instructions for writing the data and index files, but are more sketchy on the other steps: you will have to assemble the data, write translation functions and write any cosmetic wrapping functions for yourself.

Step 1: Prepare the directory. Make a new directory, 'NewDB' say, and copy the files `data_spec.m`, `write.m`, `init_info.m`, `write_tools.m`, `write_func.m`, `create_ind_func.m` into NewDB from the MAGMA package directories. Of these files, the first two will have to be edited to conform to the required database, while the remaining four are common to all databases.

Step 2: Decide record format. Edit the file `data_spec.m`. This determines which data is stored, and places unbreakable restrictions on that data. In particular, the choice of up to 5 indexing parameters is made here. Write intrinsics that translate between the data in its original representation and in its record representation.

Step 3: Update the writing functions. Edit the file `write.m`.

Step 4: Collect the data. Write all required data as records in one or more files. It is essential that the data is written to these files so that it can be read into a single MAGMA session in increasing order (with respect to the chosen indexes).

Step 5: Build the binary data and index files.

Step 6: Move the binaries to the data libraries.

Step 7: Final cosmetics. Write as MAGMA package code any cosmetic wrappers or search routines that are to be used with the new database. Document these intrinsics.

118 TORIC VARIETIES

Chapter 118
TORIC VARIETIES

118.1 Introduction and First Examples

We describe a package to work quite generally with toric geometry within the scope of MAGMA's scheme machinery. From that point of view, we regard toric varieties as a vast array of possible ambient spaces for schemes, generalising the affine and projective spaces already available. But of course toric geometry is a large topic in its own right, and in the first place we present it for its own sake.

There are many different points of view on toric geometry. We model our approach on several sources: the primary ones are Danilov [Dan78] and Cox [Cox95], but also Fulton [Ful93] and Oda [Oda88].

One of the primary points of view, exemplified by Danilov [Dan78], is to regard the two-way relationship between a part of scheme theory and the combinatorics of polyhedra as foundational. This package can operate from that point of view.

Another, more recent, point of view is that of the Cox ring, introduced by Cox [Cox95], a (multi-)graded polynomial ring that works as a homogeneous coordinate ring for a toric variety (or indeed any variety with finitely-generated Picard group) in much the same way as the coordinate ring of affine or projective space. This package can also operate from this point of view, and indeed this is the central object in its design. Again, this is bound to impose practical restrictions on the dimensions in which calculations can reasonably be expected to work: we use these 'Cox coordinates' to define subschemes of toric varieties, which often leads to Gröbner basis calculations, and these are famously intolerant of the number of variables involved.

118.1.1 The Projective Plane as a Toric Variety

The projective plane is the toric variety corresponding to the fan with three maximal cones lying in the Euclidean plane:

$$\langle (0,1),(1,0)\rangle\,, \quad \langle (1,0),(-1,-1)\rangle\,, \quad \langle (-1,-1),(0,1)\rangle\,.$$

Example H118E1

We build the projective plane (defined over the rational field) as a toric variety. There are various simple constructors for this, but we do it slowly by constructing its fan first: we list the one-dimensional rays of the fan, and then describe each maximal cone by listing the sequence of indices of the rays that generate it.

```
> rays := [ [0,1], [1,0], [-1,-1] ];
> cones := [ [1,2], [1,3], [2,3] ];
> F := Fan(rays,cones);
> F;
```

```
Fan F with 3 rays:
    ( 0,  1),
    ( 1,  0),
    (-1, -1)
and 3 cones with indices:
    [ 1, 2 ],
    [ 1, 3 ],
    [ 2, 3 ]
```

This is enough to determine a toric variety; we name its natural (Cox) coordinates as x, y, z during the definition. (Since this is a scheme, it needs to have a base ring assigned.)

```
> X<x,y,z> := ToricVariety(Rationals(),F);
> X;
Toric variety of dimension 2
Variables: x, y, z
The irrelevant ideal is:
    (z, y, x)
The grading is:
    1, 1, 1
```

As with all schemes in MAGMA, points can be created by coercing sequences of coefficients (either from the given base field or from an extension of that) into the scheme.

```
> X ! [1,2,3];
(1 : 2 : 3)
```

When working over an extension k of the base field, one must coerce into the point set (of k-valued points of X).

```
> k<i> := QuadraticField(-1);
> X(k);
Set of points of X with coordinates in k
> X(k) ! [1,i,2*i];
(1 : i : 2*i)
```

The irrelevant ideal (described in the display of X above) describes the locus of coordinates that do not represent points; in this case, the irrelevant ideal records the fact that $(0 : 0 : 0)$ is not a point of projective space.

```
>  X ! [0,0,0];

>> X ! [0,0,0];
     ^
Runtime error in '!': Illegal coercion
> Y<u,v,w> := ProjectiveSpace(Rationals(),2);
> Y;
Projective Space of dimension 2
Variables: u, v, w
> IrrelevantIdeal(Y);
Ideal of Polynomial ring of rank 3 over Rational Field
```

```
Order: Graded Reverse Lexicographical
Variables: u, v, w
Homogeneous
Basis:
[
    u,
    v,
    w
]
> Gradings(Y);
[
    [ 1, 1, 1 ]
]
> Fan(Y);
Fan with 3 rays:
    ( 1,  0),
    ( 0,  1),
    (-1, -1)
and 3 cones with indices:
    [ 1, 2 ],
    [ 1, 3 ],
    [ 2, 3 ]
```

118.1.2 Resolution of a Nonprojective Toric Variety

Danilov translated the projectivity of a toric variety into properties of the fan. In geometry, projectivity is equivalent to the existence of an ample line bundle. In the combinatorics of the fan, the requirement is the existence of positive linear functions on each cone that agree on the boundaries and are strictly convex across boundaries. This is one small part of the theory of divisors on toric varieties that we cover in much greater detail in Section 118.6.

Example H118E2

We construct an example of a complete but non-projective toric variety following Danilov's original example of how a fan can fail to admit a strictly convex piece-wise linear support function. We will build the fan by hand, first specifying exactly the (one-dimensional) rays that it contains.

```
> rays := [ [0,0,1], [4,0,1], [0,4,1], [1,1,1], [2,1,1], [1,2,1], [-1,-1,-1] ];
```

Now we specify the top-dimensional cones that the fan contains. This is done by naming the rays that generate each cone from the list of rays above. So, for example, the sequence `[1,3,6]` below refers to the cone generated by the 1st, 3rd and 6th rays, that is by $[0, 0, 1]$, $[0, 4, 1]$ and $[1, 2, 1]$.

```
> cones := [ [1,3,6], [1,4,6], [1,2,4], [2,4,5], [2,3,5], [3,5,6], [4,5,6],
```

```
>             [1,3,7], [1,2,7], [2,3,7] ];
```

This is enough information to determine a fan. The command below to construct the fan F with this data takes a little time, since it checks that the maximal cones we nominated are indeed maximal and intersect correctly to lie in a fan.

```
> F := Fan(rays,cones);
```

Finally we move away from the lattice world to the geometry by creating the toric variety corresponding to the fan F.

```
> X := ToricVariety(Rationals(),F);
```

We can now ask questions of X as we would with any other variety or ambient space.

```
> Dimension(X);
3
> IsComplete(X);
true
> IsProjective(X);
false
```

Unfortunately our specimen is flawed: it has singularities.

```
> IsNonsingular(X);
false
> Y := Resolution(X);
> IsProjective(Y);
false
```

The last line takes a little time: MAGMA computes the ample cone of Y and then determines whether or not it is empty. In this case, Y remains non-projective, although there is no reason to expect that: Danilov's original example can be made projective by blowing up a line (or simply flopping a line).

118.1.3 The Cox Ring of a Toric Variety

The Cox ring of a toric variety is its natural homogeneous coordinate ring. It is a multigraded ring (with other data besides). It is often easier to construct the gradings for a Cox ring than it is to describe a fan.

A Cox ring requires four pieces of data:

- a polynomial ring R (a ring of coordinates for an affine space)
- a sequence B of 'irrelevant' ideals (the loci defined by these are discarded from the affine space)
- a sequence Z of sequences of integral weights for R; each element has length the number of indeterminates of R
- a sequence Q of sequences of quotient gradings for R.

Example H118E3

Cox's original construction determines a Cox ring from the fan of a toric variety, and then realises the toric variety as the quotient of the affine space (with the irrelevant locus discarded) by the action of a torus (determined by the sequences of weights). But it is also possible simply to specify this data independently of a fan.

```
> R<u,v,x,y,z> := PolynomialRing(Rationals(),5);
> irrel1 := ideal< R | u,v >;
> irrel2 := ideal< R | x,y,z >;
> B := [ irrel1, irrel2 ];
> Zwts := [
>             [ 1, 1, 0, -1, -3 ],
>             [ 0, 0, 1,  2,  3 ] ];
> Qwts := [];
> C := CoxRing(R,B,Zwts,Qwts);
> C;
Cox ring C with underlying Polynomial ring of rank 5 over Rational Field
Order: Lexicographical
Variables: u, v, x, y, z
The components of the irrelevant ideal are:
    (z, y, x), (v, u)
The 2 gradings are:
    1,  1,  0, -1, -3,
    0,  0,  1,  2,  3
```

The pieces of data can be retrieved by `Gradings(C)`, `QuotientGradings(C)` and so on.
In favourable cases, a Cox ring does indeed arise from a fan using Cox's construction. This fan can be recovered.

```
> F := Fan(C);
> F;
Fan F with 5 rays:
    ( 1,  0,  0),
    ( 0,  1,  0),
    ( 1,  1,  3),
    (-2, -2, -3),
    ( 1,  1,  1)
and 6 cones with indices:
    [ 1, 3, 4 ],
    [ 1, 3, 5 ],
    [ 1, 4, 5 ],
    [ 2, 3, 4 ],
    [ 2, 3, 5 ],
    [ 2, 4, 5 ]
```

Alternatively, one can construct a toric variety from a Cox ring—as in Cox's construction, the Cox ring contains exactly the data required to construct a variety as a torus quotient.

```
> X := ToricVariety(C);
> Dimension(X);
```

```
3
```

Sequences of coefficients not lying in the locus of the irrelevant ideal can be interpreted as closed points of X as usual.

```
> X ! [1,0,1,0,0];
(1 : 0 : 1 : 0 : 0)
>  X ! [1,0,0,0,0];

>> X ! [1,0,0,0,0];
     ^
Runtime error in '!': Illegal coercion
```

The attempted coercion of the second point fails because its x, y and z coordinates (the 3rd, 4th and 5th coefficients of the vector) are all zero, but the locus $x = y = z = 0$ is defined by a component of the irrelevant ideal and so has been discarded: points of X do not have all three of those coordinates simultaneously equal to zero.
The homogeneous coordinates that the Cox ring provides for X behave in a very similar way to the homogeneous coordinates on projective space. In particular, one can define subschemes of X by the vanishing of polynomials in the Cox ring that are homogeneous with respect to all the $\mathbf{Z}$-gradings (and the quotient gradings too).

```
> f := x^4*y + u^2*y^3 + v^5*z^2;
> Multidegree(X,f);
[ -1, 6 ]
[]
```

The multidegree is returned as two sequences: the first is the sequence of degrees of f with respect to each of the $\mathbf{Z}$-gradings in turn, and the second is that with respect to the quotient gradings (in this case there are none). One defines a scheme as usual in Magma.

```
> V := Scheme(X, f);
> V;
Scheme over Rational Field defined by
u^2*y^3 + v^5*z^2 + x^4*y
> Dimension(V);
2
```

Much of Magma's scheme machinery works for schemes inside toric varieties, although at this stage some does not. (Some functions are missing because of the absence of standard nonsingular affine patches on toric varieties. In some cases these will be replaced by their orbifold analogues in due course.)

118.2 Fans in Toric Lattices

A *fan* F (in a toric lattice L) is a collection of cones in L satisfying typical conditions of cell decompositions (the inclusion of faces of cones is part of the data, and the requirement that any two cones of the fan intersect in a common face is enforced, for instance). The *support* of F is the union of all the cones as a subset of L. The main two cases are when either the support of F is the support of a single cone (which is regarded as being subdivided by the cones of the fan) or it is the whole of L. Other cases do occur and are allowed by our package—even having cones of different dimensions lying in complementary linear subspaces of L, although that is not commonly interpreted geometrically.

There are several constructors for well-known fans, and also standard methods for modifying fans. If these are not enough, then one can simply list the top-dimensional cones of a fan; MAGMA will check that they intersect correctly and will add the lower-dimensional cones as necessary.

Fans are of type `TorFan`.

118.2.1 Construction of Fans

We first list the comprehensive constructors for fans. After that, we have a collection of constructors for well-known fans, and there also are methods for modifying fans.

`Fan(Q)`

`define_fan`	BOOLELT	*Default :* `false`
`max_cones`	BOOLELT	*Default :* `false`

The fan generated by the cones in the sequence Q.

The optional parameter `define_fan` (by default `false`) can be set to `true`, so that the verification whether the input data is correct is skipped. The optional parameter `max_cones` (by default `false`) can be set to `true` to skip the verification whether the cones are maximal. Both will lead to errors later if the cones do not in fact determine a fan as claimed.

`Fan(R,S)`

`define_fan`	BOOLELT	*Default :* `false`

The fan whose rays are the sequence of toric lattice points R (or sequences of sequences of integer coefficients of such points) and whose maximal cones correspond to the sequence S of sequences of integers: each such sequence is interpreted as the indices of a collection of rays of R, and these rays are used to generate a cone.

This constructor checks that the given data does indeed define a fan. This check can be lengthy. It can be omitted by setting the parameter `define_fan` to be `false`, although this should be used with extreme care: there is no telling what might go wrong if incorrect data is assumed to be a fan.

`Fan(C)`

The fan comprising all faces of the cone C.

`FanOfAffineSpace(n)`

The standard fan of affine space of dimension n, where n is a positive integer.

`FanOfWPS(W)`

A standard fan for the weighted projective space with weights W, a sequence of positive integers.

`#FanOfProjectiveSpace(n)`

The standard fan of projective space of dimension n, a positive integer.

`FanOfFakeProjectiveSpace(W,Q)`

A standard fan for the fake weighted projective space with weights W, a sequence of positive integers, and finite cyclic group actions given Q, a sequence of sequences of rational numbers. The finite cyclic actions are determined as follows: for $\mathbf{Z}/r$ to act diagonally with weights $(a_1, \ldots, a_n)$, include the sequence `[a1/r,...,an/r]` as an element of Q.

`ZeroFan(L)`

The fan in the toric lattice L supported at the origin.

`NormalFan(F,C)`

The normal fan to a cone C in a fan F in the toric lattice that is the quotient of the ambient lattice of F by the span of C; the quotient map of lattices is the second return value.

`SpanningFan(P)`

The toric fan that spans the polyhedron P; in particular, the rays of the fan are generated by the vertices of P.

`DualFan(P)`

The toric fan dual to the polyhedron P.

Example H118E4

The spanning fan of a polytope P is a fan in the same lattice as P with rays passing through its vertices. Here we make the fan of the Hirzebruch surface $\mathbf{F}_1$ as a spanning fan.

```
> P := Polytope([ [0,1], [1,0], [1,-1], [-1,0] ]);
> SpanningFan(P);
Fan with 4 rays:
    ( 0,  1),
    ( 1,  0),
    ( 1, -1),
    (-1,  0)
and 4 cones with indices:
    [ 1, 4 ],
```

```
    [ 1, 2 ],
    [ 2, 3 ],
    [ 3, 4 ]
```

The dual fan of a polytope P is a fan in the dual lattice to that of P whose rays are constant when evaluated on some facet of P. Here we make the fan of projective 3-space as a dual fan.

```
> Q := StandardSimplex(3);
> DualFan(Q);
Fan with 4 rays:
    (-1, -1, -1),
    ( 1,  0,  0),
    ( 0,  1,  0),
    ( 0,  0,  1)
and 4 cones with indices:
    [ 2, 3, 4 ],
    [ 1, 3, 4 ],
    [ 1, 2, 4 ],
    [ 1, 2, 3 ]
Mapping from: 3-dimensional toric lattice (Z^3)^* to 3-dimensional toric lattice
(Z^3)^* given by a rule
```

`Blowup(F,v)`

The blowup of the toric fan F at the point v that is an element of the ambient toric lattice of F.

`IsInSupport(v,F)`

Return `true` if and only if the support of the fan F contains the element v of its ambient toric lattice. In this case, the index of the first cone of F that contains v is also returned.

`Fan(F1,F2)`

`F1 * F2`

`Fan(Q)`

`F ^ n`

The nth Cartesian product of the fan F.

`F eq G`

Return `true` if and only if the two fans F and G are equal as objects in MAGMA (not simply isomorphic as fans).

118.2.2 Components of Fans

One can retrieve all the usual components of fans: their cones, rays and other dimensional skeletons, and so on.

Note the novelty of 'virtual' rays. Virtual rays occur when the rays of the fan in question do not span the ambient lattice, and so one may easily never encounter them. They occur if and only if the underlying toric variety is a product of $\mathbf{C}^*$ times X for a smaller toric variety X. If this the case, the fan is contained in a hyperplane (or smaller linear space, if there are more factors of $\mathbf{C}^*$). Virtual rays will be in the direction transversal to this hyperplane. Thus a virtual ray is not an honest ray, but a formal object introduced to allow $\mathbf{C}^*$ as a toric variety and give meaning to its coordinate. If virtual rays are not specified on creation, then MAGMA will decide where to put them (later, when it needs them).

`Skeleton(F,n)`

The fan generated by cones of the fan F of dimension at most the integer n.

`C in F`

Return `true` if and only if the cone C is one of the cones of the fan F.

`Cones(F)`

A sequence of the maximal cones of the fan F.

`Cones(F,i)`

The sequence of all i-dimensional cones in the fan F.

`ConesOfCodimension(F,i)`

The sequence of all codimension i cones in the fan F.

`AllCones(F)`

A sequence of all the cones of the fan F.

`Cone(F,i)`

The ith cone of the sequence of maximal cones of the fan F.

`Cone(F,S)`

The cone of the fan F spanned by the rays of indices given by the sequence S of integers. (If the optional parameter `extend` is set to `true`, then the smallest cone containing the given rays will be returned.)

`SingularCones(F)`

A sequence containing the minimal singular cones of the fan F. A second (parallel) sequence contains sets of the indices of the rays that generate these cones.

Example H118E5

The weighted projective space $\mathbf{P}(1,2,2,3)$ has a singular line (with stabiliser $\mathbf{Z}/2$) and a singular point (with stabiliser $\mathbf{Z}/3$).

```
> F := FanOfWPS([1,2,2,3]);
> SingularCones(F);
[
    2-dimensional simplicial cone with 2 minimal generators:
        (-1, -1,  0),
        (-1,  1,  0),
    3-dimensional simplicial cone with 3 minimal generators:
        (-1, -1,  0),
        ( 1, -1, -1),
        ( 1,  0,  1)
]
[
    { 1, 4 },
    { 1, 2, 3 }
]
```

The two cones correspond to these two singular strata; the point strata lying on the line are not returned, since they can be recovered, if needed, as the cones having this 2-dimensional cone in their boundary.

`ConesOfMaximalDimension(F)`

A sequence of maximal cones of the fan F when ordered by inclusion. (This is the same as `Cones(F)` if the support of F is equidimensional.)

`ConeIndices(F)`

The sequence S of sets of integers, such that ith cone of the fan F is generated by rays with indices $S[i]$.

`ConeIndices(F,C)`

The sequence of integers that are the indices of the rays which generate the cone C of the fan F.

`ConeIntersection(F,C1,C2)`

The intersection of the two cones C_1 and C_2, both of which are members of the fan F. (This is usually more efficient than `C1 meet C2` given that the fan F exists.)

`Face(F,C)`

The smallest cone in the fan F which contains the cone C. (An error is returned if there is no such cone in the fan.)

`DualFaceInDualFan(P,Q)`

The cone in the toric fan dual to the polyhedron P which is dual to the face of P determined by the sequence of integers Q.

`Rays(F)`

A sequence containing the rays of the fan F (as a sequence of primitive lattice points on each ray).

`Ray(F,i)`

The ith ray of the fan F (regarded as the primitive ambient toric lattice point on the ray).

`AllRays(F)`

A sequence of the rays of the fan F (including all virtual rays).

`PureRays(F)`

A sequence of the (non-virtual) rays of the fan F.

`PureRayIndices(F)`

A sequence of the indices of the non-virtual rays of the fan F among all its rays.

`VirtualRays(F)`

A sequence of the virtual rays of the fan F.

`VirtualRayIndices(F)`

A sequence of the indices of the virtual rays of the fan F among all its rays.

118.2.3 Properties of Fans

`Ambient(F)`

The ambient toric lattice of the toric fan F.

`IsComplete(F)`

Return `true` if and only if the toric fan F has its entire ambient toric lattice; that is, the cones of F cover the whole ambient space.

`IsSingular(F)`

Return `false` if and only if all the cones of the fan F are nonsingular.

`IsNonsingular(F)`

Return `true` if and only if all the cones of the fan F are nonsingular.

`IsQFactorial(F)`

Return `true` if and only if all the cones of the fan F are **Q**-factorial.

`IsTerminal(F)`

Return `true` if and only if all the cones of the fan F are terminal.

`IsCanonical(F)`

Return `true` if and only if all the cones of the fan F are canonical.

`IsGorenstein(F)`

Return `true` if and only if all the cones of the fan F are Gorenstein.

`IsQGorenstein(F)`

Return `true` if and only if all the cones of the fan F are **Q**-Gorenstein.

118.2.4 Maps of Fans

`F @ f`

The image of the fan F by the map f of toric lattices.

`SimplicialSubdivision(F)`
`SimplicialSubdivision(C)`

A toric fan that is a simplicial subdivision of the toric fan F (or of the toric cone C).

Example H118E6

If C is a cone on a square, then it has two small simplicial subdivisions—the two sides of a standard flop, in fact. The simplicial subdivision intrinsic selects one of these.

```
> L := ToricLattice(3);
> C := Cone([L| [1,0,0], [0,1,0], [0,0,1],[1,-1,1]]);
> SiC := SimplicialSubdivision(C);
> #Cones(SiC);
2
> [ ZGenerators(B) : B in Cones(SiC) ];
[
    [
        (0, 1, 0),
        (1, -1, 1),
        (1, 0, 0)
    ],
    [
        (0, 1, 0),
        (1, -1, 1),
        (0, 0, 1)
```

```
    ]
]
```

`IsFanMap(F1,F2)`

Return `true` if and only if the two fans F_1 and F_2 lie in the same toric lattice, and each cone of F_1 is a subcone of some cone of F_2.

`IsFanMap(F1,F2,f)`

Return `true` if and only if the toric lattice map f between the ambient toric lattices of the two fans F_1 and F_2 maps every cone of F_1 into a cone of F_2.

`ResolveFanMap(F1,F2)`

A toric fan F that resolves the identity map of lattices restricted to the toric fans F_1 and F_2. The two fans F_i are expected to lie in the same lattice and to have the same support, and the resulting toric fan F gives a common refinement of them; in particular, F will admit a fan map into each of the F_i. (If the F_i have different supports, the fan F will be supported on their intersection and will only refine this part of each of them. Geometrically speaking, this will produce a non-proper resolution.)

118.3 Geometrical Properties of Cones and Polyhedra

`IsSingular(C)`

Return `true` if and only if the affine variety associated with the cone C is singular.

`IsNonsingular(C)`

Return `true` if and only if the affine variety associated with the cone C is nonsingular.

`IsSmooth(P)`

Return `true` if and only if the polyhedron P is a smooth polytope.

`IsGorenstein(C)`

Return `true` if and only if the cone C has (the primitive points on its) rays contained in an affine hyperplane that is defined by an integral equation.

`IsReflexive(P)`

Return `true` if and only if the polyhedron P is reflexive; i.e. P and its dual $P^\vee$ are both integral polytopes.

`IsQGorenstein(C)`

Return `true` if and only if the cone C has (the primitive points on its) rays contained in an affine hyperplane.

`GorensteinIndex(C)`

The Gorenstein index of the affine variety corresponding to the cone C together with the dual vector determining the equation of the hyperplane. (It is an error if C is not $\mathbf{Q}$-Gorenstein.)

`GorensteinIndex(P)`

The Gorenstein index of the lattice polytope P; i.e. the smallest positive integer k such that $kP^\vee$ is an integral polytope.

`IsQFactorial(C)`
`IsSimplicial(P)`

Return `true` if and only if the cone C or polytope P is simplicial.

`IsTerminal(C)`

Return `true` if and only if the singularity of the affine variety associated to the cone C is (at worst) terminal.

`IsCanonical(C)`

Return `true` if and only if the singularity of the affine variety associated to the cone C is (at worst) canonical.

`IsFano(P)`

Return `true` if and only if the polyhedron P is a Fano polytope (i.e. of maximum dimension in the ambient lattice, containing the origin strictly in its interior, with primitive lattice vertices).

Example H118E7

We make the cone corresponding to the (affine) terminal quotient singularity $\mathbf{C}^3/(\mathbf{Z}/5)$ where $\mathbf{Z}/5$ acts as the 5th roots of unity in the diagonal representation $\mathrm{diag}(1,2,3)$.

```
> L := ToricLattice(3);
> v := L ! [1/5,2/5,3/5];
> LL,emb := AddVectorToLattice(v);
> C := PositiveQuadrant(L);
> CC := Image(emb,C);
> CC;
Cone CC with 3 generators:
    (1, 0, 0),
    (0, 1, 0),
```

```
    (3, 1, 5)
```

We can check that this really is terminal and compute its Gorenstein index, the least positive multiple of the canonical class that is Cartier.

```
> IsTerminal(CC);
true
> GorensteinIndex(CC);
5 (1, 1, -3/5)
```

We can compute a resolution of singularities of this cone, the analogue of a simplicial subdivision for cones, although we must treat it as a fan to do so.

```
> F := Fan(CC);
> F;
Fan F with 3 rays:
    (0, 1, 0),
    (1, 0, 0),
    (3, 1, 5)
and one cone with indices:
    [ 1, 2, 3 ]
> Resolution(F);
Fan with 8 rays:
    (0, 1, 0),
    (1, 0, 0),
    (3, 1, 5),
    (2, 1, 2),
    (1, 1, 1),
    (3, 1, 3),
    (3, 1, 4),
    (2, 1, 3)
and 11 cones
```

Note that this is not a minimal resolution: such a resolution would only need to subdivide at the four additional rays at the (original) lattice points $1/5(1,2,3)$, $1/5(2,4,1)$, $1/5(3,1,4)$ and $1/5(4,3,2)$.

118.4 Toric Varieties

118.4.1 Constructors for Toric Varieties

We list some simple constructors for simple toric varieties. There are more general constructors for toric varieties (either from their fans or their Cox rings) in other sections.

`ToricVariety(k,n)`

Projective n-space $\mathbf{P}^n$ defined over the field k as a toric variety.

`ToricVariety(k,Z)`

The (weighted) projective space $\mathbf{P}(Z)$ defined over the field k with weights the positive integer sequence Z as a toric variety.

`ToricVariety(k,Z,Q)`

The fake weighted projective space defined over the field k with weights the positive integer sequence Z and a single sequence of quotient weights the sequence Q of rational numbers.

`ToricVariety(k,M,v)`

The n-dimensional toric variety $n \geq 2$ defined over the field k with weights begin the two sequences of integers (of the same length $n+2$) that comprise M and linearisation the length 2 integer sequence v. (This toric variety is the GIT quotient of k^{n+2} by a 2-dimensional torus acting with weights M and linearisation v. To get a toric variety of the right dimension, v must lie in the mobile cone implicit in the notation. In practice, this means that the columns of M must generate a cone with vertex in a 2-dimensional toric lattice and v must lie in the 'very-interior' of that cone, in the sense that it must lie in the strict interior of C and in the subcone generated by all columns of M except the two most extreme.)

Example H118E8

We build a Hirzebruch surface as a GIT quotient.

```
> X<u,v,x,y> := ToricVariety(Rationals(),[[1,1,0,-1],[0,0,1,1]],[1,1]);
> X;
Toric variety of dimension 2
Variables: u, v, x, y
The components of the irrelevant ideal are:
    (y, x), (v, u)
The 2 gradings are:
    1,  1,  0, -1,
    0,  0,  1,  1
```

The polarisation $(1,1)$ that we used is forgotten—all that is left is X.

`ToricVariety(k)`

The zero-dimensional point over the field k defined as a toric variety.

`ProjectiveSpace(k,n)`

Projective n-space $\mathbf{P}^n$ defined over the field k.

`ProjectiveSpace(k,W)`

`FakeProjectiveSpace(k,W,Q)`

The (fake) weighted projective space over the field k with weights the sequence of integers W (and quotient weights the sequence of sequences of rational numbers, if provided).

118.4.2 Toric Varieties and Their Fans

`ToricVariety(k,F)`

The toric variety (defined over the field k) corresponding to the toric fan F.

`Fan(X)`

The toric fan corresponding to the toric variety X.

`Rays(X)`

The rays of the fan of the toric variety X.

`OneParameterSubgroupsLattice(X)`

The lattice of weights of the toric variety X; this is the lattice which supports the toric fan of X.

`MonomialLattice(X)`

The monomial lattice of the toric variety X, namely the toric lattice dual to that containing the fan of X.

`CoxMonomialLattice(X)`

The lattice whose elements represent Weil divisors on the toric variety X; it is dual to ray lattice of X.

`DivisorClassLattice(X)`

The divisor class lattice of the toric variety X.

`IrrelevantIdeal(X)`

A sequence of ideals that are the components of the irrelevant ideal of the toric variety X.

`QuotientGradings(X)`

A sequence of sequences of rational numbers describing the quotients by finite cyclic groups that arise in the construction of the toric variety X.

`NumberOfQuotientGradings(X)`

The number of sequences the generate the quotient gradings of the toric variety X.

118.4.3 Properties of Toric Varieties

`IsSingular(X)`

Return `false` if and only if the toric variety X is nonsingular.

`IsNonsingular(X)`

Return `true` if and only if the toric variety X is nonsingular.

`IsGorenstein(X)`

Return `true` if and only if the toric variety X is Gorenstein.

`IsQGorenstein(X)`

Return `true` if and only if the toric variety X is $\mathbf{Q}$-Gorenstein.

`IsQFactorial(X)`

Return `true` if and only if the toric variety X is $\mathbf{Q}$-factorial.

`IsTerminal(X)`

Return `true` if and only if the toric variety X has (at worst) terminal singularities.

`IsCanonical(X)`

Return `true` if and only if the toric variety X has (at worst) canonical singularities.

`IsComplete(X)`

Return `true` if and only if the toric variety X is complete.

`IsProjective(X)`

Return `true` if and only if the toric variety X is projective.

`IsFano(X)`

Return `true` if and only if the anticanonical divisor of the toric variety X is ample.

`IsFakeWeightedProjectiveSpace(X)`

Return `true` if and only if the toric variety X has exactly one $\mathbf{Z}$-grading.

`IsWeightedProjectiveSpace(X)`

Return `true` if and only if the toric variety X has exactly one $\mathbf{Z}$-grading and no quotient gradings.

118.4.4 Affine Patches on Toric Varieties

`ToricAffinePatch(X,i)`

The affine patch corresponding to i-th cone of fan of the toric variety X together with the inclusion map.

`ToricAffinePatch(X,S)`

`ToricAffinePatch(X,S)`

The toric variety, obtained from the toric variety X by set the monomials of the sequence S set to be non-zero (or alternatively the variables of X with indices from the sequence of integers S set non-zero). The inclusion map is returned as a second value.

118.5 Cox Rings

The Cox ring of a toric variety X is a polynomial ring whose variables are in bijection with the 1-skeleton of the fan of X together with three sequences of additional data:

(1) a sequence of the components of an ideal called *the irrelevant ideal*;

(2) a sequence of integral lattice points determining weights of $\mathbf{G}_m$ actions, called the $\mathbf{Z}$ *weights*;

(3) a sequence of rational lattice points determining weights of finite cyclic group actions, called the *quotient weights*.

When the Cox ring of a toric variety is displayed in MAGMA, all nontrivial data is also printed, but any sequences that are empty are omitted.

Cox rings provide a powerful way to construct toric varieties: under some mild conditions, specification of data of this nature determines a toric variety.

118.5.1 The Cox Ring of a Toric Variety

Cox [Cox95] associates a ring, now called the *Cox ring*, to a toric variety, and MAGMA allows exactly the same construction.

`CoxRing(X)`

The Cox ring of the toric variety X.

`CoxRing(k,F)`

The Cox ring of the toric variety defined over field k by the fan F.

Example H118E9

We build the weighted projective space $\mathbf{P}^2(1,2,3)$.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),[1,2,3]);
```

The Cox ring of $\mathbf{P}^2(1,2,3)$ is the usual homogeneous coordinate ring, graded by the weights $1,2,3$ of the space—that is, x has weight 1, y has weight 2 and z has weight 3.

```
> CoxRing(P);
Cox ring with underlying Graded Polynomial ring of rank 3 over Rational Field
Order: Graded Reverse Lexicographical
Variables: x, y, z
Variable weights: [1, 2, 3]
The irrelevant ideal is:
    (x, y, z)
The grading is:
    1, 2, 3
```

The irrelevant ideal is the usual one for projective spaces: it decrees that $(0,0,0)$ is not a point of $\mathbf{P}^2$ since it lies in the locus defined by the irrelevant ideal.

Example H118E10

We build a toric variety X_2 whose fan resembles that of $\mathbf{P}^2$.

```
> F2 := Fan([[1,2],[-2,-1],[1,-1]], [[1,2],[1,3],[2,3]]);
> X2<u,v,w> := ToricVariety(Rationals(),F2);
```

However, X is not isomorphic to $\mathbf{P}^2$. The small catch is that the 1-skeleton of the fan F_2 that we defined (in other words, those three vectors $(1,2)$, $(-2,-1)$ and $(1,-1)$) does not generate the lattice N, but only a sublattice. So X will be the quotient of $\mathbf{P}^2$ by some finite group action.

```
> CoxRing(X2);
Cox ring with underlying Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: u, v, w
The irrelevant ideal is:
    (w, v, u)
The quotient grading is:
    1/3( 0, 2, 1 )
The integer grading is:
         1, 1, 1
```

The returned data are very similar to those for the Cox ring of $\mathbf{P}^2$. The difference is in the third piece of data: a sequence containing the single element $1/3(0,2,1)$. This indicates that X is the quotient of $\mathbf{P}^2$ by the action of $\mathbf{Z}/3$ given by

$$\varepsilon : (u,v,w) \mapsto (u, \varepsilon^2 v, \varepsilon w).$$

where ε is a cube-root of unity.

118.5.2 Cox Rings in Their Own Right

The introduction to this section describes Cox rings in abstract terms. It is possible to define them as polynomial rings plus additional data without naming a toric variety or a fan in the first place.

`CoxRing(R,B,Z,Q)`

The Cox ring with polynomial ring R of rank n (that is, having n variables) and additional data as follows: B is a sequence of ideals (or of sequences of elements of R, each of which will be interpreted as the generators of ideals); Z is a sequence of sequences of integers, each one of length n; Q is a sequence of sequences of rationals, each one of length n.

The sequence B is regarded as the components of the irrelevant ideal, and Z and Q are the $\mathbf{Z}$ weights and quotient weights respectively.

`C1 eq C2`

Return `true` if and only if the two Cox rings C_1 and C_2 have the same underlying polynomial rings and are defined by the same combinatorial data.

`BaseRing(C)`

`CoefficientRing(C)`

The coefficient field of the Cox ring C.

`UnderlyingRing(C)`

The underlying polynomial ring of the Cox ring C.

`Length(C)`

The rank of the underlying polynomial ring of the Cox ring C, that is, the number of polynomial variables of C.

`IrrelevantIdeal(C)`

The irrelevant ideal of the Cox ring C.

`IrrelevantComponents(C)`

A sequence containing the components of the irrelevant ideal of the Cox ring C.

`IrrelevantGenerators(C)`

A sequence of sequences, each containing the generators of the components of the irrelevant ideal of the Cox ring C.

`Gradings(C)`

The $\mathbf{Z}$ gradings of the Cox ring C, that is, a sequence of sequences of integers.

`NumberOfGradings(C)`

The number of **Z** gradings of the Cox ring C.

`QuotientGradings(C)`

The quotient gradings of the Cox ring C, that is, a sequence of sequences of rational numbers.

`NumberOfQuotientGradings(C)`

The number of quotient gradings of the Cox ring C.

`C . i`

The i-th indeterminate for the underlying polynomial ring of the Cox ring C.

`AssignNames(~C, S)`

Procedure to change the printed names of the indeterminates of the Cox ring C. The ith indeterminate will be given name the ith element of the sequence S of strings (which has length at most the number of indeterminates of C). This does not change the names of the indeterminates for calling—this must be done with an explicit assignment or with the angle bracket notation when defining the Cox ring in the first place.

`Name(C,i)`

The ith variable of the underlying polynomial ring of the Cox ring C.

118.5.3 Recovering a Toric Variety From a Cox Ring

It is simple either to recover a toric variety from a Cox ring (if one exists at all) or the fan and associated lattice machinery corresponding to the toric variety. The algorithm is straightforward: use the **Z** weights to determine the rays of a fan and then the irrelevant ideal to construct the rest of the cone structure of the fan. The quotient weights may then require the lattice to be extended to a larger lattice but containing the same fan. With this point of view, the Cox ring can be regarded as the primary collection of data of a toric variety.

`ToricVariety(C)`

The toric variety whose Cox ring is C. It is not checked whether the Cox data defines a toric variety; if you are unsure, you should ask for the fan.

Example H118E11

Sometimes, rather than defining a fan, it is easier to construct a Cox ring first and build a toric variety from that.

```
> R<x1,x2,x3,y1,y2,y3,y4> := PolynomialRing(Rationals(),7);
> I := [ ideal<R|x1,x2,x3>, ideal<R|y1,y2,y3,y4> ];
> Z := [ [1,1,1,0,-3,-5,-5], [0,0,0,1,1,1,1] ];
> Q := [];
> C := CoxRing(R,I,Z,Q);
> C;
Cox ring C with underlying Polynomial ring of rank 7 over Rational Field
Order: Lexicographical
Variables: x1, x2, x3, y1, y2, y3, y4
The components of the irrelevant ideal are:
    (y4, y3, y2, y1), (x3, x2, x1)
The 2 gradings are:
    1,  1,  1,  0, -3, -5, -5,
    0,  0,  0,  1,  1,  1,  1
> X := ToricVariety(C);
> X;
Toric variety of dimension 5
Variables: x1, x2, x3, y1, y2, y3, y4
The components of the irrelevant ideal are:
    (y4, y3, y2, y1), (x3, x2, x1)
The 2 gradings are:
    1,  1,  1,  0, -3, -5, -5,
    0,  0,  0,  1,  1,  1,  1
```

Now MAGMA can compute the fan of X if we really want it.

```
> Fan(X);
Fan with 7 rays:
    ( 1,  0,  0,  0,  0),
    ( 0,  1,  0,  0,  0),
    ( 0,  0,  1,  0,  0),
    ( 1,  1,  1,  2,  0),
    (-3, -3, -3, -5,  0),
    ( 0,  0,  0,  0,  1),
    ( 2,  2,  2,  3, -1)
and 12 cones
```

`Fan(C)`

The fan associated to the Cox ring is C; an error is reported if there is no such fan.

`CoxMonomialLattice(C)`

The Cox monomial lattice of the Cox ring C.

`DivisorClassLattice(C)`

The divisor class lattice of the Cox ring C.

`MonomialLattice(C)`

The monomial lattice of the Cox ring C.

`OneParameterSubgroupsLattice(C)`

The one-parameter subgroups lattice of the Cox ring C.

`RayLattice(C)`

The ray lattice of the Cox ring C.

`DivisorClassGroup(C)`

The divisor class group of the Cox ring C.

`RayLatticeMap(C)`

The map from the ray lattice of the Cox ring C to the ambient lattice of its fan.

`WeilToClassGroupsMap(C)`
`WeilToClassLatticesMap(C)`

Comparison maps between toric lattices related to the Cox ring C of a toric variety.

118.6 Invariant Divisors and Riemann-Roch Spaces

Divisors on toric varieties work in the same way as on any other varieties, except that within each linear equivalence class it is possible to choose torus invariant representatives. These invariant divisors are composed of toric strata, and so in raw combinatorial terms one can regard divisors as being integer (or rational) labels on the rays of the fan. This is a convenient way to construct divisors, but there are many other methods.

As for other schemes on which divisor calculations are defined in MAGMA, divisors on a toric variety have a single divisor group as their parent. Divisors can be constructed by coercing appropriate data into this group, but this is not the only method so it can be ignored for most purposes. (This group is, however, the connection between divisors and the toric variety, so it is always alive in the background.)

118.6.1 Divisor Group

`DivisorGroup(X)`

The divisor group of the toric variety X. This is simply a parent object for divisors on X, and it is not computed as an abstract group.

`ToricVariety(G)`

The toric variety of which G is the divisor group.

`G1 eq G2`

Return `true` if and only if the divisor groups G_1 and G_2 are those of the same toric variety.

`Divisor(G,S)`
`Divisor(G,S)`

The divisor on the toric variety X associated to the divisor group G with coefficients given by the sequence S of integers or rationals with respect to the rays of the fan of X.

`Divisor(G,i)`

The divisor on the toric variety X associated to the divisor group G given by the vanishing of the ith coordinate of X.

118.6.2 Constructing Invariant Divisors

`Divisor(X,S)`

The Weil divisor (respectively **Q**-Weil divisor) on the toric variety X whose multiplicity on the ith coordinate divisor is the ith element of the sequence S of integers (respectively, rational numbers).

`Divisor(X,i)`

The divisor on the toric variety X given by the vanishing of the ith coordinate of X.

`Divisor(X,f)`

The divisor on the toric variety X defined by the polynomial f of the Cox ring of X.

`Divisor(X,m)`

If m is in the monomial lattice of the toric variety X, this gives the principal divisor on X corresponding to the monomial m. If m is a form on the ray lattice of X, then this gives the Weil divisor corresponding to m.

`ZeroDivisor(X)`

The zero divisor on the toric variety X.

`Representative(X,m)`

`effective` BoolElt *Default :* `true`

A divisor D on the toric variety X whose class modulo linear equivalence equals m, an element of the divisor class group of X. Unless the parameter `effective` is set to `false`, D will be chosen to be effective if possible.

`Representative(X,m)`

`effective` BoolElt *Default :* `true`

A divisor D on the toric variety X whose class modulo linear equivalence equals m, an element of the Picard lattice or divisor class lattice of X. Unless the parameter `effective` is set to `false`, D will be chosen to be effective if possible.

`CanonicalDivisor(X)`

The canonical divisor of the toric variety X.

`CanonicalClass(X)`

`group` MonStgElt *Default :* "*Pic*"

The class of canonical divisor of the toric variety X. By default this is returned as an element of the Picard lattice of X (and X must be $\mathbf{Q}$-Gorenstein for this to make sense). However, the parameter `group` can be changed to `Cl` to return the divisor in the divisor class lattice or `ClZ` to return the divisor in the divisor class group.

`D1 + D2` `n * D` `- D` `D1 - D2` `D * v`

Standard arithmetic operations for divisors D, D_1, D_2 on a toric variety, where $n \in \mathbf{Q}$ and v is a point of the ambient toric lattice of the corresponding fan.

Example H118E12

We compute the Kawamata blowup of $1/7(1, 2, 5)$. First we construct the singular cone by hand:

```
> L := ToricLattice(3);
> C := PositiveQuadrant(L);
> v := L![1/7,2/7,5/7];
> LL,phi := AddVectorToLattice(v);
> CC := Cone(phi(Rays(C)));
> CC;
3-dimensional simplicial cone CC with 3 minimal generators:
    (1, 0, 0),
    (0, 1, 0),
    (4, 1, 7)
```

Now we compute the blowup.

```
> FF := Fan(CC);
```

```
> vv := phi(v);
> vv;
(3, 1, 5)
> GG := Blowup(Fan(CC),vv);
```

The blowup map is easy to recover:

```
> X := ToricVariety(Rationals(),FF);
> Y<x,y,z,t> := ToricVariety(Rationals(),GG);
> f := ToricVarietyMap(Y,X);
> f;
A map between toric varieties described by:
    (t)^(2/7)*(x),
    (t)^(1/7)*(y),
    (t)^(5/7)*(z)
```

Finally we shall compute the discrepancy of this Kawamata blowup. It should be 1/7.

```
> KX := CanonicalDivisor(X);
> KY := CanonicalDivisor(Y);
> KY - Pullback(f,KX);
Q-Weil divisor with coefficients:
    0, 0, 0, 1/7
```

118.6.3 Properties of Divisors

`Variety(D)`

The toric variety on which the divisor D is defined.

`Parent(D)`

The divisor group of a toric variety in which the divisor D lies.

`Weil(D)`

The multiplicities on rays of the fan of X that determine the invariant divisor D, where X is the toric variety on which D is defined.

`Cartier(D)`

The sequence of toric lattice elements (of the monomial lattice of X) that determine the divisor D on the toric affine patches of the toric variety X on which D lies. This requires that D be $\mathbf{Q}$-Cartier.

`IsQCartier(D)`

Return `true` if and only if some integer multiple of the divisor D on a toric variety is Cartier.

`IsCartier(D)`

Return `true` if and only if the divisor D on a toric variety is Cartier.

`IsWeil(D)`

Return `true` if and only if the divisor D on a toric variety is a Weil divisor (that is, its coefficients are integers rather than rational numbers).

`IsAmple(D)`

Returns `true` if and only if the divisor D on a toric variety is ample.

`IsNef(D)`

Return `true` if and only if the divisor D on a toric variety is nef.

`IsBig(D)`

Return `true` if and only if the divisor D on a toric variety is big.

`PicardClass(D)`

The class in the Picard lattice corresponding to the $\mathbf{Q}$-Cartier divisor D.

`MovablePart(D)`

The movable part (or mobile part) of the divisor D on a toric variety.

Example H118E13

We compute a variety as a blowup of the projective plane.

```
> X := ProjectiveSpace(Rationals(),[1,1,1]);
> Y<u,v,x,y> := Blowup(X, &+Rays(Fan(X))[1..2]);
> Y;
Toric variety of dimension 2
Variables: u, v, x, y
The components of the irrelevant ideal are:
    (y, x), (v, u)
The 2 gradings are:
    0, 0, 1, 1,
    1, 1, 1, 0
```

We consider a (toric coordinate) divisor on Y.

```
> D := Divisor(Y,4);
> MovablePart(D);
Weil divisor with coefficients:
    0, 0, 0, 0
> MovablePart(D) eq ZeroDivisor(Y);
```

```
true
```

The movable part of this divisor is the zero divisor. Adding a little bit of another effective divisor doesn't yet make a mobile divisor, but it has made it stably mobile: some multiple now has a movable part.

```
> E := D + (1/2)*Divisor(Y,u);
> MovablePart(E);
Weil divisor with coefficients:
    0, 0, 0, 0
>   MovablePart(2*E);
Weil divisor with coefficients:
    1, 0, 0, 1
>   MovablePart(2*E) eq (D + Divisor(Y,u));
true
```

`ImageFan(D)`

The dual fan to the rational polyhedron of sections of the divisor D on a toric variety X. If X is a complete variety, this will give the fan of Proj of the ring of sections of positive powers of D.

`Proj(D)`

Proj (as a toric variety) of the ring of sections of the divisor D on a toric variety. The map of underlying lattices which determines the map `Variety(D)` $\rightarrow$ `Proj(D)` is also returned.

`RelativeProj(D)`

The relative (sheaf) Proj of sections of the divisor D on a toric variety. If D is **Q**-Cartier, then the identity will be constructed; for non **Q**-Cartier divisors, a partial **Q**-factorialisation will be given.

`IntersectionForm(X,C)`

If the cone C is a codimension 1 face of the fan of the toric variety X, return the dual toric lattice vector that represents intersection of the toric subvariety corresponding to C.

118.6.4 Linear Equivalence of Divisors

`IsQPrincipal(D)`

Return `true` if and only if some integer multiple of the divisor D on a toric variety is principal.

`IsPrincipal(D)`

Return `true` if and only if the divisor D on a toric variety is principal.

`IsLinearlyEquivalentToCartier(D)`

Return `true` if and only if the divisor D on a toric variety is linearly equivalent to a Cartier divisor; if so, then a representative Cartier divisor is also returned.

`AreLinearlyEquivalent(D,E)`

`IsLinearlyEquivalent(D,E)`

Return `true` if and only if the divisors D and E are linearly equivalent.

`DefiningMonomial(D)`

The monomial (if D is effective) or rational monomial defining the divisor D on a toric variety.

`LatticeElementToMonomial(D,v)`

The monomial in the Cox ring that corresponds to the monomial lattice element v when regarded as a section of the divisor D.

118.6.5 Riemann–Roch Spaces of Invariant Divisors

`RiemannRochPolytope(D)`

The Riemann–Roch space of the divisor D as a polytope in the monomial lattice of the underlying toric variety.

`RiemannRochBasis(D)`

A basis of the Riemann–Roch space of the divisor D on a toric variety X: this is a sequence of rational functions on X.

`RiemannRochDimension(D)`

The dimension of the Riemann–Roch space of the divisor D on a toric variety.

`GradedCone(D)`

The graded cone of sections of multiples of the divisor D on a toric variety. In other words, the integral points of the ith graded piece of this cone represent sections of the divisor $i * D$.

`Polyhedron(D)`

The integral polyhedron whose integral points corresponds to sections of the divisor D.

Example H118E14

We make a simple toric variety Y by blowing up the plane.

```
> X := ProjectiveSpace(Rationals(),[1,1,1]);
> Y<u,v,x,y> := Blowup(X, &+Rays(Fan(X))[1..2]);
> Y;
Toric variety of dimension 2
Variables: u, v, x, y
The components of the irrelevant ideal are:
    (y, x), (v, u)
The 2 gradings are:
    0, 0, 1, 1,
    1, 1, 1, 0
```

We make a non-effective divisor as a difference of fibres of the natural map from Y to the line.

```
> D := 2*Divisor(Y,u) - Divisor(Y,v);
> IsEffective(D);
false
> P := Polyhedron(D);
> monos := [ LatticeElementToMonomial(D,v) : v in Points(P) ];
> monos;
[
    u,
    v
]
```

The polyhedron P is not quite the Riemann–Roch space of D, but it is for a divisor linearly equivalent to D.

```
> [ AreLinearlyEquivalent(Divisor(Y,m),D) : m in monos ];
[ true, true ]
```

`HilbertSeries(D)`

The Hilbert series of the divisor D on a toric variety X, namely

$$\Sigma_{m\geq 0} \dim H^0(X, mD).$$

This assumes that the spaces of sections $H^0(X, D)$ of D finite dimensional. This will be true if X is projective, for example, but it holds in other cases too.

`HilbertPolynomial(D)`

The Hilbert (quasi-)polynomial for the divisor D. The space of sections of D must be finite dimensional. That is, a sequence of polynomials $[p_0, \ldots, p_{r-1}]$ of length r, the quasi-period of the Hilbert polynomial, so that $\dim H^0(X, mD)$ is the value of $p_s(k)$ where $m = kr + s$ is the Euclidean division of m by r; in other words, s is the least residue of m modulo r. Note that since MAGMA indexes sequences from 1, we have that $p_i =$ `HilbertPolynomial(D)[i+1]`.

`HilbertCoefficients(D,l)`

The first $l+1$ coefficients of the Hilbert series of the divisor D on a toric variety (starting with $0D$ up to and including lD).

`HilbertCoefficient(D,i)`

Thefirst ith coefficient of the Hilbert series of the divisor D on a toric variety.

Example H118E15

One can recreate the Cech cohomology calculation of the Riemann–Roch space of a divisor D on a toric variety X:

$$H^0(X, \mathcal{O}_X(D)) = \cap_\sigma (m_\sigma + \check{\sigma})$$

where the sum is taken over top-dimensional cones σ in the fan of X, and m_σ is the monomial in the dual lattice which determines D on the affine patch X_σ; $\check{\sigma}$ is the cone dual to σ.

```
> X<x,y,z> := ProjectiveSpace(Rationals(),[1,3,5]);
> D := Divisor(X,[2,3,1]);
> cones := Cones(Fan(X));
> RRD := &meet [ Polytope([Cartier(D)[i]]) + Dual(cones[i]) : i in [1..3]];
> IsPolytope(RRD);
true
```

We could compute the number of points of this cone RRD by saying `#Points(RRD)`. This should be regarded as a slow method to determine the number of points—after all, it requires us to find all the points before counting them. There is a specialised point-counting intrinsic `NumberOfPoints` which does not find the points first. The latter should be used for point counting, although in relatively small examples the former can be a little faster.

```
> NumberOfPoints(RRD);
14
```

To compute also the number of points of integral dilations of this polytope, we revert to using the divisor and computing its Hilbert series (or a few coefficients if that's all we need).

```
> time HilbertCoefficients(D,10);
[ 1, 14, 44, 92, 156, 238, 337, 452, 585, 735, 902 ]
> h<t> := HilbertSeries(D);
> h;
(-4*t^8 - 21*t^7 - 38*t^6 - 51*t^5 - 51*t^4 - 47*t^3 - 30*t^2 - 13*t - 1)/(t^9 -
    t^8 - t^6 + t^5 - t^4 + t^3 + t - 1)
> h * (1 - t) * (1 - t^3) * (1 - t^5);
4*t^8 + 21*t^7 + 38*t^6 + 51*t^5 + 51*t^4 + 47*t^3 + 30*t^2 + 13*t + 1
```

118.7 Maps of Toric Varieties

The initial method of expressing some maps between toric varieties is to derive them from maps between their associated lattices. These can also then be presented in terms of the variables of the Cox ring; this is the usual method for describing toric maps between projective spaces, for instance. This often results in radical expressions such as

$$(u, v) \mapsto (\sqrt{u}, v, v\sqrt{u}).$$

This example could be describing a map from $\mathbf{P}^1$ to $\mathbf{P}(1, 2, 3)$, for example: it is a 'monomial' map which observes the gradings. In that case, we could represent the same map by $(u, v) \mapsto (u, uv, u^2v)$ or $(u, v) \mapsto (1, v/u, v/u)$, or a host of other expressions. These two expressions have the benefit that they are polynomial or rational functions in u and v, and so they automatically define rational maps, but they have disadvantages too: for example, evaluating the map at the point $(0, 1)$ is not defined for these expressions, whereas it gives image $(1, 0, 1)$ in the original radical expression. (Notice that the choice of root does not matter, as long as it is assumed that the same choice $a = \sqrt{u}$ is made at each coordinate.)

More generally, one can define all maps between toric varieties (not just those arising from maps of lattices) using an appropriate notion of 'rational radical function', defined in terms of the polynomial Cox coordinates. This is very common when describing maps between standard projective spaces: one writes down a sequence of homogeneous polynomials of the same degree, without demanding that they are monomials.

The key point is that a rational map between varieties pulls rational functions (that are defined on the image) back to rational functions. It is enough to test this on a basis of rational functions. In the example above, if x, y, z are the coordinates on $\mathbf{P}(1, 2, 3)$ then y/x^2 and z/x^3 form a basis, and these both pull back to v/u, which is a rational function on $\mathbf{P}^1$.

We allow maps to be constructed from maps of the underlying toric lattices of fans. When displayed, they are described in these radical polynomial terms.

118.7.1 Maps from Lattice Maps

`ToricVarietyMap(X,Y,f)`

`ToricVarietyMap(X,Y)`

The rational map between toric varieties X and Y determined by the map f between their respective toric lattices (that is, the lattices underlying their respective fans). If the map f is not specified, it is assumed to be the identity map (and X and Y are assumed to have the same toric lattice).

`Blowup(X,v)`

The blowup of the toric variety X at the toric lattice point v of the toric lattice containing the fan of X; the natural map from the blowup to X is also returned.

`IdentityMap(X)`

The identity map on the toric variety X.

118.7.2 Properties of Toric Maps

`IsRegular(f)`

Return `true` if and only if the map f between toric varieties is regular.

`IndeterminacyLocus(f)`

A sequence of subschemes of the toric variety that is the domain of the map f between toric varieties at which f is not defined. (Note that these subschemes may in fact be empty.)

Example H118E16

We build a map from a Hirzebruch surface using the complete linear system of divisor.

```
> F2<u,v,x,y> := HirzebruchSurface(Rationals(),2);
> D := Divisor(F2,x);
> Y,f := Proj(D);
> Y;
Toric variety of dimension 2
Variables: $.1, $.2, $.3
The irrelevant ideal is:
    ($.3, $.2, $.1)
The grading is:
    1, 1, 2
> f;
Mapping from: 2-dimensional toric lattice N to 2-dimensional toric lattice N
given by a rule
```

The image variety Y is clearly the weighted projective space $\mathbf{P}(1,1,2)$. The map f returned is a map of underlying lattices. We can convert it into a map of the toric varieties, after which it will be presented in Cox coordinates.

```
> F := ToricVarietyMap(F2,Y,f);
> F;
A map between toric varieties described by:
    1,
    (v)*(u)^(-1),
    (x)*(y)^(-1)*(u)^(-2)
```

Now we can ask whether this map F is a morphism.

```
> IsRegular(F);
true
```

118.8 The Geometry of Toric Varieties

118.8.1 Resolution of Singularities and Linear Systems

`Resolution(X)`

A resolution of singularities of the toric variety X together with the natural morphism from the resolution to X. The resolution is not necessarily minimal.

`ResolveLinearSystem(D)`

The toric variety Y whose fan lives in the same lattice as the fan of the toric variety X on which the divisor D is defined, such that Y resolves the map given by the linear system of D.

118.8.2 Mori Theory of Toric Varieties

`MoriCone(X)`

The Mori Cone of toric variety X (as an abstract cone), that is, the cone generated by numerical classes of torus invariant curves on X.

`NefCone(X)`

The nef Cone of toric variety X (as an abstract cone).

`ExtremalRays(X)`

`ExtremalRayContractions(X)`

The images of extremal contractions of rays in the nef-cone of the toric variety X.

`ExtremalRayContraction(X,i)`

The toric variety that is the image of the ith extremal contraction of the toric variety X; the contraction morphism is returned as a second value.

`ExtremalRayContractionDivisor(X,i)`

The toric divisor that gives the ith extremal contraction of the toric variety X (that is, the divisor is the pullback of an ample divisor on the image).

`TypeOfContraction(X,i)`

`TypesOfContractions(X)`

A string describing the ith extremal contraction of the toric variety X (or all together in a sequence if i is not specified).

`IsMoriFibreSpace(X,i)`

Return `true` if and only if the ith extremal ray of the toric variety X gives an extremal contraction to a variety of lower dimension than X.

`IsDivisiorialContraction(X,i)`

Return `true` if and only if the ith extremal ray of the toric variety X gives a divisorial contraction of X.

`IsFlipping(X,i)`

Return `true` if and only if the ith extremal ray of the toric variety X gives a small contraction of X; in this case the intrinsic `Flip(X,i)` provides the flipped toric variety.

`Flip(X,i)`

The flipped variety of the ith extremal contraction of the toric variety X, assuming that this extremal contraction is of flipping type.

`Flip(D)`

The (generalised) flip of the morphism given by the $\mathbf{Q}$-Cartier divisor, assuming that this morphism is small.

`WeightsOfFlip(X,i)`

The weights of a $\mathbf{G}_{\mathrm{m}}$ action whose variation would give the flip of the ith extremal contraction of the toric variety X, assuming that this extremal contraction is of flipping type.

Example H118E17

```
> F0 := FanOfWPS([1,1,1,1]);
> L3 := Ambient(F0);
> F := Blowup(F0,L3 ! [2,-5,3]);
> X := ToricVariety(Rationals(),F);
> ExtremalRays(X);
[
    (0, -1),
    (1, 56)
]
> TypeOfContraction(X,1);
divisorial (K.C<0)
> TypeOfContraction(X,2);
flip
> WeightsOfFlip(X,2);
[
    [ 3, 2, -5, -1 ]
]
```

Example H118E18

We build a (nonsingular) variety X that is the projectivisation of the direct sum of line bundles $\mathcal{O}(0,0,0,1,1,1,1,2)$ on the projective line $\mathbf{P}^1$.

```
> X<[x]> := RationalScroll(Rationals(),1,[0,0,0,1,1,1,1,2]);
> X;
Toric variety of dimension 8
Variables: x[1], x[2], x[3], x[4], x[5], x[6], x[7], x[8], x[9], x[10]
The components of the irrelevant ideal are:
    (x[10], x[9], x[8], x[7], x[6], x[5], x[4], x[3]), (x[2], x[1])
The 2 gradings are:
    1,  1,  0,  0,  0, -1, -1, -1, -1, -2,
    0,  0,  1,  1,  1,  1,  1,  1,  1,  1
```

We compute its nef cone simply to initiate all its Mori theoretic data.

```
> _ := NefCone(X);
```

We can consider various extreme rays of the Mori cone of X. (Our choice of parameters mean we consider rays $[C]$ for which $DC \leq 0$, where D is the zero divisor: that is, we consider all rays.)

```
> IsFlipping(X,1: divisor:=ZeroDivisor(X), inequality:="weak");
false
> IsFlipping(X,2: divisor:=ZeroDivisor(X), inequality:="weak");
true
```

One of the rays corresponds to the fibration of X onto $\mathbf{P}^1$. The other is a ray of (anti-)flipping type. We can make the antiflip.

```
> Y<[y]> := Flip(X,2: divisor:=ZeroDivisor(X), inequality:="weak");
> Y;
Toric variety of dimension 8
Variables: y[1], y[2], y[3], y[4], y[5], y[6], y[7], y[8], y[9], y[10]
The components of the irrelevant ideal are:
    (y[10], y[9], y[8], y[7], y[6]), (y[5], y[4], y[3], y[2], y[1])
The 2 gradings are:
    0, 0, 1, 1, 1, 1, 1, 1, 1, 1,
    1, 1, 2, 2, 2, 1, 1, 1, 1, 0
> IsNonsingular(Y);
false
> IsTerminal(Y);
true
```

This antiflip can be regarded as coming from a change in the linearisation of a geometric invariant theory quotient: from a linearisation like $(1,1)$ (between variables 2 and 3 in the given order) to one like $(2,3)$ (between variables 5 and 6). To understand the antiflip better, sometimes it helps to consider its weights (the relation between vertices on the star of the flipping locus, or, in geometric invariant theory terms, the weights of the local $\mathbf{G}_{\mathrm{m}}$ action that determine the flip).

```
> WeightsOfFlip(X,2: divisor:=ZeroDivisor(X), inequality:="weak");
[
```

```
    [ 1, 1, 0, 0, 0, -1, -1, -1, -1, -2 ],
    [ 0, 0, 1, 1, 1, 1, 1, 1, 1, 1 ]
]
```

Here we see that a $\mathbf{P}^1$ has been antiflipped in favour of a weighted $\mathbf{P}^4(1,1,1,1,2)$, which is the source of the singularity on Y.

`MMP(X)`

`type` MonStgElt *Default : "terminal"*

A sequence of toric varieties that are all the varieties visited by making any sequence of extremal contractions from the toric variety X (and, if necessary, making the corresponding flip). A second sequence records the maps, in each case first by a sequence of the indices of the domain and codomain, and second by a string that describes the map.

The parameter `type` indicates which extremal rays are considered. It can be `terminal`, `canonical` or `all`. In each case, only toric varieties having these singularities will be allowed as images of the maps. (In particular, if the default value `terminal` is chosen, then only true K_X-negative extremal contractions will be followed.)

Example H118E19

First make a toric variety X, in this case some blowup of $\mathbf{P}^3$.

```
> F := FanOfWPS([1,1,1,1]);
> G := Blowup(F, Ambient(F) ! [1,-1,1]);
> X := ToricVariety(Rationals(),G);
```

We compute all minimal model programs from X. There are two outputs: first a sequence containing those toric varieties encountered during these processes, and second a sequence containing all the maps encountered.

```
> models,mmp := MMP(X);
> #models;
3
> mmp;
[ [*
    [ 1, 2 ],
    divisorial (K.C<0)
*], [*
    [ 2, 3 ],
    map to point
*] ]
```

In this case there are three varieties. We could check that they are: (1) X itself, (2) $\mathbf{P}^3$, and (3) a point. We also see two maps: the first, labelled $[1,2]$, is the contraction of X back down to $\mathbf{P}^3$, and the second is the extremal contraction of $\mathbf{P}^3$ to a point.

The intrinsic call `MMP(X)` has a parameter, and the default is to search only for true absolute minimal model programs: those which proceed only by contracting extremal rays that are negative against the canonical class (and flipping them if necessary). To allow contractions of other extremal rays (and the possibility of requiring antiflips), we can set the parameter to `type:="all"`.

```
> models,mmp := MMP(X : type:="all");
> models;
[
    Toric variety of dimension 3
    Variables: $.1, $.2, $.3, $.4, $.5
    The components of the irrelevant ideal are:
        ($.5, $.4), ($.3, $.2, $.1)
    The 2 gradings are:
        1, 0, 0, 2, 1,
        1, 1, 1, 1, 0,
    Toric variety of dimension 3
    Variables: $.1, $.2, $.3, $.4
    The irrelevant ideal is:
        ($.4, $.3, $.2, $.1)
    The grading is:
        1, 1, 1, 1,
    Toric variety of dimension 3
    Variables: $.1, $.2, $.3, $.4, $.5
    The components of the irrelevant ideal are:
        ($.3, $.2), ($.5, $.4, $.1)
    The 2 gradings are:
        1, 0, 0, 2, 1,
        1, 1, 1, 1, 0,
    Toric variety of dimension 0,
    Toric variety of dimension 1
    Variables: $.1, $.2
    The irrelevant ideal is:
        ($.2, $.1)
    The grading is:
        1, 1
]
> mmp;
[ [*
    [ 1, 2 ],
    divisorial (K.C<0)
*], [*
    [ 1, 3 ],
    flop
*], [*
    [ 2, 4 ],
    map to point
*], [*
    [ 3, 1 ],
```

```
    flop
*], [*
    [ 3, 5 ],
    fibration (K.C<0)
*] ]
```

Now we also see a flop from X to a new toric variety Y (model number 3), and then Y admits Mori fibration to $\mathbf{P}^1$ (which we could check is model number 5).

118.8.3 Decomposition of Toric Morphisms

The title of this section is that of a well-known paper of Reid [Rei83]. It applies Mori theory to toric varieties relatively over a base to compute a relative minimal model and the relative canonical model of a toric variety. Rather than wrap this up in intrinsics, we show how to apply the various components of this package to realise Reid's result.

Example H118E20

We will compute a relative minimal model and a relative canonical model of the weighted projective space $\mathbf{P}^3(1,2,5,6)$, a 3-fold that does not have canonical (nor terminal) singularities.

```
> A := ProjectiveSpace(Rationals(),[1,2,5,6]);
> IsCanonical(A);
false
```

We find the relative models by running a minimal model program on a resolution of A relative to A itself (that is, we only allow morphisms $V \to W$ if they factor the given morphism $V \to A$). So we start by constructing a resolution.

```
> V0,f0 := Resolution(A);
> V0;
Toric variety of dimension 3
Variables: $.1, $.2, $.3, $.4, $.5, $.6, $.7, $.8, $.9, $.10, $.11, $.12
The irrelevant ideal is:
   [... omitted... ]
The 9 gradings are:
    0, 0, 0, 1, 0, 0, 0, 0, 1, 0, 0, 0,
    0, 0, 1, 1, 0, 0, 0, 0, 0, 0, 1, 0,
    0, 0, 1, 2, 0, 0, 0, 1, 0, 0, 0, 0,
    0, 0, 2, 3, 0, 0, 0, 0, 0, 1, 0, 0,
    0, 1, 2, 3, 0, 0, 1, 0, 0, 0, 0, 0,
    0, 1, 3, 3, 0, 0, 0, 0, 0, 0, 0, 1,
    0, 1, 3, 4, 1, 0, 0, 0, 0, 0, 0, 0,
    0, 1, 4, 5, 0, 1, 0, 0, 0, 0, 0, 0,
    1, 2, 5, 6, 0, 0, 0, 0, 0, 0, 0, 0
```

We see that the resolution made $8 = 9 - 1$ blowups. To compute everything, we would keep track of the morphisms (as we have started with f_0 above); for brevity, we forego that.

We build a function which detects which of the extremal contractions from a given V (starting with V_0) that factor $V \to A$. This code also reports whether the contraction is divisorial or of flipping type so that we can make the next step accordingly.

```
> raysOverA := func< W |
>     [ <i,TypeOfContraction(W,i)> :
>               i in [1..#ExtremalRays(W)] |
>     IsRegular(ToricVarietyMap(ExtremalRayContraction(W,i),A)) ] >;
```

And so we look for extremal rays over A that we can contract.

```
> raysOverA(V0);
[ <1, "divisorial (K.C<0)">, <2, "divisorial (K.C<0)">,
<3, "divisorial (K.C<0)"> ]
```

In other words, the extremal rays 1, 2 and 3 all determine extremal divisorial contractions. (If we were writing a faster routine, we would probably stop as soon as we'd found that ray 1 worked.) We can pick any of these: we choose ray 1 and repeat the process.

```
> V1 := ExtremalRayContraction(V0,1);
> raysOverA(V1);
[ <1, "divisorial (K.C<0)">, <2, "divisorial (K.C<0)">, <4, "divisorial
(K.C<0)"> ]
```

This time rays 1, 2, and 4 work; again these lead to divisorial contractions. We follow ray 1.

```
> V2 := ExtremalRayContraction(V1,1);
> raysOverA(V2);
[ <2, "divisorial (K.C<0)">, <3, "divisorial (K.C<0)"> ]
> V3 := ExtremalRayContraction(V2,2);
> raysOverA(V3);
[ <2, "divisorial (K.C<0)"> ]
> V4 := ExtremalRayContraction(V3,2);
> raysOverA(V4);
[ <2, "divisorial (K.C<0)"> ]
> V5<[w]> := ExtremalRayContraction(V4,2);
> assert #raysOverA(V5) eq 0;
```

There are no extremal rays over A to contract. We have reached a relatively minimal model, V_5; we check its singularities, although there is no need.

```
> V5;
Toric variety of dimension 3
Variables: w[1], w[2], w[3], w[4], w[5], w[6]
The components of the irrelevant ideal are:
    (w[6], w[5]), (w[6], w[3]), (w[5], w[4], w[2]), (w[3], w[1]), (w[4], w[2],
        w[1])
The 3 gradings are:
    0, 0, 1, 1, 0, 1,
    0, 1, 2, 3, 1, 0,
    1, 2, 5, 6, 0, 0
> IsTerminal(V5);
```

```
true
```

To continue on to a relatively canonical model we must consider rays that are trivial against the canonical class, not negative as we have so far. We need to modify the relative rays function; we simply weaken the inequality used when evaluating against the canonical class.

```
> weakraysOverA := func< W |
>     [ <i,TypeOfContraction(W,i : inequality:="weak")> :
>                   i in [1..#ExtremalRays(W:inequality:="weak")] |
>  IsRegular(ToricVarietyMap(ExtremalRayContraction(W,i:inequality:="weak"),A))]>;
```

And so we continue.

```
> weakraysOverA(V5);
[ <2, "divisorial (K.C=0)"> ]
> V6<[u]> := ExtremalRayContraction(V5,2 : inequality:="weak");
> assert #weakraysOverA(V6) eq 0;
```

After one canonically-trivial divisorial contraction there are no rays left to contract. We have reached the relative canonical model.

```
> V6;
Toric variety of dimension 3
Variables: u[1], u[2], u[3], u[4], u[5]
The components of the irrelevant ideal are:
    (u[5], u[3]), (u[4], u[2], u[1])
The 2 gradings are:
    0, 0, 1, 1, 1,
    1, 2, 5, 6, 0
> IsTerminal(V6);
false
> IsCanonical(V6);
true
```

Of course, in this toric setting, it would have been simpler to find the single short vector in the fan of A that was causing all the trouble and blow that up.

118.9 Schemes in Toric Varieties

The polynomials of the Cox ring of a toric variety X provide homogeneous coordinates on X that can be used to define subschemes of X. These subschemes are true MAGMA schemes, and so the usual scheme machinery works for them. However, there is a substantial caveat to this for the first version of the toric geometry package: affine patches have not been installed systematically, and so scheme machinery that uses affine patches of schemes will not work.

118.9.1 Construction of Subschemes

`Scheme(X,f)`

The subscheme of the toric variety X defined by the polynomial f from the Cox ring of X.

`Scheme(X,Q)`

The subscheme of the toric variety X defined by the sequence Q of polynomials from the Cox ring of X.

Example H118E21

Toric varieties are the natural ambient space for many varieties. Here we review the example of a trigonal curve from the Schemes chapter (it is self-contained here).
First make a curve. (This curve is in fact trigonal—it admits a 3-to-1 cover of the projective line. Once you've had that thought, it's actually pretty clear: the defining equation is a cubic in y. But there's more to it than just being trigonal, as we will see.)

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^8 + x^4*y^3*z + z^8);
> Genus(C);
8
```

This curve is of general type (that is, its genus is at least 2), so we can consider the canonical map: that will either be an embedding or a 2-to-1 map to a projective line.
We make the canonical map take its image in a toric variety.

```
> eqns := Sections(CanonicalLinearSystem(C));
> X<[a]> := ProjectiveSpace(Rationals(),7);
> f := map< P -> X | eqns >;
> V := f(C);
> V;
Curve over Rational Field defined by
a[1]^3 + a[2]^2*a[4] + a[1]*a[8]^2,
a[1]^2*a[3] + a[2]^2*a[6] + a[3]*a[8]^2,
a[1]^2*a[5] + a[2]*a[4]*a[6] + a[5]*a[8]^2,
a[1]*a[4]*a[6] - a[2]^2*a[7],
a[1]*a[6]^2 - a[2]^2*a[8],
a[2]*a[6]^2 + a[1]^2*a[7] + a[7]*a[8]^2,
a[4]*a[6]^2 + a[1]^2*a[8] + a[8]^3,
a[2]*a[3] - a[1]*a[4],
a[3]^2 - a[1]*a[5],
a[3]*a[4] - a[1]*a[6],
a[4]^2 - a[2]*a[6],
a[2]*a[5] - a[1]*a[6],
a[3]*a[5] - a[1]*a[7],
a[4]*a[5] - a[2]*a[7],
a[5]^2 - a[1]*a[8],
a[3]*a[6] - a[2]*a[7],
```

```
a[5]*a[6] - a[2]*a[8],
a[3]*a[7] - a[1]*a[8],
a[4]*a[7] - a[2]*a[8],
a[5]*a[7] - a[3]*a[8],
a[6]*a[7] - a[4]*a[8],
a[7]^2 - a[5]*a[8]
```

All those binomial equations suggest that V lies on a toric variety embedded in $X = \mathbf{P}^7$. We can recover this toric variety and its map to X.

```
> W,g := BinomialToricEmbedding(V);
> Y<[b]> := Domain(g);
> Y;
Toric variety of dimension 2
Variables: b[1], b[2], b[3], b[4]
The components of the irrelevant ideal are:
    (b[3], b[2]), (b[4], b[1])
The 2 gradings are:
    0, 1, 1, 0,
    1, 0, 2, 1
```

It is a well-known consequence of (geometric) Riemann–Roch that trigonal curves lie on scrolls in their canonical embeddings. Exactly which scroll is an intrinsic property of the particular curve: the Maroni invariant of a trigonal curve can be realised as the twist that occurs in the scroll, in this case 2 (visible in the last line of output above).
This makes good sense: the scroll Y has a natural map to $\mathbf{P}^1$, and the equation of the curve W is a cubic in the fibre variables $b[2], b[3]$ so defines a 3-to-1 cover of the base.

```
> I := Saturation(DefiningIdeal(W),IrrelevantIdeal(Y));
> Basis(I);
[
     b[1]^8*b[2]^3 + b[1]*b[3]^3*b[4] + b[2]^3*b[4]^8
]
```

The need for saturation is already visible in the equations of V: all those cubics are really multiples of a single cubic on the scroll by irrelevant ideals, but written in the coordinates of the projective space.

119 RATIONAL CURVES AND CONICS

Chapter 119
RATIONAL CURVES AND CONICS

119.1 Introduction

This chapter describes the specialised categories of nonsingular plane curves of genus zero: The rational plane curves and conics. Rational curves and conics in MAGMA are nonsingular plane curves of degree 1 and 2, respectively. The central functionality for conics concerns the existence of points over the rationals. If a point is known to exist then a conic can be parametrised by a projective line or a rational curve. In addition, several algorithms are implemented to convert conics to standard Legendre, or diagonal, models and, for curves over $\mathbf{Q}$, to a reduced Legendre model or a minimal model. A rational curve in MAGMA is a linearly embedded image of the projective line to which the full machinery of algebraic plane curves can be applied. The special category of conics is called `CrvCon` and that of rational curves is `CrvRat`.

The central algorithms of this chapter deal with the classification and reduction of genus zero curves to one of the standard models to which efficient algorithms can be applied. These special types serve to classify all curves up to birational isomorphism. Since the canonical divisor K_C of a genus zero curve is of degree -2, a basis for the Riemann–Roch space of the effective divisor $-K_C$ has dimension 3 and gives an anti-canonical embedding in the projective plane. The homogeneous quadratic relations between the functions define a conic model for any genus zero curve. If the curve has a rational point then a similar construction with the divisor of this point gives a birational isomorphism with the projective line. For conics over the rationals, efficient algorithms of Simon [Sim05] allow one to first find a point, if one exists, and then to reduce to simpler models. The existence of a point is easily determined by local conditions, and this local data is carried by the data of the ramified or bad primes of reduction; if such a point exists then the existence can be certified by a certificate. Simon's algorithm in fact parametrises the curve (by the projective line) which gives a birational isomorphism with the curve.

Not every curve of genus zero can be "trivialised" by reduction to a rational curve in this way; the obstruction to having a rational point, and therefore to being parametrised by a projective line, is measured by the primes of bad reduction and also by the automorphism group, both of which are closely associated to an isomorphism class of quaternion algebras. The final algorithms of this chapter make use of this connection to compute the automorphism group of a curve and to find isomorphisms between conics.

119.2 Rational Curves and Conics

The general tools for constructing and analysing curves are described in Chapter 114. We do not repeat them here, but rather give some examples in Section 119.2.3 to demonstrate those basics that the user will need. In this section we describe the main parametrisation function for rational curves and functions which enable type change from a curve of genus zero to a rational curve.

119.2.1 Rational Curve and Conic Creation

Rational curves and conics are the specialised types for nonsingular plane curves of genus zero defined by polynomials of degree 1 and 2, respectively. The condition of nonsingularity is equivalent to that of absolute irreducibility for conics, and imposes no condition on a linear equation in the plane.

`Conic(coeffs)`

`Ambient` SCH

This creates a conic curve with the given sequence of coefficients (which should have length 3 or 6). A sequence $[a, b, c]$ designates the conic $aX^2 + bY^2 + cZ^2$, while a sequence $[a, b, c, d, e, f]$ designates the conic $aX^2 + bY^2 + cZ^2 + dXY + eYZ + fXZ$.

The optional parameter `Ambient` may be used to give the specific ambient projective space in which to create the conic; otherwise a new ambient will be created for it to lie in.

`Conic(M)`

`Ambient` SCH

This creates a conic curve associated to M, which must be a symmetric 3×3 matrix. Explicitly, the equation of the conic is $[X, Y, Z]M[X, Y, Z]^{tr}$.

The optional parameter `Ambient` may be used to give the specific ambient projective space in which to create the conic; otherwise a new ambient will be created for it to lie in.

`Conic(X, f)`

Returns the conic defined by the polynomial f in the projective plane X.

`IsConic(S)`

Returns `true` if and only if the scheme S is a nonsingular plane curve of degree 2, in which case it also returns a curve (of type `CrvCon`) with the same defining polynomial as S.

`RationalCurve(X, f)`

Returns the rational curve defined by the linear polynomial f in the projective plane X.

`IsRationalCurve(S)`

Returns `true` if and only if the scheme S is defined by a linear polynomial in some projective plane $\mathbf{P}^2$; if so, it also returns a curve of type `CrvRat` with the same defining polynomial as S in $\mathbf{P}^2$.

Example H119E1

In the following example we create a degree two curve over the rational field, then create a new curve of conic type using `IsConic`.

```
> P2<x,y,z> := ProjectivePlane(Rationals());
> C0 := Curve(P2, x^2 + 3*x*y + 2*y^2 - z^2);
> C0;
Curve over Rational Field defined by
x^2 + 3*x*y + 2*x^2 - z^2
> bool, C1 := IsConic(C0);
```

Clearly this is a nonsingular degree two curve, so `bool` must be `true` and we have created a new curve C_1 in the same ambient space P_2 but of conic type.

```
> C1;
Conic over Rational Field defined by
x^2 + 3*x*y + 2*y^2 - z^2
> AmbientSpace(C0) eq AmbientSpace(C1);
true
> DefiningIdeal(C0) eq DefiningIdeal(C1);
true
> C0 eq C1;
false
> Type(C0);
CrvPln
> Type(C1);
CrvCon
```

The equality test return `false` because the two objects are of different MAGMA type.

119.2.2 Access Functions

The basic access functions for rational curves and conics are inherited from the general machinery for plane curves and hypersurface schemes.

`DefiningPolynomial(C)`

Returns the defining polynomial of the conic or rational curve C.

`DefiningIdeal(C)`

Returns the defining ideal of the conic or rational curve C.

`BaseRing(C)` `BaseField(C)`

Returns the base ring of the curve C.

`Category(C)` `Type(C)`

Returns the category of rational curves `CrvRat` or of conics `CrvCon`; these are special subtypes of planes curves (type `CrvPln`), which are themselves subtypes of general curves (type `Crv`).

119.2.3 Rational Curve and Conic Examples

These examples illustrate how to obtain standard models of a curve of genus zero, either as a conic or as a parametrisation by the projective line.

Example H119E2

We begin with an example of a singular curve of geometric genus zero.

```
> P2<x,y,z> := ProjectivePlane(FiniteField(71));
> C := Curve(P2, (x^3 + y^2*z)^2 - x^5*z);
> C;
Curve over GF(71) defined by
x^6 + 70*x^5*z + 2*x^3*y^2*z + y^4*z^2
> ArithmeticGenus(C);
10
> Genus(C);
0
> #RationalPoints(C);
73
> Z := SingularSubscheme(C);
> Degree(Z);
18
```

We see that C is highly singular and that its desingularisation has genus zero. At most 18 of 73 points are singular; note that a nonsingular curve of genus zero would have 72 points. We now investigate the source of the extra points.

```
> cmps := IrreducibleComponents(Z);
> [ Degree(X) : X in cmps ];
[ 11, 7 ]
> [ Degree(ReducedSubscheme(X)) : X in cmps ];
[ 1, 1 ]
> [ RationalPoints(X) : X in cmps ];
[
{@ (0 : 0 : 1) @},
{@ (0 : 1 : 0) @}
]
```

Since the only singular rational points on C are $(0 : 0 : 1)$ and $(0 : 1 : 0)$, the "obvious" point $(1 : 0 : 1)$ must be nonsingular and we can use it to obtain a rational parametrisation of the curve as explained in Section 119.6.

```
> P1<u,v> := ProjectiveSpace(FiniteField(71), 1);
> p := C![1, 0, 1];
> m := Parametrization(C, Place(p), Curve(P1));
> S1 := {@ m(q) : q in RationalPoints(P1) @};
> #S1;
72
> [ q : q in RationalPoints(C) | q notin S1 ];
```

```
[ (0 : 1 : 0) ]
```

We conclude that the extra point comes from a singularity whose resolution does not have any degree one places over it (see Section 114.9 of Chapter 114 for background on places of curves). We can verify this explicitly.

```
> [ Degree(p) : p in Places(C![0, 1, 0]) ];
[ 2 ]
```

Example H119E3

In this example we start by defining a projective curve and we check that it is rational; that is, that it has genus zero.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(), 2);
> C0 := Curve(P2, x^2 - 54321*x*y + y^2 - 97531*z^2);
> IsNonsingular(C0);
true
```

The curve C_0 is defined as a degree 2 curve over the rationals. By making a preliminary type change to the type of conics, `CrvCon`, we can test whether there exists a rational point over $\mathbf{Q}$ and use efficient algorithms of Section 119.5.1 for finding rational points on curves in conic form. The existence of a point (defined over the base field) is equivalent to the existence of a parametrisation (defined over the base field) of the curve by the projective line.

```
> bool, C1 := IsConic(C0);
> bool;
true
> C1;
Conic over Rational Field defined by
x^2 - 54321*x*y + y^2 - 97531*z^2
> HasRationalPoint(C1);
true (398469/162001 : -118246/162001 : 1)
> RationalPoint(C1);
(398469/162001 : -118246/162001 : 1)
```

The parametrisation intrinsic requires a one-dimensional ambient space as one of the arguments. This space will be used as the domain of the parametrisation map.

```
> P1<u,v> := ProjectiveSpace(Rationals(), 1);
> phi := Parametrization(C1, Curve(P1));
> phi;
Mapping from: Prj: P1 to CrvCon: C1
with equations :
398469*u^2 + 944072*u*v + 559185*v^2
-118246*u^2 - 200850*u*v - 85289*v^2
162001*u^2 + 329499*u*v + 162991*v^2
and inverse
-4634102139*x + 30375658963*y + 31793350442*z
5456130497*x - 25641668406*y - 32136366969*z
and alternative inverse equations :
```

```
5456130497*x - 25641668406*y - 32136366969*z
-6424037904*x + 21645471041*y + 31600239062*z
```

The defining functions for the parametrisation may look large, but they are defined simply by a linear change of variables from the 2-uple embedding of the projective line in the projective plane. We now do a naive search for rational points on the curve.

```
> time RationalPoints(C1 : Bound := 100000);
{@ @}
Time: 2.420
```

Although there were no points with small coefficients, the parametrisation provides us with any number of rational points:

```
> phi(P1![0, 1]);
(559185/162991 : -85289/162991 : 1)
> phi(P1![1, 1]);
(1901726/654491 : -404385/654491 : 1)
> phi(P1![1, 0]);
(398469/162001 : -118246/162001 : 1)
```

Example H119E4

The first part of this example illustrates how to obtain diagonal equations for conics.

```
> P2<x,y,z> := ProjectiveSpace(RationalField(), 2);
> f := 1134*x^2 - 28523*x*y - 541003*x*z - 953*y^2 - 3347*y*z - 245*z^2;
> C := Conic(P2, f);
> LegendrePolynomial(C);
1134*x^2 - 927480838158*y^2 - 18604260593650520388494 1*z^2
> ReducedLegendrePolynomial(C);
817884337*x^2 - y^2 - 353839285266278*z^2
```

Now we demonstrate how to extend the base field of the conic; that is, to create the conic with the same coefficients but in a larger field. This can be done by calling `BaseExtend`; in this instance, we move from the rationals to a particular number field.
(Note the assignment of names to C in order to make the printing nicer.)

```
> P<t> := PolynomialRing(RationalField());
> K := NumberField(t^2 - t + 723);
> C<u,v,w> := BaseExtend(C, K);
> C;
Conic over K defined by
1134*u^2 - 28523*u*v - 953*v^2 - 541003*u*w - 3347*v*w - 245*w^2
```

119.3 Conics

In this section we discuss the creation and basic attributes of conics, particularly the standard models for them. In subsequent sections we treat the local-global theory and existence of points on conics, the efficient algorithms for finding rational points, parametrisations and isomorphisms of genus zero curves with standard models, and finally the automorphism group of conics.

119.3.1 Elementary Invariants

`Discriminant(C)`

Given a conic C, returns the discriminant of C. The discriminant of a conic with defining equation

$$a_{11}x^2 + a_{12}xy + a_{13}xz + a_{22}y^2 + a_{23}yz + a_{33}z^2 = 0$$

is defined to be the value of the degree 3 form

$$4a_{11}a_{22}a_{33} - a_{11}a_{23}^2 - a_{12}^2a_{33} + a_{12}a_{13}a_{23} - a_{13}^2a_{22}.$$

Over any ring in which 2 is invertible this is just $1/2$ times the determinant of the matrix

$$\begin{pmatrix} 2a_{11} & a_{12} & a_{13} \\ a_{12} & 2a_{22} & a_{23} \\ a_{13} & a_{23} & 2a_{33} \end{pmatrix}.$$

119.3.2 Alternative Defining Polynomials

The functions described here provide access to basic information stored for a conic C. In addition to the defining polynomial, curves over the rationals compute and store a diagonalised *Legendre* model for the curve, whose defining polynomial can be accessed.

`LegendrePolynomial(C)`

Returns the Legendre polynomial of the conic C, a diagonalised defining polynomial of the form $ax^2+by^2+cz^2$. Once computed, this polynomial is stored as an attribute. The transformation matrix defining the isomorphism from C to the Legendre model is returned as the second value.

`ReducedLegendrePolynomial(C)`

Returns the reduced Legendre polynomial of the conic C, which must be defined over $\mathbf{Q}$ or $\mathbf{Z}$; that is, a diagonalised integral polynomial whose coefficients are pairwise coprime and square-free. The transformation matrix defining the isomorphism from C to this reduced Legendre model is returned as the second value.

119.3.3 Alternative Models

`LegendreModel(C)`

Returns the Legendre model of the conic C — an isomorphic curve of the form

$$ax^2 + by^2 + cz^2 = 0,$$

together with an isomorphism to this model.

`ReducedLegendreModel(C)`

Returns the reduced Legendre model of the conic C, which must be defined over $\mathbf{Q}$ or $\mathbf{Z}$; that is, a curve in the diagonal form $ax^2 + by^2 + cz^2 = 0$ whose coefficients are pairwise coprime and square-free. The isomorphism from C to this model is returned as a second value.

119.3.4 Other Functions on Conics

`MinimalModel(C)`

Returns a conic, the matrix of whose defining polynomial has smaller discriminant than that of the conic C (where possible). The algorithm used is the minimisation stage of Simon's algorithm [Sim05], as used in `HasRationalPoint`. A map from the conic to C is also returned.

Example H119E5

In the following example we are able to reduce the conic at 13.

```
> P2<x,y,z> := ProjectiveSpace(RationalField(), 2);
> f := 123*x^2 + 974*x*y - 417*x*z + 654*y^2 + 113*y*z - 65*z^2;
> C := Conic(P2, f);
> BadPrimes(C);
[ 491, 18869 ]
> [ x[1] : x in Factorization(Integers()!Discriminant(C)) ];
[ 13, 491, 18869 ]
> MinimalModel(C);
Conic over Rational Field defined by
-9*x^2 + 4*x*y + 6*x*z + 564*y^2 + 178*y*z + 1837*z^2
Mapping from: Conic over Rational Field defined by
-9*x^2 + 4*x*y + 6*x*z + 564*y^2 + 178*y*z + 1837*z^2 to CrvCon: C
with equations :
x + 6*y - 10*z
-x - 8*y + 4*z
-8*x - 50*y + 61*z
and inverse
-144/13*x + 67/13*y - 28/13*z
29/26*x - 19/26*y + 3/13*z
-7/13*x + 1/13*y - 1/13*z
```

119.4 Local-Global Correspondence

The Hasse–Minkowski principle for quadratic forms implies that a conic has a point over a number field if and only if it has a point over its completion at every finite and infinite prime. This provides an effective set of conditions for determining whether a conic has a point: Only the finite number of primes dividing the discriminant of the curve need to be checked, and by Hensel's lemma it is only necessary to check this condition to finite precision. The theory holds over any global field (a number field or the function field of a curve over a finite field) but the algorithms implemented at present only treat the field $\mathbf{Q}$.

119.4.1 Local Conditions for Conics

We say that p is a ramified or bad prime for a conic C if there exists no p-integral model for C with nonsingular reduction. Every such prime is a divisor of the coefficients of the Legendre polynomial. However, in general it is not possible to have a Legendre model whose coefficients are divisible only by the ramified primes. We use the term ramified or bad prime for a conic to refer to the local properties of C which are independent of the models.

`BadPrimes(C)`

Given a conic C over the rationals, returns the sequence of the finite ramified primes of C: Those at which C has intrinsic locally singular reduction. This uses quaternion algebras.

N.B. Although the infinite prime is not included, the data of whether or not $C/\mathbf{Q}$ is ramified at infinity is carried by the length of this sequence. The number of bad primes, including infinity, must be even so the parity of the sequence length specifies the ramification information at infinity.

119.4.2 Norm Residue Symbol

Hilbert's norm residue symbol logically pertains to the theory of quadratic forms and lattices, and to that of quadratic fields and their norm equations. We express it here for its relevance to determining conditions for the existence of local points on conics over $\mathbf{Q}$. The norm residue symbol gives a precise condition for a quadratic form to represent zero over $\mathbf{Q}_p$, or more generally over any local field; this is equivalent to the condition that a conic has a point over that field.

An explicit treatment of the properties and theory of the norm residue symbol can be found in Cassels [Cas78]; the Hilbert symbol is treated by Lam [Lam73].

`NormResidueSymbol(a, b, p)`

Given two rational numbers or integers a and b, and a prime p, returns 1 if the quadratic form $ax^2 + by^2 - z^2$ represents zero over $\mathbf{Q}_p$ and returns -1 otherwise.

`HilbertSymbol(a, b, p : parameters)`

`Al` MonStgElt *Default :* `"NormResidueSymbol"`

Computes the Hilbert symbol $(a, b)_p$, where a and b are elements of a number field and p is either a prime number (if $a, b \in \mathbf{Q}$) or a prime ideal. For $a, b \in \mathbf{Q}$, by default Magma uses `NormResidueSymbol` to compute the Hilbert symbol; one may insist on instead using the same algorithm as for number fields by setting the optional argument `Al` to `"Evaluate"`.

Example H119E6

In the following example we show how the norm residue symbols can be used to determine the bad primes of a conic.

```
> P2<x,y,z> := ProjectiveSpace(RationalField(), 2);
> a := 234;
> b := -33709;
> c := 127;
> C := Conic(P2, a*x^2 + b*y^2 + c*z^2);
> HasRationalPoint(C);
false
> fac := Factorization(Integers()!Discriminant(C));
> fac;
[ <2, 3>, <3, 2>, <13, 2>, <127, 1>, <2593, 1> ]
```

So we only need to test the primes 2, 3, 13, 127 and 2593. By scaling the defining polynomial of the curve $ax^2 + by^2 + cz^2 = 0$ by $-1/c$, we obtain the quadratic form $-a/cx^2 - b/cy^2 - z^2$; this means that we want to check the Hilbert symbols for the coefficient pair $(-a/c, -b/c)$.

```
> [ NormResidueSymbol(-a/c, -b/c, p[1]) : p in fac ];
[ -1, 1, 1, -1, 1 ];
```

The norm residue symbol indicates that only 2 and 127 have no local p-adic solutions, which confirms the bad primes as reported by Magma:

```
> BadPrimes(C);
[ 2, 127 ]
```

119.5 Rational Points on Conics

This section contains functions for deciding solubility and finding points on conics over the following base fields: the rationals, finite fields, number fields, and rational function fields in odd characteristic.

A point on a conic C is given as a point in the pointset $C(K)$ where K is the base ring of the conic, unless that base ring is the integers in which case the returned point belongs to the pointset $C(\mathbf{Q})$.

Over the rationals (or integers), the algorithm used to find rational points is due to D. Simon [Sim05]. Simon's algorithm works with the symmetric matrix of the defining polynomial of the conic. It computes transformations reducing the determinant of the matrix by each of the primes which divide the discriminant of the conic until it has absolute value 1. After this it does an indefinite LLL which reduces the matrix to a unimodular integral diagonal matrix, which is equivalent to the conic $x^2 + y^2 - z^2 = 0$, and then the Pythagorean parametrisation of this can be pulled back to the original conic.

The existence of a point on a conic $C/\mathbf{Q}$ is determined entirely by local solubility conditions, which are encapsulated in a solubility certificate. The algorithm of Simon works prime-by-prime, determining local solubility as it goes through its calculation of square roots modulo primes. In theory the existence of a point can be determined using Legendre symbols instead of computing these square roots. This is not implemented because the running time is dominated by the time needed to factorise the discriminant.

Over number fields the algorithm for finding points is as follows. One first reduces to diagonal form, which is done with care to ensure that one can factor the coefficients (assuming that one can factor the discriminant of the original conic). The algorithm for diagonal conics is a variant of Lagrange's method (which was once the standard method for solving diagonal conics over $\mathbf{Q}$). It involves a series of reduction steps in each of which the conic is replaced by a simpler conic. Reduction is achieved by finding a short vector in a suitable lattice sitting inside two copies of the base field. (This lattice is defined by congruence conditions arising from local solutions of the conic.)

After several reduction steps one is often able to find a solution via an easy search. In other cases, one is unable to reduce further and must call `NormEquation` to solve the reduced conic. (This is still vastly superior to calling `NormEquation` on the original conic.) The basic reduction loop is enhanced with several tricks; in particular, when it is not too large the class group of the base field may be used to reduce much further than would otherwise be feasible.

Over rational function fields the algorithm for solving conics is due to Cremona and van Hoeij [CR06]. The implementation was contributed by John Cremona and David Roberts.

Over finite fields the algorithm used for finding a point $(x : y : 1)$ on a conic is to solve for y at random values of x.

119.5.1 Finding Points

The main function is `HasRationalPoint`, which also returns a point when one exists. This (and also `RationalPoint`) works over various kinds of fields; the other functions work only

over the rationals (or integers) and finite fields.

When a point is found it is also cached for later use.

`HasRationalPoint(C)`

The conic C should be defined over the integers, rationals, a finite field, a number field, or a rational function field over a finite field of odd characteristic. The function returns `true` if and only if there exists a point on the conic C, and if so also returns one such point.

`RationalPoint(C)`

The conic C should be defined over the integers, rationals, a finite field, a number field, or a rational function field over a finite field of odd characteristic. If there exists a rational point on C over its base ring then a representative such point is returned; otherwise an error results.

`Random(C : parameters)`

`Bound`	RngIntElt	*Default :* 10^9
`Reduce`	BoolElt	*Default :* `false`

Returns a randomly selected rational point of the conic C. Such a solution is obtained by choosing random integers up to the bound specified by the parameter `Bound`, followed by evaluation at a parametrisation of C, then by point reduction if the parameter `Reduce` is set to `true`. (See Section 119.5.2 for more information about point reduction.)

`Points(C : parameters)`

`RationalPoints(C : parameters)`

`Bound`	RngIntElt

Given a conic over the rationals or a finite field, returns an indexed set of the rational points of the conic. If the curve is defined over the rationals then a positive value for the parameter `Bound` *must* be given; this function then returns those points whose integral coordinates, on the reduced Legendre model, are bounded by the value of `Bound`.

Example H119E7

We define three conics in Legendre form, having the same prime divisors in their discriminants, which differ only by a sign change (twisting by $\sqrt{-1}$) of one of the coefficients.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(), 2);
> C1 := Conic(P2, 23*x^2 + 19*y^2 - 71*z^2);
> RationalPoints(C1 : Bound := 32);
{@ @}
> C2 := Conic(P2, 23*x^2 - 19*y^2 + 71*z^2);
> RationalPoints(C2 : Bound := 32);
{@ @}
```

```
> C3 := Conic(P2, 23*x^2 - 17*y^2 - 71*z^2);
> RationalPoints(C3 : Bound := 32);
{@ (-31 : 36 : 1), (-31 : -36 : 1), (31 : 36 : 1), (31 : -36 : 1),
(-8/3 : 7/3 : 1), (-8/3 : -7/3 : 1), (8/3 : 7/3 : 1), (8/3 : -7/3 : 1),
(-28/15 : 11/15 : 1), (-28/15 : -11/15 : 1), (28/15 : 11/15 : 1),
(28/15 : -11/15 : 1) @}
```

This naive search yields no points on the first two curves and numerous points on the third one. A guess that there are no points on either of the first two curves is proved by a call to `BadPrimes`, which finds that 19 and 23 are ramified primes for the first curve and 23 and 71 are ramified primes for the second.

```
> BadPrimes(C1);
[ 19, 23 ]
> BadPrimes(C2);
[ 23, 71 ]
> BadPrimes(C3);
[]
```

The fact that there are no ramified primes for the third curve is equivalent to a `true` return value from the function `HasRationalPoint`. As we will see in Section 119.6, an alternative approach which is guaranteed to find points on the third curve would be to construct a rational parametrisation.

119.5.2 Point Reduction

If a conic $C/\mathbf{Q}$ in Legendre form $ax^2 + by^2 + cz^2 = 0$ has a point, then Holzer's theorem tells us that there exists a point $(x : y : z)$ satisfying

$$|x| \leq \sqrt{|bc|}, \quad |y| \leq \sqrt{|ac|}, \quad |z| \leq \sqrt{|ab|},$$

with x, y, and z in $\mathbf{Z}$, or equivalently $\max(|ax^2|, |by^2|, |cz^2|) \leq |abc|$. Such a point is said to be Holzer-reduced. There exist constructive algorithms to find a Holzer-reduced point from a given one; the current MAGMA implementation uses a variant of Mordell's reduction due to Cremona [CR03].

`IsReduced(p)`

Returns `true` if and only if the projective point p on a conic in reduced Legendre form satisfies Holzer's bounds. If the curve is not a reduced Legendre model then the test is done after passing to this model.

`Reduction(p)`

Returns a Holzer-reduced point derived from p.

Example H119E8

We provide a tiny example to illustrate reduction and reduction testing on conics.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(), 2);
> C1 := Conic(P2, x^2 + 3*x*y + 2*y^2 - 2*z^2);
> p := C1![0, 1, 1];
> IsReduced(p);
false
```

The fact that this point is not reduced is due to the size of the coefficients on the reduced Legendre model.

```
> C0, m := ReducedLegendreModel(C1);
> C0;
Conic over Rational Field defined by
X^2 - Y^2 - 2*Z^2
> m(p);
(3/2 : 1/2 : 1)
> IsReduced(m(p));
false
> Reduction(m(p));
(-1 : 1 : 0)
> Reduction(m(p)) @@ m;
(-2 : 1 : 0)
> IsReduced($1);
true
```

Example H119E9

In this example we illustrate the intrinsics which apply to finding points on conics.

```
> P2<x,y,z> := ProjectiveSpace(RationalField(), 2);
> f := 9220*x^2 + 97821*x*y + 498122*y^2 + 8007887*y*z - 3773857*z^2;
> C := Conic(P2, f);
```

We will now see that C has a reduced solution; indeed, we find two different reduced solutions. For comparison we also find a non-reduced solution.

```
> HasRationalPoint(C);
true (157010/741 : -19213/741 : 1)
> p := RationalPoint(C);
> p;
(157010/741 : -19213/741 : 1)
> IsReduced(p);
true
> q := Random(C : Reduce := true);
> q;
(-221060094911776/6522127367379 : -49731359955013/6522127367379 : 1)
> IsReduced(q);
true
```

```
> q := Random(C : Bound := 10^5);
> q;
(4457174194952129/84200926607090 : -1038901067062816/42100463303545 : 1)
> IsReduced(q);
false
> Reduction(q);
(-221060094911776/6522127367379 : -49731359955013/6522127367379 : 1)
```

To make a parametrisation of C one can use the intrinsic `Parametrization` to create a map of schemes from a line to C.

```
> phi := Parametrization(C);
> P1<u,v> := Domain(phi);
> q0 := P1![0, 1];  q1 := P1![1, 1];  q2 := P1![1, 0];
> phi(q0);
(7946776/559407 : -21332771/1118814 : 1)
> phi(q1);
(26443817/1154900 : -5909829/288725 : 1)
> phi(q2);
(157010/741 : -19213/741 : 1)
> C1, psi := ReducedLegendreModel(C);
> psi(phi(q0));
(-1793715893111/4475256 : -22556441171843029/4475256 : 1)
> p0 := Reduction($1);
> p0;
(1015829527/2964 : -59688728328467/2964 : 1)
> IsReduced(p0);
true
> p0 @@ psi;
(157010/741 : -19213/741 : 1)
```

119.6 Isomorphisms

119.6.1 Isomorphisms with Standard Models

In this section we discuss isomorphisms between heterogeneous types — isomorphisms between combinations of curves of type `Crv`, `CrvCon`, and `CrvRat`, and their parametrisations by a projective line.

The first function which we treat here is `Conic`, which is as much a constructor as an isomorphism. It takes an arbitrary genus zero curve C and uses the anti-canonical divisor $-K_C$ of degree 2 to construct the Riemann–Roch space. For a genus zero curve this is a dimension 3 space of degree 2 functions and gives a projective embedding of C in $\mathbf{P}^2$ as a conic. This provides the starting point to make any genus zero curve amenable to the powerful machinery for point finding and isomorphism classification of conics.

An isomorphism — provided that one exists — of the projective line with a conic can be described as follows. The 2-uple embedding $\phi : \mathbf{P}^1 \to \mathbf{P}^2$ defined by $(u : v) \mapsto (u^2 : uv : v^2)$

gives an isomorphism of $\mathbf{P}^1$ with the conic C_0 with defining equation $y^2 = xz$. The inverse isomorphism $C_0 \to \mathbf{P}^1$ is defined by the maps

$$(x : y : z) \mapsto (x : y) \text{ on } x \neq 0,$$
$$(x : y : z) \mapsto (y : z) \text{ on } z \neq 0,$$

respectively. Since these open sets cover the conic C_0 this defines an isomorphism and not just a birational map. In order to describe an isomorphism of a conic C_1 with $\mathbf{P}^1$ it is then necessary and sufficient to give a change of variables which maps $C_0 = \phi(\mathbf{P}^1)$ onto the conic C_1. This matrix is called the *parametrisation matrix* and is stored with C_1 once a rational point is found.

`Conic(C)`

Given a curve of genus zero, returns a conic determined by the anti-canonical embedding of C.

Example H119E10

We demonstrate the function `Conic` on the curve of Example H119E2 to find a conic model, even though we know that it admits a rational parametrisation.

```
> P2<x,y,z> := ProjectivePlane(FiniteField(71));
> C0 := Curve(P2, (x^3 + y^2*z)^2 - x^5*z);
> C1, m := Conic(C0);
> C1;
Conic over GF(71) defined by
x^2 + 70*x*z + y^2
> m : Minimal;
(x : y : z) -> (x^3*y*z : 70*x^5 + x^4*z + 70*x^2*y^2*z : x^3*y*z + y^3*z^2)
```

`ParametrizationMatrix(C)`

This function is an optimised routine for parametrising a conic C defined over $\mathbf{Z}$ or $\mathbf{Q}$. It returns a 3×3 matrix M which defines a parametrisation of C as a projective change of variables from the 2-uple embedding of a projective line in the projective plane; i.e., for a point $(x_0 : y_0 : z_0)$ on C, the point

$$(x_1 : y_1 : z_1) = (x_0 : y_0 : z_0)M$$

satisfies the equation $y_1^2 = x_1 z_1$. Note that as usual in MAGMA the action of M is on the right and, consistently, the action of scheme maps is also on the right.

Example H119E11

In this example we demonstrate that the parametrisation matrix determines the precise change of variables to transform the conic equation into the equation $y^2 = xz$. We begin with a singular plane curve C_0 of genus zero and construct a nonsingular conic model in the plane.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(), 2);
> C0 := Curve(P2, (x^3 + y^2*z)^2 - x^5*z);
> C1, m := Conic(C0);
> C1;
Conic over Rational Field defined by
x^2 - x*z + y^2
```

The curve C_1 has obvious points, such as $(1 : 0 : 1)$, which MAGMA internally verifies without requiring an explicit user call to `HasRationalPoint`.

```
> ParametrizationMatrix(C1);
[1 0 1]
[0 1 0]
[0 0 1]
> Evaluate(DefiningPolynomial(C1), [x, y, x+z]);
-x*z + y^2
```

We note (as is standard in MAGMA) that the action of matrices, as with maps of schemes, is a right action on coordinates $(x : y : z)$.

`Parametrization(C)`

`Parametrization(C, P)`

`Parametrization(C, p)`

`Parametrization(C, p, P)`

Given a conic curve C over a general field, these functions return a parametrisation as an isomorphism of schemes $P \to C$. Here P is a copy of a projective line; it may be specified as one of the arguments or a new projective line will be created. Note that it is now required that P is given (or created) as a curve rather than as an ambient space (as used to be permitted). This allows the immediate use of pullback/push-forward functionality for the parametrisation map.

When a rational point or place is not specified as one of the arguments then the base field of C must be one of the kinds allowed in `HasRationalPoint`. If the conic has no rational points then an error results.

`ParametrizeOrdinaryCurve(C)`

`ParametrizeOrdinaryCurve(C, p)`

`ParametrizeOrdinaryCurve(C, p, I)`

`ParametrizeRationalNormalCurve(C)`

These functions are as above (see `Parametrization`), but use different algorithms.

When C is a plane curve with only ordinary singularities (see subsection 114.3.6) then a slightly different procedure is followed that relies less on the general function field machinery and tends to be faster and can produce nicer parametrisations. The variants `ParametrizeOrdinaryCurve` allow direct calls to these more specialised procedures. The I argument is the adjoint ideal of C (*loc. cit.*), which may be passed in if already computed.

The final function listed is slightly different; it applies only to rational normal curves. i.e., non-singular rational curves of degree d in ordinary d-dimensional projective space for $d \geq 1$. For the sake of speed the irreducibility of C is not checked. The function uses adjoint maps to find either a line or conic parametrisation of C: If d is odd then an isomorphism from the projective line to C is returned, and if d is even then an isomorphism from a plane conic is returned. The method uses no function field machinery and can be much faster than the general function.

Example H119E12

In this example we show how to parametrise a projective rational curve with a map from the one-dimensional projective space. First we construct a singular plane curve and verify that it has geometric genus zero.

```
> k := FiniteField(101);
> P2<x,y,z> := ProjectiveSpace(k, 2);
> f := x^7 + 3*x^3*y^2*z^2 + 5*y^4*z^3;
> C := Curve(P2, f);
> Genus(C);
0
```

In order to parametrise the curve C we need to find a nonsingular point on it, or at least a point of C over which there exists a unique degree one place; geometrically, such a point is one at which C has a cusp. To find such a point we invoke the intrinsic `RationalPoints` on C; since C is defined over a finite field this call returns an indexed set of all the points of C that are rational over its base field.
Having done the previous in the background, we demonstrate that the particular point $(2 : 33 : 1)$ is such a nonsingular rational point.

```
> p := C![2,33,1];
> p;
(2 : 33 : 1)
> IsNonsingular(C, p);
```

```
true
```

The parametrisation function takes a projective line as the third argument; this will be used as the domain of the parametrisation map.

```
> P1<u,v> := ProjectiveSpace(k, 1);
> phi := Parametrization(C, Place(p), Curve(P1));
> phi;
Mapping from: Prj: P1 to Prj: P2
with equations :
2*u^7 + 5*u^6*v + 81*u^5*v^2 + 80*u^4*v^3 + 13*u^3*v^4
33*u^7 + 88*u^6*v + 90*u^5*v^2 + 73*u^4*v^3 + 25*u^3*v^4 +
    83*u^2*v^5 + 72*u*v^6 + 24*v^7
u^7
```

Finally we confirm that the map really does parametrise the curve C. Note that the map is normalised so that the point at infinity on the projective line P_1 maps to the prescribed point p.

```
> Image(phi);
Scheme over GF(101) defined by
x^7 + 3*x^3*y^2*z^2 + 5*y^4*z^3
> Image(phi) eq C;
false
> DefiningIdeal(Image(phi)) eq DefiningIdeal(C);
true
> phi(P1![1, 0]);
(2 : 33 : 1)
```

119.7 Automorphisms

119.7.1 Automorphisms of Rational Curves

Automorphisms of the projective line $\mathbf{P}^1$ are well-known to be 3-transitive — for any three distinct points p_0, p_1, and p_∞, there exists an automorphism taking $0 = (0 : 1)$, $1 = (1 : 1)$, and $\infty = (1 : 0)$ to p_0, p_1, and p_∞. Conversely, the images of 0, 1, and ∞ uniquely characterise an automorphism. We use this characterisation of isomorphisms to define automorphisms of rational curves as bijections of three element sequences of points over the base ring.

`Automorphism(C, S, T)`

Given a rational curve C and two indexed sets $S = \{p_0, p_1, p_\infty\}$ and $T = \{q_0, q_1, q_\infty\}$, each of distinct points over the base ring of C, returns the unique automorphism of C taking p_0, p_1, p_∞ to q_0, q_1, q_∞.

119.7.2 Automorphisms of Conics

The automorphism group of a conic, and indeed the conics themselves, have a special relationship with quaternion algebras (see Lam [Lam73] or Vignéras [Vig80]). For the sake of exposition we focus on conics C/K defined by a Legendre equation

$$ax^2 + by^2 + cz^2 = 0$$

where $abc \neq 0$. We define a quaternion algebra A over K with anticommuting generators i, j, and $k = c^{-1}ij$ satisfying relations

$$i^2 = -bc, \quad j^2 = -ac, \quad k^2 = -ab,$$

and setting $I = ai$, $J = bj$, and $K = ck$. Then for any extension L/K we may identify the ambient projective pointset $\mathbf{P}^2(L)$ with the projectivisation of the trace zero part

$$A_L^0 = \{\alpha \in A_L \mid \mathrm{Tr}(\alpha) = 0\} = LI + LJ + LK$$

of the quaternion algebra $A_L = A \otimes_K L$ via $(x : y : z) \mapsto xI + yJ + zK$. Under this map, the pointsets $C(L)$ are identified with the norm zero elements

$$\mathrm{N}(xI + yJ + zK) = abc(ax^2 + by^2 + cz^2) = 0$$

in $\mathbf{P}^2(L)$. This allows us to identify the automorphism group $\mathrm{Aut}_K(C)$ with the quotient unit group A^*/K^* acting on each A_L^0 by conjugation.

In the MAGMA implementation of this correspondence, the quaternion algebra A is computed and stored as an attribute of the curve C. Automorphisms of C can be created from any invertible element of the quaternion algebra. We note that the isomorphism of two conics is equivalent to the isomorphism of their quaternion algebras, and that a rational parametrisation of a conic is equivalent to an isomorphism $A \cong \mathrm{M}_2(K)$.

We note that while the advanced features of finding rational points (and hence finding parametrisations) and determining isomorphism only exist over $\mathbf{Q}$, it is possible to represent the automorphism group and find automorphisms of the curve independently of these other problems. The current implementation works only in characteristic different from 2, as otherwise a Legendre model does not exist.

`QuaternionAlgebra(C)`

Returns the quaternion algebra in which automorphisms of the conic C can be represented.

`Automorphism(C, a)`

Given a conic C and a unit a of the quaternion algebra associated to C, returns the automorphism of C corresponding to a.

Example H119E13

In this example we demonstrate how to use the quaternion algebra of a conic to construct nontrivial automorphisms of the curve when no rational points exist over the base ring. (We use the printing level `Minimal` to produce human readable output for scheme maps.)

```
> P2<x,y,z> := ProjectiveSpace(Rationals(), 2);
> C0 := Conic(P2, 2*x^2 + x*y + 5*y^2 - 37*z^2);
> HasRationalPoint(C0);
false
> BadPrimes(C0);
[ 3, 37 ]
> A := QuaternionAlgebra(C0);
> RamifiedPrimes(A);
[ 3, 37 ]
> B := Basis(MaximalOrder(A));
> B;
[ 1, 1/52*i + 1/4*j + 2/481*k, j, 1/2 + 1/148*k ]
> m1 := Automorphism(C0, A!B[2]);
> m1 : Minimal;
(x : y : z) -> (-5/8*x + 259/48*y - 37/3*z : 37/12*x + 69/8*y - 74/3*z :
    x + 7/2*y - 61/6*z)
> m2 := Automorphism(C0, A!B[3]);
> m2 : Minimal;
(x : y : z) -> (x + 1/2*y : -y : z)
> m3 := Automorphism(C0, A!B[4]);
> m3 : Minimal;
(x : y : z) -> (-x - 1/2*y : 1/5*x - 9/10*y : z)
> [ Trace(B[2]), Trace(B[3]), Trace(B[4]) ];
[ 0, 0, 1 ]
> m1 * m1 : Minimal;
(x : y : z) -> (x : y : z)
> m2 * m2 : Minimal;
(x : y : z) -> (x : y : z)
> m3 * m3 : Minimal;
(x : y : z) -> (9/10*x + 19/20*y : -19/50*x + 71/100*y : z)
```

The last example points out that *pure* quaternions τ in A_0 give rise to involutions — a reflection of the projective plane about the point defined by τ in $\mathbf{P}^2(K)$.

One of the strengths of the scheme model in Magma is the ability to work with points of a curve over any extension. Provided that we have a rational point over some extension field L/K, we are able to apply automorphisms of the curve to generate an unbounded number of new points over that extension by means of the action of the automorphism group. We demonstrate this by looking at quadratic twists of the curve to find a point over $\mathbf{Q}$, which identifies a point on the original curve over a quadratic extension.

```
> C1 := Conic(P2, 2*x^2 + x*y + 5*y^2 - z^2);
> HasRationalPoint(C1);
false
```

```
> C2 := Conic(P2, 2*x^2 + x*y + 5*y^2 - 2*z^2);
> HasRationalPoint(C2);
true
> RationalPoint(C2);
(-1 : 0 : 1)
```

This gives rise to the obvious points $(\pm 1 : 0 : \sqrt{74}/37)$ on the original curve.

```
> P<t> := PolynomialRing(RationalField());
> L<a> := NumberField(t^2 - 74);
> p := C0(L)![1, 0, a/37];
> m1(p);
(1/1880*(207*a + 3034) : 1/940*(-37*a + 2146) : 1)
> m2(p);
(1/2*a : 0 : 1)
> m3(p);
(-1/2*a : 1/10*a : 1)
```

We could alternatively have formed the base extension of the curve to the new field L and used the known point over L to find a parametrisation of the curve by the projective line. This approach demonstrates that it is possible to work with points and curve automorphisms without passing to a new curve.

120 ELLIPTIC CURVES

Chapter 120
ELLIPTIC CURVES

120.1 Introduction

This chapter describes features for working with elliptic curves in MAGMA. It contains basic functionality that is applicable to curves over fairly general fields. There are separate chapters describing features that are specific to

- curves over finite fields (Chapter 121),
- curves over the rationals or number fields (Chapter 122),
- curves over univariate function fields (Chapter 123).

An elliptic curve E is the projective closure of the curve given by the generalised Weierstrass equation

$$y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6.$$

The curve is specified by the sequence of coefficients $[a_1, a_2, a_3, a_4, a_6]$; the two element sequence $[a_4, a_6]$ may be used instead when $a_1 = a_2 = a_3 = 0$.

Elliptic curve functionality covers both elementary invariants of curves and arithmetic in the group of rational points, as well as higher level features for computing local invariants, heights, and Mordell–Weil groups for curves over $\mathbf{Q}$, and for point counting and the determination of the group structure over $\mathbf{F}_q$. The base ring of elliptic curves is currently restricted to fields. Curves over the rationals have special features to allow the construction of integral and minimal models, and for base change to finite fields, in acknowledgement of the integral structure over $\mathbf{Z}$ or $\mathbf{Z}_p$.

For curves over the rationals or over number fields there are routines for determining minimal models and an implementation of Tate's algorithm for determining Kodaira symbols and various local invariants. Algorithms for the computation of the Mordell–Weil group are heavily based on publications of John Cremona; see [Cre97] for details. There are also separate implementations of 2-descent for curves over number fields, and 3- and 4-descent for curves over the rationals. Additionally, several aspects of the analytic theory (including modular parametrisations and Heegner points) are implemented for curves over the rationals.

Elliptic curves are specialised forms of the more general curve and scheme types, and as such all functions which apply to these general types work on elliptic curves (although a few of them behave differently for elliptic curves). Some of these functions are described here, but not all of them — refer to chapters 112 (Schemes) and 114 (Curves) for descriptions of these functions, as well as an explanation of the relationships between points, point sets, and schemes. In particular, note that the parent of a point is a point set, and *not* the curve.

The name of the category of elliptic curves is `CrvEll`, with points of type `PtEll` lying in point sets of type `SetPtEll`. There is also the category `SchGrpEll` for subgroup schemes of elliptic curves, and a special category `SymKod` exists for the datatype of Kodaira symbols, which classify the local structure of the special fibre at p of the Néron model of an elliptic curve $E/\mathbf{Q}$.

This chapter, the first of four on elliptic curves, contains a treatment of the basics for curves over general fields: their construction, their arithmetic, and their basic properties. Specialised machinery provided for elliptic curves over finite fields is described in Chapter 121; Chapter 122 presents the wide range of techniques available for determining information about the group of rational points for curves over $\mathbf{Q}$ and over number fields, while elliptic curves over function fields are discussed in Chapter 123.

120.2 Creation Functions

120.2.1 Creation of an Elliptic Curve

An elliptic curve E may be created by specifying Weierstrass coordinates for the curve over a field K, where integer coordinates are interpreted as elements of $\mathbf{Q}$. Note that the coordinate ring K defines the base point set of E, and points defined over an extension field of K must be created in the appropriate point set.

`EllipticCurve([a, b])`

`EllipticCurve([a1, a2, a3, a4, a6])`

Given a sequence of elements of a ring K, this function creates the elliptic curve E over K defined by taking the elements of the sequence as Weierstrass coefficients. The length of the sequence must either be two, that is $s = [a, b]$, in which case E is defined by $y^2 = x^3 + ax + b$, or five, that is $s = [a_1, a_2, a_3, a_4, a_6]$, in which case E is given by $y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6$. Currently K must be field; if integers are given then they will be coerced into $\mathbf{Q}$. The given coefficients must define a nonsingular curve; that is, the discriminant of the curve must be nonzero.

`EllipticCurve(f)`

`EllipticCurve(f, h)`

Given univariate polynomials f and h, this function creates the elliptic curve defined by $y^2 + h(x)y = f(x)$, or by $y^2 = f(x)$ if h is not given. The polynomial f must be monic of degree 3 and h must have degree at most 1.

`EllipticCurveFromjInvariant(j)`

`EllipticCurveWithjInvariant(j)`

Given a ring element j, this function creates an elliptic curve E over K with j-invariant equal to j defined as follows: If $j = 0$ and K does not have characteristic 3 then E is defined by $y^2 + y = x^3$; if $j = 1728$ then E is defined by $y^2 = x^3 + x$ (which covers the case where $j = 0$ and K has characteristic 3); otherwise $j - 1728$ is invertible in K and E is defined by $y^2 + xy = x^3 - (36/(j - 1728))x - 1/(j - 1728)$.

Example H120E1

We create one particular elliptic curve over **Q** in three different ways:

```
> EllipticCurve([1, 0]);
Elliptic Curve defined by y^2 = x^3 + x over Rational Field
> Qx<x> := PolynomialRing(Rationals());
> EllipticCurve(x^3 + x);
Elliptic Curve defined by y^2 = x^3 + x over Rational Field
> EllipticCurveWithjInvariant(1728);
Elliptic Curve defined by y^2 = x^3 + x over Rational Field
```

`EllipticCurve(C)`

Verbose `EllModel` *Maximum :* 3

Given a scheme C describing a curve of genus 1 with an easily recognised rational point, this function returns an elliptic curve E together with a birational map from C to E. If there is no "obvious" rational point then this routine will fail. C must belong to one of the following classes:

(i) Hyperelliptic curves of genus 1 of the form

$$C : y^2 + h(x)y = f(x)$$

with f of degree 3 or 4 and h of degree at most 1. If the function x on C has a rational branch point then that point is sent to the origin on E. Otherwise, if C has a rational point at $x = \infty$ then that point is used.

(ii) Nonsingular plane curves of degree 3. If the curve is already in general Weierstrass form up to a permutation of the variables then this is recognised and used as a model for the elliptic curve. Otherwise the base field of the curve must have characteristic different from 2 and 3; in this case, the curve is tested for having a rational flex. If it has then a linear transformation suffices to get the curve into general Weierstrass form, and this is used.

(iii) Singular plane curves of degree 4 over a base field of characteristic different from 2 with a unique cusp, with the tangent cone meeting the curve only at that point. Up to linear transformation, these are curves of type

$$y^2 = f(x),$$

with f of degree 4. Such curves are brought into the standard form above. If either a rational point exists with $x = 0$ or the curve intersects the line at infinity in a rational point then that point is used to put the curve in general Weierstrass form.

`EllipticCurve(C, P)`

Verbose `EllModel` *Maximum :* 3

Given a scheme C describing a curve of genus 1 with a nonsingular rational point P, this function returns an elliptic curve E together with a birational map sending the supplied point to the origin on E.

If C is a plane curve of degree 3 over a base field having characteristic different from 2 and 3 then particular tricks are tried. If the supplied point is a flex then a linear transformation is used. Otherwise, Nagell's algorithm [Nag28], also described in [Cas91], is used.

If C is a plane curve of degree 4 over a base field of characteristic different from 2 with a unique cusp and a tangent cone that meets the curve only in that cusp, then a construction in [Cas91] is used.

In all other cases, C has to be a plane curve and a Riemann–Roch computation is used. This is potentially very expensive.

`EllipticCurve(C, pl)`

Verbose `EllModel` *Maximum :* 3

Given a plane curve C of genus 1 and a place pl of degree 1, this function returns an elliptic curve E together with a birational map from C to E.

This routine uses a (potentially expensive) Riemann–Roch computation. This is different to the routine that takes a point instead of a place, which uses special methods when the curve has degree 3 or 4.

`SupersingularEllipticCurve(K)`

Given a finite field K, this function returns a representative supersingular elliptic curve over K.

Example H120E2

In the following example Nagell's algorithm is applied.

```
> P2<X, Y, Z> := ProjectiveSpace(Rationals(), 2);
> C := Curve(P2, X^3 + Y^2*Z - X*Y*Z - Z^3);
> pt := C![0, 1, 1];
> time E1, phi1 := EllipticCurve(C, pt);
Time: 0.070
> E1;
Elliptic Curve defined by y^2 = x^3 - 5/16*x^2 + 1/32*x + 15/1024 over Rational
Field
```

Whereas this next call (given a place) is forced to do the Riemann–Roch computation.

```
> time E2, phi2 := EllipticCurve(C, Place(pt));
Time: 0.120
> E2;
Elliptic Curve defined by y^2 + 1024*y = x^3 + 16*x^2 over Rational Field
```

```
> phi1;
Mapping from: CrvPln: C to CrvEll: E1
with equations :
9/8*X^2 - 1/4*X*Y
-1/8*X^2 + 1/4*X*Y + 13/16*X*Z - 1/8*Y*Z - 1/8*Z^2
X^2 - 2*X*Y + 2*X*Z
and inverse
$.1^2 - 3/16*$.1*$.3 + 1/128*$.3^2
1/2*$.1^2 + $.1*$.2 - 15/32*$.1*$.3 + 9/256*$.3^2
$.1*$.2 + 1/8*$.1*$.3 - 1/8*$.2*$.3 - 1/64*$.3^2
> phi2;
Mapping from: CrvPln: C to CrvEll: E2
with equations :
-64*X^2*Y + 64*X^2*Z - 128*X*Y^2 + 256*X*Y*Z - 128*X*Z^2 + 64*Y^2*Z - 64*Y*Z^2
256*X^2*Y + 256*X^2*Z + 1024*X*Y*Z - 1024*X*Z^2 + 1792*Y^2*Z - 4352*Y*Z^2 +
    2048*Z^3
Y^3 - 3*Y^2*Z + 3*Y*Z^2 - Z^3
```

Example H120E3

In this example the starting curve is less clearly elliptic. Since this curve does not match any of the special forms described the Riemann–Roch computation will be used.

```
> P2<X, Y, Z> := ProjectiveSpace(Rationals(), 2);
> C := Curve(P2, X^3*Y^2 + X^3*Z^2 - Z^5);
> Genus(C);
1
> pt := C![1, 0, 1];
> E, toE := EllipticCurve(C, pt);
> E;
Elliptic Curve defined by y^2 = x^3 + 3*x^2 + 3*x over Rational Field
> toE;
Mapping from: CrvPln: C to CrvEll: E
```

120.2.2 Creation Predicates

`IsEllipticCurve([a, b])`

`IsEllipticCurve([a1, a2, a3, a4, a6])`

The function returns `true` if the given sequence of ring elements defines an elliptic curve (in other words, if the discriminant is nonzero). When true, the elliptic curve is also returned.

`IsEllipticCurve(C)`

Given a hyperelliptic curve, the function returns `true` if C has degree 3. When true, the function also returns the elliptic curve, and isomorphisms to and from it. This function is deprecated and will be removed in a later release. Instead, use `Degree(C) eq 3` and `EllipticCurve(C)`.

Example H120E4

We check a few small primes to see which ones make certain coefficients define an elliptic curve.

```
> S := [ p : p in [1..20] | IsPrime(p) ];
> for p in S do
>     ok, E := IsEllipticCurve([GF(p) | 1, 1, 0, -3, -17 ]);
>     if ok then print E; end if;
> end for;
Elliptic Curve defined by y^2 + x*y = x^3 + x^2 + 1 over GF(3)
Elliptic Curve defined by y^2 + x*y = x^3 + x^2 + 10*x + 9 over GF(13)
Elliptic Curve defined by y^2 + x*y = x^3 + x^2 + 14*x over GF(17)
```

120.2.3 Changing the Base Ring

The following general scheme functions provide a convenient way to generate a new elliptic curve similar to an old one but defined over a different field. Some care must be taken, however: If the result is not a valid elliptic curve then the functions will still succeed but the object returned will be a general curve rather than an elliptic curve.

`BaseChange(E, K)`

`BaseExtend(E, K)`

Given an elliptic curve E defined over a field k, and a field K which is an extension of k, returns an elliptic curve E' over K using the natural inclusion of k in K to map the coefficients of E into K.

`ChangeRing(E, K)`

Given an elliptic curve E defined over a field k, and a field K, returns an elliptic curve E' over K by using the standard coercion from k to K to map the coefficients of E into K. This is useful when there is no appropriate ring homomorphism between k and K (e.g., when $k = \mathbf{Q}$ and K is a finite field).

`BaseChange(E, h)`

`BaseExtend(E, h)`

Given an elliptic curve E over a field k and a ring map $h : k \to K$, returns an elliptic curve E' over K by applying h to the coefficients of E.

`BaseChange(E, n)`

`BaseExtend(E, n)`

Given an elliptic curve E defined over a finite field K, returns the base extension of E to the degree n extension of K.

Example H120E5

```
> K1 := GF(23);
> K2 := GF(23, 2);
> f := hom<K1 -> K2 | >;
> E1 := EllipticCurve([K1 | 1, 1]);
> E2 := EllipticCurve([K2 | 1, 1]);
> assert E2 eq BaseExtend(E1, K2);
> assert E2 eq BaseExtend(E1, f);
> assert E2 eq BaseExtend(E1, 2);
> // this is illegal, since K1 is not an extension of K2
> BaseExtend(E2, K1);

>> BaseExtend(E2, K1);
              ^
Runtime error in 'BaseExtend': Coercion of equations is not possible
> assert E1 eq ChangeRing(E2, K1);  // but this is OK
```

120.2.4 Alternative Models

Given an elliptic curve E, there are standard alternative models for E that may be of interest. Each of the functions in this section returns an isomorphic curve E' that is the desired model, together with the isomorphisms $E \to E'$ and $E' \to E$.

Note: The second isomorphism is now completely redundant as it is the inverse of the first; in a later release only the first will be returned.

`WeierstrassModel(E)`

Given an elliptic curve E, this function returns an isomorphic elliptic curve E' in simplified Weierstrass form $y^2 = x^3 + ax + b$. It does not apply when the base ring of E has characteristic 2 or 3 (in which case such a simplified form may not exist).

`IntegralModel(E)`

Given an elliptic curve E defined over a number field K (which may be $\mathbf{Q}$), this function returns an isomorphic elliptic curve E' defined over K with integral coefficients.

`SimplifiedModel(E)`

A simplified model of the elliptic curve E is returned. If E is defined over $\mathbf{Q}$ this has the same effect as `MinimalModel` below. Otherwise, if the characteristic of the base ring is different from 2 and 3, the simplified model agrees with the `WeierstrassModel`. For characteristics 2 and 3 the situation is more complicated; see chapter 4 of [Con99] for the definition for curves defined over finite fields.

`MinimalModel(E)`

Given an elliptic curve E defined over $\mathbf{Q}$ or a number field K with class number one, returns a global minimal model E' for E. By definition, the global minimal model E' is an integral model isomorphic to E over K such that the discriminant of E' has minimal valuation at all non-zero prime ideals π of K. (For $\mathbf{Q}$, this means that it has minimal p-adic valuation at all primes p.)

Such a global minimal model is only guaranteed to exist when the class number of K is 1 (and so one always exists when $K = \mathbf{Q}$); depending on the curve, however, such a model may exist even when this is not the case. If no such minimal model exists then a runtime error will occur.

`MinimalModel(E, p)`

`MinimalModel(E, P : parameters)`

`UseGeneratorAsUniformiser` BoolElt *Default :* `false`

Given an elliptic curve E defined over a number field K, and a prime ideal P, returns a curve isomorphic to E which is minimal at P. If K is $\mathbf{Q}$ then the ideal may be specified by the appropriate (integer) prime p.

For curves over number fields, when the parameter `UseGeneratorAsUniformiser` is set to `true` then Magma will check whether the ideal is principal; if so, an ideal generator will be used as the uniformising element. This means that at other primes the returned model will remain integral, or minimal, if the given model was.

120.2.5 Predicates on Curve Models

`IsWeierstrassModel(E)`

Returns `true` if and only if the elliptic curve E is in simplified Weierstrass form.

`IsIntegralModel(E)`

Returns `true` if and only if the elliptic curve E is an integral model.

`IsSimplifiedModel(E)`

Returns `true` if and only if the elliptic curve E is a simplified model.

`IsMinimalModel(E)`

Returns `true` if and only if the elliptic curve E is a minimal model.

`IsIntegralModel(E, P)`

Returns `true` if the defining coefficients of the elliptic curve E, a curve over a number field, have non-negative valuation at the prime ideal P, which must be an ideal of an order of the coefficient ring of E.

Example H120E6

We define an elliptic curve over the rationals and then find an integral model, a minimal model, and an integral model for the short Weierstrass form.

```
> E := EllipticCurve([1/2, 1/2, 1, 1/3, 4]);
> E;
Elliptic Curve defined by y^2 + 1/2*x*y + y = x^3 + 1/2*x^2 + 1/3*x + 4
over Rational Field
> IE := IntegralModel(E);
> IE;
Elliptic Curve defined by y^2 + 3*x*y + 216*y = x^3 + 18*x^2 + 432*x +
186624 over Rational Field
> ME := MinimalModel(IE);
> ME;
Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 + 619*x + 193645
over Rational Field
> WE := WeierstrassModel(E);
> WE;
Elliptic Curve defined by y^2 = x^3 + 9909/16*x + 6201603/32 over
Rational Field
> IWE := IntegralModel(WE);
> IWE;
Elliptic Curve defined by y^2 = x^3 + 649396224*x + 208091266154496
over Rational Field
> IsIsomorphic(IWE, ME);
true
```

120.2.6 Twists of Elliptic Curves

In the following, all twists will be returned in the form of simplified models.

`QuadraticTwist(E, d)`

Given an elliptic curve E and an element d of the base ring, returns the quadratic twist by d. This is isomorphic to E if and only if either the characteristic is 2 and the trace of d is 0, or the characteristic is not 2 and d is a square. The routine does not always work in characteristic 2.

`QuadraticTwist(E)`

Given an elliptic curve E over a finite field, returns a quadratic twist; that is, a nonisomorphic curve whose trace is the negation of `Trace(E)`.

`QuadraticTwists(E)`

Given an elliptic curve E over a finite field, returns the sequence of nonisomorphic quadratic twists. The first of these curves is isomorphic to E.

`Twists(E)`

Given an elliptic curve over a finite field K, returns the sequence of all nonisomorphic elliptic curves over K which are isomorphic over an extension field. The first of these curves is isomorphic to E.

Example H120E7

In this example we compute the quadratic twists of an elliptic curve over the finite field $\mathbf{F}_{13}$ and verify that they fall in two isomorphism classes over the base field.

```
> E1 := EllipticCurve([GF(13) | 3, 1]);
> E5 := QuadraticTwist(E1, 5);
> E5;
Elliptic Curve defined by y^2 = x^3 + 10*x + 8 over GF(13)
> S := QuadraticTwists(E1);
> S;
[
    Elliptic Curve defined by y^2 = x^3 + 3*x + 1 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 12*x + 5 over GF(13)
]
> [ IsIsomorphic(E1, E) : E in S ];
[ true, false ]
> [ IsIsomorphic(E5, E) : E in S ];
[ false, true ]
```

`IsTwist(E, F)`

Returns `true` if and only if the elliptic curves E and F are isomorphic over an extension field — this function only tests the j-invariants of the curves.

`IsQuadraticTwist(E, F)`

Returns `true` if and only if the elliptic curves E and F are isomorphic over a quadratic extension field; if so, returns an element d of the base field such that F is isomorphic to `QuadraticTwist(E, d)`.

Example H120E8

In this example we take curves of j-invariant 0 and $12^3 = 12$ over the finite field $\mathbf{F}_{13}$, and compute all twists. Since the automorphism groups are nontrivial the number of twists is larger than the number of quadratic twists. By computing the numbers of points we see that the curves are indeed pairwise nonisomorphic over the base field.

```
> E3 := EllipticCurve([GF(13) | 0, 1]);
> jInvariant(E3);
0
> E4 := EllipticCurve([GF(13) | 1, 0]);
> jInvariant(E4);
12
> T3 := Twists(E3);
> T3;
[
    Elliptic Curve defined by y^2 = x^3 + 1 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 2 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 4 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 8 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 3 over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 6 over GF(13)
]
> [ #E : E in T3 ];
[ 12, 19, 21, 16, 9, 7 ]
> T4 := Twists(E4);
> T4;
[
    Elliptic Curve defined by y^2 = x^3 + x over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 2*x over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 4*x over GF(13),
    Elliptic Curve defined by y^2 = x^3 + 8*x over GF(13)
]
> [ #E : E in T4 ];
[ 20, 10, 8, 18 ]
```

Observe that exactly two of the twists are quadratic twists (as must always be the case).

```
> [ IsQuadraticTwist(E3, E) : E in T3 ];
[ true, false, false, true, false, false ]
> [ IsQuadraticTwist(E4, E) : E in T4 ];
[ true, false, true, false ]
```

`MinimalQuadraticTwist(E)`

Determine the minimal twist of the rational elliptic curve E. This is defined locally prime-by-prime, and the algorithm for finding it is based on this observation. For each odd prime p of bad reduction the algorithm iteratively replaces the curve by its twist by p if the latter has smaller discriminant.

For $p = 2$ there is no accepted definition of minimal, and the prime at infinity also plays a role. After having handled all the odd primes there are only twists by -1, 2, and -2 left to consider. The algorithm implemented in MAGMA first chooses a twist with minimal 2-valuation of the conductor; this is unique precisely when this 2-valuation is less than 5. [Note that others have chosen instead to minimise the 2-valuation of Δ.]

The prime 2 can be eliminated at this point as was done in the case of the odd primes, leaving only the consideration of twisting the curve by -1. Here the algorithm arbitrarily chooses the curve that has $(-1)^{v_2(c_6)}\text{odd}(c_6)$ congruent to 3 mod 4. The function returns as its second argument the integer d by which the curve was twisted to obtain the minimal twist.

Example H120E9

```
> E:=EllipticCurve([0, 1, 0, 135641131, 1568699095683]);
> M, tw := MinimalQuadraticTwist(E);
> M, tw;
Elliptic Curve defined by y^2 + y = x^3 + x^2 + 3*x + 5 over Rational Field
7132
> MinimalModel(QuadraticTwist(M, tw));
Elliptic Curve defined by y^2 = x^3 + x^2 + 135641131*x + 1568699095683 over
Rational Field
```

120.3 Operations on Curves

120.3.1 Elementary Invariants

`aInvariants(E)`

`Coefficients(E)`

`ElementToSequence(E)`

`Eltseq(E)`

Given an elliptic curve E, this function returns a sequence consisting of the Weierstrass coefficients of E; this is the sequence $[a_1, a_2, a_3, a_4, a_6]$ such that E is defined by $y^2z + a_1xyz + a_3yz^2 = x^3 + a_2x^2z + a_4xz^2 + a_6z^3$. Note that this function returns the five coefficients even if E was defined by a sequence $[a, b]$ of length two (the first three coefficients are zero in such a case).

`bInvariants(E)`

This function returns a sequence of length 4 containing the b-invariants of the elliptic curve E, namely $[b_2, b_4, b_6, b_8]$. In terms of the coefficients of E these are defined by

$$\begin{aligned} b_2 &= a_1^2 + 4a_2 \\ b_4 &= a_1a_3 + 2a_4 \\ b_6 &= a_3^2 + 4a_6 \\ b_8 &= a_1^2a_6 + 4a_2a_6 - a_1a_3a_4 + a_2a_3^2 - a_4^2. \end{aligned}$$

`cInvariants(E)`

This function returns a sequence of length 2 containing the c-invariants of the elliptic curve E, namely $[c_4, c_6]$. In terms of the b-invariants of E these are defined by

$$\begin{aligned} c_4 &= b_2^2 - 24b_4 \\ c_6 &= -b_2^3 + 36b_2b_4 - 216b_6. \end{aligned}$$

`Discriminant(E)`

This function returns the discriminant Δ of the elliptic curve E. In terms of the b-invariants of E it is defined by

$$\Delta = -b_2^2b_8 - 8b_4^3 - 27b_6^2 + 9b_2b_4b_6$$

and there is also the relationship $1728\Delta = c_4^3 - c_6^2$.

`jInvariant(E)`

Return the j-invariant of the elliptic curve E. In terms of the c-invariants and the discriminant of E it is defined by $j = c_4^3/\Delta$. Two elliptic curves defined over the same base field are isomorphic over some extension field exactly when their j-invariants are equal.

`HyperellipticPolynomials(E)`

Returns polynomials $x^3 + a_2x^2 + a_4x + a_6$ and $a_1x + a_3$, formed from the invariants of the elliptic curve E.

Example H120E10

Here are a few simple uses of the above functions.

```
> E := EllipticCurve([0, -1, 1, 1, 0]);
> E;
Elliptic Curve defined by y^2 + y = x^3 - x^2 + x over Rational Field
> aInvariants(E);
[ 0, -1, 1, 1, 0 ]
> Discriminant(E);
```

```
-131
> c4, c6 := Explode(cInvariants(E));
> jInvariant(E) eq c4^3 / Discriminant(E);
true
```

Example H120E11

By constructing a generic elliptic curve we can see that the relationships described above hold.

```
> F<a1, a2, a3, a4, a6> := FunctionField(Rationals(), 5);
> E := EllipticCurve([a1, a2, a3, a4, a6]);
> E;
Elliptic Curve defined by y^2 + a1*x*y + a3*y = x^3 + a2*x^2 + a4*x + a6
over F
> aInvariants(E);
[
    a1,
    a2,
    a3,
    a4,
    a6
]
> bInvariants(E);
[
    a1^2 + 4*a2,
    a1*a3 + 2*a4,
    a3^2 + 4*a6,
    a1^2*a6 - a1*a3*a4 + a2*a3^2 + 4*a2*a6 - a4^2
]
> b2,b4,b6,b8 := Explode(bInvariants(E));
> cInvariants(E);
[
    a1^4 + 8*a1^2*a2 - 24*a1*a3 + 16*a2^2 - 48*a4,
    -a1^6 - 12*a1^4*a2 + 36*a1^3*a3 - 48*a1^2*a2^2 + 72*a1^2*a4 +
        144*a1*a2*a3 - 64*a2^3 + 288*a2*a4 - 216*a3^2 - 864*a6
]
> c4,c6 := Explode(cInvariants(E));
> c4 eq b2^2 - 24*b4;
true
> c6 eq -b2^3 + 36*b2*b4 - 216*b6;
true
> d := Discriminant(E);
> d;
-a1^6*a6 + a1^5*a3*a4 - a1^4*a2*a3^2 - 12*a1^4*a2*a6 + a1^4*a4^2 +
    8*a1^3*a2*a3*a4 + a1^3*a3^3 + 36*a1^3*a3*a6 - 8*a1^2*a2^2*a3^2 -
    48*a1^2*a2^2*a6 + 8*a1^2*a2*a4^2 - 30*a1^2*a3^2*a4 + 72*a1^2*a4*a6 +
    16*a1*a2^2*a3*a4 + 36*a1*a2*a3^3 + 144*a1*a2*a3*a6 - 96*a1*a3*a4^2 -
    16*a2^3*a3^2 - 64*a2^3*a6 + 16*a2^2*a4^2 + 72*a2*a3^2*a4 +
```

```
    288*a2*a4*a6 - 27*a3^4 - 216*a3^2*a6 - 64*a4^3 - 432*a6^2
> d eq -b2^2*b8 - 8*b4^3 - 27*b6^2 + 9*b2*b4*b6;
true
> 1728*d eq c4^3 - c6^2;
true
```

120.3.2 Associated Structures

`Category(E)` `Type(E)`

Returns the category of elliptic curves, `CrvEll`.

`BaseRing(E)` `CoefficientRing(E)`

The base ring of the elliptic curve E; that is, the parent of its coefficients and the coefficient ring of the default point set of E.

120.3.3 Predicates on Elliptic Curves

`E eq F`

Returns `true` if and only if the elliptic curves E and F are defined over the same ring and have the same coefficients.

`E ne F`

The logical negation of `eq`.

`IsIsomorphic(E, F)`

Given two elliptic curves E and F this function returns `true` if there exists an isomorphism between E and F over the base field, and `false` otherwise. If E and F are isomorphic then the isomorphism is returned as a second value. This function requires being able to take roots in the base field.

`IsIsogenous(E, F)`

Given two elliptic curves E and F defined over the rationals or a finite field, this function returns `true` if the curves E and F are isogenous over this field and `false` otherwise. In the rational case, if the curves are isogenous then the isogeny will be returned as the second value. For finite fields the isogeny computation operates via point counting and thus no isogeny is returned.

Example H120E12

We return to the curves in the earlier quadratic twist example. By definition, these curves are not isomorphic over their base field, but are isomorphic over a quadratic extension.

```
> K := GF(13);
> E := EllipticCurve([K | 3, 1]);
> E5 := QuadraticTwist(E, 5);
> IsIsomorphic(E, E5);
false
> IsIsomorphic(BaseExtend(E, 2), BaseExtend(E5, 2));
true
```

Since they are isomorphic over an extension, their j-invariants must be the same.

```
> jInvariant(E) eq jInvariant(E5);
true
```

120.4 Polynomials

The *torsion* or *division* polynomials are the polynomials defining the subschemes of n-torsion points on the elliptic curve.

`DefiningPolynomial(E)`

Returns the homogeneous defining polynomial for the elliptic curve E.

`DivisionPolynomial(E, n)`

`DivisionPolynomial(E, n, g)`

Given an elliptic curve E and an integer n, returns the n-th division polynomial as a univariate polynomial over the base ring of E. If n is even this polynomial has multiplicity two at the nonzero 2-torsion points of the curve. The second return value is the n-th division polynomial, divided by the univariate 2-torsion polynomial if n is even. The third argument is the cofactor, equal to the univariate 2-torsion polynomial if n is even, and 1 otherwise.

If a polynomial is passed as a third argument then the division polynomial is computed efficiently modulo that polynomial.

`TwoTorsionPolynomial(E)`

Returns the multivariate 2-torsion polynomial $2y + a_1x + a_3$ of the elliptic curve E, as a bivariate polynomial.

Example H120E13

Let E be an elliptic curve over a finite field K. The following code fragment illustrates the relationship between the roots in K of the n-th division polynomial for E, and the x-coordinates of the points of n-torsion on E.

```
> K := GF(101);
> E := EllipticCurve([ K | 1, 1]);
> Roots(DivisionPolynomial(E, 5));
[ <86, 1>, <46, 1> ]
> [ P : P in RationalPoints(E) | 5*P eq E!0 ];
[ (86 : 34 : 1), (0 : 1 : 0), (46 : 25 : 1), (86 : 67 : 1), (46 : 76 : 1) ]
```

It is worth noting that even if the roots of the division polynomial lie in the field, the corresponding points may not, lying instead in a quadratic extension.

```
> Roots(DivisionPolynomial(E, 9));
[ <4, 1>, <17, 1>, <28, 1>, <34, 1>, <77, 1> ]
> Points(E, 4);
[]
> K2<w> := ext<K | 2>;
> Points(E(K2), 4);
[ (4 : 82*w + 57 : 1), (4 : 19*w + 44 : 1) ]
> Order($1[1]);
9
```

120.5 Subgroup Schemes

A subgroup scheme G of an elliptic curve E is a subscheme of E defined by a univariate polynomial ψ and closed under the group law on E. The points of G are those points of E whose x-coordinate is a root of ψ. All elliptic curves are considered to be subgroup schemes with defining polynomial $\psi = 0$.

120.5.1 Creation of Subgroup Schemes

`SubgroupScheme(G, f)`

Creates the subgroup scheme of the subgroup scheme G defined by the univariate polynomial f. No checking is done to ensure that the rational points of the result actually do form a group under the addition law. Note that G can be an elliptic curve.

`TorsionSubgroupScheme(G, n)`

Returns the subgroup scheme of n-torsion points of the subgroup scheme G. Note that G can be an elliptic curve.

120.5.2 Associated Structures

`Category(G)`

`Type(G)`

Returns the category of elliptic curve subgroup schemes, `SchGrpEll`.

`Curve(G)`

`Generic(G)`

Returns the elliptic curve E of which G is a subgroup scheme.

`BaseRing(G)`

`CoefficientRing(G)`

Returns the base ring of the subgroup scheme G; this is the same as the base ring of its curve.

`DefiningSubschemePolynomial(G)`

Returns the univariate polynomial that defines G as a subscheme of its curve.

120.5.3 Predicates on Subgroup Schemes

`G1 eq G2`

Returns `true` if and only if $G1$ and $G2$ are subgroup schemes of the same elliptic curve and are defined by equal polynomials.

`G1 ne G2`

The logical negation of `eq`.

120.5.4 Points of Subgroup Schemes

`#G`

`Order(G)`

The order of the group of rational points on the subgroup scheme G.

`FactoredOrder(G)`

The factorisation of the order of the group of rational points on the subgroup scheme G.

`Points(G)`

`RationalPoints(G)`

The indexed set of rational points of the subgroup scheme G over its base ring.

Example H120E14

We construct a curve over $\mathbf{F}_{49}$ and form several subgroup schemes from it.

```
> K<w> := GF(7, 2);
> P<t> := PolynomialRing(K);
> E := EllipticCurve([K | 1, 3]);
> G := SubgroupScheme(E, (t-4)*(t-5)*(t-6));
> G;
Subgroup scheme of E defined by x^3 + 6*x^2 + 4*x + 6
> Points(G);
{@ (0 : 1 : 0), (6 : 1 : 1), (6 : 6 : 1), (4 : 1 : 1), (4 : 6 : 1),
(5 : 0 : 1) @}
```

The points of order 3 form a further subgroup.

```
> [ Order(P) : P in $1 ];
[ 1, 3, 3, 6, 6, 2 ]
> G2 := SubgroupScheme(G, t - 6);
> G2;
Subgroup scheme of E defined by x + 1
> Points(G2);
{@ (0 : 1 : 0), (6 : 1 : 1), (6 : 6 : 1) @}
```

We can find this subgroup another way, as the intersection of the 15-torsion points of E and G.

```
> G3 := TorsionSubgroupScheme(E, 15);
> #G3;
15
> G4 := SubgroupScheme(G3, DefiningSubschemePolynomial(G));
> G4;
Subgroup scheme of E defined by x + 1
> G2 eq G4;
true
```

120.6 The Formal Group

These functions are for elliptic curves over any (exact) field.

`FormalGroupLaw(E, prec)`

This function returns a polynomial in two variables, $T_1 + T_2 + \ldots$, which expresses the formal group law associated to addition on E, up to precision `prec`. (More precisely, it contains the terms which have total degree less than or equal to `prec`.)

The formal variables T_1 and T_2 may be identified with the function $-x/y$ on E, where x and y are the standard affine coordinates on E. (Note that this function is a local parameter in a neighbourhood of O_E.)

`FormalGroupHomomorphism(phi, prec)`

This function returns the homomomorphism of formal groups associated to the isogeny `phi`, represented as a power series in one variable up to precision `prec`. As in `FormalGroupLaw`, this is in terms of the parameter $-x/y$ on each curve.

`FormalLog(E)`

`Precision` RngIntElt *Default :* 10

This function returns the formal logarithm for the elliptic curve E as a power series $f(T)$, where the parameter T is the function $-x/y$ on E. (This is the same parameter used in `FormalGroupLaw`).

The function also returns a point $P(T)$ on E with coordinates in a Laurent series ring with generator T, which again corresponds to $-x/y$. Thus $P(T)$ is a formal parametrisation of E in a neighbourhood of O_E.

120.7 Operations on Point Sets

Each elliptic curve E has associated with it a family of *point sets* of E indexed by coefficient rings. These point sets, not E, are the objects in which points lie. If K is the base ring of E and L is some extension of K then the elements of the point set $E(L)$ comprise all points lying on E whose coordinates are in L.

There is a distinguished point set $E(K)$ of E which is called the *base point set* of E. Many intrinsics (such as `#`, or `TorsionSubgroup`), strictly speaking, only make sense when applied to point sets; as a convenience, when E is passed to these functions the behaviour is the same as if the base point set $E(K)$ were passed instead. It is important to remember, however, that E and $E(K)$ are different objects and will not always behave in the same manner.

The above statements are equally valid if the elliptic curve E is replaced by some subgroup scheme G. Moreover, the types of the point sets of G and E are the same, and similarly for points. (They may be distinguished by checking the type of the scheme of which they are point sets.)

120.7.1 Creation of Point Sets

`E(L)`

`PointSet(E, L)`

Given an elliptic curve E (or a subgroup scheme thereof) and an extension L of its base ring, this function returns a point set whose elements are points on E with coefficients in L.

`E(m)`

`PointSet(E, m)`

Given an elliptic curve E (or a subgroup scheme thereof) and a map m from the base ring of E to a field L, this function returns a point set whose elements are points on E with coefficients in L. The map is retained to permit coercions between point sets.

120.7.2 Associated Structures

`Category(H)`

`Type(H)`

Given a point set H of an elliptic curve, returns the category `SetPtEll` of point sets of elliptic curves.

`Scheme(H)`

Returns the associated scheme (either an elliptic curve or a subgroup scheme) of which H is a point set.

`Curve(H)`

Returns the associated elliptic curve that contains `Scheme(H)`.

`Ring(H)`

Returns the ring that contains the coordinates of points in H.

120.7.3 Predicates on Point Sets

`H1 eq H2`

Returns whether the two point sets are equal. That is, whether the point sets have equal coefficient rings and elliptic curves (subgroup schemes).

`H1 ne H2`

The logical negation of `eq`.

Example H120E15

We create an elliptic curve E over GF(5) and then construct two associated point sets:

```
> K := GF(5);
> E := EllipticCurve([K | 1, 0]);
> H := E(K);
> H;
Set of points of E with coordinates in GF(5)
> H2 := E(GF(5, 2));
> H2;
Set of points of E with coordinates in GF(5^2)
```

We note that although these are point sets of the same curve, they are not equal because the rings are not equal.

```
> Scheme(H) eq Scheme(H2);
true
> Ring(H) eq Ring(H2);
false
> H eq H2;
```

```
false
```

Similarly, we see that a point set of a subgroup scheme is not the same object as the point set of the curve because the schemes are different.

```
> P<t> := PolynomialRing(K);
> G := SubgroupScheme(E, t - 2);
> HG := G(K);
> Scheme(HG) eq Scheme(H);
false
> Ring(HG) eq Ring(H);
true
> HG eq H;
false
```

Also note that the scheme and the parent curve of point sets of G are different:

```
> Scheme(HG);
Subgroup scheme of E defined by x + 3
> Curve(HG);
Elliptic Curve defined by y^2 = x^3 + x over GF(5)
```

120.8 Morphisms

Four types of maps between elliptic curves may be constructed: isogenies, isomorphisms, translations, and rational maps. Isogenies and isomorphisms are by far the most important and have the most functions associated to them. Isogenies are always surjective as scheme maps, even though the MAGMA parlance of a map from $E(\mathbf{Q}) \to F(\mathbf{Q})$ may seem to indicate that (for instance) the multiplication-by-two map is not surjective. There is an internal limit that the degrees of the polynomials defining an isogeny cannot be more than 10^7.

120.8.1 Creation Functions

Example H120E16

The following example gives a construction of a 2-isogeny between elliptic curves. This example follows Example III 4.5 of Silverman [Sil86], and demonstrates a parametrised family of 2-isogenies of elliptic curves together with its dual.

```
> FF := FiniteField(167);
> a := FF!2; b := FF!3; r := a^2 - 4*b;
> E1 := EllipticCurve([0, a, 0, b, 0]);
> E2 := EllipticCurve([0, -2*a, 0, r, 0]);
> _<x> := PolynomialRing(BaseRing(E1));
> Ff, f := IsogenyFromKernel(E1, x);
> Fg, g := IsogenyFromKernel(E2, x);
> b, m1 := IsIsomorphic(Ff, E2); assert b;
```

```
> b, m2 := IsIsomorphic(Fg, E1); assert b;
> // Verify that f and g are dual isogenies of degree 2
> &and[ m2(g(m1(f(P)))) eq 2*P : P in RationalPoints(E1) ];
true
> &and[ m1(f(m2(g(Q)))) eq 2*Q : Q in RationalPoints(E2) ];
true
```

`Isomorphism(E, F, [r, s, t, u])`

Given elliptic curves E and F defined over the same field K, and four elements r, s, t, u of K with $u \neq 0$, this function returns the isomorphism $E \to F$ mapping $O_E \mapsto O_F$ and mapping $(x, y) \mapsto (u^2x + r, u^3y + su^2x + t)$. This function returns an error if the values passed do not define such an isomorphism.

`Isomorphism(E, F)`

Given elliptic curves E and F defined over the same field K, this function computes and returns an isomorphism from E to F where such an isomorphism exists. The map returned will be the same as the second return value of `IsIsomorphic`.

`Automorphism(E, [r, s, t, u])`

Given an elliptic curve E defined over a field K, and four elements r, s, t, u of K with $u \neq 0$, this function returns the automorphism $E \to E$ mapping $O_E \mapsto O_E$ and mapping $(x, y) \mapsto (u^2x + r, u^3y + su^2x + t)$. This function returns an error if the values passed do not define such an automorphism.

`IsomorphismData(I)`

The sequence $[r, s, t, u]$ of elements defining the isomorphism I.

Example H120E17

We illustrate the isomorphism routines with some simple examples.

```
> K := GF(73);
> E1 := EllipticCurve([K | 3, 4, 2, 5, 1]);
> E2 := EllipticCurve([K | 8, 2, 29, 45, 28]);
> IsIsomorphic(E1, E2);
true
> m := Isomorphism(E1, E2, [3, 2, 1, 4]);
> m;
Elliptic curve isomorphism from: CrvEll: E1 to CrvEll: E2
Taking (x : y : 1) to (16*x + 3 : 64*y + 32*x + 1 : 1)
> P1 := Random(E1);
> P2 := Random(E1);
> m(P1 + P2) eq m(P1) + m(P2);
```

```
true
```

From the isomorphism data we can apply the map by hand if desired:

```
> r, s, t, u := Explode(IsomorphismData(Inverse(m)));
> P3 := E2![ 69, 64 ];
> x, y := Explode(Eltseq(P3));
> E1 ! [ u^2*x + r, u^3*y + s*u^2*x + t ];
(68 : 32 : 1)
> m($1) eq P3;
true
```

`IsIsomorphism(I)`

This function returns `true` if and only if the isogeny I has the same action as some isomorphism; if so, the isomorphism is also returned.

`IsomorphismToIsogeny(I)`

This function takes a map I of type isomorphism and returns an equivalent map with type isogeny.

Example H120E18

An example of how to use the previous two functions to transform isogenies to isomorphisms and vice versa.

```
> FF := FiniteField(23);
> E0 := EllipticCurve([FF | 1, 1]);
> E1 := EllipticCurve([FF | 3, 2]);
> b, iso := IsIsomorphic(E0, E1);
> b;
true
> iso;
Elliptic curve isomorphism from: CrvEll: E0 to CrvEll: E1
Taking (x : y : 1) to (16*x : 18*y : 1)
> isog := IsomorphismToIsogeny(iso);
> isog;
Elliptic curve isogeny from: CrvEll: E0 to CrvEll: E1
taking (x : y : 1) to (16*x : 18*y : 1)
> b, new_iso := IsIsomorphism(isog);
> b;
true
> inv := Inverse(new_iso);
> P := Random(E0);
> inv(isog(P)) eq P;
true
```

`TranslationMap(E, P)`

Given a rational point P on the elliptic curve E, this function returns the morphism $t_P : E \to E$ defined by $t_P(Q) = P + Q$ for all rational points Q of E.

`RationalMap(i, t)`

Let i be an isogeny and t be a translation map $t_P : E \to E$ where $t_P(Q) = P + Q$ for some rational point $P \in E$. This function returns the rational map $\phi : E \to F$ obtained by composing i and t (applying t first). Any rational map $E \to F$ can be represented in this form.

`TwoIsogeny(P)`

Given a 2-torsion point P of the elliptic curve E, this function returns a 2-isogeny on E with P as its kernel.

Example H120E19

One may, of course, also define maps between elliptic curves using the generic map constructors, as the following examples show.

```
> E1 := EllipticCurve([ GF(23) | 1, 1 ]);
> E2 := EllipticCurve([ GF(23, 2) | 1, 1 ]);
```

The doubling map on E_1 lifted to E_2:

```
> f := map<E1 -> E2 | P :-> 2*P>;
```

Two slightly different ways to define the negation map on E_1 lifted to E_2:

```
> f := map<E1 -> E2 | P :-> E2![ P[1], -P[2], P[3] ]>;
> f := map<E1 -> E2 | P :-> (P eq E1!0) select E2!0
>                           else E2![ P[1], -P[2], 1 ]>;
```

`IsogenyFromKernel(G)`

Let G be a subgroup scheme of an elliptic curve E. There is a separable isogeny $f : E \to E_f$ to some other elliptic curve E_f, which has kernel G. This function returns the curve E_f and the map f using Velu's formulae.

`IsogenyFromKernelFactored(G)`

Returns a sequence of isogenies whose product is the isogeny returned by the invocation `IsogenyFromKernel(G)`. These isogenies have either degree 2 or odd degree. This function was introduced because composing isogenies can be computationally expensive. The generic `Expand` function on a composition of maps can then be used if desired.

`IsogenyFromKernel(E, psi)`

Given an elliptic curve E and a univariate polynomial *psi* which defines a subgroup scheme of E, compute an isogeny using Velu's formulae as above.

`IsogenyFromKernelFactored(E, psi)`

Returns a sequence of isogenies whose product is the isogeny returned by the invocation `IsogenyFromKernel(E, psi)`. These isogenies have either degree 2 or odd degree. This function was introduced because composing isogenies can be computationally expensive. The generic `Expand` function on a composition of maps can then be used if desired.

`PushThroughIsogeny(I, v)`

`PushThroughIsogeny(I, G)`

Given an isogeny I and a subgroup G which contains the kernel of I, find the image of G under the action of I. The subgroup G may be replaced by its defining polynomial v.

`DualIsogeny(phi)`

Given an isogeny $\phi : E_1 \to E_2$, the function returns another isogeny $\phi^* : E_2 \to E_1$ such that $\phi^* \circ \phi$ is multiplication by the degree of ϕ. The result is remembered and `DualIsogeny(DualIsogeny(phi))` returns `phi`.

Example H120E20

We exhibit one way of calculating the dual of an isogeny. First we create a curve and an isogeny f with kernel equal to the full 5-torsion polynomial.

```
> E := EllipticCurve([GF(97) | 2, 3]);
> E1, f := IsogenyFromKernel(E, DivisionPolynomial(E, 5));
```

The image curve E_1 is isomorphic, but not equal, to the original curve E. We proceed to find the dual of f.

```
> deg := Degree(f);
> psi := DivisionPolynomial(E, deg);
> f1 := PushThroughIsogeny(f, psi);
> E2, g := IsogenyFromKernel(E1, f1);
> // Velu's formulae give an isomorphic curve, not the curve itself.
> IsIsomorphic(E2, E);
true
> h := Isomorphism(E2, E);
> f_dual := g*IsomorphismToIsogeny(h);
```

The latter isogeny is the dual of f, as we verify:

```
> &and [ f_dual(f(P)) eq deg*P : P in RationalPoints(E) ];
```

```
true
```

Of course, a simpler way to verify this is just to check equality:

```
> f_dual eq DualIsogeny(f);
true
```

120.8.2 Predicates on Isogenies

`IsZero(I)`

`IsConstant(I)`

Returns `true` if and only if the image of the isogeny I is the zero element of its codomain.

`I eq J`

Returns `true` if and only if the isogenies I and J are equal.

120.8.3 Structure Operations

`IsogenyMapPsi(I)`

Returns the univariate polynomial ψ used in defining the isogeny I. The roots of ψ determine the kernel of I.

`IsogenyMapPsiMulti(I)`

Returns the polynomial ψ used in defining the isogeny I as a multivariate polynomial.

`IsogenyMapPsiSquared(I)`

Returns the denominator of the fraction giving the image of the x-coordinate of a point under the isogeny I (the numerator is returned by `IsogenyMapPhi(I)`).

`IsogenyMapPhi(I)`

Returns the univariate polynomial ϕ used in defining the isogeny I.

`IsogenyMapPhiMulti(I)`

Returns the polynomial ϕ used in defining the isogeny I as a multivariate polynomial.

`IsogenyMapOmega(I)`

Returns the multivariate polynomial ω used in defining the isogeny I.

`Kernel(I)`

Returns the subgroup of the domain consisting of the elements that map to zero under the isogeny I.

`Degree(I)`

Returns the degree of the morphism I.

120.8.4 Endomorphisms

Let E be an elliptic curve defined over the field K. The set of endomorphisms $\mathrm{End}(E)$ of E to itself forms a ring under composition and addition of maps.

The endomorphism ring of E always contains a subring isomorphic to $\mathbf{Z}$. A curve E whose endomorphism ring contains additional isogenies is said to have *complex multiplication*. If E is defined over a finite field then E always has complex multiplication. The endomorphism ring of E is isomorphic to an order in either a quadratic number field or a quaternion algebra.

`MultiplicationByMMap(E, m)`

Returns the multiplication-by-m endomorphism $[m] : E \to E$ of the elliptic curve E, such that $[m](P) = m * P$.

`IdentityIsogeny(E)`

Returns the identity map $E \to E$ of the elliptic curve E as an isogeny.

`IdentityMap(E)`

Returns the identity map $E \to E$ of the elliptic curve E as an isomorphism. The defining coefficients are $[r, s, t, u] = [0, 0, 0, 1]$.

`NegationMap(E)`

Returns the isomorphism of the elliptic curve E which maps P to $-P$, for all $P \in E$.

`FrobeniusMap(E, i)`

Returns the Frobenius isogeny $(x : y : 1) \mapsto (x^{p^i} : y^{p^i} : 1)$ of an elliptic curve E defined over a finite field of characteristic p.

`FrobeniusMap(E)`

Equivalent to `FrobeniusMap(E, 1)`.

Example H120E21

We check the action of the `FrobeniusMap` function.

```
> p := 23;
> FF1 := FiniteField(p);
> FF2 := FiniteField(p, 2);
> E1 := EllipticCurve([FF1 | 1, 3]);
> E2 := BaseExtend(E1, FF2);
> frob := FrobeniusMap(E2, 1);
> #{ E1!P : P in RationalPoints(E2) | P eq frob(P) } eq #E1;
true
```

120.8.5 Automorphisms

The functions in this section deal with automorphisms in the category of elliptic curves. For an elliptic curve E these are the automorphisms of the underlying curve that also preserve the group structure (equivalently, that send the identity O_E to itself).

Warning: The behaviour of these functions depends on the type of the input curve. For a general curve in MAGMA (an object that is a `Crv` but not a `CrvEll`) over a finite field, `AutomorphismGroup` and `Automorphisms` give automorphisms in the category of curves.

`AutomorphismGroup(E)`

For an elliptic curve E over a general field K, this function determines the group of automorphisms of E that are defined over K. It returns an abstract group A (an abelian group or a polycyclic group), together with a map which sends elements of A to actual automorphisms of E (maps of schemes with domain and codomain E).

`Automorphisms(E)`

For an elliptic curve E over a general field K, this function returns a sequence containing the elements of the `AutomorphismGroup` of E.

120.9 Operations on Points

Points on an elliptic curve over a field are given in terms of projective coordinates: A point (a, b, c) is equivalent to (x, y, z) if and only if there exists an element u (in the field of definition) such that $ua = x$, $ub = y$, and $uc = z$. The equivalence class of (x, y, z) is denoted by the projective point $(x : y : z)$. At least one of the projective coordinates must be nonzero. We call the coefficients normalised if either $z = 1$, or $z = 0$ and $y = 1$.

120.9.1 Creation of Points

In this section the descriptions will refer to a point set H, which is either the H in the signature or the base point set of the elliptic curve E in the signature.

`H ! [x, y, z]` `elt< H | x, y, z >`

`E ! [x, y, z]` `elt< E | x, y, z >`

Given a point set $H = E(R)$ and coefficients x, y, z in R satisfying the equation for E, return the normalised point $P = (x : y : z)$ in H. If z is not specified it is assumed to be 1.

`H ! 0` `Id(H)` `Identity(H)`

`E ! 0` `Id(E)` `Identity(E)`

Returns the normalised identity point $(0 : 1 : 0)$ of the point set H on the elliptic curve E.

`Points(H, x)`

`Points(E, x)`

Returns the sequence of points in the pointset H on the elliptic curve E whose x-coordinate is x.

`Points(H)` `RationalPoints(H)`

`Points(E)` `RationalPoints(E)`

`Bound`	RngIntElt	*Default :* 0
`DenominatorBound`	RngIntElt	*Default :* Bound
`Denominators`	SetQ	*Default :*
`Max`	RngIntElt	*Default :*
`NPrimes`	RngIntElt	*Default :* 30

Given an elliptic curve E (or associated point set) over the rationals, a number field, or a finite field, this function returns an indexed set of points on the curve (or in the point set). When over a finite field this will contain all the rational points.

When over **Q** or a number field, a positive value for the parameter `Bound` must be given. Over **Q** this refers to the height of the x-coordinate of the points. Over number fields the algorithm searches x-coordinates in some chosen box and with some chosen denominators depending on the `Bound` (so here, too, there is loosely a linear relationship between the `Bound` and the heights of the x-coordinates searched).

The other optional parameters are only for the number field case. The denominators of x-coordinates to be searched can be specified as `Denominators` (a set of integral elements in the field) or by setting `DenominatorBound` (an integer). If an integer `Max` is specified then the routine returns as soon as this many points are found. The parameter `NPrimes` is an internal parameter that controls the number of primes used in the sieving.

The algorithm uses a sieve method; the number field case is described in Appendix A of [Bru02]. In both cases the implementation of the sieving is reasonably fast.

`PointsAtInfinity(H)`

`PointsAtInfinity(E)`

Returns the indexed set containing the identity point of the pointset H or on the elliptic curve E.

120.9.2 Creation Predicates

`IsPoint(H, S)`

`IsPoint(E, S)`

Returns `true` if the sequence of values in S are the coordinates of a point in the pointset H or on the elliptic curve E, `false` otherwise. If this is `true` then the corresponding point is returned as the second value.

`IsPoint(H, x)`
`IsPoint(E, x)`

Returns `true` if x is the x-coordinate of a point in the pointset H or on the elliptic curve E, `false` otherwise. If this is `true` then a corresponding point is returned as the second value. Note that the point at infinity of H will never be returned.

120.9.3 Access Operations

`P[i]`

Returns the i-th coefficient for an elliptic curve point P, for $1 \leq i \leq 3$.

`ElementToSequence(P)`
`Eltseq(P)`

Given a point P on an elliptic curve, this function returns a sequence of length 3 consisting of its coefficients (normalised).

120.9.4 Associated Structures

`Category(P)`
`Type(P)`

Given a point P on an elliptic curve, this function returns `PtEll`, the category of elliptic curve points.

`Parent(P)`

Given a point P on an elliptic curve, this function returns the parent point set for P.

`Scheme(P)`
`Curve(P)`

Given a point P on an elliptic curve, this function returns the corresponding scheme or elliptic curve for the parent point set of P.

120.9.5 Arithmetic

The points on an elliptic curve over a field form an abelian group, for which we use the additive notation. The identity element is the point $O = (0 : 1 : 0)$.

`-P`

Returns the additive inverse of the point P on an elliptic curve E.

`P + Q`

Returns the sum $P + Q$ of two points P and Q on the same elliptic curve.

`P +:= Q`

Given two points P and Q on the same elliptic curve, sets P equal to their sum.

`P - Q`

Returns the difference $P - Q$ of two points P and Q on the same elliptic curve.

`P -:= Q`

Given two points P and Q on the same elliptic curve, sets P equal to their difference.

`n * P`

Returns the n-th multiple of the point P on an elliptic curve.

`P *:= n`

Sets the point P equal to the n-th multiple of itself.

120.9.6 Division Points

`P / n`

Given a point P on an elliptic curve E and an integer n, this function returns a point Q on E such that $P = nQ$, if such a point exists. If no such point exists then a runtime error results.

`P /:= n`

Given a point P on an elliptic curve E and an integer n, this function sets P equal to a point Q on E such that $P = nQ$, if such a point exists. If no such point exists then a runtime error results.

`DivisionPoints(P, n)`

Given a point P on an elliptic curve E and an integer n, this function returns the sequence of all points Q on E such that $P = nQ$ holds. If there are no such points then an empty sequence is returned.

`IsDivisibleBy(P, n)`

Given a point P on an elliptic curve E and an integer n, this function returns `true` if P is n-divisible, and if so, an n-division point. Otherwise `false` is returned.

Example H120E22

```
> E := EllipticCurve([1, 0, 0, 12948, 421776]);
> P := E![ -65498304*1567, -872115836268, 1567^3 ];
> DivisionPoints(P, 3);
[ (312 : -6060 : 1), (-30 : -66 : 1), (216 : 3540 : 1) ]
```

Note that P has three three-division points — this tells us that there are three 3-torsion points in E. In fact, there are 9 points in the torsion subgroup.

```
> DivisionPoints(E!0, 9);
[ (0 : 1 : 0), (24 : 852 : 1), (24 : -876 : 1), (-24 : -300 : 1), (-24 : 324 : 1),
(600 : 14676 : 1), (600 : -15276 : 1), (132 : 2040 : 1), (132 : -2172 : 1) ]
```

Example H120E23

We construct some points in a certain elliptic curve over $\mathbf{Q}$ and try by hand to find a "smaller" set of points that generate the same group.

```
> E := EllipticCurve([0, 0, 1, -7, 6]);
> P1 := E![ 175912024457 * 278846, -41450244419357361, 278846^3 ];
> P2 := E![ -151 * 8, -1845, 8^3 ];
> P3 := E![ 36773 * 41, -7036512, 41^3 ];
> P1; P2; P3;
(175912024457/77755091716 : -41450244419357361/21681696304639736 : 1)
(-151/64 : -1845/512 : 1)
(36773/1681 : -7036512/68921 : 1)
```

Now we try small linear combinations in the hope of finding nicer looking points. We shall omit the bad guesses and just show the good ones.

```
> P1 + P2;
(777/3364 : 322977/195112 : 1)
```

Success! We replace P1 with this new point and keep going.

```
> P1 +:= P2;
> P2 + P3;
(-3 : 0 : 1)
> P2 +:= P3;
> P3 - P1;
(-1 : -4 : 1)
> P3 -:= P1;
> P1 - 2*P2;
(0 : 2 : 1)
> P1 -:= 2*P2;
> [ P1, P2, P3 ];
[ (0 : 2 : 1), (-3 : 0 : 1), (-1 : -4 : 1) ]
```

The pairwise reductions no longer help, but there is a smaller point with x-coordinate 1:

```
> IsPoint(E, 1);
```

```
true (1 : 0 : 1)
```

After a small search we find:

```
> P1 - P2 - P3;
(1 : 0 : 1)
> P2 := P1 - P2 - P3;
> [ P1, P2, P3 ];
[ (0 : 2 : 1), (1 : 0 : 1), (-1 : -4 : 1) ]
```

Using a naive definition of "small" these are the smallest possible points. (Note that there are points of smaller canonical height.) These points are in fact the generators of the Mordell–Weil group for this particular elliptic curve. Since none of the transformations changed the size of the space spanned by the points it follows that the original set of points are also generators of E. However, the reduced points form a much more convenient basis.

Example H120E24

We construct an elliptic curve over a function field (hence an elliptic surface) and form a "generic" point on it. First, we construct the function field.

```
> E := EllipticCurve([GF(97) | 1, 2]);
> K<x, y> := FunctionField(E);
```

Now we lift the curve to be over its own function field and form a generic point on E.

```
> EK := BaseChange(E, K);
> P := EK![x, y, 1];
> P;
(x : y : 1)
> 2*P;
((73*x^4 + 48*x^2 + 93*x + 73)/(x^3 + x + 2) : (85*x^6 + 37*x^4 + 5*x^3
    + 60*x^2 + 96*x + 8)/(x^6 + 2*x^4 + 4*x^3 + x^2 + 4*x + 4)*y : 1)
```

Finally, we verify that addition of the generic point defines the addition law on the curve.

```
> m2 := MultiplicationByMMap(E, 2);
> P := E![ 32, 93, 1 ];
> m2(P);
(95 : 63 : 1)
> 2*P;
(95 : 63 : 1)
```

120.9.7 Point Order

`Order(P)`

Given a point on an elliptic curve defined over **Q** or a finite field, this function computes the order of P; that is, the smallest positive integer n such that $n \cdot P = O$ on the curve. If no such positive n exists then 0 is returned to indicate infinite order. If the curve is defined over a finite field then the order of the curve will first be computed.

`FactoredOrder(P)`

Given a point on an elliptic curve defined over **Q** or over a finite field, this function returns the factorisation of the order of P. If the curve is over a finite field then on repeated applications this is generally much faster than factorising `Order(P)` because the factorisation of the order of the curve will be computed and stored. An error ensues if the curve is defined over **Q** and P has infinite order.

Example H120E25

We show a few simple operations with points on an elliptic curve over a large finite field.

```
> E := EllipticCurve([GF(NextPrime(10^12)) | 1, 1]);
> Order(E);
1000001795702
> FactoredOrder(E);
[ <2, 1>, <7, 1>, <13, 1>, <19, 1>, <31, 1>, <43, 1>, <59, 1>, <3677, 1> ]
> P := E ! [652834414164, 320964687531, 1];
> P;
(652834414164 : 320964687531 : 1)
> IsOrder(P, Order(E));
true
> FactoredOrder(P);
[ <2, 1>, <7, 1>, <13, 1>, <19, 1>, <31, 1>, <43, 1>, <59, 1>, <3677, 1> ]
> FactoredOrder(3677 * 59 * P);
[ <2, 1>, <7, 1>, <13, 1>, <19, 1>, <31, 1>, <43, 1> ]
```

120.9.8 Predicates on Points

`IsId(P)`

`IsIdentity(P)`

`IsZero(P)`

Returns `true` if and only if the point P is the identity point of its point set, `false` otherwise.

`P eq Q`

Returns `true` if and only if P and Q are points on the same elliptic curve and have the same normalised coordinates.

`P ne Q`

The logical negation of `eq`.

`P in H`

Given a point P, return `true` if and only if P is in the point set H. That is, it satisfies the equation of E and its coordinates lie in R, where $H = E(R)$.

`P in E`

Given a point P, return `true` if and only if P is on the elliptic curve E (i.e., satisfies its defining equation). Note that this is an exception to the general rule, in that P does not have to lie in the base point set of E for this to be true.

`IsOrder(P, m)`

Returns `true` if and only if the point P has order m. If you believe that you know the order of the point then this intrinsic is likely to be much faster than just calling `Order`.

`IsIntegral(P)`

Given a point P on an elliptic curve defined over $\mathbf{Q}$, this function returns `true` if and only if the coordinates of the (normalisation of) P are integers.

`IsSIntegral(P, S)`

Given a point P on an elliptic curve defined over $\mathbf{Q}$ and a sequence S of primes, this function returns `true` if and only if the coordinates of the (normalisation of) P are S-integers. That is, the denominators of $x(P)$ and $y(P)$ are only supported by primes of S.

Example H120E26

We find some integral and S-integral points on a well-known elliptic curve.

```
> E := EllipticCurve([0, 17]);
> P1 := E![ -2, 3 ];
> P2 := E![ -1, 4 ];
> S := [ a*P1 + b*P2 : a,b in [-3..3] ];
> #S;
49
> [ P : P in S | IsIntegral(P) ];
[ (43 : -282 : 1), (5234 : -378661 : 1), (2 : -5 : 1), (8 : 23 : 1),
(4 : 9 : 1), (-2 : -3 : 1), (52 : -375 : 1), (-1 : -4 : 1), (-1 : 4 : 1),
(52 : 375 : 1), (-2 : 3 : 1), (4 : -9 : 1), (8 : -23 : 1), (2 : 5 : 1),
(5234 : 378661 : 1), (43 : 282 : 1) ]
> [ P : P in S | IsSIntegral(P, [2, 3]) and not IsIntegral(P) ];
```

```
[ (1/4 : 33/8 : 1), (-8/9 : 109/27 : 1), (-206/81 : -541/729 : 1),
(137/64 : 2651/512 : 1), (137/64 : -2651/512 : 1), (-206/81 : 541/729 : 1),
(-8/9 : -109/27 : 1), (1/4 : -33/8 : 1) ]
```

120.9.9 Weil Pairing

MAGMA contains an optimised implementation of the Weil pairing on an elliptic curve. This function is used in the computation of the group structure of elliptic curves over finite fields, making the determination of the group structure efficient.

`WeilPairing(P, Q, n)`

Given n-torsion points P and Q of an elliptic curve E, this function computes the Weil pairing of P and Q.

`IsLinearlyIndependent(S, n)`

Given a sequence S of points of an elliptic curve E such that each point has order dividing n, this function returns `true` if and only if the points in S are linearly independent over $\mathbf{Z}/n\mathbf{Z}$.

`IsLinearlyIndependent(P, Q, n)`

Given points P and Q of an elliptic curve E, this function returns `true` if and only if P and Q form a basis of the n-torsion points of E.

Example H120E27

We compute the Weil pairing of two 3-torsion points on the curve $y^2 = x^3 - 3$ over $\mathbf{Q}$.

```
> E := EllipticCurve([0, -3]);
> E;
> P1, P2, P3 := Explode(ThreeTorsionPoints(E));
> P1;
(0 : 2*zeta_3 + 1 : 1)
> Parent(P1);
Set of points of E with coordinates in Cyclotomic Field
  of order 3 and degree 2
> Parent(P2);
Set of points of E with coordinates in Number Field with
  defining polynomial X^3 - 18*X - 30 over the Rational Field
```

In order to take the Weil pairing of two points we need to coerce them into the same point set. This turns out to be a point set over a number field K of degree 6.

```
> Qmu3 := Ring(Parent(P1));
> K<w> := CompositeFields(Ring(Parent(P1)), Ring(Parent(P2)))[1];
> wp := WeilPairing( E(K)!P1, E(K)!P2, 3 );
> wp;
1/975*(14*w^5 + 5*w^4 - 410*w^3 - 620*w^2 + 3964*w + 8744)
```

```
> Qmu3!wp;
zeta_3
```

121 ELLIPTIC CURVES OVER FINITE FIELDS

Chapter 121
ELLIPTIC CURVES OVER FINITE FIELDS

This chapter describes the specialised facilities for elliptic curves defined over finite fields. Details concerning their construction, arithmetic, and basic properties may be found in Chapter 120. Most of the machinery has been constructed with Elliptic Curve Cryptography in mind.

The first major group of intrinsics relate to the determination of the order of the group of rational points of an elliptic curve over a large finite field. A variety of canonical lift algorithms are provided for characteristic 2 fields while the SEA algorithm is used for fields having characteristic greater than 2. These tools are used as the basis for functions that search for curves suitable for cryptographic applications.

A function for computing the Weil pairing forms the basis of the MOV reduction of the discrete logarithm problem (DLP) for a supersingular elliptic curve to a DLP in a finite field. A second type of attack on the DLP is based on the use of Weil descent. Tools implementing a generalisation of the GHS attack for ordinary curves in characteristic 2 are provided.

Finally, for a direct attack on the DLP for elliptic curves, a parallel collision search version of the Pollard rho algorithm is available.

121.1 Supersingular Curves

`IsSupersingular(E : parameters)`

`Proof` BoolElt *Default :* `true`

Given an elliptic curve E over a finite field, this function returns `false` if E is ordinary, otherwise proves that E is supersingular and returns `true`. If the parameter `Proof` is set to `false` then the effect of the function is the same as that of `IsProbablySupersingular`.

`SupersingularPolynomial(p)`

Given a prime p, returns the separable monic polynomial over $\mathbf{F}_p$ whose roots are precisely the j invariants of supersingular elliptic curves in characteristic p. The polynomial is computed by a formula; ignoring factors corresponding to $j = 0$ or 1728, it is the partial power-series expansion of a certain hypergeometric function reduced mod p. For p of moderate size this is a very fast method.

`IsOrdinary(E)`

Given an elliptic curve E over a finite field, this function returns `true` if the elliptic curve E is ordinary, otherwise `false` (i.e., if it is supersingular). Thus, this function is the logical negation of `IsSupersingular`.

`IsProbablySupersingular(E)`

Given an elliptic curve E over a finite field, this function returns returns `false` if the elliptic curve E is proved to be ordinary, otherwise `true`. The algorithm is nondeterministic and repeated tests are independent.

121.2 The Order of the Group of Points

121.2.1 Point Counting

MAGMA contains an efficient implementation of the Schoof–Elkies–Atkin (SEA) algorithm, with Lercier's extension to base fields of characteristic 2, for computing the number of points on an elliptic curve over a finite field. There are also implementations of the faster p-adic canonical lift methods and the p-adic deformation method in small characteristic. Calculations are performed in the smallest field over which the curve is defined, and the result is lifted to the original field.

Like all group functions on elliptic curves, these intrinsics really apply to a particular point set; the curve is identified with its base point set for the purposes of these functions. To aid exposition only the versions that take the curves are shown but an appropriate point set (over a finite field) may be used instead.

`#E`

`Order(E)`

The order of the group of K-rational points of E, where E is an elliptic curve defined over the finite field K.

`FactoredOrder(E)`

This function returns the factorisation of the order of the group of K-rational points of E, where E is an elliptic curve defined over the finite field K. This factorisation is stored on E and is reused when computing the order of points on E.

`SEA(H :` *parameters*`)`

`SEA(E :` *parameters*`)`

`Al`	MONSTGELT	*Default :* `"Default"`
`MaxSmooth`	RNGINTELT	*Default :* ∞
`AbortLevel`	RNGINTELT	*Default :* 0
`UseSEA`	BOOLELT	*Default :* `false`

This is the internal algorithm used by the point counting routines, but it can be invoked directly on an elliptic curve E or a point set H if desired. The most obvious

reason to do this is because of the parameters `AbortLevel` and `MaxSmooth`, which allow the computation to be stopped early if it can be shown not to satisfy certain conditions (such as the order of the group being prime).

Warning: Unlike the external functions which call it (such as `Order` and `FactoredOrder`), `SEA` does not store the computed group order back on the curve itself and so functions which need the group order will have to recompute it.

The parameter `Al` can be set to one of `"Enumerate"`, `"BSGS"`, or `"Default"`. Setting `Al` to `"Enumerate"` causes the group order to be found by enumeration of all points on the curve and hence is only practical for small orders. Setting `Al` to `"BSGS"` is currently equivalent to setting `Al` to `"Default"`, which uses point enumeration for suitably small finite fields, the full Schoof–Elkies–Atkin algorithm if the characteristic is not small, and canonical lift methods or deformation if it is. Currently, small characteristic means $p < 1000$. For $p < 37$ or $p \in \{41, 47, 59, 71\}$, canonical lift is used; deformation is the chosen method for other small p.

The canonical lift methods use a range of techniques to lift a modular parameter of the curve to an unramified p-adic ring. If a Gaussian Normal Basis of type ≤ 2 exists for that ring (see `HasGNB` on page 1270) then the method of Lercier and Lubicz from [LL03] is used with some local adaptations by Michael Harrison to increase the speed for fields of moderate size. Otherwise, the MSST algorithm as described in [Gau02] is used for fields up to a certain size with Harley's recursive version ([Har]) taking over for larger fields.

For $p < 10$ and $p = 13$ the modular parameter used is a generator of the function field of a genus 0 modular curve $X_0(p^r)$. The parameter gives a particularly nice modular polynomial Φ for use in the above-mentioned iterative lifting processes (see [Koh03]). In these cases Φ has a relatively simple factored form and evaluations are hand-coded for extra efficiency.

For p where $X_0(p)$ is hyperelliptic (excepting the anomalous case $p = 37$) we use a new method, developed by Michael Harrison, which lifts a *pair* of modular parameters corresponding to the x and y coordinates in a simple Weierstrass model of $X_0(p)$.

The deformation method uses code designed and implemented by Hendrik Hubrechts. It is based on ideas of Dwork, first used in the design of explicit computational algorithms by Alan Lauder, and works by computing the deformation over a family of curves of the Frobenius action on rigid cohomology by solving a certain differential equation p-adically. Details can be found in [Hub07]. The method is used for E over $\mathbf{F}_{p^n}$ with $p < 1000$ for which the canonical lift method is not used and for n greater than a smallish bound that increases slowly with p. For such p and smaller n, either enumeration or small characteristic SEA is used.

To use Schoof–Elkies–Atkin in small characteristic (with Lercier's improvements) instead of canonical lift or deformation, set `UseSEA` to `true`.

The parameter `MaxSmooth` can be used to specify a limit on the number of small primes that divide the group order. That is, we will consider the group order to be "smooth" if it is divisible by the product of small primes and this product is

larger than the value of `MaxSmooth`. Then the possible values of `AbortLevel` have the following meanings:

0 : Abort if the curve has smooth order.

1 : Abort if both the curve and its twist have smooth order.

2 : Abort if either the curve or its twist have smooth order.

If the early abort is triggered then the returned group order is 0.

One common use of these parameters is when searching for a curve with prime order. Setting `MaxSmooth := 1` will cause the early termination of the algorithm if a small factor of the order is found. If, however, the algorithm did not abort then the group order is not necessarily prime — this just means that no small prime dividing the order was encountered during the computation.

Note that the canonical lift methods give no intermediate data on the order of E, so `MaxSmooth` and `AbortLevel` have no effect when these methods are used.

Example H121E1

The first examples in characteristic 2 illustrate the increased speed when we work with fields that have GNBs available:

```
> //example with no Gaussian Normal Basis (GNB)
> K := FiniteField(2, 160); // finite field of size 2^160
> E := EllipticCurve([K!1, 0, 0, 0, K.1]);
> time #E;
1461501637330902918203686141511652467686942715904
Time: 0.100
> //example with a GNB of Type 1
> HasGNB(pAdicRing(2, 1), 162, 1);
true
> K := FiniteField(2, 162); // finite field of size 2^162
> E := EllipticCurve([K!1, 0, 0, 0, K.1]);
> time #E;
5846006549323611672814738806268278193573757976576
Time: 0.020
> //example with a GNB of Type 2
> K := FiniteField(2, 173); // finite field of size 2^173
> E := EllipticCurve([K!1, 0, 0, 0, K.1]);
> time #E;
11972621413014756705924586057649971923911742202056704
Time: 0.090
```

and here is an example in characteristic 3 (with type 1 GNB)

```
> F := FiniteField(3, 100);
> j := Random(F);
> E := EllipticCurveWithjInvariant(j);
> time #E;
515377520732011331036461505619702343613256090042
```

```
Time: 0.020
```

Finally (for small characteristic), a case with $p = 37$ where the deformation method is used.

```
> F := FiniteField(37, 30);
> j := Random(F);
> E := EllipticCurveWithjInvariant(j);
> time #E;
1111864136109938119501862966932866499557824177 67
Time: 1.580
```

Here we can see the early abort feature in action:

```
> p := NextPrime(10^9);
> p;
1000000007
> K := GF(p);
> E := EllipticCurve([K | -1, 1]);
> time SEA(E : MaxSmooth := 1);
0
Time: 0.010
> time #E;
1000009476
Time: 0.070
```

For curves this small the amount of time saved by an early abort is fairly small, but for curves over large fields the savings can be quite significant. As mentioned above, even when SEA does not abort there is no guarantee that the curve has prime order:

```
> E := EllipticCurve([K | 0, 1]);
> time SEA(E : MaxSmooth := 1);
1000000008
> IsSupersingular(E);
true
> E := EllipticCurve([K | -30, 1]);
> time SEA(E : MaxSmooth := 1);
1000035283
> Factorization($1);
[ <13, 1>, <709, 1>, <108499, 1> ]
```

In the first case the curve was supersingular and so the order was easily computed directly; thus no early abort was attempted. The latter case shows that small primes may not be looked at even when the curve is ordinary.
Next we find a curve with prime order (see also CryptographicCurve on page 3987):

```
> for k in [1..p] do
>   E := EllipticCurve([K | k, 1]);
>   n := SEA(E : MaxSmooth := 1);
>   if IsPrime(n) then
>     printf "Found curve of prime order %o for k = %o\n", n, k;
>     break;
```

```
>   end if;
> end for;
Found curve of prime order 999998501 for k = 29
> E;
Elliptic Curve defined by y^2 = x^3 + 29*x + 1 over GF(1000000007)
> #E;
999998501
```

`SetVerbose("SEA", v)`

This procedure changes the verbose printing level for the SEA algorithm which counts the number of points on an elliptic curve. Currently the legal values for v are `false`, `true`, or an integer between 0 and 5 (inclusive), where `false` is equivalent to 0 and `true` is equivalent to 1. A nonzero value gives information during the course of the algorithm, increasing in verbosity for higher values of v.

N.B. The previous name for this verbose flag, `"ECPointCount"` is now deprecated and will be removed in a future release. It should continue to function in this release, but its verbose levels are different to those of `"SEA"`.

`Order(E, r)`

Returns the order of the elliptic curve E over the extension field of K of degree r, where K is the base field of E. The order is found by calculating the order of E over K and lifting.

`Trace(E)`

`TraceOfFrobenius(E)`

Returns the trace of the Frobenius endomorphism on the elliptic curve E, equal to $q + 1 - n$ where q is the cardinality of the coefficient field and n is the order of the group of rational points of E.

`Trace(E, r)`

`TraceOfFrobenius(E, r)`

Returns the trace of the r-th power Frobenius endomorphism, where E is an elliptic curve over a finite field.

Example H121E2

The computation of the order of a curve over a finite field invokes the SEA algorithm. This data determines the number of points over all finite extensions, and is equivalent to the data for the trace of Frobenius. The values of the trace of Frobenius and group order over all extensions are therefore a trivial computation.

```
> FF<w> := GF(2^133);
> E := EllipticCurve([1, 0, 0, 0, w]);
> time #E;
10889035741470030830941160923712974513152
Time: 8.830
> FactoredOrder(E);
[ <2, 10>, <3, 2>, <150959, 1>, <654749, 1>, <1195399591723677421740186 7, 1> ]
> time TraceOfFrobenius(E);
-113173485896391746559
Time: 0.000
> time TraceOfFrobenius(E, 3);
22474974662793793921125259142328990600010427887259242963159 05
Time: 0.000
```

Example H121E3

The following code demonstrates the computation of twists of an elliptic curve over a finite field, and the relationship with the trace of Frobenius.

```
> E := EllipticCurveFromjInvariant(GF(101^2)!0);
> Twists(E);
[
   Elliptic Curve defined by y^2 = x^3 + 1 over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (61*w + 91) over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (98*w + 16) over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (9*w + 66) over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (59*w + 76) over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (87*w + 81) over GF(101^2)
]
> IsSupersingular(E);
true
```

Since E is supersingular, so are the twists of E. Hence the traces are divisible by the prime:

```
> [ TraceOfFrobenius(F) : F in Twists(E) ];
[ -202, -101, 101, 202, 101, -101 ]
> [ TraceOfFrobenius(F) : F in QuadraticTwists(E) ];
[ -202, 202 ]
```

We see that the traces come in pairs; the trace of a curve is the negative of the trace of its quadratic twist. This is not just true of the supersingular curves:

```
> E := EllipticCurveFromjInvariant(GF(101^2)!12^3);
> Twists(E);
```

```
[
   Elliptic Curve defined by y^2 = x^3 + x over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (40*w + 53)*x over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (3*w + 99)*x over GF(101^2),
   Elliptic Curve defined by y^2 = x^3 + (92*w + 19)*x over GF(101^2)
]
> IsSupersingular(E);
false
> [ TraceOfFrobenius(F) : F in Twists(E) ];
[ -198, 40, 198, -40 ]
> [ TraceOfFrobenius(F) : F in QuadraticTwists(E) ];
[ -198, 198 ]
```

121.2.2 Zeta Functions

`ZetaFunction(E)`

Given an elliptic curve E over a finite field, the function returns the zeta function of E as a rational function in one variable.

Note that each of the function calls `Order(E)`, `Trace(E)`, and `ZetaFunction(E)` invoke the same call to the SEA algorithm and determine equivalent data.

Example H121E4

The zeta function $\zeta_E(t)$ of an elliptic curve E over a finite field $\mathbf{F}_q$ is a rational function whose logarithmic derivative has the power series expansion:

$$\frac{d \log \zeta_E(t)}{d \log t} = \sum_{n=1}^{\infty} |E(F_{q^n})|\, t^n$$

The following example illustrates this property of $\zeta_E(t)$.

```
> p := 11;
> E := EllipticCurve([GF(p) | 1, 2]);
> Z := ZetaFunction(E);
> Q<t> := LaurentSeriesRing(Rationals());
> t*Derivative(Log(Evaluate(Z, t))) + O(t^7);
16*t + 128*t^2 + 1264*t^3 + 14848*t^4 + 160976*t^5 + 1769600*t^6 + O(t^7)
> [ Order(E, n) : n in [1..6] ];
[ 16, 128, 1264, 14848, 160976, 1769600 ]
```

121.2.3 Cryptographic Elliptic Curve Domains

This section describes functions for generating/validating good cryptographic Elliptic Curve Domains. The basic data of such a domain is an elliptic curve E over a finite field together with a point P on E such that the order of P is a large prime and the pair (E, P) satisfies the standard security conditions for being resistant to MOV and Anomalous attacks (see [JM00]).

`CryptographicCurve(F)`

`ValidateCryptographicCurve(E, P, ordP, h)`

`OrderBound`	RngIntElt	*Default :* 2^{160}
`Proof`	BoolElt	*Default :* `true`
`UseSEA`	BoolElt	*Default :* `false`

Given a finite field F, the first function finds an Elliptic Curve Domain over F; it generates random elliptic curves over F until a suitable one is found. For each generated curve E, the order $\#E$ is calculated and a check is made as to whether sieving $\#E$ by small primes leaves a strong pseudoprime

$$p \geq \max(\texttt{OrderBound}, 4\sqrt{(\#F)}).$$

If so, the security conditions (which only depend on the order of P) are checked for p. Finally, if `Proof` is `true`, p is proven to be prime. If all of the above conditions hold true then a random point P on E of order p is found and $E, P, p, \#E/p$ are returned.

If the Schoof–Elkies–Atkins method is used for computing $\#E$ then the early abort mechanism (see SEA on page 3980) can help to shortcut the process when `OrderBound` is close to $\#F$. However, when they apply, it is generally still quicker overall to use the much faster p-adic point-counting methods for large fields. To force the use of the SEA method for point-counting set `UseSEA` to `true`. This is not recommended!

Given data of the form returned by the first function as input, the second function verifies that it is valid data for a secure EC Domain with $ordP$ satisfying the above inequality for p. If `Proof` is `true` (*resp.* `false`), $ordP$ is proven to be prime (*resp.* subjected to a strong pseudoprimality test).

`NB:` For the first function, it is required that $\#F \geq$ `OrderBound` (or $2 *$ `OrderBound` if F has characteristic 2 when all ordinary elliptic curves have even order).

`SetVerbose("ECDom", v)`

Set the verbose printing level for progress output when running the above functions. Currently the legal values for v are `true`, `false`, 0, 1, and 2 (`false` is the same as 0, and `true` is the same as 1).

Example H121E5

For a bit of extra speed, we look for curves over $F = GF(2^{196})$ where a Type 1 GNB exists for p-adic point-counting (see SEA on page 3980). We begin by looking for a curve over F with a point whose order is greater than the default `OrderBound`.

```
> SetVerbose("ECDom", 1);
> F := FiniteField(2, 196);
> E,P,ord,h := CryptographicCurve(F);
Finished! Tried 2 curves.
Total time: 1.721
> ord; h;
1255420347077336152767157884637073187358718656499286956542 1
8
```

Now we search for a curve whose order is twice a prime (the best we can do in characteristic 2!). This can be accomplished by setting `OrderBound` to half the field size.

```
> E,P,ord,h := CryptographicCurve(F : OrderBound := 2^195);
Finished! Tried 102 curves.
Total time: 22.049
> ord; h;
5021681388309344611068631538579735994185285216292918566831 9
2
> ValidateCryptographicCurve(E, P, ord, h);
Verifying primality of the order of P...
true
```

121.3 Enumeration of Points

In this section the descriptions will refer to a point set H, which is either the H in the signature or the base point set of the elliptic curve E in the signature.

`Points(E)`
`Points(H)`
`RationalPoints(E)`
`RationalPoints(H)`

Returns the set of rational points of the point set H or of the base point set of the elliptic curve E, including the point at infinity.

`Random(E)`
`Random(H)`

Returns a random rational point of the point set H or of the base point set of the elliptic curve E. Every rational point has a roughly equal chance of being selected, including the point at infinity.

121.4 Abelian Group Structure

Like all group functions on elliptic curves, these intrinsics really apply to a particular point set; the curve is identified with its base point set for the purposes of these functions. To aid exposition only the versions that take the curves are shown but an appropriate point set over a finite field may be used instead.

`AbelianGroup(E)`

`TorsionSubgroup(E)`

Computes the abelian group isomorphic to the group of rational points on the elliptic curve E over a finite field. The function returns two values: an abelian group A and a map m from A to E. The map m provides an isomorphism between the abstract group A and the group of rational points on the curve.

`Generators(H)`

`Generators(E)`

Given an elliptic curve E defined over a finite field or a pointset H of E, this function returns generators for the group of points of E. The i-th element of the sequence corresponds to the i-th generator of the group as returned by the function `AbelianGroup`.

`NumberOfGenerators(H)`

`NumberOfGenerators(E)`

`Ngens(H)`

`Ngens(E)`

The number of generators of the group of rational points of (the point set H of) the elliptic curve E; this is simply the length of the sequence returned by `Generators(E)`.

Example H121E6

A simple example of some of the above calls in action:

```
> FF<w> := GF(1048583, 2);
> E := EllipticCurve([ 1016345*w + 272405, 660960*w + 830962 ]);
> A, m := AbelianGroup(E);
> A;
Abelian Group isomorphic to Z/3 + Z/366508289334
Defined on 2 generators
Relations:
  3*A.1 = 0
  366508289334*A.2 = 0
> S := Generators(E);
> S;
[ (191389*w + 49138 : 878749*w + 1008891 : 1), (852793*w + 24192 :
```

```
    376202*w + 48552 : 1) ]
> S eq [ m(A.1), m(A.2) ];
true
```

121.5 Pairings on Elliptic Curves

Pairings on elliptic curves over finite fields have many uses, ranging from checking independence of torsion points to more practical applications in cryptography. Both destructive applications (such as the MOV attack) and constructive applications (such as pairing-based cryptography) are worth mentioning. MAGMA now contains an implementation of the most popular pairings on elliptic curves over finite fields, including the Weil pairing, the Tate pairing, and various versions of the Eta and Ate pairings.

All pairings evaluate what is now called a Miller function, denoted by $f_{n,P}$ and defined as any function on E with divisor $n(P) - ([n]P) - (n-1)\infty$, where ∞ is the point at infinity of the curve.

121.5.1 Weil Pairing

The Weil pairing is a non-degenerate bilinear map from $E[n] \times E[n]$ to μ_n, the n-th roots of unity. The Weil pairing $w_n(P,Q)$ is computed as $(-1)^n f_{n,P}(Q)/f_{n,Q}(P)$.

`WeilPairing(P, Q, n)`

Given n-torsion points P and Q on an elliptic curve E, this function computes the Weil pairing of P and Q. Both points need to be in the same point set.

121.5.2 Tate Pairing

The Tate pairing (sometimes called the Tate–Lichtenbaum pairing) is a non-degenerate bilinear map from $E[n] \times E/nE$ into $K^*/(K^*)^n$, where K is a finite field containing the n-th roots of unity. In practice one often works with the reduced version of the pairing by mapping into μ_n using the final exponentiation; i.e., powering by $\#K^*/n$. The Tate pairing $t_n(P,Q)$ is computed as $f_{n,P}(Q)$.

`TatePairing(P, Q, n)`

Given an n-torsion point P and a point Q on an elliptic curve, this function computes the Tate pairing $t_n(P,Q)$ by returning a random representative of the coset. Both points need to be in the same point set; the field K is the field of definition of this point set.

`ReducedTatePairing(P, Q, n)`

Given an n-torsion point P and a point Q on an elliptic curve, this function computes the reduced Tate pairing $e_n(P,Q) = t_n(P,Q)^{(\#K-1)/n}$. Both points need to be in the same point set; the field K is the field of definition of this point set and n should divide $\#K - 1$.

121.5.3 Eta Pairing

The Eta pairing is only defined on supersingular curves and can be considered as an optimised version of the Tate pairing. It works as follows.

Let E be a supersingular elliptic curve defined over $\mathbf{F}_q$ and $n|\#E(\mathbf{F}_q)$. The security multiplier k is the smallest positive integer such that $q^k \equiv 1 \bmod n$. Here, in the supersingular case, k divides 6. Now, $E[n] \subseteq E(\mathbf{F}_{q^k})$ is a free $\mathbf{Z}/n\mathbf{Z}$-module of rank 2 which splits into the direct sum of 2 rank one eigenspaces under the action of q-Frobenius (denoted by F in the following), with eigenvalues 1 and q (as long as $(n, k) = 1$ and $k > 1$).

The Eta pairing is defined on the subgroup of $E[n] \times E[n]$ given by the product of the two F-eigenspaces $G_1 \times G_2$, where $P \in G_1$ iff $F(P) = P$ and $Q \in G_2$ iff $F(Q) = [q]Q$. G_1 is just $E(\mathbf{F}_q)[n]$. If R is an arbitrary n-torsion point in $E(\mathbf{F}_{q^k})$, k times its G_1-component is just the F-trace of R. This can be used to find non-trivial points in G_2 (see the example below).

There are three versions of the Eta pairing: one unreduced and two reduced versions. The Eta pairing $e_T(P, Q)$ is defined as $f_{T,P}(Q)$ where $T = t - 1$ and $\#E(\mathbf{F}_q) = q + 1 - t$ or $T = q$.

As for the Tate pairing, the unreduced version takes values in $K^*/(K^*)^n$ and the reduced versions in $\mu_n(K)$ where K is $\mathbf{F}_{q^k}$.

`EtaTPairing(P, Q, n, q)`

`CheckCurve`	BoolElt	*Default :* `false`
`CheckPoints`	BoolElt	*Default :* `false`

Given a supersingular elliptic curve $E/\mathbf{F}_q$ and two points P, Q in $E[n]$ such that $P = F(P)$ and $F(Q) = [q]Q$ with F the q-power Frobenius, this function computes the Eta pairing with $T = t-1$ where $\#E(\mathbf{F}_q) = q+1-t$. The result is non-reduced and thus a random representative of a whole coset. Both points need to be in the same point set $E(\mathbf{F}_{q^k})$ and q should be the size of the base field.

`ReducedEtaTPairing(P, Q, n, q)`

`CheckCurve`	BoolElt	*Default :* `false`
`CheckPoints`	BoolElt	*Default :* `false`

The reduced version of the `EtaTPairing` function.

`EtaqPairing(P, Q, n, q)`

`CheckCurve`	BoolElt	*Default :* `false`
`CheckPoints`	BoolElt	*Default :* `false`

Given a supersingular elliptic curve $E/\mathbf{F}_q$, two points P, Q in $E[n]$ such that $P = F(P)$ and $F(Q) = [q]Q$ with F the q-power Frobenius, this function computes the Eta pairing with $T = q$. This pairing is automatically reduced: It maps directly into n-th roots of unity. Both points need to be in the same point set $E(\mathbf{F}_{q^k})$ and q should be the size of the base field.

In the previous intrinsics one can explicitly check that the curve is supersingular by setting the parameter `CheckCurve` to `true`, and that the input points are indeed in the eigenspaces of Frobenius by setting the parameter `CheckPoints` to `true`. By default MAGMA does not perform these checks for efficiency reasons.

121.5.4 Ate Pairing

The Ate pairing generalises the Eta pairing to all elliptic curves, but is defined on $G_2 \times G_1$. i.e., the arguments are swapped with respect to the Eta pairing. Like the Eta pairing there are three versions, one unreduced and two reduced. The Ate pairing $a_T(Q, P)$ with $Q \in G_2$ and $P \in G_1$ is defined as $f_{T,Q}(P)$, where $T = t - 1$ and $\#E(\mathbf{F}_q) = q + 1 - t$ or $T = q$.

`AteTPairing(Q, P, n, q)`

`CheckPoints` BOOLELT *Default :* `false`

Given two points Q, P in $E[n]$ such that $F(Q) = [q]Q$ and $P = F(P)$ with F the q-power Frobenius, this function computes the Ate pairing with $T = t - 1$ where $\#E(\mathbf{F}_q) = q + 1 - t$. The result is non-reduced and thus a random representative of a whole coset. Both points need to be in the same point set $E(\mathbf{F}_{q^k})$ and q should be the size of the base field.

`ReducedAteTPairing(Q, P, n, q)`

`CheckPoints` BOOLELT *Default :* `false`

The reduced version of the `AteTPairing` function.

`AteqPairing(P, Q, m, q)`

`CheckPoints` BOOLELT *Default :* `false`

Given two points Q, P in $E[n]$ such that $F(Q) = [q]Q$ and $P = F(P)$ with F the q-power Frobenius, this function computes the Ate pairing with $T = q$. This pairing is automatically reduced: It maps directly into n-th roots of unity. Both points need to be in the same point set $E(\mathbf{F}_{q^k})$ and q should be the size of the base field.

In the previous intrinsics one can explicitly check that the input points are indeed in the eigenspaces of Frobenius by setting the parameter `CheckPoints` to `true`. By default MAGMA does not perform these checks for efficiency reasons.

Example H121E7

In this example, we first create a so-called BN-curve, which is an elliptic curve of the form $y^2 = x^3 + b$ defined over $\mathbf{F}_p$ of prime order n and embedding degree $k = 12$. These curves can be found easily by testing for which s both $p(s) = 36s^4 + 36s^3 + 24s^2 + 6s + 1$ and $n(s) = 36s^4 + 36s^3 + 18s^2 + 6s + 1$ are prime. Finding the parameter b is equally easy by testing a few random values, since there are only 6 isogeny classes. The point $G = (1, y)$ can be used as base point.

```
> Zs<s> := PolynomialRing(Integers());
```

```
> ps := 36*s^4 + 36*s^3 + 24*s^2 + 6*s + 1;
> ns := 36*s^4 + 36*s^3 + 18*s^2 + 6*s + 1;
> z := 513235038556;  // some random start value
> repeat
>   z := z+1;
>   p := Evaluate(ps, z);
>   n := Evaluate(ns, z);
> until IsProbablePrime(p) and IsProbablePrime(n);
> p;
24978577110957807134030566063991512750990207247 23
> n;
24978577110957807134030550259379176186344734948 29
> Fp := FiniteField(p);
> b := Fp!0;
> repeat
>   repeat b := b + 1; until IsSquare(b + 1);
>   y := SquareRoot(b + 1);
>   E := EllipticCurve([Fp!0, b]);
>   G := E![1, y];
> until IsZero(n*G);
> E;
Elliptic Curve defined by y^2 = x^3 + 18 over
  GF(24978577110957807134030566063991512750990207247 23)
> #E eq n;  // just to verify
true
> t := p + 1 - n;
> t;
158046123365646454722 9895
> k := 12; // security multiplier
> (p^k - 1) mod n; // check on p, n and k
0
> Fpk := GF(p, k);
> N := Resultant(s^k - 1, s^2 - t*s + p);  // number of points over big field
> Cofac := N div n^2;
> P := E(Fpk)!G;
> Q := Cofac*Random(E(Fpk));  // Q has order n now
```

Up to this point we have constructed a BN-curve and two points of order n. As such we can test, for instance, that P and $2P$ are linearly dependent:

```
> WeilPairing(P, 2*P, n) eq 1;
true
```

and also that the Weil pairing can be obtained from 2 Tate pairing computations:

```
> WeilPairing(P, Q, n) eq (-1)^n*TatePairing(P, Q, n)/TatePairing(Q, P, n);
true
```

or test the bilinearity of the reduced Tate pairing

```
> ReducedTatePairing(P, 2*Q, n) eq ReducedTatePairing(P, Q, n)^2;
```

```
true
```

and that the corresponding test for the Tate pairing would fail since the result is a random representative of the coset:

```
> TatePairing(P, 2*Q, n) eq TatePairing(P, Q, n)^2;
false
```

Since the curve is ordinary we cannot use the Eta pairing on this curve. We can use the Ate pairing, but this is defined on $G_2 \times G_1$ and up to this point we only have a generator of G_1. To find a generator of G_2 we need to remove the component in Q that lies in G_1. This can be done easily by using the trace of the point Q: $\mathrm{Tr}(Q) = \sum_{i=0}^{k-1} F(Q)$ with F the p-power Frobenius. The trace equals k times the component of Q in G_1.

```
> TrQ := &+[ E(Fpk) ! [Frobenius(Q[1], Fp, i), Frobenius(Q[2], Fp, i)]  :
>                       i in [0..k-1]];
> Q := k*Q - TrQ;
```

At this point Q is in G_2 and we can compute the Ate pairing of Q and P. For instance, we can test compatibility of the reduced Ate pairing with the reduced Tate pairing:

```
> T := t - 1;
> L := (T^k - 1) div n;
> c := &+[ T^(k - 1 - i)*p^i : i in [0..k-1] ] mod n;
> ReducedAteTPairing(Q, P, n, p)^c eq ReducedTatePairing(Q, P, n)^L;
true
> Frobenius(AteqPairing(Q, P, n, p)^k, Fp, k - 1) eq ReducedTatePairing(Q, P, n);
true
```

To test the Eta pairing computations we will use one of the supersingular elliptic curves $y^2 + y = x^3 + x + b$ with $b = 0$ or 1 over a finite field $\mathbf{F}_{2^m}$ and m odd. These curves have security parameter $k = 4$.

```
> F2m := GF(2, 163);
> q := #F2m;
> E := EllipticCurve([F2m!0, 0, 1, 1, 1]);
> #E;
11692013098647223345629483497433542615764159168513
> IsPrime($1);
true
> n := #E;
> t := TraceOfFrobenius(E);
> P := Random(E);
> k := 4;
> F2m4 := ExtensionField<F2m, X | X^4 + X + 1>;
> N := Resultant(s^k - 1, s^2 - t*s + q);  // number of points over big field
> Cofac := N div n^2;
> P := E(F2m4) ! P;
> Q := Cofac*Random(E(F2m4));  // Q has order n now
> TrQ := &+[ E(F2m4) ! [Frobenius(Q[1], F2m, i), Frobenius(Q[2], F2m, i)]  :
>                       i in [0..k-1]];
```

```
> Q := k*Q - TrQ;
```

After this setup we can now compute the Eta pairing and test compatibility with the Tate pairing.

```
> d := GCD(k, q^k - 1);
> Frobenius(EtaqPairing(P, Q, n, q)^(k div d), F2m, k - 1) eq
>                                         ReducedTatePairing(P, Q, n);
true
```

Example H121E8

The following example demonstrates the Menezes, Okamoto, and Vanstone (MOV) reduction of the discrete logarithm on a supersingular elliptic curve to a discrete logarithm in a finite field using the Weil Pairing. The group structure of a supersingular curve E over a finite prime field $\mathbf{F}_p$ for $p > 3$ can be $\mathbf{Z}/n\mathbf{Z}$ or $\mathbf{Z}/2\mathbf{Z} \times \mathbf{Z}/(n/2)\mathbf{Z}$, where $n = p + 1$, and the group structure over a degree 2 extension is $\mathbf{Z}/n\mathbf{Z} \times \mathbf{Z}/n\mathbf{Z}$. The nontrivial Weil pairing on this is the basis for this reduction.

```
> p := NextPrime(2^131);
> n := p + 1;
> n;

> WeilPairing(P1, r*P1, n);
1
```

121.6 Weil Descent in Characteristic Two

One approach to attacking the discrete logarithm problem for elliptic curves over finite fields is through Weil descent. Let E have base field K and let k be a subfield of K. The basic idea is to find a higher genus curve C/k along with a non-trivial homomorphism from $E(K)$ to $\mathrm{Jac}(C)(k)$ [the Jacobian of C]. This transfers the problem to one over a smaller field and Index Calculus methods over C can then be applied.

Magma now contains an implementation, due to Florian Heß, of the GHS Weil Descent for ordinary (i.e., $j(E) \neq 0$) elliptic curves in characteristic 2 (see [Gau00] or the chapter by F. Heß in [Bla05]), which constructs such a C along with the divisor map from E to C.

`WeilDescent(E, k, c)`

`HyperellipticImage` BoolElt *Default :* `true`

The curve E/K is an ordinary elliptic curve over a finite field K of characteristic 2. The argument k is a subfield of K and c is a non-zero element of K.

The function uses GHS descent to construct a plane curve C/k and a map from $E(K)$ to k-divisors of C. There are two possibilities:

i) The curve C is hyperelliptic and Magma implements the group law on its Jacobian, $\mathrm{Jac}(C)$. In this case, C will be returned as a hyperelliptic curve (type `CrvHyp`) and the map returned will actually be the divisor class homomorphism from $E(K)$ to $\mathrm{Jac}(C)(k)$ with points of $E(K)$ being identified with divisor classes in the usual way: $P \leftrightarrow (P) - (0)$.

ii) Otherwise, C is returned as a general plane curve and the map is from points of $E(K)$, considered as divisors of degree 1, to the corresponding k-divisor of C. In this case, where specialised Jacobian arithmetic is not available, it may be more convenient to work with the effective divisors rather than degree 0 divisors. The user may readily convert to the degree 0 case by getting $h(0)$ initially and then using $h((P) - (0)) = h(P) - h(0)$, where h is the divisor map.

In case ii), no reduction of the image divisor is performed by the divisor map and if $[K : k]$ is large then this divisor will have high degree and the computation may be quite slow. h is defined by divisor pullback corresponding to the function field inclusion $K(E) \hookrightarrow K(C)$ followed by the trace from K down to k.

If the user prefers to have C and h returned as in case ii), even when C is hyperelliptic, the parameter `HyperellipticImage` should be set to `false`.

The third argument c is a parameter to specify the precise data for the descent. If $r = \sqrt{(1/j(E))}$ and $b = r/c$, the function field $K(E)$ is isomorphic to the degree 2 extension of the rational function field $K(x)$ with equation

$$y^2 + y = c/x + a_2(E) + bx$$

and it is this Artin–Schreier extension that is used for the GHS descent as explained in the above references.

It is possible to work directly with function fields, if preferred, using the function `WeilDescent`. However this function produces a divisor map between function fields rather than curves and does not give the divisor class map in case i) above.

The genus of C and its degree are very dependent on the choice of c. For a description of how to choose a good c for given E and k, see sections VIII.2.4 and VIII.2.5 in the chapter by Heß cited in the introduction to this section.

We merely note here that $c \in k$ or $b \in k$ leads to a hyperelliptic C, though this may have very large genus and other choices, giving non-hyperelliptic curves, may be better.

`WeilDescentGenus(E, k, c)`

Returns the genus of the Weil descent curve C produced by `WeilDescent` for input E, k, c.

`WeilDescentDegree(E, k, c)`

Returns the degree in the second variable of the plane Weil descent curve C produced by `WeilDescent` for input E, k, c.

Example H121E9

The following example is similar to one from the article of F. Heß referred to above. E is defined over $\mathbf{F}_{2^{155}}$ and C is a hyperelliptic curve of genus 31 over $\mathbf{F}_{2^5}$.

```
> K<w> := FiniteField(2, 155);
> k := FiniteField(2, 5);
> Embed(k, K);
> b :=  w^154 + w^152 + w^150 + w^146 + w^143 + w^142 + w^141 +
>    w^139 + w^138 + w^137 + w^136 + w^134 + w^133 + w^132 + w^131 +
>    w^127 + w^125 + w^123 + w^121 + w^117 + w^116 + w^115 + w^112 +
>    w^111 + w^109 + w^108 + w^107 + w^105 + w^104 + w^102 + w^101 +
>    w^100 + w^99 + w^98 + w^97 + w^95 + w^90 + w^89 + w^88 + w^85 +
>    w^83 + w^81 + w^80 + w^79 + w^78 + w^76 + w^75 + w^73 + w^72 +
>    w^69 + w^68 + w^62 + w^61 + w^59 + w^54 + w^52 + w^47 + w^45 +
>    w^44 + w^43 + w^40 + w^39 + w^37 + w^36 + w^34 + w^32 + w^31 +
>    w^25 + w^15 + w^13 + w^10 + w^8 + w^7 + w^6;
> E := EllipticCurve([K| 1, 0, 0, b, 0]);
> C,div_map := WeilDescent(E, k, K!1);
> C;
Hyperelliptic Curve defined by y^2 + (k.1^16*x^32 + k.1^27*x^8 + k.1^2*x^4 +
    k.1^29*x^2 + k.1^30*x + k.1^20)*y = k.1^30*x^32 + k.1^10*x^8 + k.1^16*x^4 +
    k.1^12*x^2 + k.1^13*x + k.1^3 over GF(2^5)
> ptE := Points(E, w^2)[1];

> // check that order ptJ on J = order ptE on E
> J := Jacobian(C);
> ord*ptJ eq J!0;
true
> [ (ord div p[1])*ptJ eq J!0 : p in Factorization(ord) ];
```

```
[ false, false, false, false, false, false, false, false ]
```

121.7 Discrete Logarithms

Computing discrete logarithms on elliptic curves over finite fields is considered to be a very difficult problem. The best algorithms for general elliptic curves take exponential time, and do not take much advantage of properties of the curve. Solving such problems can thus be computationally infeasible for large curves. Indeed, elliptic curves are becoming increasingly appealing for applications in cryptography.

Although hard instances of the elliptic curve discrete logarithm may be impossible to solve, MAGMA is able to efficiently solve reasonable sized instances, or instances where the large prime factor of the order of the base point is not too big. MAGMA does this as follows: The first step is to compute the factorisation of the order of the base point, which may require calling SEA if the order of the curve is not already known to MAGMA. Then it checks that the order of the base point is a multiple of the order of the other point. If this is not true then there is no solution. It next breaks the problem down to solving the discrete logarithm modulo the prime power factors of the order using the Pohlig–Hellman algorithm.

For very small primes it will try to solve this by exhaustive search. If a solution does not exist then MAGMA might determine this during the exhaustive search and abort the remaining computations. For the larger prime power factors, MAGMA uses the parallel collision search version of Pollard's rho algorithm. The implementation includes Edlyn Teske's idea of r-adding walks and Michael Wiener's and Robert Zuccherato's idea of treating the point P the same as $-P$ (for curves of the form $y^2 = x^3 + ax + b$) so as to reduce the search space by a factor of $1/\sqrt{2}$ (this idea was independently discovered by other researchers). It should be noted that MAGMA is not always able to determine the nonexistence of a solution and therefore may run forever if given very bad parameters. For this reason, the user has the option of setting a time limit on the calculation.

`Log(Q, P)`

The discrete log of P to the base Q (an integer n satisfying $n * Q = P$ where $0 \leq n <$ `Order`(Q)). The arguments Q and P must be points on the same elliptic curve, which must be defined over a finite field. The function returns -1 if it is determined that no solution exists.

`Log(Q, P, t)`

The discrete log of P to the base Q (an integer n satisfying $n * Q = P$ where $0 \leq n <$ `Order`(Q)). The arguments Q and P must be points on the same elliptic curve, which must be defined over a finite field. The argument t is a time limit in seconds on the calculation; if this limit is exceeded then the calculation is aborted. The time limit t must be a small positive integer. This function returns -1 if it is determined that no solution exists; if the calculation is aborted due to the time limit being exceeded then -2 is returned.

Example H121E10

In the example below we create a random elliptic curve over a randomly chosen 40-bit prime field. Our base point Q is chosen randomly on the curve, and the other point P is selected as a random multiple of Q. Using the `Log` function, we recover that multiplier (m) and finally we verify that the solution is correct.

```
> GetSeed();
1020 132
> K := GF(RandomPrime(40));
> E := EllipticCurve([Random(K), Random(K)]);
> E;
Elliptic Curve defined by y^2 = x^3 + 456271502613*x + 504334195864
over GF(742033232201)
> Q := Random(E);
> Q;
(174050269867 : 191768822966 : 1)
> FactoredOrder(Q);
[ <31, 1>, <7789, 1>, <3073121, 1> ]
> P := Random(Order(Q))*Q;
> P;
(495359429535 : 455525174166 : 1)
> m := Log(Q, P);
> m;
597156621194
> m*Q - P;
(0 : 1 : 0)
```

122 ELLIPTIC CURVES OVER Q AND NUMBER FIELDS

Chapter 122
ELLIPTIC CURVES OVER Q AND NUMBER FIELDS

122.1 Introduction

This chapter deals with functionality that is specific to elliptic curves defined over the rationals or over number fields. As a general goal, these functions are developed in parallel. Naturally however, the functionality available over $\mathbf{Q}$ is far ahead of that available for general number fields, both in the range of functions and in the efficiency of implementations.

Functions declared for number fields may also be used over $\mathbf{Q}$: to do so, it is usually necessary to construct $\mathbf{Q}$ as `RationalsAsNumberField()` rather than `Rationals()`.

122.2 Curves over the Rationals

122.2.1 Local Invariants

`Conductor(E)`

The conductor of the elliptic curve E defined over $\mathbf{Q}$.

`BadPrimes(E)`

Given an elliptic curve E defined over $\mathbf{Q}$, return the sequence of primes dividing the minimal discriminant of E. These are the primes at which the minimal model for E has bad reduction; note that there may be other primes dividing the discriminant of the given model of E.

`TamagawaNumber(E, p)`

Given an elliptic curve E defined over $\mathbf{Q}$ and a prime number p, this function returns the local Tamagawa number of E at p, which is the index in $E(\mathbf{Q}_p)$ of the subgroup $E^0(\mathbf{Q}_p)$ of points with nonsingular reduction modulo p. For any prime p that is of good reduction for E, this function returns 1.

`TamagawaNumbers(E)`

Given an elliptic curve E defined over $\mathbf{Q}$, this function returns the sequence of Tamagawa numbers at each of the bad primes of E, as defined above.

`LocalInformation(E, p)`

Given an elliptic curve E defined over $\mathbf{Q}$ and a prime number p, this function returns the local information at the prime p as a tuple of the form $< P, vpd, fp, c_p, K, split >$, consisting of p, its multiplicity in the discriminant, its multiplicity in the conductor, the Tamagawa number at p, the Kodaira symbol, and finally a boolean which is false iff the curve has nonsplit multiplicative reduction. The second object returned is a local minimal model for E at p.

`LocalInformation(E)`

Given an elliptic curve E this function returns a sequence of tuples of the kind described above, for the primes dividing the discriminant of E.

`ReductionType(E, p)`

Returns a string describing the reduction type of E at p; the possibilities are "Good", "Additive", "Split multiplicative" or "Nonsplit multiplicative". These correspond to the type of singularity (if any) on the reduced curve. This function is necessary as the Kodaira symbols (see below) do not distinguish between split and unsplit multiplicative reduction.

`FrobeniusTraceDirect(E, p)`

Given a rational elliptic curve E and a prime p, this function provides an efficient way to directly compute the trace of Frobenius (without having to create $GF(p)$, coercing E into this field, etc). The argument p is **not** checked to be prime.

`TracesOfFrobenius(E, B)`

The sequence of traces of Frobenius $a_p(E)$, of the reduction mod p of E, for all primes p up to B. This function is very carefully optimised.

Example H122E1

```
> E := EllipticCurve([ 0, 1, 1, 3, 5 ]);
> T := TracesOfFrobenius(E, 100); T;
[ 0, 1, -3, -2, -5, 1, -3, -1, 5, 6, 8, -1, -6, 7, -2, 1, 14, -1, -12,
16, -16, -7, 6, 12, 2 ]
> time T := TracesOfFrobenius(E, 10^6);
Time: 5.600
```

122.2.2 Kodaira Symbols

Kodaira symbols have their own type `SymKod`. Apart from the two functions that determine symbols for elliptic curves, there is a special creation function and a comparison operator to test Kodaira symbols.

`KodairaSymbol(E, p)`

Given an elliptic curve E defined over $\mathbf{Q}$ and a prime number p, this function returns the reduction type of E modulo p in the form of a Kodaira symbol.

`KodairaSymbols(E)`

Given an elliptic curve E defined over $\mathbf{Q}$, this function returns the reduction types of E modulo the bad primes in the form of a sequence of Kodaira symbols.

`KodairaSymbol(s)`

Given a string s, return the Kodaira symbol it represents. The values of s that are allowed are: `"I0"`, `"I1"`, `"I2"`, ..., `"In"`, `"II"`, `"III"`, `"IV"`, and `"I0*"`, `"I1*"`, `"I2*"`, ..., `"In*"`, `"II*"`, `"III*"`, `"IV*"`. The dots stand for `"I`k`"` with k a positive integer. The 'generic' type `"In"` allows the matching of types `"I`n`"` for any integer $n > 0$ (and similarly for `"In*"`).

`h eq k`

Given two Kodaira symbols h and k, this function returns `true` if and only if either both are identical, or one is generic (of the form `"In"`, or `"In*"`) and the other is specific of the same type: `"In"` will compare equal with any of `"I1"`, `"I2"`, `"I3"`, etc., and `"In*"` will compare equal with any of `"I1*"`, `"I2*"`, `"I3*"`, etc. Note however that `"In"` and `"I3"` are different from the point of view of set creation.

`h ne k`

The logical negation of `eq`.

Example H122E2

We search for curves with a particular reduction type '`I0*`' in a family of curves.

```
> S := [ ];
> for n := 2 to 100 do
>    E := EllipticCurve([n, 0]);
>    for p in BadPrimes(E) do
>       if KodairaSymbol(E, p) eq KodairaSymbol("I0*") then
>          Append(~S, <p, n>);
>       end if;
>    end for;
> end for;
> S;
[ <3, 9>, <3, 18>, <5, 25>, <3, 36>, <3, 45>, <7, 49>, <5, 50>,
<3, 63>, <3, 72>, <5, 75>, <3, 90>, <7, 98>, <3, 99>, <5, 100> ]
```

122.2.3 Complex Multiplication

`HasComplexMultiplication(E)`

Given an elliptic curve E over the rationals (or a number field), the function determines whether the curve has complex multiplication or not and, if so, also returns the discriminant of the CM quadratic order. The algorithm uses fairly straightforward analytic methods, which are not suited to very high degree j-invariants with CM by orders with discriminants more than a few thousand.

122.2.4 Isogenous Curves

`IsogenousCurves(E)`

The set of curves $\mathbf{Q}$-isogenous to a rational elliptic curve E. The method used is to proceed prime-by-prime. Mazur's Theorem restricts the possibilities to a short list, and j-invariant considerations leave only p-isogenies for $p = 2, 3, 5, 7, 13$ to be considered. For $p = 2$ or 3, the method proceeds by finding the rational roots of the p-th division polynomial for the curve E. From these roots, one can then recover the isogenous curves. The question as to whether or not there is a p-isogeny is entirely a function of the j-invariant of the curve, and this idea is used for $p = 5, 7, 13$. In these cases the algorithm first takes a minimal twist of the elliptic curve, and then finds rational roots of the polynomial of degree $(p + 1)$ that comes from a fibre of $X_0(p)$. The isogenous curves of the minimal twist corresponding to these roots are then computed, and then these curves are twisted back to get the isogenous curves of E. In all cases, if the conductor is squarefree, some small values of the Frobenius traces are checked mod p to ensure the feasibility of a p-isogeny. Other similar ideas involving checking congruences are also used to try to eliminate the possibility of a p-isogeny without finding roots. Tree-based methods are used to extend the isogeny tree from (say) 2-isogenies to 4-isogenies to 8-isogenies, etc. The integer returned as a second argument corresponds to the largest degree of a cyclic isogeny between two curves in the isogeny class. The ordering of the list of curves returned is well-defined; the first curve is always the curve of minimal Faltings height, and the heights generically increase upon going down the list. However, when there are isogenies of two different prime degrees, a different ordering is used. In the case where there is a 4-isogeny (or a certain type of 9-isogeny), there is an arbitrary choice made on the bottom tree leaves in order to make the ordering consistent.

`FaltingsHeight(E)`

`Precision` RngIntElt *Default :*

Compute the Faltings height of a rational elliptic curve. This is given by $-\frac{1}{2}\log \mathrm{Vol}(E)$ where $\mathrm{Vol}(E)$ is the volume of the fundamental parallelogram.

Example H122E3

First we compute isogenous curves using `DivisionPolynomial`; in this special case we obtain the entire isogeny class by considering only 3-isogenies directly from E.

```
> E:=EllipticCurve([1,-1,1,1,-1]);
> F:=Factorization(DivisionPolynomial(E,3));
> I:=IsogenyFromKernel(E,F[1][1]); I;
Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 - 29*x - 53 over Rational
Field
> I:=IsogenyFromKernel(E,F[2][1]); I;
Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 - 14*x + 29 over Rational
Field
```

Alternatively, we can get the `IsogenousCurves` directly. Note that `IsogenyFromKernel` also returns the map between the isogenous curves as a second argument.

```
> IsogenousCurves(E);
[
    Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 + x - 1 over Rational
    Field,
    Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 - 29*x - 53 over
    Rational Field,
    Elliptic Curve defined by y^2 + x*y + y = x^3 - x^2 - 14*x + 29 over
    Rational Field
]
9
```

122.2.5 Mordell–Weil Group

The Mordell–Weil theorem states that for an elliptic curve E defined over $\mathbf{Q}$, the set $E(\mathbf{Q})$ of points on E with $\mathbf{Q}$-rational coordinates forms a finitely generated abelian group, known as the *Mordell–Weil group*.

To compute Mordell–Weil groups in MAGMA, there are several ways to proceed:

(i) A large array of relevant tools (various descents, and other techniques) are described elsewhere in this chapter, and may be applied "by hand".

(ii) The routine `MordellWeilShaInformation` automates the process: it applies all relevant tools in a suitable order.

(iii) The older routines `Rank` and `MordellWeilGroup` use an (independent) implementation of an algorithm similar to the famous program `mwrank` by John Cremona. These routines do 2-descent or 2-isogeny descent, but use no additional techniques.

Warning: No algorithm has been implemented that is guaranteed to determine the Mordell-Weil rank! In some cases the functions `Rank` and `MordellWeilGroup` return a lower bound which is not known to be the true rank (or group). In cases where the rank is not proven, a warning message is printed the first time either `Rank` or `MordellWeilGroup` is called for a particular elliptic curve; on subsequent calls, the unproven result will be

returned without any warning. It is recommended to use `RankBounds` instead of `Rank`, to avoid confusion.

`MordellWeilShaInformation(E: parameters)`

`DescentInformation(E: parameters)`

`RankOnly`	BoolElt	*Default :* `false`
`ShaInfo`	BoolElt	*Default :* `false`
`Silent`	BoolElt	*Default :* `false`

This is a special function which uses all relevant Magma machinery to obtain as much information as possible about the Mordell-Weil group and the Tate-Shafarevich group of the given elliptic curve E over $\mathbf{Q}$. The tools used include 2-descent, 4-descent, Cassels-Tate pairings, 3-descent, and also analytic routines (rank and Heegner points) when the conductor of E is not too large. The information is progressively refined as the tools are applied (in order of their estimated cost), and a summary is printed at each stage. At the end, the collected information is returned in three sequences.

The first sequence returned contains lower and upper bounds on the Mordell-Weil rank of $E(\mathbf{Q})$, and the second is the sequence of independent generators of the Mordell-Weil group (modulo the torsion subgroup) that have been found. The third sequence returned contains the information obtained about the Tate-Shafarevich group $Sha(E)$: letting r_n denote the largest integer such that $\mathbf{Z}/n\mathbf{Z}$ is contained in $Sha(E)$, the tuple `<n, [l,u]>` would indicate that the computations prove $l \leq r_n \leq u$.

By default, the routine attempts to determine the rank and generators, and returns whenever it succeeds in determining them. When `RankOnly` is set to true, it returns as soon as the Mordell-Weil rank has been determined. When `ShaInfo` is set to true, it additionally probes the structure of $Sha(E)$ using all available tools.

Example H122E4

Conductor 389 is the smallest conductor of a curve with rank 2:

```
> E := EllipticCurve("389a1");
> time rank, gens, sha := MordellWeilShaInformation(E);
Torsion Subgroup is trivial
Analytic rank = 2
The 2-Selmer group has rank 2
Found a point of infinite order.
Found 2 independent points.
After 2-descent:
    2 <= Rank(E) <= 2
    Sha(E)[2] is trivial
(Searched up to height 100 on the 2-coverings.)
```

```
Time: 0.280
```

We now take a curve of conductor 571, which has rank 0 and nontrivial Tate-Shafarevich group:

```
> E := EllipticCurve("571a1");
> time rank, gens, sha :=MordellWeilShaInformation(E);
Torsion Subgroup is trivial
Analytic rank = 0
     ==> Rank(E) = 0
Time: 0.010
```

We must specify that we want information about the Tate-Shafarevich group:

```
> time rank, gens, sha :=MordellWeilShaInformation(E : ShaInfo);
Torsion Subgroup is trivial
Analytic rank = 0
     ==> Rank(E) = 0
The 2-Selmer group has rank 2
After 2-descent:
    0 <= Rank(E) <= 0
    (Z/2)^2 <= Sha(E)[2] <= (Z/2)^2
(Searched up to height 10000 on the 2-coverings.)
The Cassels-Tate pairing on Sel(2,E)/E[2] is
[0 1]
[1 0]
After using Cassels-Tate:
    0 <= Rank(E) <= 0
    (Z/2)^2 <= Sha(E)[4] <= (Z/2)^2
The 3-Selmer group has rank 0
After 3-descent:
    0 <= Rank(E) <= 0
    (Z/2)^2 <= Sha(E)[12] <= (Z/2)^2
Time: 0.840
```

`TorsionSubgroup(E)`

Given an elliptic curve E defined over $\mathbf{Q}$, this function returns an abelian group A isomorphic to the torsion subgroup of the Mordell–Weil group, and a map from this abstract group A to the elliptic curve providing the isomorphism. By a theorem of Mazur, A is either C_k (for k in $\{1..10\}$ or 12) or $C_2 \times C_{2k}$ (for k in $\{1..4\}$). If there are two generators then the first generator returned in this case will have order 2.

`Rank(E: parameters)`

`MordellWeilRank(E: parameters)`

`Bound` RngIntElt *Default :* 150

Given an elliptic curve E defined over $\mathbf{Q}$, this function returns the rank of the Mordell–Weil group of E.

The general procedure to calculate the rank involves searching for rational points on certain homogeneous spaces represented by equations of the form $y^2 = ax^4+bx^3+cx^2+dx+e$. The parameter `Bound` is a bound on the numerator and denominator of x that will be used when searching for such points.

`RankBounds(E: parameters)`

`MordellWeilRankBounds(E: parameters)`

`Bound` RngIntElt *Default :* 150

Given an elliptic curve E defined over $\mathbf{Q}$, this computes and returns lower and upper bounds on the rank of the Mordell–Weil group of E. The parameter `Bound` is as described in the intrinsic `Rank`. This function will not generate the usual warning message if the upper and lower bounds are not equal.

`MordellWeilGroup(E: parameters)`

`AbelianGroup(E: parameters)`

`Bound` RngIntElt *Default :* 150

`HeightBound` RngIntElt *Default :* 15

The Mordell–Weil group of an elliptic curve E defined over $\mathbf{Q}$. The function returns two values: an abelian group A and a map m from A to E. The map m provides an isomorphism between the abstract group A and the Mordell–Weil group.

The parameter `Bound` is used during the rank computation part of the algorithm, and has the same meaning as described in the intrinsic `Rank`, above. The group computation involves searching for points on E up to a certain (naive) height. The parameter `HeightBound` is used to limit this search as the rigorous bounds may not be feasible. When the `HeightBound` is less than the rigorous bound, a warning message is printed. In this situation, the user may wish to also use `Saturation` (see below).

As explained above for `Rank`, the computed rank may be less than the actual rank. In cases where the rank is not proven, a warning message is printed (the first time). The best way to check whether the rank has been proven is to use `RankBounds`.

`Generators(E)`

Given an elliptic curve E defined over $\mathbf{Q}$, this function returns generators for the Mordell–Weil group of E, in the form of a sequence of points of E. The i-th element of the sequence corresponds to the i-th generator of the group as returned by the function `MordellWeilGroup`; the generators of the torsion subgroup will come first (in the order described in `TorsionSubgroup`), followed by the points of infinite order.

`NumberOfGenerators(E)`

`Ngens(E)`

The number of generators of the group of rational points of the elliptic curve E; this is simply the length of the sequence returned by `Generators(E)`.

`Saturation(points, n)`

`TorsionFree`	BoolElt	*Default :* `false`
`OmitPrimes`	[RngIntElt]	*Default :* []
`Check`	BoolElt	*Default :* `true`

Given a sequence of points on an elliptic curve E over the rationals, and an integer n, this function returns a sequence of points generating a subgroup of $E(\mathbf{Q})$ which contains the given points and which is *p-saturated* for all primes p up to n. (A subgroup S is p-saturated in a group G if there is no intermediate subgroup H for which the index $[H : S]$ is finite and divisible by p.)

If `OmitPrimes` is set to be a sequence of primes, then the group is not checked to be p-saturated for those primes. If `TorsionFree` is set to tt true, torsion points are omitted from the result (that is, the result contains independent generators modulo torsion). If `Check` is set to `false`, the input sequence of points are assumed to be independent modulo torsion.

Example H122E5

```
> E := EllipticCurve([73, 0]);
> E;
Elliptic Curve defined by y^2 = x^3 + 73*x over Rational Field
> Factorization(Integers() ! Discriminant(E));
[ <2, 6>, <73, 3> ]
> BadPrimes(E);
[ 2, 73 ]
> LocalInformation(E);
[ <2, 6, 6, 1, II, true>, <73, 3, 2, 2, III, true> ]
> G, m := MordellWeilGroup(E);
> G;
Abelian Group isomorphic to Z/2 + Z + Z
Defined on 3 generators
Relations:
    2*G.1 = 0
```

```
> Generators(E);
[ (0 : 0 : 1), (36 : -222 : 1), (4/9 : 154/27 : 1) ]
> 2*m(G.1);
(0 : 1 : 0)
```

Example H122E6

Here is a curve with moderately large rank; we do not attempt to compute the full group since that would be quite time-consuming.

```
> E := EllipticCurve([0, 0, 0, -9217, 300985]);
> T, h := TorsionSubgroup(E);
> T;
Abelian Group of order 1
> time RankBounds(E);
7 7
Time: 0.070
```

This curve was well-behaved in that the computed lower and upper bounds on the rank are the same, and so we know that we have computed the rank exactly. Here is a curve where that is not the case:

```
> E := EllipticCurve([0, -1, 0, -140, -587]);
> time G, h := MordellWeilGroup(E);
Warning: rank computed (2) is only a lower bound
(It may still be correct, though)
Time: 0.250
> RankBounds(E);
2 3
```

The difficulty here is that the Tate–Shafarevich group of E is not trivial, and this blocks the 2-descent process used to compute the rank. We can compute the `AnalyticRank` of the curve to be 2, but this is only conjecturally equal to the rank. In cases like this, higher level descents may provide a more definitive answer; the machinery for two- and four-descents described in the next two sections can be used to confirm that the rank is indeed 2. In any case, we can certainly get the group with rank equal to the lower bound.

```
> G;
Abelian Group isomorphic to Z + Z
Defined on 2 generators (free)
> S := Generators(E);
> S;
[ (-6 : -1 : 1), (-7 : 1 : 1) ]
> [ Order(P) : P in S ];
[ 0, 0 ]
> h(G.1) eq S[1];
true
> h(G.2) eq S[2];
true
> h(2*G.1 + 3*G.2);
```

```
(-359741403/57729604 : 940675899883/438629531192 : 1)
> 2*S[1] + 3*S[2];
(-359741403/57729604 : 940675899883/438629531192 : 1)
```

As mentioned above, the rank of this curve is actually 2, so we have computed generators for the full group of E.

122.2.6 Heights and Height Pairing

These functions require that the corresponding elliptic curve has integral coefficients.

`NaiveHeight(P)`

`WeilHeight(P)`

Given a point $P = (a/b, c/d, 1)$ on an elliptic curve E defined over **Q** with integral coefficients, this function returns the naive (or Weil) height $h(P)$ whose definition is $h(P) = \log \max\{|a|, |b|\}$.

`Height(P: parameters)`

`CanonicalHeight(P: parameters)`

`Precision`	RngIntElt	*Default :*

Given a point P on an elliptic curve E defined over **Q** with integral coefficients, this function returns the canonical height $\hat{h}(P)$.

One definition of $\hat{h}(P)$ is $\hat{h}(P) = \lim_{n\to\infty} 4^{-n} h(2^n P)$, although this is of limited computational use. A more useful computational definition is as the sum of local heights: $\hat{h}(P) = \sum_{p\leq\infty} \hat{h}_p(P)$, where the sum ranges over each prime p and the so-called 'infinite prime'. Each of these local heights can be evaluated fairly simply, and in fact most of them are 0. The function *always* uses a minimal model for the elliptic curve internally, as otherwise the local height computation could fail. The computation at the infinite prime uses a slight improvement over the σ-function methods given in Cohen, with the implementation being based on an AGM-trick due to Mestre.

`LocalHeight(P, p)`

`Precision`	RngIntElt	*Default :*
`Check`	BoolElt	*Default :* `false`
`Renormalization`	BoolElt	*Default :* `false`

Given a point P on an elliptic curve E defined over **Q** with integral coefficients, this function returns $\hat{h}_p(P)$, the local height of P at p as described in `Height` above. The integer p must be either a prime number or 0; in the latter case the height at the infinite prime is returned. The `Check` vararg determines whether to check if the second argument is prime. The `Renormalization` vararg changes what definition of heights is used. Without this flag, a factor of $\frac{1}{6}\log \Delta_v$ is added at every place.

`HeightPairing(P, Q: parameters)`

`Precision` RngIntElt *Default :*

Given two points P, Q on the same elliptic curve defined over $\mathbf{Q}$ with integral coefficients, this function returns the height pairing of P and Q, which is defined by $\hat{h}(P,Q) = (\hat{h}(P+Q) - \hat{h}(P) - \hat{h}(Q))/2$.

`HeightPairingMatrix(S: parameters)`

`HeightPairingMatrix(E: parameters)`

`Precision` RngIntElt *Default :*

Given a sequence of points on an elliptic curve defined over $\mathbf{Q}$ with integral coefficients, this function returns the height pairing matrix. If an elliptic curve is passed to it, the corresponding matrix for the Mordell–Weil generators is returned.

`Regulator(S)`

`Precision` RngIntElt *Default :*

Given a sequence of points S on an elliptic curve E over $\mathbf{Q}$, this function returns the determinant of the Néron-Tate height pairing matrix of the sequence.

`Regulator(E)`

`Precision` RngIntElt *Default :*

Given an elliptic curve E this function returns the regulator of E; i.e., the determinant of the Néron-Tate height pairing matrix of a basis of the free quotient of the Mordell–Weil group.

Example H122E7

```
> E := EllipticCurve([0,0,1,-7,6]);
> P1, P2, P3 := Explode(Generators(E));
> Height(P1);
0.66820516565192793503314205 09
> IsZero(Abs(Height(2*P1) - 4*Height(P1)));
true
> BadPrimes(E);
[ 5077 ]
```

The local height of a point P at a prime is 0 except possibly at the bad primes of E, the 'infinite' prime, and those primes dividing the denominator of the x-coordinate of P. Since these generators have denominator 1 we see that only two local heights need to be computed to find the canonical heights of these points.

```
> P2;
(2 : 0 : 1)
> LocalHeight(P2, 0);
-0.65503594715968618249727806 9814
> LocalHeight(P2, 5077); // 0 + Log(5077)/6
```

```
1.42207930249123238829272871637
> LocalHeight(P2, 0 : Renormalization);
0.76704335533154620579545064655 2
> LocalHeight(P2, 5077 : Renormalization);
0.00000000000000000000000000000
> Height(P2);
0.7670433553315462057954506466
```

The above shows that the local height at a bad prime may still be zero, at least in the renormalised value.

`SilvermanBound(E)`

Given an elliptic curve E over $\mathbf{Q}$ with integral coefficients, this function returns the Silverman bound B of E. For any point P on E we will have $h(P) - \hat{h}(P) \leq B$.

`SiksekBound(E:` *parameters*`)`

`Torsion`	BoolElt	*Default :* `false`

Given an elliptic curve E over $\mathbf{Q}$ which is a minimal model, this function returns a real number B such that for any point P on E $h(P) - \hat{h}(P) \leq B$. In many cases, the Siksek bound is much better than the Silverman bound.

If the parameter `Torsion` is `true` then a potentially better bound B_{Tor} is computed, such that for any point P on E there exists a torsion point T so that $h(P+T) - \hat{h}(P) \leq B_{Tor}$. Note that $\hat{h}(P+T) = \hat{h}(P)$.

Example H122E8

We demonstrate the improvement of the Siksek bound over the Silverman bound for the three example curves from Siksek's paper [Sik95].

```
> E := EllipticCurve([0, 0, 0, -73705, -7526231]);
> SilvermanBound(E);
13.00022113685530200655193
> SiksekBound(E);
0.82150471924479497959096194911
> E := EllipticCurve([0, 0, 1, -6349808647, 193146346911036]);
> SilvermanBound(E);
21.75416864448061105008
> SiksekBound(E);
0.61777729068784838634233492172850957748 0
> E := EllipticCurve([1, 0, 0, -5818216808130, 5401285759982786436]);
> SilvermanBound(E);
27.56255914401769757660
> SiksekBound(E);
15.70818965430290161142481294545
```

This last curve has a torsion point, so we can further improve the bound:

```
> T := E![ 1402932, -701466 ];
```

```
> Order(T);
2
> SiksekBound(E : Torsion := true);
11.030987623117983983183295126526 88
```

Here is a point which demonstrates the applicability of the modified bound.

```
> P := E![ 14267166114 * 109, -495898392903126, 109^3 ];
> NaiveHeight(P) - Height(P);
12.193000709615680011116868901084
> NaiveHeight(P + T) - Height(P);
2.60218831527724007036
```

`IsLinearlyIndependent(P, Q)`

Given points P and Q on an elliptic curve E, this function returns `true` if and only if P and Q are independent free elements of the group of rational points of an elliptic curve (modulo torsion points). If `false`, the function returns a vector $v = (r, s)$ as a second value such that $rP + sQ$ is a torsion point.

`IsLinearlyIndependent(S)`

Given a sequence of points S belonging to an elliptic curve E, this function returns `true` if and only if the points in S are linearly independent (modulo torsion). If `false`, the function returns a vector v in the kernel of the height pairing matrix, i.e. giving a torsion point as a linear combination of the points in S.

`ReducedBasis(S)`

Given a sequence of points S belonging to an elliptic curve E over the rationals, the function returns a sequence of points that are independent modulo the torsion subgroup (equivalently, they have non-degenerate height pairing), and which generate the same subgroup of $E(\mathbf{Q})/E_{tors}(\mathbf{Q})$ as points of S.

Example H122E9

We demonstrate the linear independence test on an example curve with an 8-torsion point and four independent points. The torsion point is easily recognized and we establish the independence of the remaining points using the height function.

```
> E := EllipticCurve([0,1,0,-95549172512866864, 116909987427985538083349 00]);
> P0 := E![ 39860582, 2818809365988 ];
> P1 := E![ 144658748, -946639447182 ];
> P2 := E![ 180065822, 569437198932 ];
> P3 := E![ -339374593, 2242867099638 ];
> P4 := E![ -3492442669/25, 590454479818404/125 ];
> S0 := [P0, P1, P2, P3, P4];
> IsLinearlyIndependent(S0);
false (1 0 0 0 0)
> Order(P0);
```

```
8
> S1 := [P1, P2, P3, P4];
> IsLinearlyIndependent(S1);
true
```

We now demonstrate the process of solving for a nontrivial linear dependence among points on an elliptic curve by constructing a singular matrix, forming the corresponding linear combination of points, and establishing that the dependence is in the matrix kernel.

```
> M := Matrix(4, 4, [-3,-1,2,-1,3,3,3,-2,3,0,-1,-1,0,2,1,1]);
> Determinant(M);
0
> S2 := [ &+[ M[i, j]*S1[j] : j in [1..4] ] : i in [1..4] ];
> IsLinearlyIndependent(S2);
false ( 5 -3  8  7)
> Kernel(M);
RSpace of degree 4, dimension 1 over Integer Ring
Echelonized basis:
( 5 -3  8  7)
```

Despite the moderate size of the numbers which appear in the matrix M, we note that height is a quadratic function in the matrix coefficients. Since height is a logarithmic function of the coefficient size of the points, we see that the sizes of the points in this example are very large:

```
> [ RealField(16) | Height(P) : P in S2 ];
[ 137.376951049198, 446.51954933694, 52.724183282292, 59.091649046171 ]
> Q := S2[2];
> Log(Abs(Numerator(Q[1])));
467.65985870406594118081172 53
> Log(Abs(Denominator(Q[1])));
449.25545877278405839494427 65
```

`pAdicHeight(P, p)`

`Precision`	RngIntElt	*Default :* 0
E2	FldPadElt	*Default :* 0

Given a point P on an elliptic curve defined on the rationals and a prime $p \geq 5$ of good ordinary reduction, this function computes the p-adic height of P to the desired precision. The value of the `EisensteinTwo` function for the curve can be passed as a parameter. The algorithm dates back to [MT91] with improvements due to [MST06] and [Har08]. The normalization is that of the last-named paper and is $2p$ (or $-2p$ in some cases) as large as in other papers.

`pAdicRegulator(S, p)`

`Precision`	RngIntElt	*Default :* 0
`E2`	FldPadElt	*Default :* 0

Given a set of points S on an elliptic curve defined over the rationals and a prime $p \geq 5$ of good ordinary reduction, this function computes the p-adic height regulator of S to the desired precision. Here the normalization divides out a power of p from the individual heights.

`EisensteinTwo(E, p)`

`Precision`	RngIntElt	*Default :* 0

Given an elliptic curve over the rationals and a prime $p \geq 5$ of good ordinary reduction, this function computes the value of the Eisenstein series E_2 using the Monsky-Washnitzer techniques via Kedlaya's algorithm. See `pAdicHeight` above for references.

Example H122E10

We give examples for computing p-adic heights.

```
> E := EllipticCurve("5077a");
> P1 := E ! [2, 0];
> P2 := E ! [1, 0];
> P3 := E ! [-3, 0];
> assert P1+P2+P3 eq E!0; // the three points sum to zero
> for p in PrimesInInterval(5,30) do pAdicHeight(P1, p); end for;
4834874647277 + O(5^20)
5495832406058373*7 + O(7^20)
-1240398531370452467 4*11 + O(11^20)
6167277315947533603 89*13 + O(13^20)
5314497586743410875 4867*17 + O(17^20)
6514787540337334207 44924*19 + O(19^20)
1382894029404692415656094*23^2 + O(23^20)
-2615503441214747688800993518*29 + O(29^20)
>  pAdicHeight(P1, 37); // 37 is not ordinary for this curve
>> pAdicHeight(P1, 37); // 37 is not ordinary for this curve
Runtime error in 'pAdicHeight': p cannot be supersingular
> for p in PrimesInInterval(5,30) do pAdicRegulator([P1, P2], p); end for;
-263182161797834*5^-2 + O(5^20)
-35022392779944725 + O(7^20)
-331747503271490921584 + O(11^20)

122.2.7 Two-Descent and Two-Coverings

The two-descent process determines the locally soluble two-coverings of an elliptic curve defined over a number field K, giving them as hyperelliptic curves $C : y^2 = f(x)$ with f of degree four. To be practical, K must be of rather small degree, and for various parts of 2-descent to run (particularly reduction), K must have certain properties (such as being totally real). Also, the algorithms over the rationals have now been revisited, and are now faster than when using the general number field descent machinery.

A separate implementation is available for the case where E admits a 2-isogeny: this involves first computing the 2-coverings for the isogeny and its dual (in this case the covering maps have degree 2 instead of degree 4), and then lifting these to the level of a "full 2-descent".

This section also provides some tools for manipulating such curves, including generators for some rings of invariants of quartic forms, minimisation and reduction of such forms, and the maps back to the associated elliptic curve. This functionality overlaps with the package for genus one models (see 124). There is a straightforward interface to the 2-Selmer group machinery, which also works over number fields.

`TwoDescent(E:` *parameters*`)`

`RemoveTorsion`	BoolElt	*Default :* `false`
`RemoveGens`	{PtEll}	*Default :* {}
`WithMaps`	BoolElt	*Default :* `true`
Verbose	`TwoDescent`	*Maximum :* 1

Given an elliptic curve E over the rationals 2-descent can be used to construct a sequence of hyperelliptic curves (quartics) representing the elements of the 2-Selmer group. The group structure is not preserved by this function: the intrinsic `TwoSelmerGroup` should be used if this is desired. If `RemoveTorsion` is `true`, the generators of the torsion subgroup are factored out from the set. If `RemoveGens` is nonempty, the image of the specified points is factored out from the set. If `AppendMaps` is `true`, then the maps from the covers to the curve are appended as a second argument.

AssociatedEllipticCurve(f)

AssociatedEllipticCurve(C)

E CrvEll *Default :*

Gives the minimal model of the elliptic curve associated with a two-covering given as a polynomial f or a hyperelliptic curve C, along with a map from points $[x, y]$ on the two-covering to the curve.

If an elliptic curve is given as E, this must be isomorphic to the Jacobian of C, and then the map returned will be a map to the given E.

Example H122E11

```
> SetSeed(1); // results may depend slightly on the seed
> E := EllipticCurve([0, 1, 0, -7, 6]);
> S := TwoDescent(E);
> S;
[
    Hyperelliptic Curve defined by y^2 = x^4 + 4*x^3 - 2*x^2 - 20*x + 9 over
    Rational Field,
    Hyperelliptic Curve defined by y^2 = x^4 - x^3 - 2*x^2 + 2*x + 1 over
    Rational Field,
    Hyperelliptic Curve defined by y^2 = 2*x^4 - 4*x^3 - 8*x^2 + 4*x + 10 over
    Rational Field
]
```

E has three non-trivial two-descendants, hence its rank is at most 2. The first two curves yield obvious rational points, so we can find two independent points on E (and it has exact rank 2).

```
> pt_on_S1 := Points(S[1] : Bound:=10 )[1];
> pt_on_S1;
// We obtain the map from S[1] to E by
> _, phi := AssociatedEllipticCurve(S[1] : E:=E );
> phi( pt_on_S1 );
(1 : -1 : 1)
// Now do the same for the second curve.
> pt_on_S2 := Points(S[2] : Bound:=10 )[1];
> _, phi := AssociatedEllipticCurve(S[2] : E:=E );
> phi( pt_on_S2 );
(-3 : 3 : 1)
```

122.2.7.1 Two Descent Using Isogenies

`TwoIsogenyDescent(E : parameters)`

`Isogeny`	MapSch	*Default :*
`TwoTorsionPoint`	PtEll	*Default :*

Given an elliptic curve E over $\mathbf{Q}$ admitting a 2-isogeny $\phi : E' \to E$, this function computes 2-coverings representing the nontrivial elements of the Selmer groups of ϕ and of the dual isogeny $\phi' : E \to E'$. These coverings are given as hyperelliptic curves $C : y^2 = quartic(x)$. Six objects are returned: (i) the sequence of coverings C of E for ϕ; (ii) the corresponding list of maps $C \to E$; (iii) and (iv) the coverings C' and maps $C' \to E'$ for ϕ'; (v) and (vi) the isogenies ϕ and ϕ' that were used.

It's advisable to give a model for E that is close to minimal.

`LiftDescendant(C)`

This routine performs a higher descent on curves arising in `TwoIsogenyDescent(E)` on an elliptic curve E over $\mathbf{Q}$. The curves obtained are 2-coverings of E in the sense of ordinary (full) `TwoDescent`; more precisely, they are exactly the set of 2-coverings D for which the covering map $D \to E$ factors through C. Up to isomorphism, they are a subset of the 2-coverings returned by `TwoDescent(E)`. The advantage of this approach is that it works entirely over the base field of E, whereas `TwoDescent` will in general compute a class group over a quadratic extension of the base field. The example below explains how to recover all coverings produced by `TwoDescent(E)` using the 2-isogeny approach.

This function accepts any curve C in the first sequence of curves returned by `TwoIsogenyDescent(E)` (these are the 2-isogeny-coverings of E). More generally it accepts any hyperelliptic curve of the form $y^2 = d_1x^4 + cx^2 + d_2$. A model for the associated elliptic curve E is then $y^2 = x(x^2 + cx + d_1d_2)$.

The function returns three objects: a sequence containing the covering curves D, a list containing the corresponding maps $D \to C$, and lastly the covering map $C \to E$ from the given curve to some model of its associated elliptic curve.

122.2.7.2 Invariants

`QuarticIInvariant(q)` `QuarticJInvariant(q)`

`QuarticG4Covariant(q)` `QuarticG6Covariant(q)`

`QuarticHSeminvariant(q)` `QuarticPSeminvariant(q)`

`QuarticQSeminvariant(q)` `QuarticRSeminvariant(q)`

Compute invariants, semivariants, and covariants, as in paper [Cre01], of a given quartic polynomial q. The G4 and G6 covariants are polynomials of degrees four and six respectively; the I and J invariants are integers that generate the ring of integer invariants of the polynomial and satisfy $J^2 - 4I^3 = 27\Delta(f)$. The names H

and P have been used for essentially the same seminvariant in different papers; they are related by $H = -P$.

`QuarticNumberOfRealRoots(q)`

Using invariant theory, compute the number of real roots of a real quartic polynomial q.

`QuarticMinimise(q)`

This computes a minimal model of the quartic polynomial q over the rationals or a univariate rational function field.

Three objects are returned: the minimised quartic, the transformation matrix, and the scaling factor.

For further explanation see Chapter 124. The algorithm can be found in [CFS10].

`QuarticReduce(q)`

Given a quartic q, the algorithm of [Cre99] is applied to find the reduced quartic and the matrix that reduced it.

`IsEquivalent(f,g)`

Determines if the quartics f and g are equivalent.

122.2.8 The Cassels-Tate Pairing

The Tate–Shafarevich group of any elliptic curve E admits an alternating bilinear form on Ш(E) with values in $\mathbf{Q}/\mathbf{Z}$, known as the Cassels-Tate pairing. The key property is that if Ш(E) is finite (as conjectured), the Cassels-Tate pairing is non-degenerate. When restricted to the 2-torsion subgroup, one obtains a non-degenerate alternating bilinear form on Ш(E)[2]/2Ш(E)[4], or equivalently on $Sel^2(E)$ modulo the image of $Sel^4(E)$, with values in $\mathbf{Z}/2\mathbf{Z}$.

This means that if C and D are 2-coverings of E and the pairing (C, D) has value 1, then both C and D represent elements of order 2 in Ш(E), and moreover there are no locally solvable 4-coverings of E lying above them (in other words, `FourDescent(C)` and `FourDescent(D)` would both return an empty sequence). In this sense the Cassels-Tate pairing provides the same information as 4-descent, but is much easier to compute.

Similarly, for an element in Ш(E)[4]/2Ш(E)[8], the values of the pairing between this element and all elements in Ш(E)[2]/2Ш(E)[4] provides the same information as performing an 8-descent on C. These elements may be represented by a 4-covering $C \to E$ and a 2-covering $D \to E$ respectively.

In Magma the pairing between 2-coverings is implemented over $\mathbf{Q}$ number fields, and rational function fields $F(t)$ for F finite of odd characteristic. The pairing between a 2-covering and a 4-covering is implemented over $\mathbf{Q}$. A new, very efficient implementation of pairing on 2-coverings over $\mathbf{Q}$ was released in Magma V2.15.

The algorithms are due to Steve Donnelly and will be described in a forthcoming paper, a draft of which is available on request. For the pairing between 2-coverings, the only nontrivial computation is to solve a conic over the base field of E, so over $\mathbf{Q}$ the pairing

is easy to compute. For the pairing between 2- and 4-coverings, the key step is to solve a conic defined over a degree 4 field; this is also the case for performing 8-descent on the 4-covering, however the advantage here is that there is considerable freedom to choose the field to have small discriminant. Consequently it is more efficient to use the pairing than to apply `EightDescent`.

122.2.8.1 Verbose Information

To have information about the computation printed while it is running, one may use `SetVerbose("CasselsTate",n);` with $n = 1$ (for fairly concise information) or $n = 2$.

`CasselsTatePairing(C, D)`

Verbose `CasselsTate` *Maximum :* 2

This evaluates the Cassels-Tate pairing on 2-coverings of an elliptic curve over **Q**, a number field, or a function field $F(t)$ where F is a finite field of odd characteristic. The given curves C and D must be hyperelliptic curves of the form $y^2 = q(x)$ where $q(x)$ has degree 4, and they must admit 2-covering maps to the same elliptic curve. In addition, they must both be locally solvable over all completions of their base field (otherwise the pairing is not defined).

Typically the input curves C and D would be obtained using `TwoDescent(E)`.

The pairing takes values in $\mathbf{Z}/2\mathbf{Z}$ (returned as elements of **Z**).

`CasselsTatePairing(C, D)`

Verbose `CasselsTate` *Maximum :* 2

This evaluates the Cassels-Tate pairing between a 4-covering C and a 2-covering D of the same elliptic curve over **Q**. The arguments should be curves over **Q**, with C an intersection of two quadrics in $\mathbf{P}^3$ (for instance, a curve obtained from `FourDescent`), and D a hyperelliptic curve of the form $y^2 = q(x)$. In addition, they must both be locally solvable over all completions of **Q** (otherwise the pairing is not defined).

The pairing takes values in $\mathbf{Z}/2\mathbf{Z}$ (returned as elements of **Z**).

Example H122E12

We consider the first elliptic curve with trivial 2-torsion and nontrivial Tate-Shafarevich group.

```
> E := EllipticCurve("571a1"); E;
Elliptic Curve defined by y^2 + y = x^3 - x^2 - 929*x - 10595 over Rational Field
> #TorsionSubgroup(E);
1
> time covers := TwoDescent(E); covers;
Time: 0.270
[
    Hyperelliptic Curve defined by y^2 = -11*x^4 - 68*x^3 - 52*x^2 + 164*x - 64
    over Rational Field,
    Hyperelliptic Curve defined by y^2 = -19*x^4 + 112*x^3 - 142*x^2 - 68*x - 7
    over Rational Field,
```

```
    Hyperelliptic Curve defined by y^2 = -4*x^4 + 60*x^3 - 232*x^2 + 52*x - 3
    over Rational Field
]
> time CasselsTatePairing(covers[1], covers[2]);
1
Time: 0.130
```

This proves that these two coverings both represent nontrivial elements in the Tate-Shafarevich group; in fact our computations show that the 2-primary part of Ш(E) is precisely $\mathbf{Z}/2 \times \mathbf{Z}/2$. We could have reached the same conclusion using 4-descent:

```
> time FourDescent(covers[1]);
[]
Time: 0.460
```

122.2.9 Four-Descent

In a 1996 paper [MSS96], Merriman, Siksek and Smart described a four-descent algorithm for elliptic curves over $\mathbf{Q}$. This section describes the MAGMA implementation of that algorithm. Another useful reference is Tom Womack's PhD thesis [Wom03]. Four-descent is performed on a two-cover, that is a hyperelliptic curve defined by a polynomial of degree four, with the assumption that the quartic of this descendant does not have a rational root. The terminology "four-descent" is thus slightly incorrect; MAGMA actually performs a second descent on a specific two-cover, and does not try to combine such information from all two-covers into the 4-Selmer group.

A *four-covering* F is a pair of symmetric 4×4 matrices, defining an intersection of two quadrics in P^3. Associated to F is an elliptic curve E; there is a rational map from F to E of degree 16. The four-descent process takes a two-covering curve C (something of the shape $y^2 = f(x)$ with f quartic, and possessing points over $\mathbf{Q}_p$ for all p), and returns a set of four-coverings that arise from C.

In particular, if C represents an element of order two in the Tate–Shafarevich group of E, then the four-descent process will return the empty set. If C represents an element of the Mordell–Weil group, at least one of the four-coverings arising from C will have a rational point — all of them will do so if the Tate–Shafarevich group of E is trivial — and once found this point can be lifted to a point on E.

`FourDescent(f : parameters)`

`FourDescent(C : parameters)`

`RemoveTorsion`	BOOLELT	*Default :* `false`
`IgnoreRealSolubility`	BOOLELT	*Default :* `false`
`RemoveTorsion`	BOOLELT	*Default :* `false`
`RemoveGensEC`	{PTELL}	*Default :* {}
`RemoveGensHC`	{PTHYP}	*Default :* {}

Verbose	`FourDescent`	*Maximum :* 3
Verbose	`LocalQuartic`	*Maximum :* 2
Verbose	`MinimiseFD`	*Maximum :* 2
Verbose	`QISearch`	*Maximum :* 1
Verbose	`ReduceFD`	*Maximum :* 2
Verbose	`QuotientFD`	*Maximum :* 2

Performs a four-descent on the curve $y^2 = f(x)$, where f is a quartic. Returns a set of four-coverings of size 2^{s-1}, where s is the Selmer 2-rank of the curve. If the verbose level of the main function is set to 3, then the auxiliary verbose levels are all set to at least 1. If `RemoveTorsion` is `true`, the generators of the torsion subgroup are factored out from the set. The optional argument `RemoveGensHC` performs a quotient by the images of given points that are on the input quartic to `FourDescent`. The optional argument `RemoveGensEC` forms a quotient by the images of given points; these can be on any elliptic curve that is isomorphic to the `AssociatedEllipticCurve` of the quartic (though all given points must be on the same elliptic curve). These options can be used together. It can be non-trivial to remove torsion and generators, as points on the elliptic curve need not pull-back to the given $y^2 = f(x)$ curve. The algorithm used exploits various primes of good reduction, and attempts to determine whether the images under the μ_p are the same. This in turn can be tricky, due to the Cassels kernel, and even more so when there are extra automorphisms (that is, when $j = 0, 1728$ over $\mathbf{F}_p$).

Example H122E13

This example shows that a well-known curve has rank 0 and that the 2-torsion subgroup of its Tate–Shafarevich group is isomorphic to $(\mathbf{Z}/2\mathbf{Z})^2$.

```
> D := CremonaDatabase();
> E := EllipticCurve(D, 571, 1, 1);
> time td := TwoDescent(E);
Time: 2.500
> #td;
3
```

There are three 2-covers, so the 2-Selmer group has order four (since `TwoDescent` elides the trivial element).

```
> time [ FourDescent(t) : t in td ];
[
    [],
    [],
    []
]
Time: 3.290
```

So none of the two-covers have four-covers lying over them; hence they all represent elements of Ш, and the Mordell–Weil rank must be zero.

`AssociatedEllipticCurve(qi)`

`AssociatedHyperellipticCurve(qi)`

`E`	CrvEll	*Default :*

Given an intersection of quadrics qi, return the associated elliptic and hyperelliptic curves, respectively, together with maps to them.

If an elliptic curve is given as E, this must be isomorphic to the Jacobian of the curve qi, and then the map returned will be a map to the given E.

`QuadricIntersection(F)`

`QuadricIntersection(P, F)`

Given a pair of symmetric 4×4 matrices F, this function returns the associated quadric intersection in $P = P^3$.

`QuadricIntersection(E)`

`QuadricIntersection(C)`

Given an elliptic curve E or a hyperelliptic curve C, write it as an intersection of quadrics. The inverse map for the hyperelliptic curve has problems due to difficulties with weighted projective space.

`IsQuadricIntersection(C)`

Given a curve C, determines if C is in P^3 and has two defining equations, both of which involve only quadrics. In the case where C is a quadric intersection, the associated pair of matrices are also returned.

`PointsQI(C, B :` *parameters*`)`

`OnlyOne`	BoolElt	*Default :* `false`
`ExactBound`	BoolElt	*Default :* `false`
Verbose	`QISearch`	*Maximum :* 1

Given a quadric intersection C, this function searches, by a reasonably efficient method due to Elkies [Elk00], for a point on C of naïve height up to B; the asymptotic running time is $O(B^{2/3})$.

If `OnlyOne` is set to `true`, the search stops as soon as it finds one point; however, the algorithm is p-adic and there is no guarantee that points with small coordinates in $\mathbf{Z}$ will be found first. If `ExactBound` is set to `true`, then points that are found with height larger than B will be ignored.

`TwoCoverPullback(H, pt)`

`TwoCoverPullback(f, pt)`

Given a two-covering of a rational elliptic curve (as either a hyperelliptic curve or a quartic) and a point on the elliptic curve, compute the pre-images on the two-covering. This is faster than using the generic machinery.

`FourCoverPullback(C, pt)`

Given a four-covering of a rational elliptic curve as an intersection of quadrics and a point either on the associated elliptic curve or the associated hyperelliptic curve, this function computes the pre-images on the covering. This is faster than using the generic machinery.

Example H122E14

This example exhibits a four-descent computation, and manipulation of points once they have been found, by mapping from the curve to its two- and four-covers.

```
> P<x> := PolynomialRing(Integers());
> E := EllipticCurve([0, -1, 0, 203, -93]);
> f := P!Reverse([-7, 12, 20, -120, 172]);
> f;
-7*x^4 + 12*x^3 + 20*x^2 - 120*x + 172
```

The quartic given was obtained with `mwrank`; the two-descent routine could have been used instead, although it provides a different (but equivalent) quartic.

```
> time S := FourDescent(f);
Time: 4.280
> #S;
1
```

The single cover indicates that the curve E has Selmer rank 1, though this was already known from the calculation that constructed f.

```
> _,m := AssociatedEllipticCurve(S[1] : E:=E );
> pts := PointsQI(S[1], 10^4);
> pts;
[ (-5/3 : 13/3 : -34/3 : 1) ]
```

We now map this point back to E.

```
> m(pts[1]);
(2346223045599488598/1033322524668523441 :
2032660922346093775326473 5467/1050397899358266605692672489 : 1)
> Height($1);
44.19679596739622477261983370
```

122.2.10 Eight-Descent

One may perform 8-descent (ie a further 2-descent) on curves of the kind produced by a 4-descent on an elliptic curve E over $\mathbf{Q}$. These are nonsingular intersections of two quadrics in $\mathbf{P}^3$ that are locally soluble. The 8-descent determines whether such a curve has any 2-coverings (in the sense of 2-descent) that are locally soluble everywhere.

The routine can therefore be used to prove, in many cases, that a given 4-covering of E is in fact an element of order 4 in the Tate–Shafarevich group of E. It can also be used to find 8-coverings of E, and to verify these are elements of the 8-Selmer group.

The 8-coverings are given as genus one normal curves of degree 8 in $\mathbf{P}^8$. They are minimised and reduced, so are useful in searching for points on E.

The algorithm and implementation (from MAGMA 2.17) are due to Tom Fisher; this implementation partly incorporates and partly replaces an earlier one by Sebastian Stamminger.

`EightDescent(C : parameters)`

`BadPrimesHypothesis`	BOOLELT	*Default :* `false`
`DontTestLocalSolvabilityAt`	{RNGINTELT}	*Default :* {}
`StopWhenFoundPoint`	BOOLELT	*Default :* `false`
Verbose	`EightDescent`	*Maximum :* 4
Verbose	`LegendresMethod`	*Maximum :* 3

For a curve C obtained from `FourDescent` on some elliptic curve E over $\mathbf{Q}$, this performs a further 2-descent on C. It returns a sequence of curves D, together with a sequence containing maps $D \to C$ from each of these curves to C. The curves returned are precisely the 8-descendants of E that lie above C and are locally soluble at all places.

When the optional argument `StopWhenFoundPoint` is set to `true`, the computation will stop if it happens to find a rational point on C, and immediately return the point instead of continuing to computing the 8-coverings.

In some cases local solubility testing (at large primes which may arise due to choices made in the algorithm) can be time-consuming. Testing at specified primes may be skipped by setting the optional argument `DontTestLocalSolvabilityAt` to the desired set of prime integers, or by setting `BadPrimesHypothesis` to be true. In that case, certain primes are omitted from the set of bad primes (namely those primes at which the intersection of C with an auxiliary third quadric has bad reduction, and which are not bad primes for any other reason).

The algorithm involves class group and unit computations in a number field of degree 4 (and sometimes also 8). It is recommended to set the bounds to be used in all such computations before calling EightDescent, via `SetClassGroupBounds`.

Verbose output: For a readable summary of the computation, set the verbose level to 1 by entering `SetVerbose("EightDescent",1)`. For full information about all the time-consuming steps in the process, set the verbose level to 3. For additional

information about solving the conic, set the verbose level for `"LegendresMethod"` to 2.

122.2.11 Three-Descent

Three descent is implemented for elliptic curves over the rationals. This involves computing the 3-Selmer group of the curve, and then representing the elements as plane cubics.

There is also a separate implementation of "descent by three isogenies", for elliptic curves over the rationals which admit a **Q**-rational isogeny of degree 3.

The main application of full three-descent is in studying elements of order 3 in Tate–Shafarevich groups. For the problem of determining the Mordell–Weil group, three-descent has no advantage over four descent except in special cases: the cost is greater (three-descent requires computing the class group and S-units in a degree 8 number field, compared with degree 4 for four-descent), and the reward is smaller (a point on a 3-coverings has height 1/6 as large as its image on the elliptic curve, while with four-descent the ratio is 1/8). However three-descent can be useful when there are elements of order 4 in the Tate–Shafarevich group, which four-descent cannot deal with.

On the other hand, for a curve with a **Q**-rational isogeny of degree 3, descent by 3-isogenies is likely to be the most efficient way to bound the Mordell–Weil rank, because it only requires class group and S-unit computations in quadratic fields.

There are two steps to the 3-descent process: firstly, computing the 3-Selmer group as a subgroup of $H^1(\mathbf{Q}, E[3])$ (explicitly, as a subgroup of $A^\times/A^{\times 3}$ for a suitable algebra A), and secondly, expressing the elements as genus one curves with covering maps to E. The elements of the 3-Selmer group are given as plane cubics, and the process of obtaining these cubics is far from trivial. (Note that in general, an element of $H^1(\mathbf{Q}, E[3])$ can only be given as a curve of degree 9 rather than degree 3). The main commands are `ThreeSelmerGroup(E)`, which performs the first step, and `ThreeDescent(E)`, which performs both steps together, while `ThreeDescentCubic` performs the second step for a given element of 3-Selmer group.

The algorithm for the first step is presented in [SS04], while the theory and algorithms for the second step are developed in the forthcoming series of papers [CFO+08], [CFO+09], [CFO+]. The bulk of the code was written by Michael Stoll and Tom Fisher (however, responsibility for the final version rests with Steve Donnelly).

The following verbose flags provide information about various stages of the three descent process: `Selmer, ThreeDescent, CSAMaximalOrder, Minimise` and `Reduce`. For instance, to see what `ThreeSelmerGroup` is doing while it is running, first enter `SetVerbose("Selmer",2);`. The verbose levels range from 0 to 3.

`ThreeDescent(E : parameters)`

`Method`	MonStgElt	*Default :* "*HessePencil*"
Verbose	`Selmer`	*Maximum :* 3
Verbose	`ThreeDescent`	*Maximum :* 3

Given an elliptic curve over the rationals, this function returns the elements of the 3-Selmer group as projective plane cubic curves C, together with covering maps

$C \to E$. Two objects are returned: a sequence containing one curve for each inverse pair of nontrivial elements in the 3-Selmer group, and a corresponding list of maps from these curves to E. (Note that a pair of inverse elements in the 3-Selmer group both correspond to the same cubic curve C, and their covering maps $C \to E$ differ by composition with the negation map $E \to E$.)

The function simply calls `ThreeSelmerGroup(E)`, and then `ThreeDescentCubic` on the Selmer elements. Note that if `ThreeSelmerGroup(E)` has already been computed, it will not be recomputed, because the results are stored in the attribute `E‘ThreeSelmerGroup`.

For more information see the description of `ThreeDescentCubic` below.

Example H122E15

Here is Selmer's famous example $3x^3 + 4y^3 + 5z^3 = 0$, which is an element of order 3 in the Tate–Shafarevich group of its Jacobian, the elliptic curve $x^3 + y^3 + 60z^3 = 0$.

```
> Pr2<x,y,z> := ProjectiveSpace(Rationals(),2);
> J := x^3 + y^3 + 60*z^3;
> E := MinimalModel(EllipticCurve(Curve(Pr2,J)));
> cubics, mapstoE := ThreeDescent(E);
> cubics;
[
    Curve over Rational Field defined by 2*x^3 + 30*y^3 - z^3,
    Curve over Rational Field defined by x^3 + 5*y^3 - 12*z^3,
    Curve over Rational Field defined by 6*x^3 + 5*y^3 - 2*z^3,
    Curve over Rational Field defined by 3*x^3 + 5*y^3 - 4*z^3
]
```

The 3-Selmer group of E is isomorphic to $\mathbf{Z}/3\mathbf{Z} \oplus \mathbf{Z}/3\mathbf{Z}$, and one element for each (nontrivial) inverse pair is returned. (Note: $3x^3+4y^3+5z^3$ will not necessarily appear; due to random choices in the program, an equivalent model may appear instead.)
The covering maps from these curves to E have degree 9, and are given by forms of degree 9 in x, y, z. For example, the map from the first curve $2x^3 - 3y^3 + 10z^3$ to E is given by:

```
> DefiningEquations(mapstoE[1]);
[
    -1377495072000*x*y^7*z + 4591650240000*x*y^4*z^4 - 15305500800000*x*y*z^7,
    24794911296000*y^9 - 123974556480000*y^6*z^3 - 413248521600000*y^3*z^6 +
    918330048000000*z^9,
    -4251528000*x^3*y^3*z^3
]
```

Since E has trivial Mordell–Weil group, we should not find any rational points on these curves! (In fact they are all nontrivial in the Tate–Shafarevich group.) Here we search for rational points on the first cubic, up to height roughly 10^4:

```
> time PointSearch( cubics[1], 10^4);
[]
```

```
Time: 0.490
```

An extended example, concerning "visible" 3-torsion in a Tate–Shafarevich group, can be found at the end of Chapter 124.

`ThreeSelmerGroup(E : parameters)`

`ThreeTorsPts`	TUP	*Default :*
`MethodForFinalStep`	MONSTGELT	*Default :* "*UseSUnits*"
`CompareMethods`	BOOLELT	*Default :* `false`
Verbose	`Selmer`	*Maximum :* 3

Given an elliptic curve E over the rationals, this function returns its 3-Selmer group as an abelian group, together with a map to the natural affine algebra.

The parameter `MethodForFinalStep` can be either "Heuristic" (which is usually much faster in large examples), "FindCubeRoots", or "UseSUnits" (the default, which has the advantage that it usually takes roughly the same amount of time as the S-unit computation that has already been performed). To try all three methods and compare the times, set `CompareMethods` to `true`.

Most of the computation time is usually spent on class group and unit group computations. These computations can be speeded up by using non-rigorous bounds, and there are two ways to control which bounds are used. The recommended way is to preset them using one of the intrinsics `SetClassGroupBounds` or `SetClassGroupBoundMaps` (see Section 37.6.1). The other way is to precompute the class groups of the fields involved, setting the optional parameters in `ClassGroup` as desired. (The relevant fields can be obtained as the fields over which the points in `ThreeTorsionPoints(E)` are defined.) The fields and their class group data would then be stored internally, and automatically used when `ThreeSelmerGroup(E)` is called (even when no optional parameters are provided).

When `ThreeTorsPts` is specified, it determines the fields used in the computation, and the algebra used to express the answers.

`ThreeDescentCubic(E, α : parameters)`

`ThreeTorsPts`	TUP	*Default :*
`Method`	MONSTGELT	*Default :* "*HessePencil*"
Verbose	`ThreeDescent`	*Maximum :* 3

Given an elliptic curve E over the rationals, and an element α in the 3-Selmer group of E, the function returns a projective plane cubic curve C, together with a map of schemes $C \to E$. The cubic is a principal homogeneous space for E, and the covering map $C \to E$ represents the same Selmer element as either α or $1/\alpha$ (and α can be recovered, up to inverse, by calling `ThreeSelmerElement` of the cubic).

The 3-Selmer element α is given as an element of the algebra associated to the 3-Selmer group (the algebra is the codomain of the map returned by `ThreeSelmerGroup`, as in `S3, S3toA := ThreeSelmerGroup(E)`). In this situation,

where α is `S3toA(s)` for some `s`, there is no need to specify the optional parameter `ThreeTorsPts`.

The algorithm comes from the series of papers cited in the introduction. There are three alternative ways to perform the final step of computing a ternary cubic. All three ways are implemented, and the optional parameter `Method` may be "HessePencil" (default), "FlexAlgebra" or "SegreEmbedding". However, the choice of `Method` is not expected to make a big difference to the running time.

The optional parameter `ThreeTorsPts` is a tuple containing one representative from each Galois orbit of $E[3] \setminus O$. Its purpose is to fix an embedding of the 3-Selmer group in $A^\times/A^{\times 3}$ (otherwise there is ambiguity when the fields involved have nontrivial automorphisms, or occur more than once). When `ThreeTorsPts` is not specified, `ThreeTorsionPoints(E)` is called (its value is stored internally and used throughout the MAGMA session).

`ThreeIsogenyDescent(E : parameters)`

`Isog`	MAPSCH	*Default :*
Verbose	`Selmer`	*Maximum :* 3
Verbose	`ThreeDescent`	*Maximum :* 3

Given an elliptic curve E over $\mathbf{Q}$ that admits a $\mathbf{Q}$-rational isogeny $E \to E_1$ of degree 3, the function performs "descent by 3-isogenies" on E. This involves computing the Selmer groups attached to the isogeny and its dual, and representing the elements of both Selmer groups as plane cubics, with covering maps of degree 3 to E_1 or E respectively. One cubic is given for each nontrivial pair of inverse Selmer elements, and one covering map is given for each cubic (the other covering map, which can be obtained by composing with the negation map on the elliptic curve, would correspond to the inverse Selmer element.)

There are five returned values, in the following order: a list of curves for $Sel(E \to E_1)$, a corresponding list of covering maps to E_1, a list of curves for the dual isogeny Selmer group $Sel(E_1 \to E)$, a corresponding list of covering maps to E, and finally the isogeny $E \to E_1$.

This function works simply by calling `ThreeIsogenySelmerGroups(E)`, and then calling `ThreeIsogenyDescentCubic` for each Selmer element.

The isogeny $E \to E_1$ may be passed in as `Isog`. If `Isog` is not specified, and E admits more than one such isogeny, then this is chosen at random.

`ThreeIsogenySelmerGroups(E : parameters)`

`Isog`	MAPSCH	*Default :*
Verbose	`Selmer`	*Maximum :* 3

Given an elliptic curve E over the rationals that admits a $\mathbf{Q}$-rational isogeny $E \to E_1$ of degree 3, the function computes the Selmer groups associated to the isogeny, and to its dual isogeny $E_1 \to E$. The Selmer groups are returned as abstract groups, together with maps to the relevant algebra. There are five returned values, in the

following order: the group, and the map, for $E \to E_1$, the group, and the map, for $E_1 \to E$, and finally the isogeny $E \to E_1$.

A bound for the rank of $E(\mathbf{Q})$ can be deduced, by taking the sum of the ranks of the Selmer groups for the two isogenies, and subtracting 1 if the kernel of one of the isogenies consists of rational points.

The isogeny $E \to E_1$ may be passed in as `Isog`. If `Isog` is not specified, and E admits more than one such isogeny, then this is chosen at random.

The algebra in which the Selmer group of a particular isogeny is exhibited is the etale algebra corresponding to the nontrivial points in the kernel of the dual isogeny; it is either a quadratic field, or a Cartesian product of two copies of **Q**.

`ThreeIsogenyDescentCubic(`ϕ`,` α`)`

Verbose `ThreeDescent` *Maximum :* 3

Given an isogeny ϕ of degree 3 between elliptic curves over **Q**, and any element α of $H^1(\mathbf{Q}, E[\phi])$, this function returns a plane cubic curve C representing α, together with a covering map $C \to E$ of degree 3.

The element α is given as an element in the algebra A associated to the Selmer group of ϕ; the algebra can be obtained from `ThreeIsogenySelmerGroups`. $H^1(\mathbf{Q}, E[\phi])$ is represented as the subgroup of $A^\times/(A^\times)^3$ consisting of elements whose norm is a cube.

`ThreeDescentByIsogeny(E)`

Verbose `Selmer` *Maximum :* 3

This performs a full 3-descent, returning models for the nontrivial inverse pairs in the 3-Selmer group and maps to E making them into 3-coverings. The only difference with `ThreeDescent` is that the computation is by first and second 3-isogeny descents. This restricts the number fields used to cubic extensions, rather than the sextic fields which may be needed for the generic `ThreeDescent` routine. The advantage is noticeable for larger examples.

Example H122E16

```
> E := EllipticCurve([0,0,0,0,131241]);
> G,m := TorsionSubgroup(E);
> #G;
1
> Rank(E);
2
> S1,_,S2 := ThreeIsogenyDescent(E);
> #S1,#S2;
0 4
```

This shows that there is nontrivial 3-torsion in Ш on some isogenous curve. Without computing the full 3-Selmer group of E it is impossible to tell if there is any nontrivial 3-torsion in Ш(E/**Q**).

```
> time Sel3 := ThreeDescentByIsogeny(E);
```

```
Time: 5.280
> #Sel3*2+1;
9
```

This shows that $Ш(E/\mathbf{Q})[3] = 0$ (since we know the rank is 2). Alternatively one could get the same by calling `ThreeDescent`. This would require computing class and unit group information in the sextic field below (and would be much slower).

```
> E3reps := ThreeTorsionPoints(E);
> Parent(E3reps[2,1]);
Number Field with defining polynomial x^6 + 14174028 over the Rational Field
>  time Sel3_slow := ThreeDescent(E);
forever!
```

`Jacobian(C)`

Given the equation of a nonsingular projective plane cubic curve C over the rationals, this function returns the Jacobian of C (over the rationals) as an elliptic curve. Note that C will be a principal homogeneous space of E.

`ThreeSelmerElement(E, C)`

`ThreeSelmerElement(C)`

Given an elliptic curve E over the rationals, and a plane cubic C with the same invariants as E (for instance, with E equal to `Jacobian(C)`) the function returns an element α in the algebra A associated to the 3-Selmer group of E. This α represents the same element of $H^1(\mathbf{Q}, E[3])$ that is represented by a covering $C \to E$ that takes the flex points of C to O. Note that α is only determined up to inverse in $H^1(\mathbf{Q}, E[3])$.

In particular, if we have computed `S3, S3toA := ThreeSelmerGroup(E)`, and if C is an everywhere locally soluble covering corresponding to the element `s` in `S3`, then α equals either `S3toA(s)` or `S3toA(-s)` in $A^\times/(A^\times)^3$.

`AddCubics(cubic1, cubic2 : parameters)`

`E`	CrvEll	*Default :*
`ReturnBoth`	BoolElt	*Default :* `false`

Given equations of two plane cubics over the rationals with the same invariants (in other words, they are homogeneous spaces for the same elliptic curve E, which is their Jacobian, over the rationals), the function computes the sum of the corresponding elements of $H^1(\mathbf{Q}, E[3])$. The sum is returned as another plane cubic, if possible (and otherwise an error results).

An element of $H^1(\mathbf{Q}, E[3])$ may be expressed as a plane cubic when it has index 3, equivalently when the so-called "obstruction" is trivial. This is always the case for elements that are everywhere locally soluble. In particular, the function will always succeed when the two given cubics are everywhere locally soluble (in other words, when they belong to the 3-Selmer group). The computation is done by converting

the cubics to elements of $H^1(\mathbf{Q}, E[3])$ as given by `ThreeSelmerElement`, adding the cocycles, and then converting the result to a cubic.

Note that a cubic only determines an element of $H^1(\mathbf{Q}, E[3])$ up to taking inverse, so the sum is not well defined; if the function is called with `ReturnBoth := true`, it returns both of the possible cubics.

`ThreeTorsionType(E)`

For an elliptic curve E over the rationals, this function classifies the Galois action on $E[3]$. The possibilities are "Generic", "2Sylow", "Dihedral", "Generic3Isogeny", "Z/3Z-nonsplit", "mu3-nonsplit", "Diagonal" and "mu3+Z/3Z".

`ThreeTorsionPoints(E : parameters)`

`OptimisedRep` BoolElt *Default :* `true`

For an elliptic curve E over the rationals, this function returns a tuple containing one representative point from each set of Galois conjugates in $E[3] \setminus O$.

Each point belongs to a point set $E(L)$, where L is the field generated by the coordinates of that point.

If `OptimisedRep` is set to `false`, then optimised representations of the fields will not be computed, in general.

`ThreeTorsionMatrices(E, C)`

Given an elliptic curve E over the rationals, and a plane cubic with the same invariants as E (in other words, a principal homogeneous space for E of index 3), the function returns a tuple of matrices. The matrices M_i correspond to the points T_i in `ThreeTorsionPoints(E)`, and have the corresponding base fields. Each matrix describes the action-by-translation on C of the corresponding point: the action of P_i on C is the restriction to C of the automorphism of the ambient projective space $\mathbf{P}^2$ given by the image of M_i in PGL_3.

Note that only the images in PGL_3 of the matrices are well-determined.

122.2.11.1 Six and Twelve Descent

If a 3-descent has been performed, the results can be used in conjunction with a 2-descent or a 4-descent to obtain coverings of degree 6 or 12 respectively. These "combined" coverings can be useful for finding Mordell-Weil generators of large height on the underlying elliptic curve.

The coverings are given as genus one normal curves (of degree 6 in $\mathbf{P}^5$, and of degree 12 in $\mathbf{P}^1 1$, respectively).

The algorithms are described in [Fis08].

`SixDescent(C2, C3)`

`SixDescent(model2, model3)`

Given a 2-covering and a 3-covering of an elliptic curve E (either as curves or as genus one models), this returns the 6-covering that represents their sum in the 6-Selmer group. The covering map $C6 \to C3$ is also returned.

`TwelveDescent(C3, C4)`

`TwelveDescent(model3, model4)`

Given a 3-covering and a 4-covering of an elliptic curve E (either as curves or as genus one models), this returns the two 12-coverings that represent their sum and difference in the 12-Selmer group. The covering maps to $C12 \to C4$ are also returned.

122.2.12 Nine-Descent

A nine-descent is performed on an everywhere locally solvable plane cubic curve. The cubic represents a class in the 3-Selmer group of its Jacobian (up to sign). A nine-descent computes the fibre above this class under the map from the 9-Selmer group to the 3-Selmer group induced by multiplication by 3. This fibre is the set of everywhere locally solvable 3-coverings of the cubic. These coverings are given as intersections of 27 quadrics in $\mathbf{P}^8$. As with four-descents the terminology "nine-descent" is slightly incorrect, as MAGMA performs a second 3-descent on a specific 3-covering and does not try to combine such information from all 3-coverings to form the 9-Selmer group.

The algorithm was developed in the PhD thesis of Brendan Creutz [Cre10]. Typically most of the computation time is spent on class group and unit group computations in the constituent fields of the degree 9 etale algebra associated to the flex points on the cubic. The primary use is to obtain information on the 3-primary part of the Shafarevich–Tate group. It is only in very rare circumstances that a nine descent is required (in addition to the other descent machinery) to determine the Mordell–Weil rank (e.g. if there were elements of order 24 in Ш).

`NineDescent(C : parameters)`

`ExtraReduction`	RNGINTELT	*Default :* 10
Verbose	`Selmer`	*Maximum :* 3
Verbose	`ComputeL`	*Maximum :* 2

Given a plane cubic curve C over $\mathbf{Q}$ this returns a sequence of curves in $\mathbf{P}^8$ defined by 27 quadrics and a list of degree 9 maps making these curves into 3-coverings of C. This is the 3-Selmer set of C (i.e. the set of everywhere locally solvable 3-coverings of C). If there are no coverings, then $C(\mathbf{Q}) = \emptyset$ and the class of C in the Shafarevich-Tate group of its Jacobian is not divisible by 3. Otherwise the coverings returned are lifts of C to the 9-Selmer group.

The coverings returned are minimised and reduced in an ad hoc fashion. If `ExtraReduction` is set to a larger value, more time will be spent reducing possibly resulting in smaller models. The current implementation requires that Galois act transitively on the flex points. If this is not the case, then one can use `pIsogenyDescent` instead.

`NineSelmerSet(C)`

Computes the 3-rank of the 3-Selmer set of plane cubic curve C defined over $\mathbf{Q}$. The value -1 is returned when the 3-Selmer set is empty. In this case $C(\mathbf{Q}) = \emptyset$ and the class of C in the Shafarevich-Tate group of its Jacobian is not divisible by 3. If the 3-Selmer set is nonempty, its 3-rank is the same as that of the 3-Selmer group of the Jacobian. In this case the class of C in the Shafarevich-Tate group of the Jacobian is divisible by 3.

122.2.13 p-Isogeny Descent

Given an isogeny $\phi : E_1 \to E_2$ of elliptic curves, one may define the ϕ-Selmer group of E_2 to be the set of everywhere locally solvable ϕ-coverings of E_2. Given a genus one curve C with Jacobian E_2, one may define its ϕ-Selmer set to be the set of everywhere locally solvable ϕ-coverings of C. A ϕ-isogeny descent computes the ϕ-Selmer group (or ϕ-Selmer set).

We denote the dual isogeny by $\phi^\vee$. In the case of elliptic curves, performing ϕ- and $\phi^\vee$-descents can be used to bound the Mordell-Weil rank and get information on Ш. For general genus one curves descent by isogeny can be used to rule out divisibility in Ш and consequently prove that there are no rational points.

In practice it is often easier to compute a 'fake' Selmer set. This is a set parameterising everywhere locally solvable unions of ϕ-coverings, with the property that every ϕ-covering lies in exactly one such union. Any locally soluble ϕ-covering gives rise to a locally soluble union, hence there is a map from the Selmer set to the fake Selmer set. In general this map may be neither surjective nor injective. However, if the fake Selmer set is empty, then this is also true of the Selmer set.

Current functionality allows one to compute ϕ-Selmer groups for an isogeny ϕ of prime degree in a number of situations. For isogenies of degree 2 or 3, they may be computed using `TwoIsogenyDescent` and `ThreeIsogenyDescent`. When ϕ is the quotient by a subgroup generated by a $\mathbf{Q}$-rational point of order $p \in \{5, 7\}$ the dimensions of the ϕ- and $\phi^\vee$-Selmer groups can be computed using an algorithm of Fisher [Fis00] and [Fis01]. This method also produces models for the everywhere locally solvable $\phi^\vee$-coverings of E.

Given a genus one normal curve C of prime degree p produced by a ϕ-isogeny descent on an elliptic curve, the $\phi^\vee$-Selmer set of C can be computed using an algorithm of Creutz described in [Cre10] and [CM12]. Computing the $\phi^\vee$-Selmer sets of all elements in the ϕ-Selmer group yields information that is equivalent to that given by the $\phi^\vee \circ \phi$-Selmer group.

Current functionality allows one to perform these second isogeny descents when ϕ has degree $p = 3$ or when $p \in \{5, 7\}$ and the flex points of C lie on the coordinate hyperplanes in $\mathbf{P}^{p-1}$. If the kernel of the isogeny is generated by a $\mathbf{Q}$-rational point of order p, then such a model always exists. Moreover, the models returned by the algorithm of Fisher have this property. For $p = 7$, computation of the coverings is not practical and only a 'fake'-Selmer set can be computed (see [CM12]).

`pIsogenyDescent(E,P)`

`pIsogneyDescent(E,p)`

`pIsogenyDescent(lambda,p)`

This performs a ϕ-descent on an elliptic curve over $\mathbf{Q}$ using the algorithm of Fisher. The descent requires an isogeny ϕ whose kernel is generated by a $\mathbf{Q}$-rational point of order $p \in \{5, 7\}$.

The input can be specified in one of three ways: (1) by giving an elliptic curve and a point of order p on the curve; (2) by giving an elliptic curve containing a point of order p and specifying p; or (3) by specifying p and a $\mathbf{Q}$-rational point on the modular curve $X_1(p)$. In the final case the choice for the coordinate λ on $X_1(p)(\mathbf{Q})$ is as described in [Fis00].

The return values are the p-ranks of the ϕ- and $\phi^\vee$-Selmer groups, a sequence of genus one normal curves of degree p representing the inverse pairs of nontrivial elements of the $\phi^\vee$-Selmer group modulo the image of the subgroup generated by the p-torsion point, and the isogenous elliptic curve. If the input is a coordinate on $X_1(p)$, the curve E is also returned.

`pIsogenyDescent(C,phi)`

`pIsogenyDescent(C,E1,E2)`

`pIsogenyDescent(C,P)`

Verbose `Selmer` *Maximum :* 3

This performs an isogeny descent on the genus one normal curve C of degree $p \in \{3, 5\}$ as described in [CM12]. C must be a projective plane cubic (in case $p = 3$) or an intersection of 5 quadrics in $\mathbf{P}^4$, with the additional requirement that the flex points of C lie on the coordinate hyperplanes. For the descent one must specify: (1) the isogeny ϕ; (2) the domain $E1$ and the codomain $E2$ of the isogeny; or (3) a $\mathbf{Q}$-rational point P of order p on an elliptic curve E which generates the kernel of the isogeny.

The return values are a sequence consisting of genus one normal curves of degree p representing the elements of the ϕ-Selmer set and a list of maps making these into ϕ-coverings of C.

`FakeIsogenySelmerSet(C,phi)`

`FakeIsogenySelmerSet(C,E1,E2)`

`FakeIsogenySelmerSet(C,P)`

Verbose `Selmer` *Maximum :* 3

This determines the $\mathbf{F}_p$-dimension of the 'fake'-ϕ-Selmer set of the genus one normal curve C of degree $p \in \{3, 5, 7\}$ (see [CM12] for the definition). By convention the empty set has dimension -1. The input is exactly as for `pIsogenyDescent`, however coverings are not produced. This makes the computations feasible as well for $p = 7$.

Example H122E17

We use a 5-isogeny descent to show that the elliptic curve with Cremona reference 570l3 has rank 0 and that there are nontrivial elements of order 5 in its Shafarevich-Tate group.

```
> lambda := 48/5;
> r_phiSel,r_phidualSel,Sha,E1,E2 := pIsogenyDescent(lambda,5);
> CremonaReference(E1);
570l1
> CremonaReference(E2);
570l3
> TorsionSubgroup(E1);
Abelian Group isomorphic to Z/10
Defined on 1 generator
Relations:
    10*$.1 = 0
> r_phiSel;
0
> r_phidualSel;
3
```

This shows that $E_2(\mathbf{Q})/\phi(E_1(\mathbf{Q})) \simeq 0$, while the $\phi^\vee$-Selmer group gives an exact sequence: $0 \to E_2(\mathbf{Q})/\phi^\vee(E_1(\mathbf{Q})) \subset (\mathbf{Z}/5\mathbf{Z})^3 \to Ш(\mathrm{E}_2/\mathbf{Q})[\phi^\vee] \to 0$. From this we conclude that the rank (for both curves) is 0, and so $Ш(\mathrm{E}_2/\mathbf{Q})[\phi^\vee]$ has $\mathbf{F}_5$-dimension 2. Representatives for the inverse pairs of nontrivial elements are given by the third return value.

```
> #Sha*2 + 1;
25
> C := Sha[1];
> CremonaReference(Jacobian(GenusOneModel(C)));
570l3
```

The above computation does not conclusively show that $Ш(\mathrm{E}_1/\mathbf{Q})$ has no nontrivial 5-torsion. For this we need a second isogeny descent. Namely we show that the C is not divisible by ϕ in Ш.

```
> time DimSelC := FakeIsogenySelmerSet(C,E1,E2);
Time: 2.950
> DimSelC;
-1
```

Example H122E18

Now we use a full 5-descent to find a large generator.

```
> r1,r2,SelModTors,E,EE := pIsogenyDescent(326/467,5);
> r1,r2;
0 2
> E5,m := TorsionSubgroup(E);
> E5;
Abelian Group isomorphic to Z/5
```

```
Defined on 1 generator
Relations:
    5*E5.1 = 0
>  time ConjecturalRegulator(E);
242.013813460415708000138268958 1
Time: 70.180
> Conductor(E);
271976526950
> ThreeTorsionType(E);
Generic
```

This shows that $E(\mathbf{Q}) \simeq \mathbf{Z} \times \mathbf{Z}/5\mathbf{Z}$ and that (assuming Ш(E/**Q**) is trivial) that the regulator is 242.01... This means one probably needs more than a 4-descent to find the generator. The conductor is too large for Heegner point techniques and the 3-torsion on E is generic, meaning 6- or 12-descent will be very slow (even if they are performed nonrigorously). We can do a further isogeny descent to obtain a full 5-covering.

```
> P := m(E5.1);
> C := Curve(Minimize(GenusOneModel(SelModTors[2])));
> time Ds,Pis := pIsogenyDescent(C,P);
7.880
> D := Ds[1];
> pi := Pis[1];
> time rp := PointSearch(D,10^10 :
>     Dimension := 1, OnlyOne := true, Nonsingular := true);
Time: 39.410
> Q := rp[1];
> Q;
(-11610740223/2573365369 : 1350220049/2573365369 :
-110993809/2573365369 : -3970329088/2573365369 : 1)
> piQ := pi(Q); // gives the point on C
> Dnew,Enew,FiveCovering := nCovering(GenusOneModel(D));
> Qnew := Dnew(Rationals())!Eltseq(Q);
> Ecan,EnewtoEcan := MinimalModel(Enew);
> P2 := EnewtoEcan(FiveCovering(Qnew));
> P2;

Example H122E19

Finally we give an example which shows that the map from the genuine Selmer set to the fake Selmer set need not be surjective.

```
> E1 := EllipticCurve("254a1");
> E2 := EllipticCurve("254a2");
> bool, phi := IsIsogenous(E1,E2);
> phicoveringsofE2,_,phidualcoveringsofE1,_,phi := ThreeIsogenyDescent(E1);
> C := phicoveringsofE2[1];
> C;
x^3 - x^2*y - x^2*z - 2*x*y^2 + 3*x*y*z - 2*x*z^2 + 2*y^2*z
> phidual := DualIsogeny(phi);
> MinimalModel(Codomain(phidual)) eq MinimalModel(Jacobian(C));
true
> time FakeIsogenySelmerSet(C,phidual);
2
Time: 0.620
> time SelC := pIsogenyDescent(C,phidual);
Time: 1.160
> Ilog(3,#SelC);
1
```

122.2.14 Heegner Points

For an elliptic curve of rank 1, it is possible to compute the generator by an analytic process; the elliptic logarithm of some multiple nP of the generator is the sum of the values of the modular parameterization at a series of points in the upper half-plane corresponding to a full set of class representatives for an appropriately-chosen quadratic field. There is no such thing as a free lunch, sadly; the calculation requires computing $O(hN)$ terms to a precision of $O(h)$ digits, so in practice it works best for curves contrived to have small conductors.

The calculation proceeds in three stages: choosing the quadratic field $\mathbf{Q}(\sqrt{-d})$, evaluating the modular parameterization, and recovering the generator from the elliptic logarithm value. Essentially, this is an implementation of the method of Gross and Zagier [GZ86]; Elkies performed some substantial computations using this method in 1994, and much of the work required to produce this implementation was done by Cremona and Womack. An array of tricks have been added, and are described to some extent in some notes of Watkins.

`HeegnerPoint(E : parameters)`

`NaiveSearch`	RngIntElt	*Default :* 1000
`Discriminant`	RngIntElt	*Default :*
`Cover`	Crv	*Default :*
`DescentPossible`	BoolElt	*Default :* `true`

`IsogenyPossible`	BoolElt	*Default :* `true`
`Traces`	SeqEnum	*Default :* []
Verbose	`Heegner`	*Maximum :* 1

Attempts to find a point on a rank 1 rational elliptic curve E using the method of Heegner points, returning `true` and the point if it finds one, otherwise `false`. The parameter `NaiveSearch` indicates to what height the algorithm will first do a search (using `Points`) before turning to the analytic method. The `Discriminant` parameter allows the user to specify an auxiliary discriminant; this must satisfy the Heegner hypothesis, and the corresponding quadratic twist must have rank 0. The `Cover` option allows the user to specify a 2-cover or 4-cover (perhaps obtained from `TwoDescent` or `FourDescent`) to speed the calculation. This should be either a hyperelliptic curve or a quadric intersection, and there must be a map from the cover to the given elliptic curve. If the `DescentPossible` option is true, then the algorithm might perform such a descent in any case. If the `IsogenyPossible` option is true, then the algorithm will first try to guess the best isogenous curve on which to do the calculation — if a `Cover` is passed to the algorithm, it will be ignored if E is not the best isogenous curve. The `Traces` option takes an array of integers which correspond to the first however-many traces of Frobenius for the elliptic curve, thus saving having to recompute them.

The algorithm assumes that the Manin constant of the given elliptic curve is 1 (which is conjectured in this case), and does not return a generator for the Mordell–Weil group, but a point whose height is that given by a conjectural extension of the Gross–Zagier formula. This should be $\sqrt{Sha}$ times a generator.

`HeegnerPoint(C :` *parameters*`)`

`HeegnerPoint(f :` *parameters*`)`

`NaiveSearch`	RngIntElt	*Default :* 10000
`Discriminant`	RngIntElt	*Default :*
`Traces`	SeqEnum	*Default :* []
Verbose	`Heegner`	*Maximum :* 3

These are utility functions for the above. The input is either a hyperelliptic curve given by a polynomial of degree 4, or this quartic polynomial — in both cases the quartic should have no rational roots — or a nonsingular intersection of two quadrics in $\mathbf{P}^3$. These functions call `HeegnerPoint` on the underlying elliptic curve. They then map the computed point back to the given covering curve. The rational reconstruction step of the `HeegnerPoint` algorithm can be quite time-consuming for some coverings, especially if the index is large. Also, if a cover corresponds to an element of the Tate–Shafarevich group, the algorithm will likely enter an infinite loop. These functions have not been as extensively tested as the ordinary `HeegnerPoint` function, and thus occasionally might fail due to unforeseen problems.

`ModularParametrization(E, z, B :` *parameters*`)`

`ModularParametrization(E, z :` *parameters*`)`

`ModularParametrization(E, Z, B :` *parameters*`)`

`ModularParametrization(E, Z :` *parameters*`)`

`Traces`	SeqEnum	*Default :* []

`ModularParametrization(E, f, B :` *parameters*`)`

`ModularParametrization(E, f :` *parameters*`)`

`ModularParametrization(E, F, B :` *parameters*`)`

`ModularParametrization(E, F :` *parameters*`)`

`Traces`	SeqEnum	*Default :* []
`Precision`	RngIntElt	*Default :*

Given a rational elliptic curve E and a point z in the upper-half-plane, compute the modular parametrization $\int_z^\infty f_E(\tau)\,d\tau$ where f_E is the modular form associated to E. The version with a bound B uses the first B terms of the q-expansion, while the other version determines how many terms are needed. The optional parameter `Traces` allows the user to pass the first however-many traces of Frobenius. There are also versions which take an array Z of complex points, and versions which take positive definite binary quadratic forms f (or an array F) rather than points in the upper-half-plane (a `Precision` can be specified with the latter).

`HeegnerDiscriminants(E,lo,hi)`

`Fundamental`	BoolElt	*Default :* `false`
`Strong`	BoolElt	*Default :* `false`

Given a rational elliptic curve and a range from lo to hi, compute the negative fundamental discriminant in this range that satisfies the Heegner hypothesis for the curve. The `Fundamental` option restricts to fundamental discriminants. The `Strong` option restricts to discriminants that satisfy a stronger Heegner hypothesis, namely that $a_p = -1$ for all primes p that divide $\gcd(D, N)$.

`HeegnerForms(E,D :` *parameters*`)`

`UsePairing`	BoolElt	*Default :* `false`
`UseAtkinLehner`	BoolElt	*Default :* `true`
`Use_wQ`	BoolElt	*Default :* `true`
`IgnoreTorsion`	BoolElt	*Default :* `false`

Given a rational elliptic curve of conductor N and a negative discriminant that meets the Heegner hypothesis for N, the function computes representatives for the complex multiplication points on $X_0(N)$.

In general the return value is a sequence of 3-tuples (Q, m, T) where Q is a quadratic form, m is a multiplicity, and T is a torsion point on E. Letting ϕ be

the modular parametrization map, the sum on E of the values $m(\phi(Q)+T)$ is a Heegner point in $E(\mathbf{Q})$. When the number of these values equals the class number $h = h(D)$ (and the multiplicities are all 1 or -1) then they are actually the images on E of the CM points on $X_0(N)$. (They all correspond to a single choice of square root of D modulo $4N$.)

If `UsePairing` is added, then CM points that give conjugate values under the modular parametrisation map are combined. If `UseAtkinLehner` is added, then more than one square root of D modulo $4N$ can be used. If `Use_wQ` is added, then forms can appear with extra multiplicity, due to primes that divide the GCD of the conductor and the fundamental discriminant. If `IgnoreTorsion` is added, then the fact that Atkin-Lehner can change the result by a torsion point will be ignored. The `UsePairing` option requires that `IgnoreTorsion` be true.

This function requires (so as not to confuse the user) that the ManinConstant of the curve be equal to 1.

`HeegnerForms(N,D : parameters)`

`AtkinLehner`	[RngIntElt]	*Default :* []

Given a level N and a discriminant that meets the Heegner hypothesis for the level, the function returns a sequence of binary quadratic forms which correspond to the Heegner points. The Atkin-Lehner option takes a sequence of q with $\gcd(q, N/q) = 1$ and has the effect of allowing more than one square root of D modulo $4N$ to be used.

`ManinConstant(E)`

Compute the Manin constant of a rational elliptic curve. This is in most cases simply a conjectural value (and most often just 1).

`HeegnerTorsionElement(E)`

Given a rational elliptic curve and an integer Q corresponding to an Atkin-Lehner involution (so that $\gcd(Q, N/Q) = 1$), this function computes the torsion point on the curve corresponding to the period given by the integral from $i\infty$ to $w_Q(i\infty)$.

`HeegnerPoints(E, D : parameters)`

`ReturnPoint`	BoolElt	*Default :* `false`
`Precision`	RngIntElt	*Default :* 100
Verbose	`Heegner`	*Maximum :* 1

Given an elliptic curve E over $\mathbf{Q}$, and a suitable discriminant D (of a quadratic field) this function computes the images on E under the modular parametrization of the CM points on $X_0(N)$ associated to D. It returns a tuple $\langle p_D, m\rangle$, where p_D is an irreducible polynomial whose roots are the x-coordinates of these images, and where m is the multiplicity of each of these images (the number of CM points on $X_0(N)$ mapping to a given point on E). These x-coordinates lie in the ring class field of $\mathbf{Q}(\sqrt{D})$, and the class number $h(D)$ must equal either $m\deg(p_D)$ or $2m\deg(p_D)$.

The conductor of the order $\mathbf{Q}(\sqrt{D})$ is required to be coprime to the conductor of E.

The second object returned by the function is one of the conjugate points, as an element of the point set $E(H)$ where H is the field defined by p_D, or a quadratic extension of it. This step can be time consuming; if `ReturnPoint` is set to `false`, the point is not computed.

Warning: The computation is not rigorous, as it involves computing over the complex numbers, and then recognising the coefficients of the polynomial as rationals. However, the program performs a heuristic check: it checks that the polynomial has the correct splitting at some small primes (sufficiently many to be sure that wrong answers will not occur in practice).

Example H122E20

```
> time HeegnerPoint(EllipticCurve([1,0,0,312,-3008])); //uses search
true (12 : -56 : 1)
Time: 0.240
> time HeegnerPoint(EllipticCurve([0,0,1,-22787553,-41873464535]));
true (1100363782947843220359298466100412 9/1048524607168660222036584535396 :
-1004181871409718654255966342764883958203316448270339/10736628855783147946
99393270058310986889998056 : 1)
Time: 1.380
```

Example H122E21

Here are some more complicated examples. In the first one, the curve has a 163-isogenous curve, which the algorithm uses to speed the computation. This occurs automatically, with most of the time taken being in computing the isogeny map.

```
> E := EllipticCurve([0,0,1,-57772164980,-5344733777551611]);
> b, pt:= HeegnerPoint(E);
> Height(pt);
373.47866156914237988407748041 2
```

Example H122E22

In this next example, we first use descent to get a covering on which the desired point will have smaller height.

```
> E := EllipticCurve([0,-1,0,-71582788120,-7371563751267600]);
> T := TwoDescent(E : RemoveTorsion)[1];
> T;
Hyperelliptic Curve defined by y^2 = -2896*x^4 - 57928*x^3 - 202741*x^2
 + 868870*x - 651725 over Rational Field
> S := FourDescent(T : RemoveTorsion)[1];
> b, pt := HeegnerPoint(S);
> pt;
```

```
(-34940281640330765977951793/729633174814530114300522 32 :
46087465795237503244048957/729633174814530114300522 32 :
82501230298438806677528297/729633174814530114300522 32 : 1)
```

We obtain a point on S, not on the original curve. We map it to E using the descent machinery.

```
> _, m := AssociatedEllipticCurve(S);
> PT := m(pt);
> PT;
(269356432396748248246118697936017740034773039452236777412444550587 53

476.811182818720336949724781780
> ConjecturalRegulator(E : Precision := 5);
476.81 1
```

Example H122E23

Finally, we do some Heegner point calculation with the curve 43A and the discriminant -327. Note that the obtained trace down to the rationals is 3-divisible, but the point over the Hilbert class field is not.

```
> E := EllipticCurve([0,1,1,0,0]);
> HeegnerDiscriminants(E,-350,-300);
[ -347, -344, -340, -335, -331, -328, -327, -323, -319, -308, -303 ]
> HF := HeegnerForms(E,-327); HF;
[ <<43,19,4>, 1, (0 : 1 : 0)>, <<43,67,28>, 1, (0 : 1 : 0)>,
<<86,105,33>, 1, (0 : 1 : 0)>, <<86,153,69>, 1, (0 : 1 : 0)>,
<<129,105,22>, 1, (0 : 1 : 0)>, <<129,153,46>, 1, (0 : 1 : 0)>,
<<172,67,7>, 1, (0 : 1 : 0)>, <<258,363,128>, 1, (0 : 1 : 0)>,
<<258,411,164>, 1, (0 : 1 : 0)>, <<301,67,4>, 1, (0 : 1 : 0)>,
<<473,621,204>, 1, (0 : 1 : 0)>, <<473,841,374>, 1, (0 : 1 : 0)> ]
> H := [x[1] : x in HF]; mul := [x[2] : x in HF];
> params := ModularParametrization(E,H : Precision := 10);
> wparams := [ mul[i]*params[i] : i in [1..#H]];
> hgpt := EllipticExponential(E,&+wparams);
```

```
> hgpt;
[ 1.000000002 - 1.098466121E-9*I, 1.000000003 - 1.830776870E-9*I ]
> HeegnerPt := E![1,1];
> DivisionPoints(HeegnerPt, 3);
[ (0 : -1 : 1) ]
```

So the Heegner point is 3 times $(0, -1)$ in $E(\mathbf{Q})$. We now find algebraically one of the points (of which we took the trace to get $HeegnerPt$). This point will be defined over a subfield of the class field of $\mathbf{Q}(\sqrt{-327})$, and will have degree dividing the class number. The *poly* below is the minimal polynomial of the x-coordinate.

```
> ClassNumber(QuadraticField(-327));
12
> poly, pt := HeegnerPoints(E, -327 : ReturnPoint);
> poly;
<t^12 + 10*t^11 + 76*t^10 - 1150*t^9 + 475*t^8 - 4823*t^7 +
 997*t^6 - 5049*t^5 - 2418*t^4 - 468*t^3 - 3006*t^2 + 405*t - 675, 1>
> pt;
(u : 1/16976844562625*(58475062076*u^11 + 568781661961*u^10 +
 4238812569862*u^9 - 68932294336288*u^8 + 42534102728187*u^7 -
 238141610215111*u^6 + 134503848441911*u^5 - 122884262733563*u^4 -
 58148031982456*u^3 + 129014145075851*u^2 -
 68190988248855*u + 40320643901175) : 1)
> DivisionPoints(pt,3);
[]
```

Here is another example of Heegner points over class fields.

Example H122E24

```
> E := EllipticCurve([0,-1,0,-116,-520]);
> Conductor(E);
1460
> ConjecturalRegulator(E);
4.488874747706661735767268062 64 1
> HeegnerDiscriminants(E,-200,-100);
[ -119, -111 ]
> P := HeegnerPoints(E,-119);
> P;
<1227609449333996689*t^10 - 10626150637714398460 3*t^9 +
    24598266676939452036 84*t^8 - 12539974356047058417320*t^7 -
    29852470882365441140 8343*t^6 + 44408766844345979261611 75*t^5 +
    75735490991206189798332 41*t^4 - 39393804886040638610811 3130*t^3 -
    21531810713569162829866 8863*t^2 + 13958289016298162706904 004974*t
    + 38624559371249968900024945369, 1>
```

The function automatically performs a heuristic check that the polynomial has the right properties, using reduction mod small primes. A more expensive check is the following.

```
> G := GaloisGroup( P[1] );
```

```
> IsIsomorphic(G,DihedralGroup(10));
true
```

The extension of $\mathbf{Q}(-119)$ defined by the polynomial is the class field. We now obtain a nice representation of it, and use this to compute the height of the point (which is a bit quicker than computing the height directly).

```
> K<u> := NumberField(P[1]);
> L<v>, m := OptimizedRepresentation(K);
> _<y> := PolynomialRing(Rationals());  // use 'y' for printing
> DefiningPolynomial(L);
y^10 + 2*y^9 - y^8 - 7*y^7 - 7*y^6 + 10*y^5 + 13*y^4 - 9*y^3 - 5*y^2 +
    5*y - 1
> PT := Points(ChangeRing(E,L),m(u))[1];  // y-coord is defined over L
> Height(PT);
6.97911761109714376876370533
```

122.2.15 Analytic Information

`Periods(E: parameters)`

`Precision` RngIntElt *Default :*

Returns the sequence of periods of the Weierstrass $\wp$-function associated to the (rational) elliptic curve E, to `Precision` digits. The first element of the sequence is the real period. The function accepts a non-minimal model, and returns the periods corresponding to that model. As with many algorithms involving analytic information on elliptic curves, the implementation exploits an AGM-trick due to Mestre. There is some functionality for elliptic curves over number fields, though the exact normalisation is not always given.

`EllipticCurveFromPeriods(om: parameters)`

`Epsilon` FldReElt *Default :* 0.001

Given two complex numbers ω_1, ω_2 such that ω_2/ω_1 is in the upper half-plane that correspond to an integral model of an elliptic curve over $\mathbf{Q}$, return such a minimal model of such a curve. This uses the classical `Eisenstein` series, with the vararg `Epsilon` indicating how close to integers the computed $-27c_4$ and $-54c_6$ need to be.

`RealPeriod(E: parameters)`

`Precision` RngIntElt *Default :*

Returns the real period of the Weierstrass $\wp$-function associated to the elliptic curve E to `Precision` digits.

`EllipticExponential(E, z)`

Given a rational elliptic curve E and a complex number z, the function computes the pair $[\wp(z), \wp'(z)]$ where $\wp(s)$ is the Weierstrass $\wp$-function. The algorithm used is taken from [Coh93] for small precision, and Newton iteration on `EllipticLogarithm` is used for for high precision. The function returns a sequence rather than a point on the curve.

`EllipticExponential(E, S)`

Given a rational elliptic curve E and a sequence $S = [p, q]$, where p and q are rational numbers, this function computes the elliptic exponential of p times the `RealPeriod` and q times the imaginary period.

`EllipticLogarithm(P:` *parameters*`)`

`Precision`	RngIntElt	*Default :*

Denote by ω_1, ω_2 the periods of the Weierstrass $\wp$-function related to E. This function returns the elliptic logarithm $\phi(P)$ of the point P, such that $-\omega_1/2 \leq \mathrm{Re}(\phi(P)) < \omega_1/2$ and $-\omega_2/2 \leq \mathrm{Im}(\phi(P)) < \omega_2/2$. The value is returned to `Precision` digits. As with `Periods`, a non-minimal model can be given, and the `EllipticLogarithm` will be computed with respect to it. The algorithm is again an AGM-trick due to Mestre.

`EllipticLogarithm(E, S)`

`Precision`	RngIntElt	*Default :*
`Check`	BoolElt	*Default :* `true`

Given an elliptic curve E and a sequence $S = [z_1, z_2]$, where z_1 and z_2 are complex numbers approximating a point P on E, this function returns the elliptic logarithm $\phi(P)$. For details see the previous intrinsic. When `Check` is false, z_1 and z_2 need not have any relation to a point on the curve, in which case only the x-coordinate matters up to (essentially) a choice of sign in the resulting logarithm.

`pAdicEllipticLogarithm(P, p:` *parameters*`)`

`Precision`	RngIntElt	*Default :* 50

For a point P on an elliptic curve E which is a minimal model and a prime p, returns the p-adic elliptic logarithm of P to `Precision` digits. The order of P must not be a power of p.

Example H122E25

Verify that `EllipticExponential` and `EllipticLogarithm` are inverses.

```
> C<I>:=ComplexField(96);
> E:=EllipticCurve([0,1,1,0,0]);
> P:=EllipticExponential(E,0.571+0.221*I); P;
[ 1.6569476052101862388682981 75 + -1.7854401800676814186186959 47*I,
```

```
-2.417077284700315330385200257 + 3.894153792661208360153853530*I ]
> EllipticLogarithm(E,P);
0.571000000000000000000000000 + 0.221000000000000000000000000*I
```

Add points on a curve via Napier's method.

```
> E:=EllipticCurve([0,0,1,-7,6]);
> P1:=E![0,2]; P2:=E![2,0]; P3:=E![1,0];
> L:=EllipticLogarithm(E!P1)+EllipticLogarithm(E!P2)+EllipticLogarithm(E!P3);
> L;
0.52174821975779076985312019793 7 + 1.480548268241414993307331110 64*i
> P:=EllipticExponential(E,L);
> [Round(Real(x)) : x in P];
[ 4, -7 ]
> P1+P2+P3;
(4 : -7 : 1)
```

`RootNumber(E)`

Calculates the global root number of an elliptic curve E defined over $\mathbf{Q}$. This is equal to the sign in the functional equation of the L-series associated to the curve. The method used is to take a product of local root numbers over the primes of bad reduction.

`RootNumber(E, p)`

Calculates the local root number at a prime p of an elliptic curve E. The method used is due to Halberstadt; for $p > 3$ it is a straightforward calculation involving the valuation of the discriminant, while for $p = 2, 3$ it involves a more careful analysis of the reduction type.

`AnalyticRank(E)`

Verbose	`AnalyticRank`	*Maximum :* 1
`Precision`	RngIntElt	*Default :* 5

Determine the analytic rank of the rational elliptic curve E. The algorithm used is heuristic, computing derivatives of the L-function $L(E, s)$ at $s = 1$ until one appears to be nonzero. Local power series methods are used to compute the special functions used for higher derivatives. The function returns the first nonzero derivative $L^{(r)}(1)/r!$ as a second argument. The precision is optional, and is taken to be 17 bits if omitted; the time taken can increase dramatically if this is increased much beyond 50 digits as the time to compute the special functions then starts to dominate the running time.

`ConjecturalRegulator(E)`

`Precision` RngIntElt *Default :*

Using the `AnalyticRank` function, this function calculates an approximation, assuming that the Birch–Swinnerton-Dyer conjecture holds, to the product of the regulator of the elliptic curve E and the order of the Tate–Shafarevich group. The (assumed) analytic rank is returned as a second value.

`ConjecturalRegulator(E, v)`

Given an elliptic curve E with L-function $L(E, s)$ and the value v of the first nonzero derivative $L^{(r)}(1)/r!$, this function calculates an approximation, assuming that the Birch–Swinnerton-Dyer conjecture holds, to the product of the regulator of the elliptic curve E and the order of its Tate–Shafarevich group.

Example H122E26

```
> E:=EllipticCurve([1,1,0,-2582,48720]);
> time r, Lvalue := AnalyticRank(E : Precision:=9); r,Lvalue;
Time: 17.930
6 320.781164
> ConjecturalRegulator(E,Lvalue);
68.2713770
> time G, map := MordellWeilGroup(E : HeightBound := 8); G;
Time: 21.540
Abelian Group isomorphic to Z (6 copies)
Defined on 6 generators (free)
> Regulator([map(g): g in OrderedGenerators(G)]);
68.2713769
```

Example H122E27

```
> ConjecturalRegulator(EllipticCurve([0,-1,1,0,0]) : Precision := 8);
1.0000000 0
> ConjecturalRegulator(EllipticCurve([0,-1,1,0,0]) : Precision := 21);
1.00000000000000000000 0
> ConjecturalRegulator(EllipticCurve([0,-1,1,0,0]) : Precision := 35);
1.0000000000000000000000000000000000 0
> ConjecturalRegulator(EllipticCurve([0,-1,1,0,0]) : Precision := 50);
1.00000000000000000000000000000000000000000000000000 0
```

`ModularDegree(E)`

Verbose `ModularDegree` *Maximum :* 1

Determine the modular degree of a rational elliptic curve E. The algorithm used is described in [Wat02]. One computes the special value $L(Sym^2 E, 2)$ of the motivic symmetric-square L-function of the elliptic curve, and uses the formula

$$deg(phi) = L(Sym^2 E, 2)/(2 * Pi * \Omega) * (Nc^2) * E_p(2)$$

where Ω is the area of the fundamental parallelogram of the curve, N is the conductor, c is the Manin constant, and $E_p(2)$ is a product over primes whose square divides the conductor. The Manin constant is assumed to be 1 except in the cases described in [SW02], where it is conjectured that the optimal curves for parameterizations from $X_1(N)$ and $X_0(N)$ are different. A warning is given in these cases. The optimal curve for parameterizations from $X_1(N)$ is assumed to be the curve in the isogeny class of E that has minimal Faltings height (maximal Ω). The algorithm is based upon a sequence of real-number approximations converging to an integer — the use of verbose printing for `ModularDegree` allows the user to see the sequence of approximations.

Example H122E28

First we define a space of ModularForms.

```
> M:=ModularForms(Gamma0(389),2);
```

The first of the newforms associated to M corresponds to an elliptic curve.

```
> f := Newform(M,1); f;
q - 2*q^2 - 2*q^3 + 2*q^4 - 3*q^5 + 4*q^6 - 5*q^7 + q^9 + 6*q^10 - 4*q^11 +
O(q^12)
> E := EllipticCurve(f); E;
Elliptic Curve defined by y^2 + y = x^3 + x^2 - 2*x over Rational Field
```

We can compute the modular degree of this using modular symbols.

```
> time ModularDegree(ModularSymbols(f));
40
Time: 0.200
```

Or via the algorithm based on elliptic curves.

```
> time ModularDegree(E);
40
Time: 0.000
```

The elliptic curve algorithm is capable of handling examples of high level, particularly when bad primes have multiplicative reduction.

```
> E := EllipticCurve([0,0,0,0,-(10^4+9)]);
> Conductor(E);
```

```
14425931664
> time ModularDegree(E);
6035544576
Time: 3.100
```

122.2.16 Integral and S-integral Points

Let E be an elliptic curve defined over the rational numbers $\mathbf{Q}$ and denote by $S = \{p_1, \ldots, p_{s-1}, \infty\}$ a finite set of primes containing the prime at infinity. There are only finitely many S-integral points on E. (That is, points where the denominators of the coordinates are only supported by primes in S.) Note that the point at infinity on E is never returned, since it is supported at every prime.

The following algorithms use the technique of linear forms in complex and p-adic elliptic logarithms.

The main routine here is `(S)IntegralPoints` for an elliptic curves. The functions listed afterwards, for determining integral points on various other kinds of genus one curves, are applications of the main routine.

`IntegralPoints(E)`

`FBasis`	[PtEll]	*Default :*
`SafetyFactor`	RngIntElt	*Default :*

Given an elliptic curve E over the $\mathbf{Q}$, this returns a sequence containing all the integral points on E, modulo negation. Secondly, a sequence is returned containing representations of the same points in terms of a fixed basis of the Mordell-Weil group (each such representation is a sequence of tuples of the form $[\langle P_i, n_i \rangle]$).

The algorithm involves first computing generators of the Mordell-Weil group, by calling `MordellWeilShaInformation` which accesses the appropriate tools available in Magma. Alternatively, the user may precompute generators and pass them to `IntegralPoints` as the optional parameter `FBasis`. This should be a sequence of points on E that are independent modulo torsion (for instance, as returned by `ReducedBasis`). `IntegralPoints` will then find all integral points on E that are in the group generated by `FBasis` and torsion.

If the optional argument `SafetyFactor` is specified, the search phase at the final step is extended as a safety check. (The height bound is increased in such a way that the search region expands by roughly the specified factor.)

`SIntegralPoints(E, S)`

`FBasis`	[PtEll]	*Default :*
`SafetyFactor`	RngIntElt	*Default :*

Given an elliptic curve E over the rationals and a set S of finite primes, returns the sequence of all S-integral points, modulo negation. The second return value, and the optional arguments `FBasis` and `SafetyFactor`, are the same as in `IntegralPoints`.

Example H122E29

We find all integral points on a certain elliptic curve:

```
> E := EllipticCurve([0, 17]);
> Q, reps := IntegralPoints(E);
> Q;
[ (-2 : -3 : 1), (8 : 23 : 1), (43 : -282 : 1), (4 : 9 : 1),
(2 : -5 : 1), (-1 : 4 : 1), (52 : -375 : 1), (5234 : 378661 : 1) ]
> reps;
[
    [ <(-2 : -3 : 1), 1> ],
    [ <(-2 : -3 : 1), 2> ],
    [ <(-2 : -3 : 1), 1>, <(4 : -9 : 1), -2> ],
    [ <(4 : -9 : 1), -1> ],
    [ <(-2 : -3 : 1), 1>, <(4 : -9 : 1), -1> ],
    [ <(-2 : -3 : 1), 1>, <(4 : -9 : 1), 1> ],
    [ <(-2 : -3 : 1), 2>, <(4 : -9 : 1), 1> ],
    [ <(-2 : -3 : 1), 1>, <(4 : -9 : 1), 3> ]
]
```

We see here that the chosen basis consists of the points $(-2 : -3 : 1)$ and $(4 : -9 : 1)$, and that coefficients which are zero are omitted.

Example H122E30

We find all S-integral points on an elliptic curve of rank 2, for the set of primes $S = \{2, 3, 5, 7\}$.

```
> E := EllipticCurve([-228, 848]);
> Q := SIntegralPoints(E, [2, 3, 5, 7]);
> for P in Q do P; end for;    // Print one per line
(4 : 0 : 1)
(-11 : 45 : 1)
(16 : 36 : 1)
(97/4 : -783/8 : 1)
(-44/9 : -1160/27 : 1)
(857/4 : -25027/8 : 1)
(6361/400 : -282141/8000 : 1)
(534256 : -390502764 : 1)
(946/49 : -20700/343 : 1)
(-194/25 : -5796/125 : 1)
(34/9 : 172/27 : 1)
(814 : 23220 : 1)
(13 : 9 : 1)
(-16 : 20 : 1)
(1/4 : -225/8 : 1)
(52 : -360 : 1)
(53 : 371 : 1)
(16/49 : 9540/343 : 1)
(-16439/1024 : -631035/32768 : 1)
```

```
(34 : 180 : 1)
(-2 : 36 : 1)
(-14 : -36 : 1)
(14 : -20 : 1)
(754 : -20700 : 1)
(94/25 : -828/125 : 1)
(2 : 20 : 1)
(94 : 900 : 1)
(-818/49 : 468/343 : 1)
(49/16 : -855/64 : 1)
(196 : -2736 : 1)
(629/25 : 13133/125 : 1)
(1534/81 : -42020/729 : 1)
(8516/117649 : -1163623840/40353607 : 1)
```

`IntegralQuarticPoints(Q)`

If Q is a sequence of five integers $[a, b, c, d, e]$ where e is a square, this function returns all integral points (modulo negation) on the curve $y^2 = ax^4 + bx^3 + cx^2 + dx + e$.

`IntegralQuarticPoints(Q, P)`

If Q is a list of five integers $[a, b, c, d, e]$ defining the hyperelliptic quartic $y^2 = ax^4 + bx^3 + cx^2 + dx + e$ and P is a sequence representing a rational point $[x, y]$, this function returns all integral points on Q.

`SIntegralQuarticPoints(Q, S)`

Given a sequence of integers $Q = [a, b, c, d, e]$ where a is a square, this function returns all S-integral points on the quartic curve $y^2 = ax^4 + bx^3 + cx^2 + dx + e$ for the set S of finite primes.

Example H122E31

We find all integral points (modulo negation) on the curve $y^2 = x^4 - 8x^2 + 8x + 1$. Since the constant term is a square we can use the first form and do not have to provide a point as well.

```
> IntegralQuarticPoints([1, 0, -8, 8, 1]);
[
    [ 2, -1 ],
    [ -6, 31 ],
    [ 0, 1 ]
]
```

`SIntegralLjunggrenPoints(Q, S)`

Given a sequence of integers $Q = [a, b, c, d]$, this function returns all S-integral points on the curve $C : ay^2 = bx^4 + cx^2 + d$ for the set S of finite primes, provided that C is nonsingular.

`SIntegralDesbovesPoints(Q, S)`

Given a sequence of integers $Q = [a, b, c, d]$, this function returns all S-integral points on $C : ay^3 + bx^3 + cxy + d = 0$ for the set S of finite primes, provided that C is nonsingular.

Example H122E32

We find the points supported by $[2, 3, 5, 7]$ on the curve $9y^3 + 2x^3 + xy + 8 = 0$.

```
> S := [2, 3, 5, 7];
> SIntegralDesbovesPoints([9, 2, 1, 8], S);
[
    [ 1, -1 ],
    [ -94/7, 172/21 ],
    [ -11/7, 2/7 ],
    [ 5, -3 ],
    [ 2, -4/3 ],
    [ 2/7, -20/21 ],
    [ -8/5, -2/15 ]
]
```

122.2.17 Elliptic Curve Database

MAGMA includes John Cremona's database of all elliptic curves over **Q** of small conductor (up to 200 000 as of December 2011). This section defines the interface to that database.

For each conductor in the range stored in the database the curves with that conductor are stored in a number of isogeny classes. Each curve in an isogeny class is isogenous (but not isomorphic) to the other curves in that class. Isogeny classes are referred to by number rather than the alphabetic form given in the Cremona tables.

All of the stored curves are global minimal models.

`EllipticCurveDatabase(: parameters)`

`CremonaDatabase(: parameters)`

`BufferSize` RNGINTELT *Default :* 10000

This function returns a database object which contains information about the elliptic curve database and is used in the functions which access it. The optional parameter `BufferSize` controls the size of an internal buffer — see the description of `SetBufferSize` for more information.

`SetBufferSize(D, n)`

The elliptic curve database D uses an internal buffer to cache disk reads; if the buffer is large enough then the entire file can be cached and will not need to be read from the disk more than once. On the other hand, if only a few curves will be accessed then a large buffer is not especially useful. `SetBufferSize` can be used to set the size n (in bytes) of this buffer. There are well defined useful minimum and maximum sizes for this buffer, and values outside this range will be treated as the nearest useful value.

`LargestConductor(D)`

Returns the largest conductor of any elliptic curve stored in the database. It is an error to attempt to refer to larger conductors in the database.

`ConductorRange(D)`

Returns the smallest and largest conductors stored in the database. It is an error to attempt to refer to conductors outside of this range.

`#D`

`NumberOfCurves(D)`

Returns the number of elliptic curves stored in the database.

`NumberOfCurves(D, N)`

Returns the number of elliptic curves stored in the database for conductor N.

`NumberOfCurves(D, N, i)`

Returns the number of elliptic curves stored in the database in the i-th isogeny class for conductor N.

`NumberOfIsogenyClasses(D, N)`

Returns the number of isogeny classes stored in the database for conductor N.

`EllipticCurve(D, N, I, J)`

`EllipticCurve(D, N, S, J)`

Returns the J-th elliptic curve of the I-th isogeny class of conductor N from the database. I may be specified either as an integer (first form) or as a label like `"A"` (second form).

`EllipticCurve(D, S)`

`EllipticCurve(S)`

Returns a representative elliptic curve with label S (e.g., `"101a"` or `"101a1"`) from the specified database (or if not specified, from the Cremona database).

`Random(D)`

Returns a random curve from the database.

`CremonaReference(D, E)`

`CremonaReference(E)`

Returns the database reference to the minimal model for E (e.g., `"101a1"`). E must be defined over $\mathbf{Q}$ and its conductor must lie within the range of the database. The second form of this function must open the database for each call, so if it is being used many times the database should be created once and the first form used instead.

Example H122E33

```
> D := CremonaDatabase();
> #D;
847550
> minC, maxC := ConductorRange(D);
> minC, maxC;
1 130000
> &+[ NumberOfCurves(D, C) : C in [ minC .. maxC ] ];
847550
```

These numbers agree (which is nice). The conductor in that range with the most curves is 100800.

```
> S := [ NumberOfCurves(D, C) : C in [ minC .. maxC ] ];
> cond := maxval + minC - 1 where _,maxval := Max(S);
> cond;
100800
> NumberOfCurves(D, cond);
924
> NumberOfIsogenyClasses(D, cond);
418
```

The unique curve of conductor 5077 has rank 3.

```
> NumberOfCurves(D, 5077);
1
> E := EllipticCurve(D, 5077, 1, 1);
> E;
Elliptic Curve defined by y^2 + y = x^3 - 7*x + 6 over Rational Field
> CremonaReference(D, E);
5077a1
> Rank(E);
3
```

`EllipticCurves(D, N, I)`

`EllipticCurves(D, N, S)`

Returns the sequence of elliptic curves in the I-th isogeny class for conductor N from the database. I may be specified either as an integer (first form) or as a label like `"A"` (second form).

`EllipticCurves(D, N)`

The sequence of elliptic curves for conductor N from the database.

`EllipticCurves(D, S)`

The sequence of elliptic curves with label S from the database. S may specify just a conductor (like `"101"`), or both a conductor and an isogeny class (like `"101A"`).

`EllipticCurves(D)`

The sequence of elliptic curves stored in the database. Note: this function is extremely slow due to the number of curves involved. Where possible it would be much better to iterate through the database instead (see example).

Example H122E34

Here are two ways to iterate through the database:

```
> D := CremonaDatabase();
25508696848625044861003843159331265666415824
Time: 21.130
> sum := 0;
> time for E in D do sum +:= Discriminant(E); end for;
> sum;
25508696848625044861003843159331265666415824
Time: 20.060
```

Now we create a random curve and find the other curves in its isogeny class.

```
> E := Random(D);
> E;
Elliptic Curve defined by y^2 = x^3 - 225*x over Rational Field
> Conductor(E);
7200
> CremonaReference(E);
7200bg1
> EllipticCurves(D, "7200bg");
[
    Elliptic Curve defined by y^2 = x^3 - 225*x over Rational Field,
    Elliptic Curve defined by y^2 = x^3 - 2475*x - 47250 over Rational Field,
    Elliptic Curve defined by y^2 = x^3 - 2475*x + 47250 over Rational Field,
    Elliptic Curve defined by y^2 = x^3 + 900*x over Rational Field
]
```

122.3 Curves over Number Fields

The functions in this section are for elliptic curves defined over number fields. For the most part, the functionality is a subset of that available for curves over **Q**, with functions having similar names and arguments.

The main items implemented are Tate's algorithm, 2-descent and descent by 2-isogenies, the Cassels-Tate pairing, height machinery, and analytic tools.

122.3.1 Local Invariants

The routines listed here, when nontrivial, are based on an implementation of Tate's algorithm.

`Conductor(E)`

The conductor is part of the data computed by `LocalInformation` (described below).

`BadPlaces(E)`

Given an elliptic curve E defined over a number field K, returns the places of K of bad reduction for E. i.e., the places dividing the discriminant of E.

`BadPlaces(E, L)`

Given an elliptic curve E defined over a number field K and a number field L, such that K is a subfield of L, returns the places of L of bad reduction for E.

`LocalInformation(E, P)`

`UseGeneratorAsUniformiser`

BoolElt *Default :* `false`

Implements Tate's algorithm for the elliptic curve E over a number field. This intrinsic computes local reduction data at the prime ideal P, and a local minimal model. The model is not required to be integral on input. Output is $\langle P, v_p(d), f_p, c_p, K, s\rangle$ and E_{min} where P is the prime ideal, $v_p(d)$ is the valuation of the local minimal discriminant, f_p is the valuation of the conductor, c_p is the Tamagawa number, K is the Kodaira Symbol, and s is `false` if the curve has non-split multiplicative reduction at P and `true` otherwise. E_{min} is a model of E (integral and) minimal at P.

When the optional parameter `UseGeneratorAsUniformiser` is set `true`, the computation checks whether P is principal, and if so, uses generator of P as the uniformiser. This means that at primes other that P, the returned model will still be integral or minimal if the given curve was.

`LocalInformation(E)`

Return a sequence of the tuples returned by `LocalInformation(E, P)` for all prime ideals P in the decomposition of the discriminant of E in the maximal order of the number field the elliptic curve E is over.

`Reduction(E, p)`

Given an elliptic curve E over a number field given by a model which is integral at p and has good reduction at p, returns an elliptic curve over the residue field of p which represents the reduction of E at p. The reduction map is also returned.

122.3.2 Complex Multiplication

`HasComplexMultiplication(E)`

Given an elliptic curve E over a number field, the function determines whether the curve has complex multiplication and, if so, also returns the discriminant of the CM quadratic order. The algorithm uses fairly straightforward analytic methods, which are not suited to very high degree j-invariants with CM by orders with discriminants more than a few thousand.

122.3.3 Mordell–Weil Groups

`TorsionBound(E, n)`

Given an elliptic curve E defined over a number field, returns a bound on the size of the torsion subgroup of E by looking at the first n non-inert primes of sufficiently low ramification degree and good reduction.

`pPowerTorsion(E, p)`

`Bound`	RngIntElt	*Default :* -1

Given an elliptic curve E defined over a number field or **Q**, returns the p-power torsion of E over its base field as an abelian group, together with the map from the group into the curve. One can specify a bound on the size of the p-power torsion, which may help the computation.

`TorsionSubgroup(E)`

Given an elliptic curve E defined over a number field, returns the torsion subgroup of E.

The algorithm involves using `TorsionBound` (described above).

`MordellWeilShaInformation(E: parameters)`

`DescentInformation(E: parameters)`

`RankOnly`	BoolElt	*Default :* `false`
`ShaInfo`	BoolElt	*Default :* `false`
`Silent`	BoolElt	*Default :* `false`

This is a special function which uses all relevant Magma machinery to obtain as much information as possible about the Mordell-Weil group and the Tate-Shafarevich group of the elliptic curve E. The tools used include 2-descent and

the Cassels-Tate pairing on the 2-Selmer group; analytic routines may also be used when the conductor has small norm.

The arguments and returned values are the same as for curves over $\mathbf{Q}$, and are described in Section 122.2.5.

Note: The function `PseudoMordellWeilGroup` is obsolete and should not be used; this function should be used instead.

`RankBound(E)`

`Isogeny`	MAP	*Default :*

The upper bound on the rank of $E(K)$, for an elliptic curve over a number field K (or $\mathbf{Q}$), obtained by computing the Selmer group(s) associated to some isogeny on E. The isogeny is either multiplication by 2, or a 2-isogeny if any exist, and may be specified by the optional parameter `Isogeny`.

122.3.4 Heights

`NaiveHeight(P)`

Given a point P on an elliptic curve over a number field K, the function returns the naive height of P; i.e., the absolute logarithmic height of the x-coordinate.

`Height(P : parameters)`

`Precision`	RNGINTELT	*Default :* 27
`Extra`	RNGINTELT	*Default :* 8

Given a point P on an elliptic curve defined over a number field K, returns the Néron-Tate height $\hat{h}(P)$. (This is based on the absolute logarithmic height of the x-coordinate.) The parameter `Precision` may be used to specify the desired precision of the output. The parameter `Extra` is used in the cases when one of the points $2^n P$ gets too close to the point at infinity, in which case there is a huge loss in precision in the archimedean height and increasing `Extra` remedies that problem.

`HeightPairingMatrix(P : parameters)`

Compute the height pairing matrix for an array of points. Same parameters as above.

`LocalHeight(P, Pl : parameters)`

`Precision`	RNGINTELT	*Default :* 0
`Extra`	RNGINTELT	*Default :* 8

Given a point P on an elliptic curve defined over a number field K, and a place Pl (finite or infinite) of K, returns the local height $\lambda_{Pl}(P)$ of P at Pl. The parameter `Precision` sets the precision of the output. A value of 0 takes the default precision.

When Pl is an infinite place, the parameter `Extra` can be used to remedy the huge loss in precision when one of the points $2^n P$ gets too close to the point at infinity.

122.3.5 Two Descent

The functions here have similar syntax to the corresponding ones for curves over **Q**. The current implementation from 2011 is the first complete implementation of 2-descent over number fields. Previously there have been several implementations that are effective for computing rank bounds, but not for obtaining nice models of the 2-coverings which is necessary in order to search for points. Some of the key ingredients here are the routine for solving conics over number fields (see `HasRationalPoint`), and techniques for minimisation and reduction over number fields developed by Donnelly and Fisher.

`TwoDescent(E:`*parameters*`)`

`RemoveTorsion`	BoolElt	*Default :* `false`
`RemoveGens`	{PtEll}	*Default :* {}
`WithMaps`	BoolElt	*Default :* `true`
`MinRed`	BoolElt	*Default :*
Verbose	`TwoDescent`	*Maximum :* 1

This function has the same arguments and return values as the corresponding function for curves over **Q**. It returns the 2-coverings as a sequence of hyperelliptic curves, and a corresponding list of maps.

Additionally, it returns a third object which specifies the group structure on the 2-coverings. This is a map (with inverse) from an abstract group to the sequence of 2-coverings; the abstract group is either `TwoSelmerGroup(E)`, or the appropriate quotient in the case where `RemoveTorsion` or `RemoveGens` are specified.

Currently, there is an additional optional argument `MinRed`, which controls whether the coverings are minimised and reduced. (This may be expensive for various reasons, especially when the field discriminant is not small: for one thing, a large integer may need to be factored.)

`TwoCover(e)`

`TwoCover(e)`

The purpose of this function is to obtain 2-covers arising in `TwoDescent` individually rather than all together.

The argument e is an element of a cubic extension A/F, where F is a number field, and where A may be either a number field over F or an affine algebra over F. The element e determines a 2-cover of some elliptic curve over F (by the construction given in the description of `DescentMaps` in the next section).

122.3.6 Selmer Groups

First we give a short overview of the theory of Selmer groups. This enables us to fix the notation that is used in the naming of the Magma functions. For a more complete account, see [Sil86]. The actual algorithms to compute the Selmer groups are closer to the description in [Cas66].

Let E', E be elliptic curves over a number field K and let $\phi : E' \to E$ be an isogeny. The only cases currently implemented are where ϕ is a 2-isogeny, i.e., an isogeny of degree 2, and where $E' = E$ and ϕ is multiplication by 2.

Let $E'[\phi]$ be the kernel subscheme of ϕ. By taking Galois cohomology of the short exact sequence of schemes over K,

$$0 \to E'[\phi] \to E' \to E \to 0,$$

we obtain

$$E'(K) \to E(K) \to H^1(K, E'[\phi]) \to H^1(K, E').$$

For the middle map, we write $\mu : E(K) \to H^1(K, E'[\phi])$. Thus, $E(K)/\phi(E'(K))$ injects in $H^1(K, E'[\phi])$ and the image consists exactly of the cocycles that vanish in $H^1(K, E')$.

As an approximation to this image, we define the ϕ-Selmer group of E over K to consist of those cocycles $H^1(K, E'[\phi])$ that vanish in all restrictions $H^1(K_p, E')$, where p runs though all places of K. It fits in the exact sequence

$$0 \to S^{(\phi)}(E/K) \to H^1(K, E'[\phi]) \to \prod_p H^1(K_p, E')$$

The main application of Selmer groups is that they provide the bound:

$$\#E(K)/\phi E'(K) \leq \#S^{(\phi)}(E/K).$$

If $\phi^* : E \to E'$ is the isogeny dual to ϕ, then $\phi \circ \phi^* : E \to E$ is multiplication by $d = \mathrm{Deg}(\phi)$. Thus, one can use the ϕ and ϕ^* Selmer groups to provide a bound on $\#E(K)/dE(K)$ and thus on the Mordell–Weil rank of $E(K)$.

Representation of $H^1(K, E'[\phi])$:

If ϕ is a 2-isogeny, then $H^1(K, E'[\phi]) \sim K^*/K^{*2}$. Thus, we can represent elements by $\delta \in K^*$. In MAGMA, the map μ corresponds to a representation of the map $E(K) \to K^*$. The map μ also accepts just x-coordinates.

If ϕ is multiplication-by-2 and $E : y^2 = f(x)$, we write $A = K[x]/(f(x))$ then

$$H^1(K, E[2]) \sim \{\delta \in A^*/A^{*2} | N_{A/K}(\delta) \in K^{*2}\}.$$

In fact, the full set A^*/A^{*2} corresponds to $H^1(K, E[2] \times \{\pm 1\})$.

The set $H^1(K, E'[\phi])$ also corresponds to the set of covers $\tau_\delta : T_\delta \to E$ over K, modulo isomorphy over K, that are isomorphic to $\phi : E' \to E$ over the algebraic closure of K (see [Sil86], Theorem X.2.2). In this section, we write `tor` for the map $\delta \mapsto \tau_\delta$.

`DescentMaps(phi)`

`CasselsMap(phi)`

`Fields` SETENUM *Default :* {}

Given an isogeny $\phi : E \to E_1$ of elliptic curves over a number field K (or $\mathbf{Q}$), the function returns the connecting homomorphism

$$\mu : E_1(K) \to H^1(K, E[\phi]),$$

and a map τ sending an element of $H^1(K, E[\phi])$ to the corresponding homogeneous space. Here elements of $H^1(K, E[\phi])$ are represented as elements of $A^*/(A^*)^2$ (as described above). The maps are actually given as maps to, and from, A (rather than $A^*/(A^*)^2$).

The isogeny ϕ must be either a 2-isogeny or multiplication–by–2.

When ϕ is multiplication–by–two, then the computation of μ involves a call to `AbsoluteAlgebra`. The optional parameter `Fields` is passed on to that. If the fields mentioned in this set are found to be of any use, then these will be used and whatever class group and unit data stored on the fields will be used in subsequent computations.

When ϕ is multiplication–by–two, the second map τ accepts all elements $\delta \in A^*$. An element $\delta \in A^*$ represents an element of $H^1(K, E[2])$ if and only if δ must have square norm. In general, $\delta \in A^*$ represents an element of $H^1(K, E[2] \times \{\pm 1\})$, in which case $\tau(\delta)$ is the corresponding covering $T_\delta \to \mathbf{P}^1$. (This covering is a twist of the covering $E \to E \to \mathbf{P}^1$ given by $P \mapsto 2P \mapsto x(2P)$.)

`SelmerGroup(phi)`

`Hints`	SetEnum	*Default :* {}
`Raw`	BoolElt	*Default :* `false`
`Bound`	RngIntElt	*Default :* -1
Verbose	`Selmer`	*Maximum :* 2

Given an isogeny $\phi : E \to E_1$ defined over a number field K, computes the associated Selmer group $Sel(\phi) := Sel^\phi(E/K)$.

The Selmer group is returned as a finite abelian group S, together with a map $AtoS : A \to S$, where A is as in the introduction. This is a map only in the Magma sense; it is defined only on a finite subset of A. Its "inverse" $S \to A$ provides the mathematically meaningful injection $S \hookrightarrow A^*/(A^*)^2$. The standard map

$$E_1(K) \to E_1(K)/\phi E(K) \to Sel(\phi)$$

is given by the composition of μ with $AtoS$, where $\mu : E_1(K) \to H^1(K, E[\phi])$ is the first map returned by `DescentMaps`.

If the optional parameter `Hints` is given, it is used as a list of x-coordinates to try first when determining local images. Supplying `Hints` does not change the outcome, but may speed up the computation.

The calculation of the Selmer group involves possibly expensive class group and unit group computations. If no such data has been precomputed, `SelmerGroup` will attempt to obtain this information unconditionally, unless `Bound` is positive. This

bound is then passed on to any called `ClassGroup`. However, if such data is already stored, it will be used and subsequent results will be conditional on whatever assumptions were made while computing this information. If conditional results are desired (for instance, assuming GRH), one should precompute class group information on the codomain of `CasselsMap(phi)` prior to calling `SelmerGroup(phi)`.

If `Raw` is `true`, then three technical items are also returned. The first two of these, $toVec$ and FB, enable one to represent elements of the Selmer group in terms of a "factor base" FB consisting of elements of A that generate a relevant subgroup of $A^*/(A^*)^2$. The map $toVec$ sends an element of S to an exponent vector relative to FB. The map from S to A obtained by multiplying out the results is inverse to $AtoS$.

The final returned value (when `Raw` is `true`) is a set of `Hints` (just as in the optional parameter).

`TwoSelmerGroup(E)`

`Hints`	SetEnum	*Default :* {}
`Raw`	BoolElt	*Default :* `false`
`Bound`	RngIntElt	*Default :* -1
Verbose	`EllSelmer`	*Maximum :* 2

The 2-Selmer group of an elliptic curve defined over $\mathbf{Q}$ or a number field. The function simply calls `SelmerGroup` for the multiplication–by–two isogeny. The given model for E should be integral. The options and return values are the same as for `SelmerGroup`.

Example H122E35

In this example, we determine the rank of $y^2 = x^3 + 9x^2 - 10x + 1$ by computing the 2-Selmer group.

```
> E := EllipticCurve([0,9,0,-10,1]);
> two := MultiplicationByMMap(E,2);
> mu, tor := DescentMaps(two);
```

The hard work: computing the Selmer group.

```
> S, AtoS := SelmerGroup(two);
> #S;
8
```

So the Selmer rank is 3. We deduce the following upper bound on the rank of $E(\mathbf{Q})$, taking into account any 2-torsion.

```
> RankBound(E : Isogeny := two);
3
```

In fact, there are 3 points: $(0, 1), (1, 1)$ and $(2, 5)$.

```
> g1 := E![ 0, 1 ];
```

```
> g2 := E![ 1, 1 ];
> g3 := E![ 2, 5 ];
```

We now test these points for linear independence. It will follow that the points generate $E(K)/2E(K)$, which means they are independent nontorsion points in $E(K)$ (since we know there is no 2-torsion).

```
> IsLinearlyIndependent ([g1, g2, g3]);
true
```

Next we compute the homogeneous space associated to the point $g1 + g2$. It must have a rational point mapping to $g1 + g2$. Note that @@ always denotes "preimage" in MAGMA. The algebra for `AtoS` is not the same as the original cubic, so we must translate before applying the requisite map.

```
> K := NumberField(Modulus(Domain(AtoS)));
> L := NumberField(Polynomial([1,-10,9,1]));
> b, m := IsIsomorphic (K, L); assert b;
> theta := (Rationals()! (L.1 - m(K.1))) + Domain(AtoS).1;
> H, mp := TwoCover((g1+g2)[1] - theta : E:=E); H;
Hyperelliptic Curve defined by y^2 = 9*x^4 - 4*x^3 - 18*x^2 + 4*x + 13
```

The next command finds all **Q**-rational points in the preimage of the point $g1 + g2$ on E. (In MAGMA the preimage is constructed as a scheme.)

```
> RationalPoints( (g1+g2) @@ mp);
{@ (-1 : -2 : 1) @}
```

Example H122E36

We consider the elliptic curve $E : y^2 = dx(x + 1)(x + 3)$ where d is the product of the primes less than 50. Since E has full 2-torsion, we can carry out 2-isogeny descent in three non-equivalent ways, resulting in three different rank bounds.

```
> P<x> := PolynomialRing(Integers());
> d := &*[ p : p in [1..50] | IsPrime(p) ];
> E := EllipticCurve(HyperellipticCurve(d*x*(x + 1)*(x + 3)));
```

The nontrivial 2-torsion points in $E(\mathbf{Q})$:

```
> A, mp := TorsionSubgroup(E);
> T := [ t : a in A | t ne E!0 where t := mp(a) ];
```

The corresponding 2-isogenies:

```
> phis := [ TwoIsogeny(t) : t in T ];
```

The rank bounds obtained from these isogenies:

```
> [ RankBound(E : Isogeny := phi) : phi in phis ];
[ 9, 5, 7 ]
```

We find [9, 5, 7]! Each descent gives a different rank bound. However, a full 2-descent gives:

```
> two := MultiplicationByMMap(E,2);
> RankBound(E : Isogeny := two);
```

```
1
```

Now doing full 2-descent on the three isogenous curves, we see where the obstacle for sharp rank bounds comes from.

```
> OtherTwos := [ MultiplicationByMMap(Codomain(phi), 2) : phi in phis ];
> [ RankBound(Domain(two) : Isogeny := two) : two in OtherTwos ];
[ 9, 5, 7 ]
```

We find [9, 5, 7] again.

Example H122E37

The next example is a classic one from [Kra81].

```
> E := EllipticCurve([0, 977, 0, 976, 0]);
> twoE := MultiplicationByMMap(E, 2);
> muE := CasselsMap(twoE);
> SE, toSE := SelmerGroup(twoE);
> rkEQ := RankBound(E);
> ptE := [ E | [-4, 108], [4, 140] ]; // ignore torsion
> IsLinearlyIndependent (ptE);
true
> // So E is really of rank 2
> d := 109;
> Ed := QuadraticTwist(E, d);
> Ed![ -976, -298656, 1];
(-976 : -298656 : 1)
> // So Ed is of rank at least 1
> rkEdQ := RankBound(Ed);
> _<x> := PolynomialRing(Rationals());
> K := NumberField(x^2 - d);
> EK := BaseChange(E, K);
> rkEK := RankBound(EK);
> rkEQ;
2
> rkEdQ;
3
> rkEK;
3
```

We know that the rank of $E_d(\mathbf{Q})$ must be the rank of $E(K)$ minus the rank of $E(Q)$; thus $E_d(\mathbf{Q})$ has rank 1. This is smaller than the bound of 3 we get from a 2-descent on E_d alone.

Example H122E38

Here we give some examples of using `TwoDescent`, `TwoSelmerGroup`, and `TwoCover`.

```
> E := EllipticCurve( [ 0, 0, 1, -7, 6] ); // rank 3 curve
> T := TwoDescent(E);
> T[6];
```

```
Hyperelliptic Curve defined by y^2 = 3*x^4 - 10*x^3 + 10*x + 1 over
Rational Field
> G, m := TwoSelmerGroup(E);
> G.1 @@ m;
theta^2 - 12*theta + 33
> Parent($1); // Modulus has y^2 = modulus isomorphic to E
Univariate Quotient Polynomial Algebra in theta over Rational Field
with modulus theta^3 - 112*theta + 400
> TwoCover( (G.1 + G.2) @@ m);
Hyperelliptic Curve defined by y^2 = 3*x^4 - 10*x^3 + 10*x + 1 over
Rational Field
> TwoCover( Domain(m) ! 1 );
Hyperelliptic Curve defined by y^2 = 2*x^3 - 12*x^2 - 32*x + 196 over
Rational Field
```

122.3.7 The Cassels-Tate Pairing

The pairing between elements of the 2-Selmer group is implemented, in the same way as for curves over the rationals. This is described in Section 122.2.8.

122.3.8 Elliptic Curve Chabauty

This refers to a method for finding the rational points on a curve, if the curve admits a suitable map to an elliptic curve over some extension field. The method was developed principally by Nils Bruin (see [Bru03] or [Bru04]). The first intrinsic follows a Mordell-Weil sieve based strategy, similar to that used in `Chabauty` for genus 2 curves (see [BS10]).

`Chabauty(MWmap, Ecov)`

`InertiaDegreeBound`	RngIntElt	*Default :* 20
`SmoothBound`	RngIntElt	*Default :* 50
`PrimeBound`	RngIntElt	*Default :* 30
`IndexBound`	RngIntElt	*Default :* -1
`InitialPrimes`	RngIntElt	*Default :* 50
Verbose	`EllChab`	*Maximum :* 3

Let E be an elliptic curve defined over a number field K. This function attempts to determine the subset of $E(K)$ consisting of those points that have a **Q**-rational image under a given map $E \to \mathbf{P}^1$.

The arguments are as follows:

- a map `MWmap`: $A \to E$ from an abstract abelian group into $E(K)$ (for instance, the map returned by `PseudoMordellWeilGroup`),
- A map `Ecov` : $E \to \mathbf{P}^1$ defined over K.

The returned values are a finite subset V of A and an integer R. The set V consists of all the points in the image of A in $E(K)$ that have a **Q**-rational image under

the given map `Ecov`. If the index of A in $E(K)$ is finite and coprime to R then V consists of all points in $E(K)$ with $\mathbf{Q}$-rational image. Changing the various optional parameters can change the performance of this routine considerably. In general, it is not proven that this routine will return at all.

The parameter `InertiaDegreeBound` determines the maximum inertia degree of primes at which local information is obtained.

Only places at with the group order of the rational points on the reduction of E are `SmoothBound`-smooth are used.

The Mordell-Weil sieving process only uses information from $E(K)/BE(K)$, where B is `PrimeBound`-smooth.

If `IndexBound` is set to a value different from -1, then the returned value R will only contain prime divisors from `IndexBound`. Setting this parameter may make it impossible for the routine to return.

`Chabauty(MWmap, Ecov, p)`

`Cosets`	Tup	*Default :*
`Aux`	SetEnum	*Default :*
`Precision`	RngIntElt	*Default :*
`Bound`	RngIntElt	*Default :*
Verbose	`EllChab`	*Maximum :* 3

Let E be an elliptic curve defined over a number field K. This function bounds the set of points in $E(K)$ whose images under a given map $E \to \mathbf{P}^1$ are $\mathbf{Q}$-rational.

The arguments are as follows:

- a map `MWmap` : $A \to E$ from an abstract group into $E(K)$ (for instance, the map returned by `PseudoMordellWeilGroup`),
- a map of varieties `Ecov` : $E \to \mathbf{P}^1$ defined over K, and
- a rational prime p, such that E and the map `Ecov` have good reduction at primes above p.

The returned values are N, V, R and L as follows. Let G denote the image of A in $E(K)$.

- N is an upper bound for the number of points $P \in G$ such that $\mathbf{Ecov}(P) \in \mathbf{P}^1(\mathbf{Q})$ (note that N can be ∞).
- V is a set of elements of A found by the program that have images in $\mathbf{P}^1(\mathbf{Q})$,
- R is a number with the following property: if $[E(K) : G]$ is finite and coprime to R, then N is also an upper bound for the number of points $P \in E(K)$ such that $\mathbf{Ecov}(P) \in \mathbf{P}^1(\mathbf{Q})$, and
- L is a collection of cosets in A such that $(\bigcup L) \cup V$ contains all elements of A that have images in $\mathbf{P}^1(\mathbf{Q})$.

If `Cosets` ($< C_j >$) are supplied (a coset collection of A), then the bounds and results are computed for $A \cap (\bigcup C_j)$.

If `Aux` is supplied (a set of rational primes), then the information at p is combined with the information at the other primes supplied.

If `Precision` is supplied, this is the p-adic precision used in the computations. If not, a generally safe default is used.

If `Bound` is supplied, this determines a search bound for finding V.

The algorithm used is based on [Bru03] and [Bru02].

For examples and a more elaborate discussion, see [Bru04].

Example H122E39

This example is motivated and explained in great detail in [Bru04] (Section 7). Let E be the elliptic curve

$$y^2 = x^3 + (-3\zeta^3 - \zeta + 1)dx^2 + (-\zeta^2 - \zeta - 1)d^2x, \quad d = 2\zeta^3 - 2\zeta^2 - 2$$

over $K := \mathbf{Q}(\zeta)$ where ζ is a primitive 10th root of unity.

```
> _<z> := PolynomialRing(Rationals());
> K<zeta> := NumberField(z^4-z^3+z^2-z+1);
> OK := IntegerRing(K);
> d := 2*zeta^3-2*zeta^2-2;
> E<X,Y,Z> := EllipticCurve(
>         [ 0, (-3*zeta^3-zeta+1)*d, 0, (-zeta^2-zeta-1)*d^2, 0 ]);
```

Next we determine as much as possible of $E(K)$, allowing MAGMA to choose the method.

```
> success, G, GtoEK := PseudoMordellWeilGroup(E);
> G;
Abelian Group isomorphic to Z/2 + Z/2 + Z + Z
Defined on 4 generators
Relations:
    2*G.1 = 0
    2*G.2 = 0
> success;
true
```

Here G is an abstract group and `GtoEK` injects it into $E(K)$. Since the flag is `true`, this is a subgroup of finite, odd index in $E(K)$. Next, we determine the points $(X : Y : Z)$ in this subgroup for which the function

$$u : E \to \mathbf{P}^1 : (X : Y : Z) \to d(-X + (\zeta^3 - 1)Z : X + d(-\zeta^3 - \zeta)Z)$$

takes values in $\mathbf{P}^1(\mathbf{Q})$.

```
> P1 := ProjectiveSpace(Rationals(),1);
> u := map< E->P1 | [-X + (zeta^3 - 1)*d*Z, X+(-zeta^3-zeta)*d*Z] >;
> V, R := Chabauty( GtoEK, u);
> V;
{
    0,
```

```
    G.3 - G.4,
    -G.3 + G.4,
    G.3 + G.4,
    -G.3 - G.4
}
> R;
320
```

We see that the routine assumed that the image of `GtoEK` is 2- and 5-saturated in $E(K)$. We can ask it to not assume anything outside 2.

```
> V2, R := Chabauty( GtoEK, u: IndexBound:= 2);
> V eq V2;
true
> R;
16
```

This means that we have found all points in $E(K)$ that have a rational image under u. If one wants to find the images of these points then it is necessary in this example to first extend u (by finding alternative defining equations for it) so that it is defined on all the points.

```
> u := Extend(u);
> [ u( GtoEK(P) ) : P in V ];
[ (-1 : 1), (-1/3 : 1), (-1/3 : 1), (-3 : 1), (-3 : 1) ]
```

Alternatively, we can apply Chabauty's method without Mordell-Weil sieving.

```
> N, V, R, C := Chabauty( GtoEK, u, 3);
> N;
5
> V;
{
    0,
    G.3 - G.4,
    -G.3 + G.4,
    G.3 + G.4,
    -G.3 - G.4
}
> R;
4
```

The `Chabauty` calculations prove that there are at most N elements in G whose image under u is $\mathbf{Q}$-rational. Also, V is a set of elements with this property. Since here $N = 5 = \#V$, these are the only such elements. Moreover, the calculations prove that *if* $[E(K) : G]$ is coprime to R, then N is actually an upper bound on the number of elements in $E(K)$ whose image under u is $\mathbf{Q}$-rational. We know from the `PseudoMordellWeilGroup` computation that $[E(K) : G]$ is odd. Therefore we have solved our problem for $E(K)$, not just for G.

122.3.9 Auxiliary Functions for Etale Algebras

This section contains machinery for number fields (and more generally "etale algebras", i.e. algebras of the form $\mathbf{Q}[x]/p(x)$), intended to perform the number field calculations that are involved in computing Selmer groups of geometric objects.

It has become conventional to refer to "the p-Selmer group" of a number field K (or, more generally, of an etale algebra) relative to a finite set S of K-primes. It means the finite subgroup $K(S,p)$ of $K^*/(K^*)^p$, consisting of those elements whose valuation at every prime outside S is a multiple of p.

`AbsoluteAlgebra(A)`

`Fields`	SetEnum	*Default :* {}
Verbose	`EtaleAlg`	*Maximum :* 1

Given a separable commutative algebra over **Q**, an absolute number field or a finite field, the function returns the isomorphic direct sum of absolute fields as a cartesian product and the isomorphisms to and from this product. The optional parameter `Fields` enables the user to suggest representations of the absolute fields. If this function finds it needs a field isomorphic to one occurring in the supplied list, then it will use the given field. Otherwise it will construct a field itself. The isomorphism is returned as a second argument. If called twice on the same algebra, it will recompute if the Fields argument is given. Otherwise it will return the result computed the first time.

`pSelmerGroup(A, p, S)`

Verbose	`EtaleAlg`	*Maximum :* 1

Returns the p-Selmer group of a semi-simple algebra A. The set S of ideals should be prime ideals of the underlying number field. The group returned is the direct sum of the p-Selmer groups of the irreducible summands of A and the map is the obvious embedding in the multiplicative group of A. An implied restriction is that `BaseRing(A)` be of type `FldNum`. See also pSelmerGroup on page 1006. If an algebra over the rationals is required, create a degree 1 extension by

```
RationalsAsNumberField();
```

`LocalTwoSelmerMap(P)`

Let K be the number field associated with the prime ideal P. The map returned is $K^* \to K_P^*/K_P^{*2}$, where K_P is the completion of K at P. The codomain is represented as a finite abelian group.

`LocalTwoSelmerMap(A, P)`

Let K be the base field of the commutative algebra A and let P be a prime ideal in K. Then this function returns a map $A^* \to A^*/A^{*2} \otimes K_P$, where K_P is the completion of K at P. The codomain is represented as a finite abelian group.

This map is computed by using `LocalTwoSelmerMap(Q)` for the various extensions Q of P to the fields making up `AbsoluteAlgebra(A)`. The map returned is

essentially the direct sum of all these maps. For technical purposes, one may also wish to use the components of the map coming from each number field; these are given by the second return value, which is a sequence of records (ordered in the same way as the results are concatenated in the returned map). Each record contains items `i, p, map and vmap`. Here `i` is an index indicating which number field in `AbsoluteAlgebra(A)` the record corresponds to, `p` is an extension of P to a prime in that number field, `map` is `LocalTwoSelmerMap(p)`, and `vmap` is the valuation map at p on that number field.

Example H122E40

```
> P<x> := PolynomialRing(Rationals());
> A := quo<P | x^3 - 1>;
> AA := AbsoluteAlgebra(A);
> AA;
Cartesian Product
<Number Field with defining polynomial x - 1 over the Rational Field,
 Number Field with defining polynomial x^2 + x + 1 over the Rational Field>
```

122.3.10 Analytic Information

`RootNumber(E, P)`

The local root number of the elliptic curve E (defined over a number field) at the prime ideal P. The formulae are due to Rohrlich, Halberstadt, Kobayashi and the Dokchitser brothers.

`RootNumber(E)`

Calculates the global root number of an elliptic curve E defined over a number field K. This is the product of local root numbers over all places of K (-1 from each infinite place), and is the (conjectural) sign in the functional equation relating $L(E/K, s)$ to $L(E/K, 2 - s)$.

`AnalyticRank(E)`

`Precision` RngIntElt *Default :* 6

Determine the analytic rank of the elliptic curve E, which is defined over a number field K. The algorithm used is heuristic, computing derivatives of the L-function $L(E/K, s)$ at $s = 1$ until one appears to be nonzero; it also assumes the analytic continuation and the functional equation for the L-function. The function returns the first nonzero derivative $L^{(r)}(1)/r!$ as a second argument. The precision is optional, and is taken to be 6 digits if omitted.

`ConjecturalRegulator(E)`

`Precision`	RngIntElt	*Default :* 10

Using the `AnalyticRank` function, this function calculates an approximation, assuming that the Birch–Swinnerton-Dyer conjecture holds, to the product of the regulator of the elliptic curve E and the order of the Tate–Shafarevich group. The (assumed) analytic rank is returned as a second value.

`ConjecturalSha(E, Pts)`

`Precision`	RngIntElt	*Default :* 6

For an elliptic curve E defined over a number field K and a sequence of points in $E(K)$ which purpotedly form its basis modulo torsion, computes the conjectural order of the Tate-Shafarevich group Ш(E/K). This function computes the product of the regulator and Ш from the Birch–Swinnerton-Dyer conjecture (using `ConjecturalRegulator`) and divides by the determinant of the height pairing matrix for the points supplied in `Pts`. It returns 0 if the points are linearly dependent or they generate a group of rank less than the analytic rank. If the points generated a subgroup of index $n > 1$, it returns $n^2 \cdot |Ш|$.

122.3.11 Elliptic Curves of Given Conductor

This section describes search routines for finding elliptic curves with given conductor, or with good reduction outside a given set of primes. The aim is not to provably find all such curves; in most cases, this would be a very difficult task using current algorirthms. Rather the aim is to efficiently search for these curves, using a variety of techniques, taking advantage of all available information, and taking advantage of all the tools available in Magma which can be applied to the problem.

The routine is particularly effective when some traces of Frobenius of the desired are specified. The obvious application here is to find an elliptic curve that matches a known modular form.

These functions can be used to find elliptic curves over **Q**, as well as number fields, by using `RationalsAsNumberField()`.

`EllipticCurveSearch(N, Effort)`

`EllipticCurveWithGoodReductionSearch(S, Effort)`

`Full`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :*
`Primes`	SeqEnum	*Default :*
`Traces`	SeqEnum	*Default :*
Verbose	`ECSearch`	*Maximum :* 2

These functions perform a search for elliptic curves with specified conductor(s). The first function finds curves with conductor equal to the given ideal N; the "good reduction" functions find curves with conductors divisible only by primes that belong

to the given set S (or that divide the given ideal N). The functions return a sequence containing all such curves that were found. This sequence will not contain curves that are isomorphic to each other. It may contain isogenous curves, however no attempt is made to find full isogeny classes.

The second argument, `Effort`, is an integer which controls how much effort is used before returning; the running time depends on this variable in a roughly linear way, except with significant step-ups at values where an additional technique begins to be used. Currently, `Effort := 400` is the smallest value which tries all available techniques (however this is subject to change).

There are two ways to specify an early stopping condition:

(i) If the optional argument `Max` is set to some positive integer, the routine will return whenever this many non-isogenous curves have been found.

(ii) The optional arguments `Primes` and `Traces`, which must correspond to eachother, may be used to specify some traces of Frobenius of the desired curve(s). Here `Primes` is a sequence of prime ideals coprime to the conductor(s), and `Traces` is a sequence of integers of the form $[a_P : P in$ Primes $]$. Alternatively, to search for several curves with different traces, `Traces` may instead by a sequence of sequences of that form.

If an early stopping condition has been specified, the routine initially tries with lower effort, in order to succeed quickly for easier input; the effort is incremented exponentially up to the specified `Effort` level. (This strategy is desirable because the algorithm involves performing a large number of independent searches in alternation.) However if the option `Full` is set, the full specified `Effort` is used from the beginning.

If `SetVerbose("ECSearch", 1)` is used, information about the search is printed during computation. In particular, curves with the desired conductor are printed when they are found, so that they can be obtained without waiting for the routine to finish.

122.4 Curves over p-adic Fields

The functions in this section are for elliptic curves defined over p-adic fields. They provide an interface to the same code for Tate's algorithm that is used for curves over number fields.

122.4.1 Local Invariants

`Conductor(E)`

The conductor of the elliptic curve E defined over a p-adic field.

`LocalInformation(E)`

Implements Tate's algorithm for the elliptic curve E over a p-adic field. This intrinsic computes local reduction data at the prime ideal P, and a local minimal model. The model is not required to be integral on input. Output is $\langle P, v_p(d), f_p, c_p, K, s\rangle$ and E_{min} where P is the uniformizer of the ground field, $v_p(d)$ is the valuation of the local minimal discriminant, f_p is the valuation of the conductor, c_p is the Tamagawa number, K is the Kodaira Symbol, and s is `false` if the curve has non-split multiplicative reduction and `true` otherwise. E_{min} is an integral minimal model of E.

`RootNumber(E)`

The local root number of the elliptic curve E (defined over a p-adic field).

123 ELLIPTIC CURVES OVER FUNCTION FIELDS

Chapter 123
ELLIPTIC CURVES OVER FUNCTION FIELDS

This section involves elliptic curves with coefficients in a function field $k(C)$ where C is a regular projective curve over some field k (usually a number field or a finite field). The commands are largely parallel to those for elliptic curves over the rationals; one can compute local information (Tate's algorithm and so forth), a minimal model, the L-function, the 2-Selmer group, and the Mordell–Weil group. This goes in order of decreasing generality: Local information is available for curves over univariate function fields over any exact base field, while at the other extreme Mordell–Weil groups are available only for curves over rational function fields over finite fields for which the associated surface is a rational surface. The generality of many of the commands will be expanded in future releases.

123.1 An Overview of Relevant Theory

An elliptic curve over $K = k(C)$ may be regarded as a surface $\mathcal{E}$ over k with a map $\pi : \mathcal{E} \to C$ (in other words, an *elliptic surface*); the generic fibre of $\mathcal{E}$ is E. Under this interpretation, elements of the Mordell–Weil group $E(K)$ are in one-to-one correspondence with sections of π. (A section is a morphism $s : C \to \mathcal{E}$ such that $\pi \circ s = \mathrm{Id}_C$.) This means that one may study the Mordell–Weil group by studying the geometry of the surface.

Given E, there is a unique $\mathcal{E}$ up to isomorphism that is projective, regular, and relatively minimal. This is called the Kodaira–Néron model, and we will always assume that we are working with this model of the surface.

Let $\bar{k}$ denote the separable closure of k, and $\mathcal{E}_{\bar{k}}$ the elliptic surface considered over $\bar{k}$. The Néron–Severi group $\mathrm{NS}(\mathcal{E}_{\bar{k}})$ of $\mathcal{E}_{\bar{k}}$ is the group of divisors of $\mathcal{E}_{\bar{k}}$ modulo algebraic equivalence. It is a finitely generated group and is closely connected with the Mordell–Weil group $E(K)$.

Let N be the subgroup of $\mathrm{NS}(\mathcal{E}_{\bar{k}})$ that is generated by all components of all the fibres of π together with the section corresponding to the zero point of $E(\bar{k}(C))$; this is known as the *trivial lattice* of $\mathrm{NS}(\mathcal{E}_{\bar{k}})$. It can easily be determined since the number of components in reducible fibres can be computed by Tate's algorithm. The following divisor classes together form a basis of N

(i) the image of the section corresponding to the zero point;

(ii) one complete fibre; and

(iii) the components of all the reducible fibres, with one component from each fibre omitted.

It is known that the quotient $\mathrm{NS}(\mathcal{E}_{\bar{k}})/N$ is generated by images of sections of π, and that $\mathrm{NS}(\mathcal{E}_{\bar{k}})/N \cong E(\bar{k}(C))$ (via the identification of sections with points). In particular, this implies the Shioda–Tate formula

$$\mathrm{rank}(E(\bar{k}(C))) + 2 + \sum_{v \in C(\bar{k})} (m_v - 1) = \mathrm{rank}(\mathrm{NS}(\mathcal{E}_{\bar{k}}))$$

where m_v denotes the number of components of the fibre $\pi^{-1}(v)$.

The Galois group $G = G_{\bar{k}/k}$ acts on $\mathrm{NS}(\mathcal{E}_{\bar{k}})$, and it maps N to itself. Moreover, after extending scalars to $\mathbf{Q}$ one can split the Galois representation. That is, there exists $M \subset \mathrm{NS}(\mathcal{E}_{\bar{k}}) \otimes \mathbf{Q}$ such that $\mathrm{NS}(\mathcal{E}_{\bar{k}}) \otimes \mathbf{Q} \cong M \oplus (N \otimes \mathbf{Q})$ and $M \cong E(\bar{k}(C)) \otimes \mathbf{Q}$ as G-modules. In particular, $M^G \cong E(K) \otimes \mathbf{Q}$. In the case that k is a finite field, the Frobenius action on N can be determined with the functions `FrobeniusActionOnReducibleFiber` and `FrobeniusActionOnTrivialLattice`.

In order to study $\mathrm{NS}(\mathcal{E}_{\bar{k}})$ as a G-module, one can embed it in the ℓ-adic cohomology group $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)$. To get a G-equivariant map one must slightly change the G-action on $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)$. Let $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)(1)$ denote the (1)-Tate twist of $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)$. The main property that we need to know about this twist is that it transforms the q-eigensubspace in $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)$ of some q-Frobenius element to the 1-eigenspace of this Frobenius in $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)(1)$. The cycle class map then yields a G-equivariant embedding

$$\mathrm{NS}(\mathcal{E}_{\bar{k}}) \otimes \mathbf{Q}_\ell \hookrightarrow H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)(1).$$

It is conjectured by Tate that the image of $(\mathrm{NS}(\mathcal{E}_{\bar{k}}) \otimes \mathbf{Q}_\ell)^G$ under this map exactly equals $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)(1)^G$.

In the case that k is a finite field one can in principal determine $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)(1)^G$ via the Lefschetz trace formula. Suppose that $k \subset \mathbf{F}_q$ and let F_q denote the q-th power Frobenius map. Then

$$\#\mathcal{E}(\mathbf{F}_q) = 1 + q^2 - (1+q)\,\mathrm{Trace}(F_q | H^1(C_{\bar{k}}, \mathbf{Q}_\ell)) + \mathrm{Trace}(F_q | H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)).$$

The trace on $H^1(C_{\bar{k}}, \mathbf{Q}_\ell)$ is zero if C is a rational curve, and it can be determined by counting $\mathbf{F}_q$-rational points on C in the general case. Hence one can determine $\mathrm{Trace}(F_q | H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell))$ by counting $\mathbf{F}_q$-rational points on $\mathcal{E}$. By doing this for various powers of q one can determine the characteristic polynomial of F_q acting on $H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell)$, and hence the conjectural ranks of $E(\bar{k}(C))$ and $E(K)$ by using Tate's conjectures. The conjectural ranks obtained in this way give unconditional upper bounds on the true ranks.

As the Galois action on N can be determined, the difficult part is to compute

$$\det(1 - T \cdot F_q | H^2(\mathcal{E}_{\bar{k}}, \mathbf{Q}_\ell) / \mathrm{im}(N \otimes \mathbf{Q}_\ell)),$$

where $\mathrm{im}(N \otimes \mathbf{Q}_\ell)$ stands for the image of $N \otimes \mathbf{Q}_\ell$ under the cycle class map. It can be shown that this polynomial is equal to the L-function of E over K; it follows that this L-function is a polynomial. This shows that Tate's conjectures are linked to a geometric

version of the Birch and Swinnerton-Dyer conjecture. Just as in the number field case, this conjecture expresses the rank and the product of the order of the Tate–Shafarevich group and the regulator of E in terms of its L-function. The L-function can be computed with the function `LFunction` and the conjectural information on the rank, Tate–Shafarevich group, and regulator can be obtained with the function `AnalyticInformation`.

If E can be defined by a Weierstrass equation in which the coefficients a_i are polynomials of degree at most i, then $\mathcal{E}_{\bar{k}}$ is a rational surface and $\text{rank}(\text{NS}(\mathcal{E}_{\bar{k}})) = 10$. In this case $\text{rank}(E(\bar{k}(C))) = 10 - \text{rank}(N)$ can be easily determined. In the case that k is a finite field then $E(\bar{k}(C))$ and $E(K)$ can be computed using functions in this section.

123.2 Local Computations

`BadPlaces(E)`

A sequence containing the places where the given model of E has bad reduction, for an elliptic curve E defined over a function field.

`Conductor(E)`

The conductor of an elliptic curve E defined over a function field F. In general this is returned as a divisor of F. When F is a rational function field it is returned as a sequence of tuples $\langle f, e\rangle$ of places (specified by field elements f) and multiplicities e.

`LocalInformation(E, Pl)`

`LocalInformation(E, f)`

This function performs Tate's algorithm for an elliptic curve E over a function field to determine the reduction type and a minimal model at the given place Pl. When E is defined over a rational function field $F(t)$ the place is simply given as a field element f (which must either be $1/t$ or an irreducible polynomial in t.)

The model is not required to be integral on input. The output is of the form $\langle Pl, v_p(d), f_p, c_p, K, split\rangle$ and E_{min} where Pl is the place, $v_p(d)$ is the valuation of the local minimal discriminant, f_p is the valuation of the conductor, c_p is the Tamagawa number, K is the Kodaira Symbol, *split* is a boolean that is false if reduction is of nonsplit multiplicative type and true otherwise, and E_{min} is a model of E (integral and) minimal at Pl.

`LocalInformation(E)`

Returns a sequence of tuples as described above for all places of bad reduction of the elliptic curve E.

`KodairaSymbols(E)`

A sequence of tuples $\langle K, n\rangle$, corresponding to the places of bad reduction of the elliptic curve E. Here K is the Kodaira symbol and n is the degree of the corresponding place.

`NumberOfComponents(K)`

The number of components of a fibre with the Kodaira symbol K.

`MinimalModel(E)`

A model of the elliptic curve E (defined over a function field, which must have genus 0) that is minimal at all finite places, together with a map from E to this minimal model.

`MinimalDegreeModel(E)`

A model of the elliptic curve E (defined over a rational function field) which minimises the quantity Max([Degree(a_i)/i]), where a_1, a_2, a_3, a_4, a_6 are the Weierstrass coefficients.

`IsConstantCurve(E)`

For an elliptic curve E defined over a rational function field $F(t)$, the function returns `true` if and only if E is isomorphic over $F(t)$ to an elliptic curve with coefficients in F (and also returns such a curve in that case).

`TraceOfFrobenius(E, p)`

The trace of Frobenius a_p for the reduction of E at the place p, specified as an element of the base field.

123.3 Elliptic Curves of Given Conductor

`EllipticCurveSearch(N, Effort)`

`Full`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :*
`Primes`	SeqEnum	*Default :*
`Traces`	SeqEnum	*Default :*
Verbose	`ECSearch`	*Maximum :* 2

This routine searches for elliptic curves over a field $F_q(t)$ whose conductor is equal to the specified conductor N. Alternatively, the first argument may be a set or sequence of possible conductors. Here a conductor is specified in the same format as returned by `Conductor`.

For explanation of the optional parameters and other details, see the description of `EllipticCurveSearch` for elliptic curves over number fields.

123.4 Heights

`NaiveHeight(P)`

The naive x-coordinate height of a point P on an elliptic curve over a function field K; in other words, the degree of the point $(x(P) : 1)$ on the projective line.

`Height(P)`

The Néron–Tate height $\hat{h}(P)$ of the given point P on an elliptic curve defined over a function field.

`LocalHeight(P, Pl)`

Given a point P on an elliptic curve defined over a function field F and a place Pl of the function field F, returns the local height $\lambda_{Pl}(P)$ at Pl of P.

`HeightPairing(P, Q)`

Returns the height pairing of the points P and Q, defined as $\langle P, Q\rangle = (\hat{h}(P+Q) - \hat{h}(P) - \hat{h}(Q))/2$ (where as usual $\hat{h}$ denotes the Néron–Tate height).

`HeightPairingMatrix(S)`

Given a sequence S of points P_i on an elliptic curve defined over a function field, this function returns the matrix $(\langle P_i, P_j\rangle)$, where $\langle , \rangle$ is the height pairing.

`HeightPairingLattice(S)`

The height pairing lattice of a sequence of independent points on an elliptic curve defined over a function field.

`Basis(S)`

Given a sequence S of points on an elliptic curve, returns a sequence of points that form a basis for the free part of the subgroup generated by the points in S. The second returned value is a Gram matrix for this basis with respect to the Néron–Tate pairing.

`Basis(S, r, disc)`

Given a sequence S of points on an elliptic curve, returns a sequence of independent points in the free part of the subgroup generated by S such that these points generate a lattice of rank r and discriminant *disc*. The answer is returned as soon as such a lattice has been found, ignoring any additional points in the given sequence.

`IsLinearlyDependent(points)`

`IsLinearlyIndependent(points)`

`IndependentGenerators(points)`

These functions are available for elliptic curves over function fields, and behave the same way as for elliptic curves over the rationals.

123.5 The Torsion Subgroup

`TorsionSubgroup(E)`

Given an elliptic curve E defined over a function field F, this function returns an abelian group A isomorphic to the torsion subgroup of $E(F)$, together with a map from A to $E(F)$.

`TorsionBound(E, n)`

`TorsionBound(E, n, B)`

Given an elliptic curve over a function field F and an integer n, this function computes a bound on the size of the torsion subgroup of $E(F)$ by considering the torsion subgroups of the fibres of E at n different places of F.

When an integer B is given as a third argument then the subgroup of elements of order dividing B is bounded, rather than the whole torsion subgroup.

`GeometricTorsionBound(E)`

Given an elliptic curve E defined over a function field F, this function computes a bound for the geometric torsion subgroup of E. That is, the torsion group of $E(K)$ where K/F is the smallest extension with algebraically closed constant field. In cases where a bound cannot be computed then 0 is returned.

123.6 The Mordell–Weil Group

The machinery in this section and the next section is for curves defined over a rational function field $k(t)$ whose field of constants k is finite.

The Mordell–Weil group can be computed (and generators found) for a curve $y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6$ where each a_i is a *polynomial* in $k[t] \subset k(t)$ of degree at most i.

When this hypothesis is not satisfied, it may still be possible to bound the Mordell–Weil rank and find Mordell–Weil generators using the 2-descent routines described in the next section.

`RankBounds(E)`

`RankBound(E)`

These functions return lower and upper bounds (or just an upper bound) on the rank of the Mordell–Weil group $E(F)$ for an elliptic curve E defined over a function field F with finite constant field. The bound is obtained by applying all the available tools (those described in this section together with the `AnalyticInformation` obtained from the L-function).

`MordellWeilGroup(E : parameters)`

`Al` MonStgElt *Default :* `"Geometric"`

This function computes the Mordell–Weil group of an elliptic curve E that satisfies the hypotheses stated in the introduction immediately above. The function returns two values: an abelian group A and a map m from A to E. The map m provides an isomorphism between the abstract group A and the Mordell–Weil group.

The algorithm used by default is the geometric method described above. However, when `Al` is set to `"Descent"` it instead uses the 2-descent tools described in the next section; if the curve admits 2-isogenies then it uses a separate implementation of descent by 2-isogenies (described in [Rob07]). These descent methods do not always determine the full Mordell–Weil group (in which case a warning is printed); their advantages are that they do not require the degrees of the coefficients to be bounded and in many cases are very efficient.

`MordellWeilLattice(E)`

This function computes the Mordell–Weil lattice of an elliptic curve E that satisfies the hypotheses stated in the introduction immediately above. This is the free part of the Mordell–Weil group with an inner product given by the Néron–Tate height pairing. The function returns two values: the lattice L and a map m from L to E.

`GeometricMordellWeilLattice(E)`

This function computes the geometric Mordell–Weil lattice of an elliptic curve E that satisfies the hypotheses stated in the introduction immediately above. This consists of the free part of the group of points on E that are defined over the function field with a possibly extended constant field, together with the Néron–Tate pairing. The function returns two values: a lattice L and a map m from L to E', where E' is a base change of E over the larger field.

`Generators(E)`

Given an elliptic curve E over a rational function field F that satisfies the hypotheses stated in the introduction immediately above, this function returns a sequence of points in $E(F)$ which are generators of the Mordell–Weil group.

Example H123E1

We find that the curve $y^2 = x^3 + (t^4 + 2t^2)x + t^3 + 2t$ over $F_3(t)$ has rank 2 and has no 2-torsion in its Tate–Shafarevich group.

```
> F<t> := FunctionField(GF(3));
> E := EllipticCurve([ t^4 + 2*t^2, t^3 + 2*t ]);
> S2E := TwoSelmerGroup(E);
> S2E;
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*S2E.1 = 0
```

```
    2*S2E.2 = 0
> MordellWeilGroup(E);
Abelian Group isomorphic to Z + Z
Defined on 2 generators (free)
Mapping from: Abelian Group isomorphic to Z + Z
Defined on 2 generators (free) to CrvEll: E given by a rule [no inverse]
```

Furthermore, we may compute the regulator of E as follows.

```
> Determinant(HeightPairingMatrix(Generators(E)));
12
```

123.7 Two Descent

In odd characteristic the 2-Selmer group can be computed and its elements can be represented as minimised 2-coverings. A search for points on these 2-coverings can be made.

In characteristic 2 descent by 2-isogeny can be performed for an ordinary curve E using the isogenies $E \to E^{frob} \to E$. The Selmer groups for both isogenies are computed; if these have ranks s_1 and s_2 then the rank of E is at most $s_1 + s_2 - 1$.

`TwoSelmerGroup(E)`

This function computes the 2-Selmer group of an elliptic curve E defined over a rational function field $\mathbf{F}_q(t)$ of odd characteristic. This is returned as an abstract group together with a map from the group to the relevant algebra.

The algorithm is standard (similar to the one used for elliptic curves over number fields).

`TwoDescent(E)`

This represents the nontrivial elements of the 2-Selmer group of E as hyperelliptic curves $C : y^2 = f(x)$ of degree 4, and returns a sequence containing the curves together with a list containing the corresponding covering maps $C \to E$. The elliptic curve should be defined over a rational function field $\mathbf{F}_q(t)$ of odd characteristic.

The curves returned have polynomial coefficients and are minimised at all finite places. The conic parametrisation step uses the algorithm by Cremona and van Hoeij.

`QuarticMinimize(f)`

This is the routine used by `TwoDescent` to minimise two-coverings. The function takes a homogeneous quartic in two variables with coefficients in a rational univariate function field and returns a minimal quartic equivalent to f together with the appropriate transformation matrix.

`Points(C : parameters)`

`Bound` RngIntElt *Default :*

This finds all rational points with height up to the given `Bound` on the hyperelliptic curve C, which must be defined over a rational function field $\mathbf{F}_q(t)$. The parameter `Bound` is *not optional*, and it refers to the x-coordinate (logarithmic) height of the points: In other words, the routine finds all projective points $(X : Y : Z)$ where X and Z are polynomials in t of degree less than or equal to `Bound`.

`PointsQI(C, H)`

`OnlyOne` BoolElt *Default :* `false`

`ExactBound` BoolElt *Default :* `false`

This is an optimised routine for finding rational points on a curve given as an intersection of two quadrics defined over a rational function field $\mathbf{F}_q(t)$. It searches for projective points whose coordinates are polynomials in t of degree up to H. To guarantee finding *all* such points the parameter `ExactBound` must be set to true.

The algorithm uses a lattice reduction method described in [Rob07].

`TwoIsogenySelmerGroups(E)`

This performs descent by 2-isogenies for a non-supersingular elliptic curve E defined over a rational function field $k(t)$ where k is finite *of characteristic 2*. The isogenies used are the Frobenius map $E \to E^{frob} : (x, y) \mapsto (x^2, y^2)$ and the dual isogeny $E^{frob} \to E$ (which is separable). The function returns four objects: the Selmer group S^{sep} of the separable isogeny (as an abstract group), followed by the Selmer group S^{Frob} of the Frobenius isogeny, followed by maps $S^{sep} \to k(t)/\Phi(k(t))$ and $S^{Frob} \to k(t)^*/(k(t)^*)^2$. Here Φ denotes the Artin–Schreier map $a \mapsto a^2 + a$.

Notes describing the algorithm will be made available (on request). The theoretical background is presented in [Kra77].

123.8 The L-function and Counting Points

To compute the L-function one can use the intrinsic `LFunction` or alternatively one can do it "by hand", using the tools in this section and the next (as illustrated in Example H123E6).

`LFunction(E)`

`LFunction(E, S)`

`Check` BoolElt *Default :* `true`

The L-function of the elliptic curve E, which should be defined over a rational function field over a finite field.

To speed up the computation, the points in S are used to reduce the unknown part of H^2; S should be a sequence of points on E or on some base change of E by an extension of the constant field. If the parameter `Check` is set to `false` then the points in S must form a basis for a subgroup of the geometric Mordell–Weil group

modulo torsion that is mapped to itself by the Galois group of the extension of the fields of constants.

`LFunction(E, e)`

The L-function for the base change of the elliptic curve E by a constant field extension of degree e.

`AnalyticRank(E)`

The Mordell–Weil rank of E as predicted by Tate's version of the Birch–Swinnerton-Dyer conjecture (or equivalently, the Artin–Tate conjecture). This is an unconditional upper bound and is proved to be the actual rank for several classes of curves, such as those arising from rational elliptic surfaces and K3 elliptic surfaces. It is required that E is defined over a function field over a finite field.

`AnalyticInformation(E)`

`AnalyticInformation(E, L)`

`AnalyticInformation(E, e)`

This function computes what is predicted by the Birch–Swinnerton-Dyer (or Artin–Tate) conjecture about E, which should be an elliptic curve defined over a function field over a finite field. The data is given as a tuple consisting of the rank, geometric rank, and the product of the order of Tate–Shafarevich group and the regulator.

When a polynomial L is given as a second argument then function will assume that L is the L-function of E.

When an integer e is given as a second argument then the function will return analytic data for the base change of E by the constant field extension of degree e. This is more efficient than simply calling `AnalyticInformation` on the base change.

Example H123E2

The curve $y^2 = x^3 + 2t^2x + (t^3 + 2t^2 + 2t)$ over $\mathbf{F}_3(t)$ has rank 0 and its Tate–Shafarevich group contains $\mathbf{Z}/3 \oplus \mathbf{Z}/3$. We may conclude this (unconditionally) from the analytic information, since the Tate conjecture is proved for rational elliptic surfaces.

```
> F<t> := FunctionField(GF(3));
> E := EllipticCurve([ 2*t^2, t^3 + 2*t^2 + 2*t ]);
> AnalyticInformation(E);
<0, 4, 9>
```

Furthermore, the rank of $E(\overline{F_3}(t))$ is 4.

Example H123E3

We consider again the curve $y^2 = x^3 + (t^4 + 2t^2)x + t^3 + 2t$ over $\mathbf{F}_3(t)$, which was found to have rank 2 and regulator 12 in Example H123E1.

```
> F<t> := FunctionField(GF(3));
> E := EllipticCurve([ t^4 + 2*t^2, t^3 + 2*t ]);
> AnalyticInformation(E);
<2, 8, 12>
```

This confirms that the rank is 2 and tells us that the regulator multiplied by the order of Sha is 12; hence the Tate–Shafarevich group is trivial. Again this is unconditional.

`NumberOfPointsOnSurface(E, e)`

Returns the number of points on the Kodaira–Néron model of the elliptic curve E over an extension of the constant field of degree e.

`NumbersOfPointsOnSurface(E, e)`

If an elliptic curve E is defined over a function field over a finite field of q elements then this intrinsic computes a sequence containing the number of points on the corresponding Kodaira–Néron model of E over extensions of $\mathbf{F}_q$ of degree up to e, together with the number of points on the base curve over these extensions.

`BettiNumber(E, i)`

Returns the i-th Betti number of the Kodaira–Néron model of the elliptic surface corresponding to the elliptic curve E.

`CharacteristicPolynomialFromTraces(traces)`

Given a sequence $traces = [t_1, t_2, \ldots, t_d]$, this function computes a polynomial of degree d with constant coefficient equal to 1 such that the j-th powersum of the reciprocal zeroes of this polynomial is equal to t_j. This is typically used when one wants to compute the characteristic polynomial of Frobenius acting on some piece of cohomology from traces of various powers of Frobenius.

`CharacteristicPolynomialFromTraces(traces, d, q, i)`

Given a sequence of field elements $[t_1, t_2, \ldots, t_k]$ and integers d, q, and i, this function computes a polynomial of degree d with constant coefficient 1 such that the reciprocals of the zeroes of this polynomial have absolute value $q^{i/2}$ and the j-th powersum of the reciprocals of these zeroes equals t_j. For this function one must have k at least equal to Floor$(d/2)$. A priori the leading coefficient of the polynomials is not determined from the list of traces; in this case two polynomials are returned, one for each choice of sign. One usually needs to provide Ceiling$(d/2)$ traces in order to determine the sign, but in certain cases more traces are required. This function is typically used when one wants to compute the characteristic polynomial of Frobenius acting on a piece of the i-th cohomology group from traces of various powers of Frobenius.

123.9 Action of Frobenius

`Frobenius(P, q)`

The q-th power Frobenius map on the point P of an elliptic curve that can be defined over a function field with constant field $\mathbf{F}_q$).

`FrobeniusActionOnPoints(S, q : parameters)`

`gram`	AlgMatElt	*Default :*

A matrix representing the q-power Frobenius map on the subgroup of the geometric Mordell–Weil group (modulo torsion) with the given basis S. (This subgroup is assumed to be invariant under the q-power Frobenius.)

The optional parameter `gram` should be the Gram matrix with respect to the height pairing of the points in S.

`FrobeniusActionOnReducibleFiber(L)`

Given reduction data L for an elliptic curve E, such as given by the command `LocalInformation`, this function returns a matrix representing the Frobenius action on the non-identity components of corresponding fibres.

`FrobeniusActionOnTrivialLattice(E)`

Given an elliptic curve E defined over a rational function field over a finite field, returns a matrix representing the Frobenius action on fibre components and the zero section of the corresponding elliptic surface.

123.10 Extended Examples

Example H123E4

In this example we construct an elliptic curve by using a pencil of cubic curves passing through 8 given points. The 8 points are defined over $GF(1831^8)$ and form a Galois orbit over $GF(1831)$.

```
> p := 1831;
> F := GF(p);
> Fe<u> := ext<F | 8>;
> K<t> := FunctionField(F);
> P2<X,Y,Z> := ProjectivePlane(K);
> // define the 8 points:
> points := [ [ u^(p^i), (u^3+u+1)^(p^i) ] : i in [0..7] ];
> M := [ [ p[1]^i*p[2]^j : i in [0..3-j], j in [0..3] ] : p in points ];
> // find the coefficients of 2 cubics that pass through the points:
> B := Basis(Kernel(Transpose(Matrix(M))));
> R<x,y> := PolynomialRing(F, 2);
> mono_aff := [ x^i*y^j : i in [0..3-j], j in [0..3] ];
> // f1 and f2 are the cubics:
> f1 := &+[ (F!B[1][i])*mono_aff[i] : i in [1..10] ];
> f2 := &+[ (F!B[2][i])*mono_aff[i] : i in [1..10] ];
```

```
> // Find the 9th intersection point, which we use as zero, to put
> // it to a nice Weierstrass model :
> P9 := Points(Scheme(Spec(R), [f1, f2]))[1];
> F1 := Homogenization(Evaluate(f1, [X, Y]), Z);
> F2 := Homogenization(Evaluate(f2, [X, Y]), Z);
> C := Curve(P2, F1 + t*F2);
> E := MinimalDegreeModel(EllipticCurve(C, C![P9[1], P9[2]]));
```

We could transfer the 8 points to this Weierstrass model, and use them to determine the Mordell–Weil group. Instead, we will see what MAGMA is able to compute just from the Weierstrass model.

```
> KodairaSymbols(E);
[ <I1, 1>, <I1, 7>, <II, 1>, <I1, 2> ]
```

All fibres are irreducible. According to the theory of rational elliptic surfaces, the geometric Mordell–Weil lattice should then be isomorphic to the root lattice E_8. We can check this. We also compute the Mordell–Weil lattice over the ground field.

```
> Lgeom := GeometricMordellWeilLattice(E);
> IsIsomorphic(Lgeom, Lattice("E", 8));
true
[-1  0 -2  1  1 -1  0 -1]
[ 0  0  0  1  0  0 -1  1]
[ 2  0  2 -2 -1  1  1  0]
[-2  0 -1  0  1  0  0 -1]
[ 1  0  0  1 -1 -1 -1  1]
[-1  0  0  0  1  0  1 -1]
[ 2 -1  2 -3 -1  1  1  1]
[ 1 -1  1 -1  0  0  0  0]
> L, f := MordellWeilLattice(E);
> L;
Standard Lattice of rank 1 and degree 1
Inner Product Matrix:
[8]
> f(L.1);
((1057*t^8 + 384*t^7 + 351*t^6 + 728*t^5 + 872*t^4 + 948*t^3 + 1473*t^2 + 257*t
    + 1333)/(t^6 + 100*t^5 + 1565*t^4 + 1145*t^3 + 927*t^2 + 1302*t + 1197) :
    (1202*t^12 + 1506*t^11 + 1718*t^10 + 1365*t^9 + 656*t^8 + 325*t^7
    + 1173*t^6    + 902*t^5 + 1555*t^4 + 978*t^3 + 616*t^2 + 779*t +
    964)/(t^9 + 150*t^8 + 1520*t^7 + 747*t^6 + 1065*t^5 + 340*t^4 +
    1618*t^3 + 1669*t^2 + 1150*t + 1768) : 1)
```

That the rank equals 1 is not surprising; this point corresponds to the $\mathbf{F}_{1831}$-rational degree 8 divisor consisting of the sum of the 8 points we started with.
To determine the L-function of E one would normally have to count points over various extension fields of $\mathbf{F}_{1831}$, in this case up to $\mathbf{F}_{1831^4}$. This would be costly using current techniques. But since MAGMA is able to determine the geometric Mordell–Weil lattice, it can compute the L-function by simply considering the Galois action on points. MAGMA automatically uses this when asked for the L-function:

```
> LFunction(E);
```

```
-126330075128099803866555841*T^8 + 1
```

Example H123E5

In this example we determine the $\mathbf{C}(t)$-rank of an elliptic curve, following [Klo07].

```
> K<t> := FunctionField(Rationals());
> E := EllipticCurve([-(2*t-1)^3*(4*t-1)^2, t*(2*t-1)^3*(4*t-1)^3]);
```

To determine where the surface has bad reduction we determine the primes at which singular fibres collapse.

```
> &*BadPlaces(E);
(t^5 - 99/32*t^4 + 337/128*t^3 - 251/256*t^2 + 3/16*t - 1/64)/t
> Discriminant(Numerator($1));
-87887055375/4503599627370496
> Factorisation(Numerator($1));
[ <3, 15>, <5, 3>, <7, 2> ]
> Factorisation(Denominator($2));
[ <2, 52> ]
```

So 11 and 13 are the smallest primes of good reduction. We remark that in [Klo07] the primes 17 and 19 were used.

```
> K11<t11> := FunctionField(GF(11));
> E11 := ChangeRing(E,K11);  // Reduce E mod 11
> LFunction(E11);
161051*T^5 - 7986*T^4 - 363*T^3 - 33*T^2 - 6*T + 1
> AnalyticInformation(E11);
<0, 1, 1>
> AnalyticInformation(E11, 2);
<1, 1, 35/2>
```

So modulo 11 the rank is 0, but over $\mathbf{F}_{11^2}(t)$ the rank equals the geometric rank of 1, and the height of a generator is congruent to $\frac{35}{2}$ modulo $\mathbf{Q}^2$. From this it can be concluded that the geometric rank in characteristic 0 is at most 1. As the L-function has odd degree 5 for any p of good reduction, it will always have a zero at $1/p$ or $-1/p$ and consequently the geometric rank modulo p will always be at least 1. To determine what the geometric rank is in characteristic zero, one can combine information at 2 different primes.

```
> K13<t13> := FunctionField(GF(13));
> E13 := ChangeRing(E, K13);  // Redude E mod 13
> AnalyticInformation(E13);
<0, 1, 1>
> AnalyticInformation(E13,2);
<1, 1, 121/2>
```

So over $\mathbf{F}_{13^2}(t)$ the rank equals the geometric rank of 1. The height of a generator is congruent to $\frac{121}{2}$ modulo $\mathbf{Q}^2$. As the quotient of the heights of generators in characteristics 11 and 13 is not a square in $\mathbf{Q}$, there cannot exist a Mordell–Weil group in characteristic zero that both modulo 11 and 13 reduces to a finite index subgroup of the Mordell–Weil group modulo p. Hence one can conclude that the geometric Mordell–Weil rank in characteristic zero is zero.

Example H123E6

In this example we calculate part of the L-function of an elliptic curve for which it is not feasible to compute the L-function completely. The simplest way to compute an L-function is to call `LFunction`, which counts points on the surface over certain constant field extensions. However, if the required extension fields are too big then `LFunction` will not terminate. One can determine the required extension degrees as follows.

```
> K<t> := FunctionField(GF(5));
> E := EllipticCurve([t^9+t^2, t^14+t^4+t^3]);
> h2 := BettiNumber(E, 2);
> N := FrobeniusActionOnTrivialLattice(E);
> [h2, h2 - NumberOfRows(N)];
[ 34, 21 ]
```

So the H^2 has dimension 34, of which a 13-dimensional piece is generated by the trivial lattice and a 21-dimensional piece is unknown. To determine the L-function one would have to at least count points over $\mathbf{F}_{5^{10}}$. As this is not feasible we will instead count points over extension degrees up to 5 and print the first few coefficients of the L-function.

```
> nop := NumbersOfPointsOnSurface(E, 5);
> traces := [ nop[i] - 1 - 25^i - 5^i*Trace(N^i) : i in [1..5] ];
> CharacteristicPolynomialFromTraces(traces);
5750*T^5 + 875*T^4 - 40*T^3 - 40*T^2 + 1
```

124 MODELS OF GENUS ONE CURVES

Chapter 124
MODELS OF GENUS ONE CURVES

124.1 Introduction

This chapter deals with curves of genus one that are given by equations in a particular form. Most of the functionality involves invariant theory of these models and applications of this theory to arithmetic problems concerning genus one curves over number fields.

Geometrically (viewed over an algebraically closed field), a genus one model of degree n is an elliptic curve embedded in $\mathbf{P}^{n-1}$ via the linear system $|n.O|$. In general, a genus one model of degree n is a principal homogeneous space for an elliptic curve (of order n in the Weil–Châtelet group) which is embedded in $\mathbf{P}^{n-1}$ in an analogous way. Such models are sometimes called genus one normal curves. Not every element of order n in the Weil–Châtelet group admits such an embedding, although it does if it is everywhere locally soluble.

Genus one models may be defined in MAGMA over any ring. The degree n can be 2, 3, 4, or 5. Genus one models have their own type in MAGMA: `ModelG1`, which is not a subtype of any other type. In particular, these objects are not curves or even schemes. The data that defines a genus one model is one of: a multivariate polynomial (for degree 2 or 3), a pair of multivariate polynomials (degree 4), or a matrix of linear forms (degree 5). Each of these are now described in detail.

A genus one model of degree 2 in MAGMA is defined either by a binary quartic $g(x, z)$ (referred to as a model without cross terms), or more generally by an equation $y^2 + f(x, z)y - g(x, z)$ where f and g are homogeneous of degrees 2 and 4 and the variables x, z, y are assigned weights 1, 1, 2 respectively. A binary quartic $g(x, z)$ defines the same model as the equation $y^2 - g(x, z)$. (The implicit map is the projection to $\mathbf{P}^1_{x,z}$, which in this case is not an embedding but rather has degree 2.)

A genus one model of degree 3 in MAGMA is defined by a cubic form in 3 variables (in other words, the equation of a projective plane cubic curve).

A genus one model of degree 4 in MAGMA is defined by a sequence of two homogeneous polynomials of degree 2 in 4 variables. This represents an intersection of two quadric forms in $\mathbf{P}^3$, and is the standard form in which MAGMA returns curves that are obtained by doing `FourDescent` on an elliptic curve.

A genus one model of degree 5 in MAGMA is defined by a 5×5 alternating matrix whose entries are linear forms in 5 variables. The associated subscheme of $\mathbf{P}^4$ is cut out by the 4×4 Pfaffians of the matrix. It is known that every genus one normal curve of degree 5 arises in this way.

Note: Degenerate cases are allowed, which means that the scheme associated to a genus one model is not always a smooth curve of genus 1 (or even a curve).

124.2 Related Functionality

Section 122.2.11, which concerns three descent on elliptic curves, is relevant for studying rational points on plane cubics (genus one models of degree 3) over the rationals.

A very efficient point search for schemes is available; for details see Section 112.13.4. This will find all rational points up to absolute height H on the curve associated to a given genus one model in time $O(H^{2/d})$, where d is the dimension of the ambient projective space.

124.3 Creation of Genus One Models

`GenusOneModel(n, seq)`

`GenusOneModel(seq)`

`GenusOneModel(n, str)`

The genus one model of degree n (where n is 2, 3, 4, or 5) determined by the coefficients in the given sequence or string. The coefficients may belong to any ring.

A sequence $[a, b, c, d, e]$ of length 5 is interpreted as the degree 2 model $ax^4 + bx^3z + cx^2z^2 + dxz^3 + ez^4$. A sequence $[f, g, h, a, b, c, d, e]$ of length 8 is interpreted as the degree 2 model $y^2 + y(fx^2 + gxz + hz^2) - (ax^4 + bx^3z + cx^2z^2 + dxz^3 + ez^4)$.

A sequence $[a, b, c, d, e, f, g, h, i, j]$ of length 10 is interpreted as the degree 3 model $ax^3 + by^3 + cz^3 + dx^2y + ex^2z + fy^2x + gy^2z + hz^2x + iz^2y + jxyz$.

Sequences of lengths 20 or 50 are interpreted as models of degree 4 or 5 respectively; however, it is easier to create these by specifying matrices instead (see below).

The sequence of coefficients can be recovered by calling `Eltseq`.

`GenusOneModel(C)`

A genus one model that represents the given curve C.

For degree 2, C should either be a subscheme of a weighted projective space $\mathbf{P}(1, 1, 2)$, or a hyperelliptic curve. For degrees $n = 3$, 4, or 5, C should be a genus one normal curve of degree n; in other words, a plane cubic for $n = 3$, an intersection of two quadrics in $\mathbf{P}^3$ for $n = 4$, or an intersection of five quadrics in $\mathbf{P}^4$ for $n = 5$.

`GenusOneModel(f)`

`GenusOneModel(seq)`

The genus one model given by the polynomial f or the sequence of equations `seq`.

`GenusOneModel(n, E)`

A genus one model of degree n (where n is 2, 3, 4, or 5) representing the elliptic curve E embedded in $\mathbf{P}^{n-1}$ via the linear system $|n.O|$. Also returned are the image of the embedding as a curve C together with the maps of schemes $E \to C$ and $C \to E$.

`GenusOneModel(mat)`

The genus one model of degree 5 associated to the given 5×5 matrix.

`GenusOneModel(mats)`

The genus one model of degree 4 determined by the given pair of 4×4 symmetric matrices in the sequence `mats`. (The matrices can be recovered by calling `ModelToMatrices`).

`CompleteTheSquare(model)`

Given a genus one model of degree 2, returns a simplified genus one model of degree 2 without cross terms; this is computed by completing the square on the multivariate polynomial defining the original model.

`RandomGenusOneModel(n)`
`RandomModel(n)`

`Size` RngIntElt *Default :*

A random genus one model of degree n, where n is 2, 3, 4, or 5.

`GenericModel(n)`

The generic genus one model of degree n, where n is 2, 3, 4 or 5. The coefficients are indeterminates in a suitable polynomial ring.

`ChangeRing(model, B)`

The genus one model defined over the ring B obtained by coercing the coefficients of the given genus one model into B.

`CubicFromPoint(E, P)`

The 3-covering corresponding to the rational point P on an elliptic curve E. The 3-covering is returned as the equation of a projective plane cubic curve. Also returned are the covering map and a point that maps to P under the covering map.

`HesseModel(n, seq)`

A genus one model of degree n invariant under the standard representation of the Heisenberg group. The second argument should be a sequence of two ring elements.

`DiagonalModel(n, seq)`

A genus one model of degree n invariant under the diagonal action of μ_n. The second argument should be a sequence of n ring elements.

Example H124E1

We construct the genus one model of degree 5 obtained from the generic elliptic curve $E_{a,b} : y^2 = x^3 + ax + b$ over $\mathbf{Q}(a, b)$. The model is the image of $E_{a,b}$ under the embedding in $\mathbf{P}^4$ given by the linear system $|5.O|$.

```
> K<a,b> := FunctionField(Rationals(), 2);
> Eab := EllipticCurve([a, b]);
> model := GenusOneModel(5, Eab);
> model;
[           0 -b*x1 - a*x2           x5           x4           x3]
[ b*x1 + a*x2            0           x4           x3           x2]
[         -x5          -x4            0          -x2            0]
[         -x4          -x3           x2            0           x1]
[         -x3          -x2            0          -x1            0]
```

From this matrix, which is the data storing the model, the equations of the curve in $\mathbf{P}^4$ can be computed; they are quadratic forms given by the 4×4 Pfaffians of the matrix.

```
> Equations(model);
[
    -x1*x4 + x2^2,
    x1*x5 - x2*x3,
    b*x1^2 + a*x1*x2 + x2*x4 - x3^2,
    -x2*x5 + x3*x4,
    -b*x1*x2 - a*x2^2 + x3*x5 - x4^2
]
```

Note that the degree 5 model has the same invariants $c4, c6, \Delta$ as $E_{a,b}$:

```
> Invariants(model);
-48*a
-864*b
-64*a^3 - 432*b^2
> cInvariants(Eab), Discriminant(Eab);
[
    -48*a,
    -864*b
]
-64*a^3 - 432*b^2
```

124.4 Predicates on Genus One Models

`IsGenusOneModel(f)`
`IsGenusOneModel(seq)`
`IsGenusOneModel(mat)`

Returns `true` if and only if the given polynomial, sequence of polynomials, or matrix determines a "genus one model" in the sense described in the introduction to this chapter. When true, the model is also returned.

Important note: This does *not* imply that the associated scheme is a curve of genus 1, as degenerate cases are allowed!

`IsEquivalent(model1, model2)`
`IsEquivalent(cubic1, cubic2)`

Return `true` if and only if the two given cubics (or genus one models of degree 3) are equivalent as genus one models. In other words, that there exists a linear transformation of the ambient projective space $\mathbf{P}^2_{\mathbf{Q}}$ which takes one cubic to the other, up to scaling. The algorithm is given in [Fis06].

When true, the transformation is also returned as a tuple (the syntax is explained in Section 124.9, on transformations, below).

124.5 Access Functions

`Degree(model)`

The degree (2, 3, 4, or 5) of the given model.

`DefiningEquations(model)`

A sequence containing the equations by which the given genus one model (which must have degree 2, 3, or 4) is defined.

`Equations(model)`

A sequence containing equations for the scheme associated to the given genus one model (of any degree). For degree 2, 3, or 4 this is the same as `DefiningEquations`.

`Matrix(model)`

The defining matrix of a genus one model of degree 5.

`Curve(model)`

`HyperellipticCurve(model)`

`QuadricIntersection(model)`

The curve associated to the given genus one model.

In the degree 2 case the curve is hyperelliptic of the form $y^2 + f(x, z)y - g(x, z) = 0$, but is only created explicitly as a hyperelliptic curve when `HyperellipticCurve` is called; otherwise it is created as a general curve in a weighted projective space in which the variables x, z, and y have weights 1, 1, and 2).

In the degree 4 case the curve is an intersection of two quadrics in $\mathbf{P}^3$.

An error results in degenerate cases where the equations of the model do not define a curve

`Matrices(model)`

For a genus one model of degree 4 this function returns a sequence containing two 4×4 symmetric matrices representing the quadrics.

`BaseRing(model)`

The coefficient ring of the given model.

`PolynomialRing(model)`

The polynomial ring used to define the model.

`Eltseq(model)`

`ModelToString(model)`

A sequence or string containing the coefficients of the defining data of the given genus one model (which is either a polynomial, a pair of polynomials, or a matrix). The model may be recovered by using `GenusOneModel`.

124.6 Minimisation and Reduction

This section contains functions for obtaining a simpler model of a given genus one curve.

We use the following terminology, which has become fairly standard. Here a model will always mean a global integral model.

Minimisation refers to computing a model which is isomorphic to the original one (over its ground field) but possibly not integrally equivalent. A model is *minimal* if it is locally minimal at all primes; a model is locally minimal if the valuation of its discriminant is as small as possible among all integral models. For locally solvable models this minimal discriminant is equal to that of the associated elliptic curve.

Reduction refers to computing a model which is integrally equivalent to the original one (meaning there exist transformations in both directions over the ring of integers of the base field). Informally, a *reduced model* is one whose coefficients have small height. One approach to formulating this precisely is to attach to each model an *invariant* in some symmetric space: The model is then said to be reduced iff its invariant lies in some fixed

fundamental domain. This idea is also the basis for algorithms used to obtain reduced models.

The algorithms used for models of degree 2, 3, and 4 over $\mathbf{Q}$ are described in [CFS10]. For degree 5 it is necessary to use some different techniques developed by Fisher. For models of degree 2 over number fields the algorithms use additional techniques developed by Donnelly and Fisher.

`Minimise(model : parameters)`

`Transformation`	BoolElt	*Default :* `true`
`CrossTerms`	BoolElt	*Default :* `false`
`UsePrimes`	SeqEnum	*Default :* []
`ClassGroupPrimes`	SeqEnum	*Default :* []
Verbose	`Minimise`	*Maximum :* 3

Given a genus one model (of degree 2, 3, 4, or 5) with coefficients in $\mathbf{Q}$, this returns a minimal model in the sense described above.

It is also implemented for genus one models of degree 2 without cross terms, and returns a model that is minimal among models without cross terms when this is possible. When this is not possible (due to class group obstructions) it returns a model that is nearly minimal, in the sense that the extra factor appearing in the discriminant is chosen to have small norm. The primes dividing the extra factor may be specified via the optional argument `ClassGroupPrimes`.

The transformation taking the original model to the minimal model is also returned, unless the optional argument `Transformation` is set to `false`. (The syntax for transformations is explained in Section 124.9).

For degree 2, when the optional argument `CrossTerms` is set to `false` then a model without cross terms is returned that is minimal among models of this kind.

The third value returned is the set of primes where the minimal model has positive level. These are the primes where the model is not soluble over $\mathbf{Q}_p^{nr}$, the maximal non-ramified extension of $\mathbf{Q}_p$ (except for $p = 2$ for models of degree 2 when `CrossTerms` is `false`).

The degree 5 routine is not yet proven to work in all cases.

`Minimise(f)`

Given the equation f of a nonsingular projective plane cubic curve, this returns the equation of a minimal model of the curve and a tuple specifying the transformation (as explained in Section 124.9 below).

`pMinimise(f, p)`

Given the equation f of a nonsingular projective plane cubic curve, this function returns a model of the curve which is minimal at p. Also returned is a matrix M giving the transformation; up to scaling, the minimised cubic is the original cubic evaluated at $M[x, y, z]^{tr}$.

`Reduce(model)`

`Reduce(f)`

Verbose `Reduce` *Maximum :* 3

Given a genus one model of degree 2, 3, or 4 over **Q**, this function computes a reduced model in the sense described above.

The model may instead be described by the appropriate polynomial f, which must be either a homogeneous polynomial that defines a genus one model of degree 2 or 3, or a univariate polynomial that defines a genus one model of degree 2 without cross terms.

The transformation taking the original model to the reduced model is also returned. (The syntax for transformations between genus one models is explained in Section 124.9).

`ReduceQuadrics(seq)`

Verbose `Reduce` *Maximum :* 3

This function computes a reduced basis for the space spanned by the given quadrics (which should be given as a sequence of homogeneous quadratic forms in variables $x_1, \ldots, x_n$). This means making a linear change of the homogeneous coordinates, and also finding a new basis for the space of forms, with the aim of making the resulting coefficients small. The second and third objects returned are matrices S and T giving the transformation. The change of homogeneous coordinate variables is given by S, while T specifies the change of basis of the space of forms. The returned forms are therefore obtained by substituting $[x_1, \ldots, x_n].S$ for $[x_1, \ldots, x_n]$ in the original forms, and then applying T to this basis of forms (where T acts from the left).

The current implementation of this routine is not optimal; nevertheless it is useful in some situations.

124.7 Genus One Models as Coverings

The curve defined by a genus one model of degree n is a principal homogeneous space for some elliptic curve (namely the Jacobian of the curve). The data of the Jacobian, and the covering map of degree n^2, can be read from the invariants and covariants of the model.

Any two models with the same Jacobian can be added together as elements of the Weil–Châtelet group. Below are functions for adding two models of degree 3, and for "doubling" models of degree 4 or 5.

A related function for degree 3 models is `ThreeSelmerElement` (see Section 122.2.11). For degree 4 models the maps can also be computed using `AssociatedEllipticCurve` and `AssociatedHyperellipticCurve` from the package on four descent (see Section 122.2.9).

`Jacobian(model)`

`Jacobian(C)`

The Jacobian, returned as an elliptic curve, of the given genus one model, or of the curve C corresponding to a genus one model.

`nCovering(model : parameters)`

`E`	CrvEll	*Default :*

The covering map from the given genus one model to its Jacobian. Three values are returned: the curve C of degree n corresponding to the given model, its Jacobian as an elliptic curve E, and a map of schemes $C \to E$.

If an elliptic curve E is given it must be isomorphic to the Jacobian and then this curve will be the image of the map.

`AddCubics(cubic1, cubic2 : parameters)`

`AddCubics(model1, model2 : parameters)`

`model1 + model2`

`E`	CrvEll	*Default :*
`ReturnBoth`	BoolElt	*Default :* `false`

Given two ternary cubic polynomials, or two genus one models of degree 3, that both have the same invariants, returns the sum of the corresponding elements of $H^1(\mathbf{Q}, E[3])$.

An error results if the two cubics do not belong to the same elliptic curve E, See Section 122.2.11 for more information about `AddCubics`.

`DoubleGenusOneModel(model)`

Given a genus one model of degree 4 or 5, this function computes twice the associated element in the Weil–Châtelet group and returns this as a genus one model (which will have degree 2 or 5, respectively).

`FourToTwoCovering(model : parameters)`

`FourToTwoCovering(C : parameters)`

`C2`	Crv	*Default :*

Given a genus one model of degree 4 or an associated curve, this function returns three values: the curve C_4 in $\mathbf{P}^3$ corresponding to the model, a plane quartic curve C_2 representing twice the model in the Weil–Châtelet group, and the map of schemes $C_4 \to C_2$. Calling `AssociatedHyperellipticCurve(Curve(model))` provides the same information.

124.8 Families of Elliptic Curves with Prescribed n-Torsion

In [RS95], Rubin and Silverberg explicitly construct families of elliptic curve over $\mathbf{Q}$ which have the same Galois representation on the n-torsion subgroups as a given elliptic curve.

`RubinSilverbergPolynomials(n, J : parameters)`

`Parameter` RngElt *Default :*

Suppose that $n = 2$, 3, 4, or 5 and let $E : y^2 = x^3 + ax + b$ be an elliptic curve over the rationals with j-invariant $1728J$. This function returns polynomials $\alpha(t)$ and $\beta(t)$ that determine a family of elliptic curves with fixed n-torsion, in the following sense: Every nonsingular member F_t of the family $F : y^2 = x^3 + a\alpha(t)x + b\beta(t)$ has $F_t[n]$ isomorphic to $E[n]$ as $\mathbf{Z}[G]$-modules, where G is the absolute Galois group of $\mathbf{Q}$, and furthermore the isomorphisms between $F_t[n]$ and $E[n]$ preserve the Weil pairing. When n is 3, 4, or 5, all such "n-congruent" curves belong to the same family.

124.9 Transformations between Genus One Models

A transformation between two genus one models of degree $n = 2$, 3, 4, or 5 is a tuple consisting of two elements. The second element is an $n \times n$ matrix determining a linear transformation of the projective coordinates (acting on them from the right). The first element is a "rescaling", which is either a matrix or a scalar.

For degree 2 models $q(x, z)$ without cross terms, or for degree 3 models, a transformation is a tuple $\langle k, S\rangle$, where k is an element of the coefficient ring; the transformed model is obtained by making the substitution of coordinate variables determined by S and multiplying the equation by k. For degree 2 models with cross terms a transformation is a tuple $\langle k, [A, B, C], S\rangle$, where k and S are as above and in addition $y + Ax^2 + Bxz + Cz^2$ is substituted for y in the transformation. For degree 4, the first element is a 2×2 matrix; a model of degree 4 is given by two quadric equations, and the 2×2 matrix determines a change of basis of the quadrics (acting on them from the left). A transformation of degree 5 models is a tuple $\langle T, S\rangle$ where T and S are both 5×5 matrices; a model of degree 5 is given by a 5×5 matrix of linear forms M, and the transformed model is given by TM_ST^{tr} where M_S is obtained from M by making the substitution of coordinate variables specified by S.

Two genus one models are said to be equivalent if they differ by one of these transformations. Equivalent models have the same invariants up to scaling by the 4th and 6th powers of some element, given by `ScalingFactor`.

`IsTransformation(n, g)`

Return `true` if and only if the tuple g represents a transformation between genus one models of degree n.

`RandomTransformation(n : parameters)`

`Size`	RngIntElt	*Default :* 5
`Unimodular`	BoolElt	*Default :* `false`
`CrossTerms`	BoolElt	*Default :* `false`

A tuple that represents a random transformation between genus one models of degree n. When `Unimodular` is set to `true` then the returned transformation is integrally invertible.

The optional parameter `Size` is passed to `RandomSL` or `RandomGL`.

In degree 2, if `CrossTerms` is false then the returned transformation preserves the set of models with no cross terms.

`g * model`

`ApplyTransformation(g, model)`

The result of applying the transformation g to the second argument, which should be a genus one model.

`g1 * g2`

`ComposeTransformations(g1, g2)`

The composition $g1 * g2$ of two transformations of genus one models. Transformations of genus one models act on the left, so $(g1 * g2) * f = g1 * (g2 * f)$.

`ScalingFactor(g)`

The scaling factor of a transformation g between genus one models is an element λ such that if a genus one model has invariants c_4 and c_6 then the transformed model has invariants $\lambda^4 c_4$ and $\lambda^6 c_6$.

124.10 Invariants for Genus One Models

`aInvariants(model)`

The invariants $[a_1, a_2, a_3, a_4, a_6]$ of the given genus one model which must have degree 2, 3, or 4. The formulae in the degree 3 case come from [ARVT05].

`bInvariants(model)`

The invariants $[b_2, b_4, b_6, b_8]$ of the given genus one model which must have degree 2, 3, or 4. These are computed from the `aInvariants` in the standard way (as for elliptic curves).

`cInvariants(model)`

The invariants $[c_4, c_6]$ of the given genus one model. For $n = 2$, 3, or 4 these are the classical invariants, as can be found in [AKM$^+$01]. For $n = 5$ the algorithm is described in [Fis08].

`Invariants(model)`

The invariants c_4, c_6 and Δ (the discriminant) of the given genus one model.

`Discriminant(model)`

The discriminant Δ of the given genus one model.

`SL4Invariants(model)`

The SL_4-invariants of a genus one model of degree 4.

124.11 Covariants and Contravariants for Genus One Models

The functions in this section implement the invariant theory developed in [Fis].

`Hessian(model)`

We write X_n for the (affine) space of genus one models of degree n. The module of covariants $X_n \to X_n$ is a free module of rank 2 over the ring of invariants. The generators are the identity map and a second covariant which we term the Hessian. (In the cases where $n = 2$ or 3 this is the determinant of a matrix of second partial derivatives.) This function evaluates the Hessian of the given genus one model.

`CoveringCovariants(model)`

The covariants that define the covering map from the given genus one model to its Jacobian (this is the same as the defining equations of the `nCovering`).

`Contravariants(model)`

We write X_n for the (affine) space of genus one models of degree n, and X_n^* for its dual. The module of contravariants $X_n \to X_n^*$ is a free module of rank 2 over the ring of invariants. This function evaluates the generators P and Q at the given genus one model.

`HesseCovariants(model, r)`

Evaluates a pair of covariants, which depend on an integer r, at the genus one model of degree prime to r. The pencil spanned by these genus one models is a family of genus one curves invariant under the same representation of the Heisenberg group. (In other words, the universal family above a twist of $X(n)$.)

If $r \equiv 1 \pmod{n}$ then the covariants evaluated are the identity map and the Hessian. If $r \equiv -1 \pmod{n}$ then the covariants evaluated are the contravariants. If $n = 5$ there are two further possibilities. We identify $X_5 = \wedge^2 V \otimes W$ where V and W are 5-dimensional vector spaces. Then the covariants evaluated for $r \equiv 2, 3 \pmod{5}$ take values in $\wedge^2 W \otimes V^*$ and $\wedge^2 W^* \otimes V$ respectively.

`HessePolynomials(n, r, invariants : parameters)`

`Variables` [RngMPolElt] *Default :*

The Hesse polynomials $D(x, y), c_4(x, y), c_6(x, y)$. These polynomials give the invariants for the pencil of genus one models computed by `HesseCovariants`. The `RubinSilverbergPolynomials` are closely related to these formulae in the case $r \equiv 1 \pmod{n}$.

124.12 Examples

Example H124E2

We find a cubic which is a counterexample to the Hasse principle. The approach involves the idea of "visibility" of Tate–Shafarevich elements, which was introduced by Mazur (see [CM00]).
The cubic will be a nontrivial element of the Tate–Shafarevich group of the curve 4343B1 in Cremona's tables, which we call E. The cubic will be obtained from a rational point on an auxiliary elliptic curve F.
First, we compute that E has rank 0, and F has rank 1:

```
> E := EllipticCurve([ 0, 0, 1, -325259, -71398995 ]);
> F := EllipticCurve([ 1, -1, 1, -24545, 1486216 ]);
> CremonaReference(E);
4343b1
> RankBounds(E);
0 0
> RankBounds(F);
1 1
```

We take a plane cubic representing one of the nontrivial elements in the 3-Selmer group of F, which has order 3, so that its elements are all in the image of $F(\mathbf{Q})$ since $F(\mathbf{Q})$ has rank 1:

```
> SetClassGroupBounds(500);
> #ThreeSelmerGroup(F);
3
> coverings := ThreeDescent(F);
> coverings;
[
    Curve over Rational Field defined by
    -3*x^2*z - 3*x*y^2 - 27*x*y*z + 12*x*z^2 + 2*y^3 + 21*y^2*z + 3*y*z^2 - 4*z^3
]
> C := Equation(coverings[1]);
```

We now try to find a linear combination of C and its Hessian (which is also a plane cubic) that has j-invariant equal to the j-invariant of E. To find the right linear combination we may work geometrically (that is, with F instead of C since they are isomorphic over $\overline{\mathbf{Q}}$). We work with the family $tF + H$ where t is an indeterminate.

```
> B<t> := PolynomialRing(Rationals());
> F_BR := ChangeRing(Parent(Equation(F)), B);
```

```
> F_B := F_BR ! Equation(F);
> H_B := Hessian(F_B);
> c4,c6,Delta := Invariants(t*F_B + H_B);
```

Alternatively we could get these invariants as follows:

```
> D,c4,c6 := HessePolynomials(3, 1, cInvariants(F) : Variables := [t, 1] );
> Delta := Discriminant(F)*D^3;
// Solve c4(t)^3/Delta(t) = j(E) for t:
> jpoly := c4^3 - jInvariant(E)*Delta;
> Roots(jpoly);
[ <7479/7, 1> ]
```

So we take the following linear combination (and replace the equation by a nicer equation):

```
> C2raw := 7479/7*C + Hessian(C);
> C2 := Reduce(Minimise(C2raw));
> C2;
7*x^3 + 7*x^2*y + 3*x^2*z - 4*x*y^2 - 30*x*y*z + 12*x*z^2 - 13*y^3 - 2*y^2*z -
    15*y*z^2 - 17*z^3
```

The Jacobian of $C2$ is E, so $C2$ is a principal homogeneous space for E of index 3, and in fact it is everywhere locally soluble:

```
> IsIsomorphic(Jacobian(C2), E);
true
> PrimeDivisors(Integers()!Discriminant(GenusOneModel(C2)));
[ 43, 101 ]
> C2_crv := Curve(ProjectiveSpace(Parent(C2)), C2);
> IsLocallySolvable(C2_crv, 43);
true (7 + O(43) : 1 + O(43^50) : O(43))
> IsLocallySolvable(C2_crv, 101);
true (1 + O(101^50) : 32 + O(101) : 1 + O(101))
// Find the preimage of the covering map C2 -> E:
> _, _, maptoE := nCovering(GenusOneModel(C2) : E := E);
> preimage := Pullback(maptoE, E!0);
> Points(preimage);   // Q-rational points
{@ @}
> TorsionSubgroup(E);
Abelian Group of order 1
```

We conclude that $C2$ has no rational points since, as $E(\mathbf{Q})$ is trivial, any rational points on $C2$ must map to O_E.

125 HYPERELLIPTIC CURVES

Chapter 125
HYPERELLIPTIC CURVES

125.1 Introduction

This chapter contains descriptions of functions designed to perform calculations with hyperelliptic curves and their Jacobians. A hyperelliptic curve, which is taken to include the genus one case, is given by a nonsingular generalized Weierstrass equation

$$y^2 + h(x)y = f(x),$$

where $h(x)$ and $f(x)$ are polynomials over a field K. The curve is viewed as embedded in a weighted projective space, with weights 1, $g + 1$, and 1, in which the points at infinity are nonsingular.

Functionality for hyperelliptic curves includes optimized algorithms for working on genus two curves over $\mathbf{Q}$, including heights on the Jacobian, and a datatype for the Kummer surface of the Jacobian. For Jacobians of curves over finite fields, there exist specialized algorithms for computing the group structure of the set of rational points.

The category of hyperelliptic curves is `CrvHyp` and points on curves are of type `PtHyp`. Jacobians of hyperelliptic curves are of type `JacHyp` and points `JacHypPt`. Similarly, the Kummer surface of a genus two curve is of type `SrfKum` with points of type `SrfKumPt`.

The initial development of machinery for hyperelliptic curves was undertaken by Michael Stoll, supported by members of the MAGMA group.

125.2 Creation Functions

125.2.1 Creation of a Hyperelliptic Curve

A hyperelliptic curve C given by a generalized Weierstrass equation $y^2 + h(x)y = f(x)$ is created by specifying polynomials $h(x)$ and $f(x)$ over a field K. The class of hyperelliptic curves includes curves of genus one, and a hyperelliptic curve may also be constructed by type change from an elliptic curve E. Note that the ambient space of C is a weighted projective space in which the one or two points at infinity are nonsingular.

`HyperellipticCurve(f, h)`

`HyperellipticCurve(f)`

`HyperellipticCurve([f, h])`

Given two polynomials h and $f \in R[x]$ where R is a field or integral domain, this function returns the nonsingular hyperelliptic curve $C : y^2 + h(x)y = f(x)$. If $h(x)$ is not given, then it is taken as zero. If R is an integral domain rather than a field, the base field of the curve is taken to be the field of fractions of R. An error is returned if the given curve C is singular.

`HyperellipticCurve(P, f, h)`

Create the hyperelliptic curve as described above using the projective space P as the ambient. The ambient P should have dimension 2.

`HyperellipticCurveOfGenus(g, f, h)`

`HyperellipticCurveOfGenus(g, f)`

`HyperellipticCurveOfGenus(g, [f, h])`

Given a positive integer g and two polynomials h and $f \in R[x]$ where R is a field or integral domain, this function returns the nonsingular hyperelliptic curve of genus g given by $C : y^2 + h(x)y = f(x)$. If $h(x)$ is not given, then it is taken as zero. Before attempting to create C, the function checks that its genus will be g by testing various numerical conditions on f and g. If the genus is not correct, a runtime error is raised. If R is an integral domain rather than a field, the base field of C is taken to be the field of fractions of R. An error is returned if the curve C is singular.

`HyperellipticCurve(E)`

Returns the hyperelliptic curve C corresponding to the elliptic curve E, followed by the map from E to C.

125.2.2 Creation Predicates

`IsHyperellipticCurve([f, h])`

Given a sequence containing two polynomials h, $f \in R[x]$, where R is an integral domain, return `true` if and only if $C : y^2 + h(x)y = f(x)$ is a hyperelliptic curve. In this case, the curve is returned as a second value.

`IsHyperellipticCurveOfGenus(g, [f, h])`

Given a positive integer g and a sequence containing two polynomials h, $f \in R[x]$ where R is an integral domain, return `true` if and only if $C : y^2 + h(x)y = f(x)$ is a hyperelliptic curve of genus g. In this case, the curve is returned as a second value.

Example H125E1

Create a hyperelliptic curve over the rationals:

```
> P<x> := PolynomialRing(RationalField());
> C := HyperellipticCurve(x^6+x^2+1);
> C;
Hyperelliptic Curve defined by y^2 = x^6 + x^2 + 1 over Rational Field
> C![0,1,1];
(0 : 1 : 1)
```

Now create the same curve over a finite field:

```
> P<x> := PolynomialRing(GF(7));
> C := HyperellipticCurve(x^6+x^2+1);
```

```
> C;
Hyperelliptic Curve defined by y^2 = x^6 + x^2 + 1 over GF(7)
> C![0,1,1];
(0 : 1 : 1)
```

125.2.3 Changing the Base Ring

`BaseChange(C, K)`

`BaseExtend(C, K)`

Given a hyperelliptic curve C defined over a field k, and a field K which is an extension of k, return a hyperelliptic curve C' over K using the natural inclusion of k in K to map the coefficients of C into elements of K.

`BaseChange(C, j)`

`BaseExtend(C, j)`

Given a hyperelliptic curve C defined over a field k and a ring map $j : k \to K$, return a hyperelliptic curve C' over K by applying j to the coefficients of E.

`BaseChange(C, n)`

`BaseExtend(C, n)`

If C is a hyperelliptic curve defined over a finite field k and a positive integer n, let K denote the extension of k of degree n. This function returns a hyperelliptic curve C' over K using the natural inclusion of k in K to map the coefficients of C into elements of K.

`ChangeRing(C, K)`

Given a hyperelliptic curve C defined over a field k, and a field K, return a hyperelliptic curve C' over K that is obtained from C by by mapping the coefficients of C into K using the standard coercion map from k to K. This is useful when there is no appropriate ring homomorphism between k and K (e.g., when $k = \mathbf{Q}$ and K is a finite field).

Example H125E2

We construct a curve C over the rationals and use `ChangeRing` to construct the corresponding curve $C1$ over $GF(101)$.

```
> P<x> := PolynomialRing(RationalField());
> C := HyperellipticCurve([x^9-x^2+57,x+1]);
> C1 := ChangeRing(C, GF(101));
> C1;
Hyperelliptic Curve defined by y^2 + (x + 1)*y = x^9 + 100*x^2 + 57
over GF(101)
> Q<t> := PolynomialRing(GF(101));
> HyperellipticPolynomials(C1);
t^9 + 100*t^2 + 57
t + 1
> C2, f := SimplifiedModel(C1);
> HyperellipticPolynomials(C2);
4*t^9 + 98*t^2 + 2*t + 27
0
> P1 := C1![31,30,1];
> P1;
(31 : 30 : 1)
> Q := P1@f; // evaluation
> Q;
(31 : 92 : 1)
> Q@@f; // pullback
(31 : 30 : 1)
```

An explanation of the syntax for isomorphisms of hyperelliptic curves and the functions for models is given below.

125.2.4 Models

`SimplifiedModel(C)`

Given a hyperelliptic curve C defined over a field of characteristic not equal to 2, this function returns an isomorphic hyperelliptic curve C' of the form $y^2 = f(x)$, followed by the isomorphism $C \to C'$.

`HasOddDegreeModel(C)`

Given a hyperelliptic curve C, this function returns `true` if C has a model C' of the form $y^2 = f(x)$, with f of odd degree. If so, C' is returned together with the isomorphism $C \to C'$.

`IntegralModel(C)`

`Reduce` BoolElt *Default :* `false`

Given a hyperelliptic curve C defined over the rationals, this function returns an isomorphic curve C' given by polynomials with integral coefficients, together with the isomorphism $C \to C'$. If `Reduce` is set `true`, common divisors of the coefficients are eliminated as far as possible.

`MinimalWeierstrassModel(C)`

`Bound` RngIntElt *Default :* 0

Verbose `CrvHypMinimal` *Maximum :* 3

Given a hyperelliptic curve C defined over the rationals, this function returns a globally minimal Weierstrass model C' of C. If `Bound` is set, it gives an upper bound for the bad primes that are checked. As this calculation uses trial division, `Bound` should not be set much larger than 10^7. The isomorphism $C \to C'$ is returned as a second value.

`pIntegralModel(C, p)`

Verbose `CrvHypMinimal` *Maximum :* 3

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function returns a model C' of the curve that is integral at the place p given as an integer, rational, polynomial, rational function or ∞. The isomorphism $C \to C'$ is returned as a second value.

`pNormalModel(C, p)`

Verbose `CrvHypMinimal` *Maximum :* 3

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function returns a model C' of the curve that is normal at the place p given as an integer, rational, polynomial, rational function or ∞. The isomorphism $C \to C'$ is returned as a second value.

`pMinimalWeierstrassModel(C, p)`

Verbose `CrvHypMinimal` *Maximum :* 3

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function returns a Weierstrass model C' of the curve that is minimal at the place p given as an integer, rational, polynomial, rational function or ∞. The isomorphism $C \to C'$ is returned as a second value.

`ReducedModel(C)`

`Simple`	BoolElt	*Default :* `false`
`Al`	MonStgElt	*Default :* "*Stoll*"
Verbose	`CrvHypReduce`	*Maximum :* 3

Given a hyperelliptic curve C with integral coefficients, this computes a reduced model C'. If the Stoll algorithm is used (default) then the curve argument must have integral coefficients and reduction is performed with respect to the action of $\mathrm{SL}_2(\mathbf{Z})$ on the (x, z)-coordinates. If the Wamelen algorithm is used, (`Al := "Wamelen"`), the curve must have genus 2. The isomorphism $C \to C'$ is currently returned only for the algorithm of Stoll.

`ReducedMinimalWeierstrassModel(C)`

`Simple`	BoolElt	*Default :* `false`
Verbose	`CrvHypMinimal`	*Maximum :* 3
Verbose	`CrvHypReduce`	*Maximum :* 3

Given a hyperelliptic curve C defined over the rationals, this function returns a globally minimal integral Weierstrass model C' of C that is reduced with respect to the action of $\mathrm{SL}_2(\mathbf{Z})$, using Stoll's algorithm in `ReducedModel`. The isomorphism $C \to C'$ is returned as a second value.

`SetVerbose("CrvHypReduce", v)`

This sets the verbose printing level for the curve reduction algorithms of Stoll and Wamelen. The second argument can take integral values in the interval $[0, 3]$, or boolean values: `false` (equivalent to 0) and `true` (equivalent to 1).

125.2.5 Predicates on Models

`IsSimplifiedModel(C)`

Returns `true` if the hyperelliptic curve C is of the form $y^2 = f(x)$.

`IsIntegral(C)`

Given a hyperelliptic curve C, the function returns `true` if C has integral coefficients, and `false` otherwise.

`IspIntegral(C, p)`

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function returns `true` if the given model of C is integral at the given place.

`IspNormal(C, p)`

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function returns `true` if the given model of C is normal at the given place.

`IspMinimal(C, p)`

Given a hyperelliptic curve C defined over $\mathbf{Q}$ or a rational function field, this function decides whether the given model of C is minimal at the given place. The returned values as follows:

- `false`, `false` if C is not an integral minimal model at the given place.
- `true`, `false` if C is integral and minimal at the given place, but not the unique minimal model (up to transformations that are invertible over the local ring).
- `true`, `false` if C is the unique integral minimal model at the given place, (up to transformations that are invertible over the local ring).

125.2.6 Twisting Hyperelliptic Curves

There are standard functions for quadratic twists of hyperelliptic curves in characteristic not equal to 2. In addition, from the new package of Lercier and Ritzenthaler (described in more detail in the next section) there are functions to return *all* twists of a genus 2 hyperelliptic curve over a finite field of any characteristic.

`QuadraticTwist(C, d)`

Given a hyperelliptic curve C defined over a field k of characteristic not equal to 2 and an element d that is coercible into k, return the quadratic twist of C by d.

`QuadraticTwist(C)`

Given a hyperelliptic curve C defined over a finite field k, return the standard quadratic twist of C over the unique extension of k of degree 2. If the characteristic of k is odd, then this is the same as the twist of C by a primitive element of k.

`QuadraticTwists(C)`

Given a hyperelliptic curve C defined over a finite field k of odd characteristic, return a sequence containing the non-isomorphic quadratic twists of C.

`IsQuadraticTwist(C, D)`

Verbose `CrvHypIso` *Maximum :* 3

Given hyperelliptic curves C and D over a common field k having characteristic not equal to two, return `true` if and only if C is a quadratic twist of D over k. If so, the twisting factor is returned as the second value.

`Twists(C)`

For C a genus 2 or 3 hyperelliptic curve over a finite field k, returns the sequence of *all* twists of C (*ie*, a set of representatives of all isomorphism classes of curves over k isomorphic to C over $\bar{k}$) along with the abstract geometric automorphism group of C (and all of its twists) as a permutation group.

For genus 2, k can be any characteristic. For genus 3, the characteristic of k must be at least 11 and the model of C of the form $y^2 = f(x)$.

There is also a version where the argument is GI, the sequence of Cardona-Quer-Nart-Pujola invariants of a genus 2 curve over a finite field (see Section 125.3.2) which returns the full set of isomorphism classes (twists) of curves over k with the given invariants.

These functions are part of the package contributed by Lercier and Ritzenthaler which is more fully described in the Igusa invariants section.

`HyperellipticPolynomialsFromShiodaInvariants(JI)`

Computes and returns all twists of a genus 3 hyperelliptic curve and its geometric automorphism group corresponding to a sequence of Shioda invariants JI (see Section 125.3.3) over a finite field of characteristic at least 11. In fact the first return value is a sequence of polynomials $f(x)$ of degree 7 or 8 such that the twisted curves correspond to $y^2 = f(x)$. The reason for this is that JI could be a *singular* set of invariants corresponding to polynomials f with discriminant zero. In that case, these do not correspond to hyperelliptic curves, but it might be useful to get the full set of twists anyway.

This function comes from the genus 3 package contributed by Lercier and Ritzenthaler.

Example H125E3

We construct the quadratic twists of the hyperelliptic curve $y^2 = x^6 + x^2 + 1$ defined over $\mathbf{F}_7$.

```
> P<x> := PolynomialRing(GF(7));
> C := HyperellipticCurve(x^6+x^2+1);
> QuadraticTwists(C);
[
    Hyperelliptic Curve defined by y^2 = x^6 + x^2 + 1 over GF(7),
    Hyperelliptic Curve defined by y^2 = 3*x^6 + 3*x^2 + 3 over GF(7)
]
> IsIsomorphic($1[1],$1[2]);
false
```

Example H125E4

We take a hyperelliptic curve over the rationals and form a quadratic twist of it.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+x);
> C7 := QuadraticTwist(C, 7);
> C7;
Hyperelliptic Curve defined by y^2 = 7*x^6 + 7*x over Rational Field
```

We now use the function `IsIsomorphic` to verify that C and C_7 are nonisomorphic. We then extend the field of definition of both curves to $\mathbf{Q}(\sqrt{7})$ and verify that the curves become isomorphic over this extension.

```
> IsIsomorphic(C, C7);
```

```
false
> K<w> := ext< Rationals() | x^2-7 >;
> CK := BaseChange(C, K);
> C7K := BaseChange(C7, K);
> IsIsomorphic(CK, C7K);
true (x : y : z) :-> (x : -1/7*w*y : z)
```

Example H125E5

We find all the twists of a supersingular genus 2 curve over $\mathbf{F}_2$.

```
> P<x> := PolynomialRing(GF(2));
> C := HyperellipticCurve(x^5,P!1);
> C;
Hyperelliptic Curve defined by y^2 + y = x^5 over GF(2)
> tws,auts := Twists(C);
> tws;
[
    Hyperelliptic Curve defined by y^2 + y = x^5 over GF(2),
    Hyperelliptic Curve defined by y^2 + y = x^5 + x^4 over GF(2),
    Hyperelliptic Curve defined by y^2 + y = x^5 + x^4 + 1 over GF(2)
]
> #auts; // auts is the geometric automorphism group of C
160
```

125.2.7 Type Change Predicates

`IsEllipticCurve(C)`

The function returns `true` if and only if C is a genus one hyperelliptic curve of odd degree, in which case it also returns an elliptic curve E isomorphic to C followed by the isomorphism $C \to E$ and the inverse isomorphism $E \to C$.

125.3 Operations on Curves

125.3.1 Elementary Invariants

`HyperellipticPolynomials(C)`

The univariate polynomials $f(x)$, $h(x)$, in that order, defining the hyperelliptic curve C by $y^2 + h(x)y = f(x)$.

`Degree(C)`

The degree of the hyperelliptic curve C or a pointset C of a hyperelliptic curve.

`Discriminant(C)`

The discriminant of the hyperelliptic curve C.

`Genus(C)`

The genus of the hyperelliptic curve C.

125.3.2 Igusa Invariants

The Clebsch, Igusa–Clebsch and Igusa invariants may be computed for curves of genus 2.

The MAGMA package implementing the functions was written by Everett W. Howe (however@alumni.caltech.edu) with some advice from Michael Stoll and is based on some `gp` routines written by Fernando Rodriguez–Villegas as part of the Computational Number Theory project funded by a TARP grant. The `gp` routines may be found at `http://www.ma.utexas.edu/users/villegas/cnt/inv.gp`.

In addition, a package of functions written by Reynald Lercier and Christophe Ritzenthaler has been added which contains, amongst other things, functionality for working with a different set of absolute (as opposed to weighted projective) invariants referred to as Cardona-Quer-Nart-Pujola invariants. These work in characteristic 2 as well as other characteristics, although the definitions are different in the two cases.

Rodriguez–Villegas's routines are based on a paper of Mestre [Mes91]. The first part of Mestre's paper summarizes work of Clebsch and Igusa, and is based on the classical theory of invariants. This package contains functions to compute three types of invariants of quintic and sextic polynomials f (or, perhaps more accurately, of binary sextic forms):

- The *Clebsch invariants* A, B, C, D of f, as defined on p. 317 of Mestre;
- The *Igusa–Clebsch invariants* A', B', C', D' of f, as defined on p. 319 of Mestre; and
- The *Igusa invariants* (or *Igusa J-invariants*, or *J-invariants*) J_2, J_4, J_6, J_8, J_{10} of f, as defined on p. 324 of Mestre.

The corresponding functions are `ClebschInvariants`, `IgusaClebschInvariants`, and `JInvariants`, respectively. For convenience, we use `IgusaInvariants` as a synonym for `JInvariants`.

Igusa invariants may be defined for a curve of genus 2 over any field and for polynomials of degree at most 6 over fields of characteristic not equal to 2. The Igusa invariants of the curve $y^2 + hy = f$ are equal to the Igusa invariants of the polynomial $h^2 + 4 * f$ except in characteristic 2, where the latter are not defined. In practice, the functions below will

not calculate the Igusa invariants of a polynomial unless 2 is a unit in the coefficient ring. However, Igusa invariants of curves are available for all coefficient rings. (But see below.)

Igusa invariants are given by a sequence $[J_2, J_4, J_6, J_8, J_{10}]$ of five elements of the coefficient ring of the polynomials defining the curve. This sequence should be thought of as living in weighted projective space, with weights 2, 4, 6, 8, and 10.

It should be noted that many of the people who work with genus 2 curves over the complex numbers prefer not to work with the real Igusa invariants, but rather work with some related numbers, $[I_2, I_4, I_6, I_{10}]$ (or $[A', B', C', D']$ in Mestre's terminology), that we call the *Igusa–Clebsch invariants*, of the curve. Once again, these live in weighted projective space. The Igusa–Clebsch invariants of a polynomial are defined in terms of certain nice symmetric polynomials in its roots, and, in characteristic zero, the J-invariants may be obtained from the I-invariants by some simple homogeneous transformations. In fact, many of the genus-2-curves-over-the-complex-numbers people refer to the elements $i1 := I_2^5/I_{10}$, $i2 := I_2^3 * I_4/I_{10}$ and $i3 := I_2^2 * I_6/I_{10}$ as the "invariants" of the curve. The problem with the Igusa–Clebsch invariants is that they do not work in characteristic 2 and it was for this reason that Igusa defined his J-invariants.

The coefficient ring of the polynomial f must be an algebra over a field of characteristic not equal to 2 or 3.

The Cardona-Quer-Nart-Pujola invariants are three absolute invariants g_1, g_2, g_3 which can be derived from the J-invariants and which provide an affine classification of all genus two curves over a basefield k up to isomorphism over $\bar{k}$. That is, there is a 1-1 correspondence between $\bar{k}$-isomorphism classes of such curves and triples (g_1, g_2, g_3) in k^3. There are also functions to construct a curve with given invariants and to find all twists of such a curve (*ie* representatives of the k-isomorphism classes in the given $\bar{k}$-isomorphism class), which will be described in later sections.

The invariants are different in the characteristic 2 and odd (or 0) characteristic cases. Details about the former case may be found in [CNP05]. See [CQ05] for the latter case. In the odd characteristic case, the formulae for $[g_1, g_2, g_3]$ in terms of the J-invariants are as follows:

$$[\frac{J_2^5}{J_{10}}, \frac{J_2^3 J_4}{J_{10}}, \frac{J_2^2 J_6}{J_{10}}] \quad J_2 \neq 0$$

$$[0, \frac{J_4^5}{J_{10}^2}, \frac{J_4 J_6}{J_{10}}] \quad J_2 = 0, J_4 \neq 0$$

$$[0, 0, \frac{J_6^5}{J_{10}^2}] \quad J_2 = J_4 = 0$$

In the characteristic 2 case, the field k must be perfect. Formulae for the invariants (labelled j_i rather than g_i) may be found on p. 191 of [CNP05].

`ClebschInvariants(C)`

Given a hyperelliptic curve C having genus 2, compute the Clebsch invariants A, B, C and D as described on p. 317 of [Mes91]. The base field of C may not have characteristic 2, 3 or 5. The invariants are found using Überschiebungen.

`ClebschInvariants(f)`

Given a polynomial f of degree at most 6, compute the Clebsch invariants A, B, C and D as described on p. 317 of [Mes91]. The coefficient ring of the polynomial f must be an algebra over a field of characteristic not equal to 2, 3 or 5. The invariants are found using Überschiebungen.

`IgusaClebschInvariants(C: parameters)`

`Quick` BoolElt *Default :* `false`

Given a curve C of genus 2 defined over a field, the Igusa–Clebsch invariants A', B', C' and D' as described on p. 319 of [Mes91] are found. These will be all be zero in characteristic 2. If `Quick` is `true`, the base field of C may not have characteristic 2, 3 or 5 and a faster method using Überschiebungen is employed; otherwise, universal formulae are used.

`IgusaClebschInvariants(f, h)`

Given a polynomial h having degree at most 3 and a polynomial f having degree at most 6, the Igusa–Clebsch invariants A', B', C' and D' of the curve $y^2 + hy - f = 0$ are found. These will be all be zero in characteristic 2.

`IgusaClebschInvariants(f: parameters)`

`Quick` BoolElt *Default :* `false`

Given a polynomial f having degree at most 6 and defined over a ring in which 2 is a unit, the Igusa–Clebsch invariants A', B', C' and D' of the polynomial f are found. These will be all be zero in characteristic 2. If `Quick` is `true`, the coefficient ring of f may not have characteristic 2, 3 or 5 and a faster method using Überschiebungen is employed; otherwise, universal formulae are used.

`IgusaInvariants(C: parameters)`

`JInvariants(C: parameters)`

`Quick` BoolElt *Default :* `false`

Given a curve C of genus 2 defined over a field, the function returns the Igusa invariants (or J-invariants) J_2, J_4, J_6, J_8, J_{10} as described on p. 324 of [Mes91]. If `Quick` is `true`, the base field of C may not have characteristic 2, 3 or 5 and a faster method using Überschiebungen is employed; otherwise, universal formulae are used.

`IgusaInvariants(f, h)`

`JInvariants(f, h)`

Given a polynomial h having degree at most 3 and a polynomial f having degree at most 6, this function returns the Igusa invariants (or J-invariants) J_2, J_4, J_6, J_8, J_{10} of the curve $y^2 + hy = f$. The coefficient ring R of the polynomials h and f must either (a) have characteristic 2, or (b) be a ring in which MAGMA can apply the operator `ExactQuotient(n,2)`. For example, R may be an arbitrary field, the ring of rational integers, a polynomial ring over a field or over the integers and so forth. However, R may not be a p-adic ring, for instance. If the desired coefficient ring does not meet either condition (a) or condition (b), then `ScaledIgusaInvariants` should be used and its invariants then scaled by the appropriate powers of $\frac{1}{2}$.

`IgusaInvariants(f: parameters)`

`JInvariants(f: parameters)`

`Quick` BOOLELT *Default :* `false`

Given a polynomial f having degree at most 6 which is defined over a ring in which 2 is a unit, return the Igusa invariants (or J-invariants) J_2, J_4, J_6, J_8, J_{10} of f. If `Quick` is `true`, the coefficient ring of f may not have characteristic 2, 3 or 5 and a faster method using Überschiebungen is employed; otherwise, universal formulae are used.

`ScaledIgusaInvariants(f, h)`

Given a polynomial h having degree at most 3 and a polynomial f having degree at most 6, return the Igusa J-invariants of the curve $y^2 + hy = f$, scaled by $[16, 16^2, 16^3, 16^4, 16^5]$.

`ScaledIgusaInvariants(f)`

Given a polynomial f having degree at most 6 which is defined over a ring not of characteristic 2, return the Igusa J-invariants of f, scaled by $[16, 16^2, 16^3, 16^4, 16^5]$.

`AbsoluteInvariants(C)`

Given a curve C of genus 2 defined over a field, the function computes the ten absolute invariants of C as described on p. 325 of [Mes91].

`ClebschToIgusaClebsch(Q)`

Convert Clebsch invariants in the sequence Q to Igusa–Clebsch invariants.

`IgusaClebschToIgusa(S)`

Convert Igusa–Clebsch invariants in the sequence S to Clebsch invariants.

`G2Invariants(C)`

Compute and return the sequence of three Cardona-Quer-Nart-Pujola invariants (see the introduction above) for C of genus 2.

`G2ToIgusaInvariants(GI)`

Convert the sequence of Cardona-Quer-Nart-Pujola invariants (see the introduction above) to a corresponding sequence of Igusa J-invariants.

`IgusaToG2Invariants(JI)`

Convert the sequence of Igusa J-invariants to Cardona-Quer-Nart-Pujola invariants (see the introduction above).

125.3.3 Shioda Invariants

The Shioda invariants may be computed for curves of genus 3 in characteristic 0 or characteristic ≥ 11. There are 9 of these, the first 6 being algebraically independent and the last 3 being algebraic over the field generated by the other 6. The discriminant is not one of these invariants. For more details, see [LR12] or [Shi67]. These invariants have weights and naturally give a point in a weighted projective space. There are also intrinsic for computing the 6 Maeda invariants of the curve ([Mae90]).

This functionality comes from a package contributed by Lercier and Ritzenthaler.

`ShiodaInvariants(C)`

`normalize` BoolElt *Default :* `false`

Returns a sequence containing the 9 Shioda invariants of a genus 3 hyperelliptic curve C along with a sequence containing the weight of the corresponding invariant (always $2, 3, 4, 5, 6, 7, 8, 9, 10$). The base field of C must be of characteristic 0 or ≥ 11. There are also versions that takes a single polynomial f of degree less than or equal to 8 as argument (corresponding to the curve $y^2 = f(x)$) or a sequence of two polynomials fh (corresponding to the curve $y^2 + h(x)y = f(x)$). In these cases if the degree of f (resp $f - h^2/4$) is less than 7, or if the discriminant is zero, the invariants will be invariants of the corresponding binary octic but not of a genus 3 hyperelliptic curve anymore. Such sequences of invariants are referred to as *singular*.

The sequence of invariants can be considered as giving a point in a dimension 8 weighted projective space with the above weights. If the parameter `normalize` is set to `true`, the sequence is scaled to give a new sequence representing the same point in a normalized fashion. This means that two isomorphic curves will not necessarily give the same sequence of invariants, but they will always give the same sequence of normalized invariants.

`ShiodaInvariantsEqual(V1,V2)`

Returns whether two sequences of Shioda invariants $V1$ and $V2$ represent the same point in the natural weighted projective space. This is equivalent to asking whether their normized versions (see previous intrinsic) are the same, which means that they represent the same isomorphism class of curves (if they are non-singular).

`DiscriminantFromShiodaInvariants(JI)`

Returns the corresponding discriminant from a sequence of Shioda invariants JI. The discriminant (of a binary octic) is just a polynomial in its 9 Shioda invariants. Note that is scaled if the invariants are scaled, so that the value is different for example, if applied to the results of calling `ShiodaInvariants` with `normalize` set to `true` or `false`. The significant thing though is whether this is non-zero or not. The value is zero if and only if JI are *singular* invariants (associated to a polynomial with multiple roots or of degree ≤ 6).

`ShiodaAlgebraicInvariants(FJI)`

`ratsolve` BoolElt *Default :* `true`

As mentioned in the introduction, the first 6 Shioda invariants are algebraically independent forms on the genus 3 hyperelliptic moduli space and the remaining 3 are algebraic over them.

This intrinsic takes a sequence FJI of 6 elements of a field k that must be of characteristic 0 or ≥ 11. If these are considered to be the first 6 Shioda invariants (of a possibly singular set), this intrinsic returns a sequence containing all possible sequences of the full 9 invariants over k that have those of FJI as the first 6, if the parameter `ratsolve` is `true` (the default). If `ratsolve` is `false`, the sequence returned instead contains the 6 polynomials in 3 variables over k, which defines a dimension 0, degree 5 system whose solutions are the possible last 3 invariants.

Example H125E6

```
> k := GF(37);
> P<t> := PolynomialRing(k);
> C := HyperellipticCurve(t^8+33*t^7+27*t^6+29*t^5+4*t^4+

]

`MaedaInvariants(C)`

Returns the six Maeda field invariants $(I2, I3, I4, I4p, I8, I9)$ of a genus 3 hyperelliptic curve C. Again, the base field of C must be of characteristic 0 or ≥ 11. For this intrinsic, the model of C must also be in simplified $y^2 = f(x)$ form. There is also a version with argument f, a univariate polynomial of degree less than or equal to 8, which returns the Maeda invariants of the binary octic given by homogenizing f (to degree 8). This is the same as asking for the invariants of $y^2 = f(x)$ when f has degree 7 or 8.

125.3.4 Base Ring

`BaseField(C)`
`BaseRing(C)`
`CoefficientRing(C)`

The base field of the hyperelliptic curve C.

125.4 Creation from Invariants

The problem is to construct a curve of genus 2 from a given set of Igusa–Clebsch invariants defined over the same field as the field of moduli (simply the smallest field in which the invariants lie). Mestre [Mes91] shows that this is not always possible, even in theory. But over a finite field or the rationals he gives a method for deciding whether it is possible and if it is, for finding such a curve. Mestre's algorithm was implemented by P. Gaudry. Mestre's algorithm does not work when the curve has a split Jacobian. Cardona and Quer [CQ05] showed that in this case one can always find a curve defined over the field of moduli and gave equations for such a curve. This works over any field of characteristic not 2, 3 or 5.

In any characteristic, the code package of Lercier and Ritzenthaler produces a genus 2 curve from a given set of Cardona-Quer-Nart-Pujola invariants (see Subsection 125.3.2). They use the work of Cardona and Quer cited in the previous paragraph in the odd characteristic case, with some extra work for characteristics 3 and 5. In characteristic 2, they use the models from [CNP05].

Lercier and Ritzenthaler have also contributed a package for genus 3 hyperelliptic curves that produces a curve from a given set of Shioda invariants (see Subsection 125.3.3). This works in characteristic not 2, 3, 5 or 7.

Over a field of characteristic zero, the equation of the curve returned by these methods can involve huge coefficients. For curves over the rationals, this curve can be processed by the algorithm of P. Wamelen [Wam99] and [Wam01]. While, in practice, this algorithm often produces a curve with much smaller coefficients, for certain curves the algorithm may not significantly reduce their size.

`HyperellipticCurveFromIgusaClebsch(S)`

`Reduce` BoolElt *Default :* `false`

This attempts to build a curve of genus 2 with the given Igusa-Clebsch invariants (see Subsection 125.3.2) by Mestre's algorithm (and Cardona's in case of non-hyperelliptic involutions) defined over the field F in which the invariants lie. Currently this field must be the rationals, a number field, or a finite field of characteristic greater than 5. If there exists no such curve defined over F, then either a curve over some quadratic extension is returned (when F is the rationals), or an error results (when F is a number field).

When the base field is the rationals, the parameter `Reduce` invokes Wamelen's reduction algorithm, and is equivalent to a call to `ReducedModel` with the algorithm specified as `"Wamelen"`.

`HyperellipticCurveFromG2Invariants(S)`

From a given sequence of Cardona-Quer-Nart-Pujola invariants (as described in Subsection 125.3.2) over a finite field or the rationals, return a genus 2 curve with these absolute invariants. This works in all characteristics as noted in the introduction to the section. The geometric automorphism group is also returned as a finitely-presented group.

`HyperellipticCurveFromShiodaInvariants(JI)`

`HyperellipticPolynomialFromShiodaInvariants(JI)`

Given a sequence of 9 Shioda invariants JI over the rationals or a finite field k, the first intrinsic returns a genus 3 hyperelliptic curve over k with these invariants. The abstract geometric automorphism group is also returned as a permutation group. This will cause an error if JI are singular Shioda invariants.

The second intrinsic also works for singular invariants. It returns a polynomial f of degree ≤ 8 with the given invariants. If JI are non-singular, $y^2 = f(x)$ is a genus 3 curve with invariants JI.

Example H125E7

A typical run would look like:

```
> SetVerbose("Igusa",1);
> IgCl := [ Rationals() |
>   -549600, 8357701824, -1392544870972992, -3126674637319431000064 ];

```

125.5 Function Field

125.5.1 Function Field and Polynomial Ring

```
FunctionField(C)
```

The function field of the hyperelliptic curve C.

```
DefiningPolynomial(C)
```

A weighted homogeneous polynomial for the hyperelliptic curve C.

```
EvaluatePolynomial(C, a, b, c)
EvaluatePolynomial(C, [a, b, c])
```

Evaluates the homogeneous defining polynomial of the hyperelliptic curve C at the point (a, b, c).

125.6 Points

The hyperelliptic curve is embedded in a weighted projective space, with weights 1, $g + 1$, and 1, respectively on x, y and z. Therefore point triples satisfy the equivalence relation $(x : y : z) = (\mu x : \mu^{g+1} y : \mu z)$, and the points at infinity are then normalized to take the form $(1 : y : 0)$.

125.6.1 Creation of Points

```
C ! [x, y]
C ! [x, y, z]
elt<  PS | x, y  >
elt<  PS | x, y, z  >
```

Returns the point on a hyperelliptic curve C specified by the coordinates (x, y, z). The `elt` constructor takes the pointset of a hyperelliptic curve as an argument. If z is not specified it is assumed to be 1.

```
C ! P
```

Given a point P on a hyperelliptic curve C_1, such that C is a base extension of C_1, this returns the corresponding point on the hyperelliptic curve C. The curve C can be, e.g., the reduction of C_1 to finite characteristic (i.e. base extension to a finite field) or the tautological coercion to itself.

`Points(C, x)`

`RationalPoints(C, x)`

The indexed set of all rational points on the hyperelliptic curve C that have the value x as their x-coordinate. (Rational points are those with coordinates in the coefficient ring of C). Note that points at infinity are considered to have ∞ as their x-coordinate.

`PointsAtInfinity(C)`

The points at infinity for the hyperelliptic curve C returned as an indexed set of points.

`IsPoint(C, S)`

The function returns `true` if and only if the sequence S specifies a point on the hyperelliptic curve C, and if so, returns this point as the second value.

Example H125E8

We look at the point at infinity on $y^2 = x^5 + 1$.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^5+1);
> PointsAtInfinity(C);
{@ (1 : 0 : 0) @}
```

There is only one, and to see that this really is a point on C it must be remembered that in MAGMA, all hyperelliptic curves are considered to live in weighted projective spaces:

```
> Ambient(C);
Projective Space of dimension 2
Variables : $.1, $.2, $.3
Gradings :
1       3       1
```

In fact, the point is nonsingular on C, as we now check. (It's worth remembering that all the functionality for curves, for instance `IsNonSingular`, applies to hyperelliptic curves as a special case.)

```
> pointAtInfinity := C![1,0,0];  // Entering the point by hand.
> IsNonSingular(pointAtInfinity);
true
```

125.6.2 Random Points

`Random(C)`

Given a hyperelliptic curve C defined over a finite field, this returns a point chosen at random on the curve. If the set of all points on C has already been computed, this gives a truly random point, otherwise the ramification points have a slight advantage.

125.6.3 Predicates on Points

`P eq Q`

Returns `true` if and only if the two points P and Q on the same hyperelliptic curve have the same coordinates.

`P ne Q`

Returns `false` if and only if the two points P and Q on the same hyperelliptic curve have the same coordinates.

125.6.4 Access Operations

`P[i]`

The i-th coordinate of the point P, for $1 \leq i \leq 3$.

`Eltseq(P)`

`ElementToSequence(P)`

Given a point P on a hyperelliptic curve, this returns a 3-element sequence consisting of the coordinates of the point P.

125.6.5 Arithmetic of Points

`-P`

`Involution(P)`

Given a point P on a hyperelliptic curve, this returns the image of P under the hyperelliptic involution.

125.6.6 Enumeration and Counting Points

`NumberOfPointsAtInfinity(C)`

The number of points at infinity on the hyperelliptic curve C.

`PointsAtInfinity(C)`

The points at infinity for the hyperelliptic curve C returned as an indexed set of points.

`#C`

Given a hyperelliptic curve C defined over a finite field, this returns the number of rational points on C.

If the base field is small or there is no other good alternative, a naive point counting technique is used. However, if they are applicable, the faster p-adic methods described in the `#J` section are employed (which actually yield the full zeta function of C). As for `#J`, the verbose flag `JacHypCnt` can be used to output information about the computation.

`Points(C)`

`RationalPoints(C)`

`Bound`	RngIntElt	*Default :*
`NPrimes`	RngIntElt	*Default :* 30
`DenominatorBound`	RngIntElt	*Default :* Bound

For a hyperelliptic curve C defined over a finite field, the function returns an indexed set of all rational points on C. For a curve C over $\mathbf{Q}$ of the form $y^2 = f(x)$ with integral coefficients, it returns the set of points such that the naive height of the x-coordinate is less than `Bound`.

For a curve C over a number field, looks for points using a sieve method, described in Appendix A of [Bru02]. The parameter `NPrimes` controls the number of primes which are used and `DenominatorBound` the size of the denominators used.

`PointsKnown(C)`

Returns `true` if and only if the points of the hyperelliptic curve C have been computed. This can especially be helpful when the curve is likely to have many points and when one does not wish to trigger the possibly expensive point computation.

`ZetaFunction(C)`

Given a hyperelliptic curve C defined over a finite field, this function computes the zeta function of C. The zeta function is returned as an element of the function field in one variable over the integers.

If the base field is small or there is no other good alternative, the method used is a naive point count on the curve over extensions of degree $1, ..., g$ of the base field. However, if they are applicable, the faster p-adic methods described in the `#J` section are employed. As for `#J`, the verbose flag `JacHypCnt` can be used to output information about the computation.

`ZetaFunction(C, K)`

Given a hyperelliptic curve C defined over the rationals, this function computes the zeta function of the base extension of C to K. The curve C must have good reduction at the characteristic of K.

Example H125E9

For the following classical curve of Diophantus' *Arithmetica*, it is proved by Joseph Wetherell [Wet97] that Diophantus found all positive rational points. The following MAGMA code enumerates the points on this curve.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+x^2+1);
> Points(C : Bound := 1);
{@ (1 : -1 : 0), (1 : 1 : 0), (0 : -1 : 1), (0 : 1 : 1) @}
> Points(C : Bound := 2);
{@ (1 : -1 : 0), (1 : 1 : 0), (0 : -1 : 1), (0 : 1 : 1), (-1 : -9 : 2),
(-1 : 9 : 2), (1 : -9 : 2), (1 : 9 : 2) @}
> Points(C : Bound := 4);
{@ (1 : -1 : 0), (1 : 1 : 0), (0 : -1 : 1), (0 : 1 : 1), (-1 : -9 : 2),
(-1 : 9 : 2), (1 : -9 : 2), (1 : 9 : 2) @}
```

125.6.7 Frobenius

`Frobenius(P, F)`

`Check` BOOLELT *Default :* `true`

Applies the Frobenius $x -> x^{(\#F)}$ to P. If `Check` is `true`, it verifies that the curve of which P is a point is defined over the finite field F.

125.7 Isomorphisms and Transformations

A hyperelliptic curve isomorphism is defined by a linear fractional transformation $t(x : z) = (ax + bz : cx + dz)$, a scale factor e, and a polynomial $u(x)$ of degree at most $g + 1$, where g is the genus of the curve. This data defines the isomorphism of weighted projective points

$$(x : y : z) \mapsto (ax + bz : ey + \tilde{u}(x, z) : cx + dz),$$

where $\tilde{u}$ is the degree $g + 1$ homogenization of u. When not specified, the values of e and u are by default taken to be 1 and 0, respectively.

An isomorphism can be created from the parent structures by coercing a tuple $\langle [a, b, c, d], e, u\rangle$ into the structure of isomorphisms between two hyperelliptic curves, or by creating it as a transformation of a given curve, i.e. creating the codomain curve together with the isomorphism from the given data.

Note that due to the projective weighting of the ambient space of the curve, two equal isomorphisms may have different representations.

125.7.1 Creation of Isomorphisms

`Aut(C)`

Given a hyperelliptic curve C, this returns the structure of all automorphisms of the curve.

`Iso(C1, C2)`

Given hyperelliptic curves $C1$ and $C2$ of the same genus and base field, this returns the structure of all isomorphisms between them.

`Transformation(C, t)`
`Transformation(C, u)`
`Transformation(C, e)`
`Transformation(C, e, u)`
`Transformation(C, t, e, u)`

Returns the hyperelliptic curve C' which is the codomain of the isomorphism from the hyperelliptic curve C specified by the sequence of ring elements t, the ring element e and the polynomial u, followed by the the isomorphism to the curve.

Example H125E10

We create the hyperelliptic curve $y^2 = x^5 - 7$ and apply a transformation to it.

```
> P<x> := PolynomialRing(Rationals());
> H1 := HyperellipticCurve(x^5-7);
> H2, phi := Transformation(H1, [0,1,1,0], 1/2, x^2+1);
> H2;
Hyperelliptic Curve defined by y^2 + (-2*x^2 - 2)*y = -7/4*x^6 - x^4 - 2*x^2 +
    1/4*x - 1 over Rational Field
```

```
> phi;
(x : y : z) :-> (z : 1/2*y + x^2*z + z^3 : x)
> IsIsomorphic(H1, H2);
true (x : y : z) :-> (z : 1/2*y + x^3 + x*z^2 : x)
```

125.7.2 Arithmetic with Isomorphisms

Hyperelliptic curve isomorphisms can be evaluated, inverted, and composed on points as right operators. Note that the functional notation $f(P)$ is not presently available for these maps of curves. However the available map syntax `@` is more consistent with functions as operating on the right (which determines and is apparent from the way composition is defined).

`f * g`

The composition of the maps f and g as right operators.

`Inverse(f)`

The inverse of the hyperelliptic curve isomorphism f.

`f in M`

Given an isomorphism of hyperelliptic curves f, and the structure of isomorphisms M between two hyperelliptic curves, this returns `true` if and only if they share the same domains and codomains.

`P @ f`

`Evaluate(f,P)`

Returns the evaluation of f at a point P in its domain. The same functions apply equally to points in the Jacobian of the domain curve and, in the case of genus 2, to points on the associated Kummer surface.

`P @@ f`

`Pullback(f,P)`

Returns the inverse image of the isomorphism f at a point P in its codomain. The same functions apply equally to points in the Jacobian of the codomain curve and, in the case of genus 2, to points on the associated Kummer surface.

`f eq g`

Given isomorphisms f and g of hyperelliptic curves having the same domain and codomain, this function returns `true` if and only if they are equal. Note that two isomorphisms may be equal even if their defining data are distinct (see example below).

125.7.3 Invariants of Isomorphisms

`Parent(f)`

The "parent structure" of an isomorphism between two hyperelliptic curves (which contains all isomorphisms with the same domain and codomain as the given isomorphism).

`Domain(f)`

The curve which is the domain of the given isomorphism.

`Codomain(f)`

The curve which is the target of the given isomorphism.

125.7.4 Automorphism Group and Isomorphism Testing

This section details the features for computing isomorphisms between two curves and determining the group of automorphisms. The function `IsGL2Equivalent` plays a central role in the isomorphism testing, and is documented here due to its central role in these computations.

The genus 2 package of Lercier and Ritzenthaler provides a function to determine the geometric automorphism group of a genus 2 curve in any characteristic by working with Cardona-Quer-Nart-Pujola invariants (see Subsection 125.3.2). This replaces the old function that only worked in odd (or 0) characteristics. They also provide a function that returns a list of all possible geometric automorphism groups for genus 2 curves over a given finite field and the number of isomorphism classes of curves with each possible group.

Lercier and Ritzenthaler's genus 3 package provides the same for genus 3 hyperelliptic curves, working with Shioda invariants. Here, the characteristic has to be 0 or ≥ 11.

`IsGL2Equivalent(f, g, n)`

This function returns `true` if and only if f and g are in the same $\mathrm{GL}_2(k)$-orbit, where k is the coefficient field of their parent, modulo scalars. The polynomials are considered as homogeneous polynomials of degree n, where n must be at least 4. The second return value is the sequence of all matrix entries $[a, b, c, d]$ such that $g(x)$ is a constant times $f\left((ax+b)/(cx+d)\right)(cx+d)^n$.

`IsIsomorphic(C1, C2)`

Verbose `CrvHypIso` *Maximum :* 3

This function returns `true` if and only if the hyperelliptic curves $C1$ and $C2$ are isomorphic over their common base field. If the curves are isomorphic, an isomorphism is returned.

`AutomorphismGroup(C)`

Given a hyperelliptic curve C of characteristic different from 2, the function returns a permutation group followed by an isomorphism to the group of automorphisms of the curve over its base ring. The curve must be of genus at least one, and the automorphism group is defined to consist of those automorphisms which commute with the hyperelliptic involution, i.e. which induce a well-defined automorphism of its quotient projective line. A third return value gives the action $C \times G \to C$.

Example H125E11

We give an example of the computation of the automorphism group of a genus one hyperelliptic curve.

```
> P<x> := PolynomialRing(GF(3));
> C1 := HyperellipticCurve(x^3+x);
> G1, m1 := AutomorphismGroup(C1);
> #G1;
> [ m1(g) : g in G1 ];
[
    (x : y : z) :-> (x : y : z),
    (x : y : z) :-> (x : -y : z),
    (x : y : z) :-> (z : y : x),
    (x : y : z) :-> (z : -y : x)
]
```

We note that due to the weighted projective space, the same map may have a non-unique representation, however the equality function is able to identify equivalence on representations.

```
> f := m1(G1.3);
> f;
(x : y : z) :-> (z : y : x)
> g := Inverse(f);
> g;
(x : y : z) :-> (2*z : y : 2*x)
> f eq g;
true
```

We see that the geometric automorphism group is much larger. By base extending the curve to a quadratic extension, we find the remaining automorphisms of the curve.

```
> K<t> := GF(3,2);
> C2 := BaseExtend(C1, K);
> G2, m2 := AutomorphismGroup(C2);
> #G2;
48
> O := C2![1,0,0];
> auts := [ m2(g) : g in G2 ];
> [ f : f in auts | O@f eq O ];
[
    (x : y : z) :-> (x : y : z),
```

```
    (x : y : z) :-> (x : -y : z),
    (x : y : z) :-> (x : t^2*y : 2*z),
    (x : y : z) :-> (x + t^6*z : t^2*y : 2*z),
    (x : y : z) :-> (x + t^6*z : y : z),
    (x : y : z) :-> (x + t^2*z : y : z),
    (x : y : z) :-> (x + t^2*z : t^2*y : 2*z),
    (x : y : z) :-> (x : t^6*y : 2*z),
    (x : y : z) :-> (x + t^6*z : t^6*y : 2*z),
    (x : y : z) :-> (x + t^6*z : -y : z),
    (x : y : z) :-> (x + t^2*z : -y : z),
    (x : y : z) :-> (x + t^2*z : t^6*y : 2*z)
]
> #$1;
12
```

Note that this curve is an example of a supersingular elliptic curve in characteristic 3. In the final computation we restrict to the automorphisms as an elliptic curve, i.e. those which fix the point at infinity — the identity element of the group law.
In the context of hyperelliptic curves of genus one, the group of automorphisms must stabilize the ramification points of the hyperelliptic involution. These are precisely the 2-torsion elements as an elliptic curve. So we have an group extension by the 2-torsion elements, acting by translation. Converting to an elliptic curve, we find that there are two 2-torsion elements over $\mathbf{F}_3$:

```
> E1 := EllipticCurve(C1);
> A1 := AbelianGroup(E1);
> A1;
Abelian Group isomorphic to Z/4
Defined on 1 generator
Relations:
    4*$.1 = 0
```

We see that two of the 2-torsion elements are defined over $\mathbf{F}_3$, and the remaining ones appear over the quadratic extension. So in the former case the automorphism group is an extension of the elliptic curve automorphism group (of order 2) by $\mathbf{Z}/2\mathbf{Z}$, and in latter case the automorphism group is an extension (of the group of order 12) by the abelian group isomorphic to $\mathbf{Z}/2\mathbf{Z} \times \mathbf{Z}/2\mathbf{Z}$. Note that there exist other curve automorphisms given by translations by other torsion points (under the addition as an elliptic curve), but that do not commute with the hyperelliptic involution, hence do not enter into the hyperelliptic automorphism group.

`GeometricAutomorphismGroup(C)`

Given a hyperelliptic curve C of genus 2 or 3 the function returns a finitely-presented group isomorphic to the geometric automorphism group, i.e. the automorphism group of the curve over an algebraic closure of its base field.

The method used for genus 2 is to compute the Cardona-Quer-Nart-Pujola invariants (see Subsection 125.3.2) of C and use the classification of the possible automorphism groups in terms of the invariants. See [SV01] and [CQ05] for the odd (and 0) characteristic case and [CNP05] for characteristic 2.

The method used for genus 3 is to compute the Shioda invariants (see Subsection 125.3.3) of C and use the classification of the possible automorphism groups in terms of the invariants. For this case, the base field must have characteristic 0 or ≥ 11.

There is also a genus 2 version where the argument is the sequence GI of Cardona-Quer-Nart-Pujola invariants of a curve rather than the actual curve. This avoids actually constructing the curve, in case the user is starting from the invariants.

The functions are part of packages for genus 2 and 3 curves contributed by Reynald Lercier and Christophe Ritzenthaler.

`GeometricAutomorphismGroupFromShiodaInvariants(JI)`

There is a variant of the last intrinsic for genus 3 curves where the argument is the sequence JI of Shioda invariants of a curve rather than the actual curve. This avoids actually constructing the curve, in case the user is starting from the invariants. The same restrictions on the characteristic of the base field apply.

Example H125E12

We give examples of the computation of the geometric automorphism group of a genus two and a genus three hyperelliptic curve.

```
> P<x> := PolynomialRing(RationalField());
> f := x^6+x^3+13;
> C := HyperellipticCurve(f);
> time GeometricAutomorphismGroup(C);
Permutation group acting on a set of cardinality 6
Order = 12 = 2^2 * 3
    (1, 2, 3, 4, 5, 6)
    (1, 6)(2, 5)(3, 4)
Time: 0.010
> f := x^8-1;
> C1 := HyperellipticCurve(f);
> GeometricAutomorphismGroup(C1);
GrpPC of order 32 = 2^5
PC-Relations:
    $.1^2 = $.4,
    $.3^2 = $.5,
    $.2^$.1 = $.2 * $.3,
    $.3^$.1 = $.3 * $.5,
    $.3^$.2 = $.3 * $.5
```

Note that `AutomorphismGroup` can be used to retrieve the same (and more!) information but this can be much slower.

```
> aut := AutomorphismGroup(C);
> aut;
Symmetric group aut acting on a set of cardinality 2
Order = 2
```

```
  (1, 2)
  Id(aut)
```

We need to extend the field!

```
> Qbar := AlgebraicClosure();
> Cbar := BaseChange(C, Qbar);
> time autbar := AutomorphismGroup(Cbar);
Time: 332.290
> autbar;
Permutation group autbar acting on a set of cardinality 12
Order = 12 = 2^2 * 3
  (1, 2)(3, 4)(5, 6)(7, 8)(9, 10)(11, 12)
  Id(autbar)
  (1, 3)(2, 4)(5, 7)(6, 8)(9, 11)(10, 12)
  (1, 5, 9)(2, 6, 10)(3, 11, 7)(4, 12, 8)
  (1, 7)(2, 8)(3, 9)(4, 10)(5, 11)(6, 12)
  (1, 9, 5)(2, 10, 6)(3, 7, 11)(4, 8, 12)
  (1, 11)(2, 12)(3, 5)(4, 6)(7, 9)(8, 10)
> IdentifyGroup(autbar);
<12, 4>
```

`GeometricAutomorphismGroupGenus2Classification(F)`

Given a finite field F (of any characteristic), the function returns two sequences. The first gives a list of all possible geometric automorphism groups for genus 2 curves defined over F and the second gives the corresponding number of isomorphism (over $\bar{F}$, the algebraic closure of F) classes of F-curves having the given automorphism group. The groups are represented as finitely-presented groups.

This function is part of a package for genus 2 curves contributed by Reynald Lercier and Christophe Ritzenthaler and is based on the classification analysis in [Car03] and [CNP05].

`GeometricAutomorphismGroupGenus3Classification(F)`

Given a finite field F of characteristic ≥ 11, the function returns two sequences. The first gives a list of all possible geometric automorphism groups for genus 3 curves defined over F and the second gives the corresponding number of isomorphism (over $\bar{F}$, the algebraic closure of F) classes of F-curves having the given automorphism group. The groups are represented as permutation groups.

This function is part of a package for genus 3 curves contributed by Reynald Lercier and Christophe Ritzenthaler.

Example H125E13

We determine the possible (geometric) automorphism groups for genus 2 curves over $\mathbf{F}_2$.

```
> gps,ncls :=  GeometricAutomorphismGroupGenus2Classification(GF(2));
> [#gp : gp in gps];
[ 2, 12, 32, 160 ]
> ncls;
[ 5, 1, 1, 1 ]
```

125.8 Jacobians

The Jacobian of a hyperelliptic curve is implemented as the divisor class group of the curve. In particular, no equations giving the Jacobian as a variety ever appear. The Jacobian of any hyperelliptic curve can be created, but most of the interesting functionality is over finite fields, or for genus 2 over number fields or $\mathbf{Q}$.

125.8.1 Creation of a Jacobian

`Jacobian(C)`

The Jacobian of the hyperelliptic curve C.

125.8.2 Access Operations

`Curve(J)`

The hyperelliptic curve from which the Jacobian J was constructed.

`Dimension(J)`

The dimension of the Jacobian J as an algebraic variety, equal to the genus of the curve C of which J is the Jacobian.

125.8.3 Base Ring

`BaseField(J)`

`BaseRing(J)`

`CoefficientRing(J)`

The base field of the Jacobian J.

125.8.4 Changing the Base Ring

`BaseChange(J, F)`

`BaseExtend(J, F)`

The base extension of the Jacobian J to the field F.

`BaseChange(J, j)`

`BaseExtend(J, j)`

The base extension of the Jacobian J obtained by the map j, where j is a ring homomorphism with the base field of C as its domain.

`BaseChange(J, n)`

`BaseExtend(J, n)`

The base extension of the Jacobian J over a finite field to its degree n extension.

125.9 Richelot Isogenies

Let k be a field of characteristic different from 2. We consider a curve of genus 2, given by an equation

$$C : y^2 = f(x)$$

where $f(x)$ is a square-free polynomial of degree 5 or 6. Let J be the Jacobian of C. In this section we mean by a *Richelot isogeny* a polarized isogeny $\Phi : J \to A$ between principally polarized abelian surfaces, such that the kernel of Φ over the algebraic closure has group structure $\mathbf{Z}/2\mathbf{Z} \times \mathbf{Z}/2\mathbf{Z}$. We have that $J[\Phi] \subset J[2]$ is maximal isotropic with respect to the Weil-pairing on $J[2]$.

We can represent the points of $J[\Phi]$ over the algebraic closure as divisors in the following way. We write

$$f(x) = cQ_1(x)Q_2(x)Q_3(x),$$

where the Q_i are degree 2 polynomials if $\deg(f) = 6$. If $\deg(f) = 5$ then Q_2, Q_3 are of degree 2 and Q_1 is of degree 1 and is considered to represent a degree 2 with a root at $x = \infty$. Then

$$\{0, [Q_1(x) = 0] - [Q_2(x) = 0], [Q_1(x) = 0] - [Q_3(x) = 0], [Q_2(x) = 0] - [Q_3(x) = 0]\}$$

is the kernel of some Richelot-isogeny and, conversely, any Richelot kernel can be represented in this way.

The Q_i do not have to be defined over the ground field individually. One way of specifying such a kernel is to write

$$f(x) = c\mathrm{Norm}_{L[x]/k[x]}Q(x)$$

where $L = k[t]/(h(t))$ for some square free cubic polynomial h and $Q(x) \in L[x]$. If L is totally split and A is the Jacobian of a genus 2 curve then a description the genus 2 curve

D such that $A = \mathrm{Jac}(D)$ is classically known. See [Smi05], Chapter 8 for an exposition that is relatively close to the description given here. See [BD09] for a description of D for general L.

In special cases, the codomain A can be a product of elliptic curves or the Weil-restriction of an elliptic curve with respect to a quadratic extension of k. In that case, the curve C has extra automorphisms that respects the representation $f(x) = c\mathrm{Norm}_{L[x]/k[x]}Q(x)$. and one can find the relevant elliptic curves as quotients of C.

`RichelotIsogenousSurfaces(J)`

`RichelotIsogenousSurfaces(C)`

`Kernels` BoolElt *Default :* `true`

Computes the richelot isogenies defined over the basefield of the given abelian varieties and returns a list of objects representing the codomains. If the codomain is the Jacobian of a genus 2 curve, then that Jacobian is returned or, if a curve is given instead of a Jacobian, the corresponding curve.

If the codomain is a product of elliptic curves, a Cartesian product of elliptic curves is returned. If the codomain is the Weil restriction of an elliptic curve relative to a quadratic extension, then the elliptic curve over the quadratic extension is returned.

If `Kernels` is specified then a second list is returned, consisting of quadratic polynomials over cubic algebras. Each describes the kernel of the relevant isogeny.

`RichelotIsogenousSurface(J, kernel)`

`RichelotIsogenousSurface(C, kernel)`

Given a genus 2 Jacobian and a Richelot kernel, return the codomain. The genus 2 curve must be given by a model of the form $C : y^2 = f(x)$ and the kernel must be a quadratic polynomial $Q(x)$ over a cubic algebra L such that $\mathrm{Norm}_{L[x]/k[x]}Q(x) = cf(x)$. The elements of the second list returned by `RichelotIsogenousSurfaces` when given `Kernels:=true` are valid kernel descriptions. The codomain is returned using the same conventions as for `RichelotIsogenousSurfaces`.

Example H125E14

We will determine the Richelot isogenies on the Jacobian of $y^2 = x^5 + x$. This Jacobian has the amusing property that there are 3 such isogenies and that each of the types of codomain (Jacobian, Weil restriction, product of elliptic curves) is represented.

```
> R<x>:=PolynomialRing(Rationals());
> C:=HyperellipticCurve(x^5+x);
> J:=Jacobian(C);
> RichelotIsogenousSurfaces(J);
[*
    Cartesian Product<Elliptic Curve defined by y^2 = x^3 + 5/32*x^2 -
    5/1024*x - 1/32768 over Rational Field, Elliptic Curve defined by
    y^2 = x^3 - 5/32*x^2 - 5/1024*x + 1/32768 over Rational Field>,
```

```
    Jacobian of Hyperelliptic Curve defined by y^2 = -2*x^5 - 2*x over
    Rational Field,
    Elliptic Curve defined by y^2 = x^3 + 5/32*$.1*x^2 + 5/1024*x +
        1/32768*$.1 over Number Field with defining polynomial x^2 + 1
    over the Rational Field
*]
```

We now illustrate how the kernels are represented.

```
> codomains,kernels:=RichelotIsogenousSurfaces(J:Kernels);
> Q:=kernels[1];
> LX<X>:=Parent(Q);
> L<alpha>:=BaseRing(LX);
> Q;
(-1/2*alpha^2 + 2*alpha)*X^2 + (-1/2*alpha^2 + alpha + 1)*X -
    1/2*alpha^2 + 2*alpha
> L;
Univariate Quotient Polynomial Algebra in alpha over Rational Field
with modulus alpha^3 - 4*alpha^2 + 2*alpha
```

Let us check that the norm of `Q` gives us $x^5 + x$ again and that calling `RichelotIsogenousSurface` allows us to recreate the corresponding codomain.

```
> _,swp:=SwapExtension(LX);
> Norm(swp(Q));
x^5 + x
```

We can use Q to recreate the corresponding codomain.

```
> codomains[1] eq RichelotIsogenousSurface(J,Q);
true
```

Finally, to verify that the computed abelian surfaces are all isogenous, we verify that their L-series over $\mathbf{Q}$ are equal. For each type of return value we have to create the L-Series in a slightly different way, but once done, we can easily check that their coefficients agree.

```
> LC:=LSeries(C : ExcFactors:="Ogg");
> myL:=func< A|
>     case<Type(A) | SetCart : LSeries(A[1])*LSeries(A[2]),
>                    JacHyp  : LSeries(Curve(A) : ExcFactors:="Ogg"),
>                    CrvEll  : LSeries(A),
>                    default : false>>;
> cfs:=[c: c in LGetCoefficients(LC,1000)];
> [[c: c in LGetCoefficients(myL(A),1000)] eq cfs : A in codomains];
[ true, true, true ]
```

125.10 Points on the Jacobian

Points on $Jac(C)$ are represented as divisors on C. They can be specified simply by giving points on C, or divisors on C, or in the Mumford representation, which is the way MAGMA returns them (and which it uses to store and manipulate them). Points can be added and subtracted.

Representation of points on $Jac(C)$: Let C be a hyperelliptic curve of genus g. A triple $\langle a(x), b(x), d\rangle$ specifies the divisor D of degree d on C defined by

$$A(x, z) = 0, \quad y = B(x, z)$$

where $A(x, z)$ is the degree d homogenisation of $a(x)$, and $B(x, z)$ is the degree $(g + 1)$ homogenisation of $b(x)$. Note that the equation $y = B(x, z)$ make sense projectively because y has weight $g + 1$ (as always for hyperelliptic curves in MAGMA).

The *point on $Jac(C)$ corresponding to* $\langle a(x), b(x), d\rangle$ is then D minus a multiple of the divisor at infinity on C. So, when there is a single point P_∞ at infinity, we have $D - dP_\infty$. Otherwise, there is a $\mathbf{Q}$-rational divisor $P_{+\infty} + P_{-\infty}$ consisting of the two points at infinity; in this case d is required to be even and we have $D - (d/2)(P_{+\infty} + P_{-\infty})$.

All points on $Jac(C)$ can be expressed in this way, except when g is odd and there are no rational points at infinity (in which case the extra points can not be created in MAGMA, and arithmetic on points is not implemented). There is a uniquely determined "reduced" triple representing each point, which MAGMA uses to represent any point it encounters.

See the examples in the following section ("Creation of Points").

Technical details: In order to make sense, a triple $\langle a(x), b(x), d\rangle$ is required to satisfy:

(a) $a(x)$ is monic of degree at most g;

(b) $b(x)$ has degree at most $g + 1$, and $a(x)$ divides $b(x)^2 + h(x)b(x) - f(x)$, where $h(x)$ and $f(x)$ are the defining polynomials of C;

(c) d is a positive integer with $\deg(a(x)) \leq d \leq g + 1$, such that the degree of $b(x)^2 + h(x)b(x) - f(x)$ is less than or equal to $2g + 2 - d + \deg(a(x))$.

For uniqueness of representation, in the case of one point at infinity, (the odd degree case, in particular), we require that $d = \deg(a(x))$.

A triple $\langle a(x), b(x), d\rangle$ is reduced to a canonical representative as follows:

(a) If $d = \deg(a(x))$, we reduce b mod a, so $\deg(b(x)) < \deg(a(x))$.

(b) If $a = 1$, we assume that $\deg(B(1, z)) = d$.

(c) A unique representative for $b(x)$ is found such that the coefficient of x^k in b is zero for $\deg(a(x)) \leq k \leq \deg(a(x)) + g + 1 - d$.

For certain models of C, not all rational points can be represented in the above form (with the restrictions on d) or the representation is not unique. The bad cases are g odd and (i) 0 or (ii) 2 rational points at infinity.

In case (i) we would have to allow divisors with $\deg(a(x)) = g + 1$, which give linear pencils of equivalent divisors, and in case (ii) a Jacobian point with $d = g+1$ has precisely two canonical representatives.

In case (i), there is no obvious canonical representative for these additional Jacobian points and currently MAGMA does not deal with them. Consequently, arithmetic is not implemented in this case.

However, in case (ii), the two representatives correspond to the two distinguished elements of a linear pencil of divisors which include contributions from one or the other point at infinity. By arbitrarily selecting one of these two infinite points as the default, a unique representative can be chosen. This is now performed internally by MAGMA, the default point being chosen at the time of creation of the Jacobian. Arithmetic is also implemented. Note that in this case, extra work is generally required in point addition to keep track of points at infinity and final reduction to the unique representation. If very fast addition is crucial when C is of this type, it is generally wise to use an isomorphic model with exactly one point at infinity, if possible, by moving a rational Weierstrass point to infinity.

125.10.1 Creation of Points

```
J ! 0
```
```
Id(J)
```
```
Identity(J)
```

The identity element on the Jacobian J.

```
J ! [a, b]
```
```
elt< J | a, b >
```
```
elt< J | [a, b] >
```
```
elt< J | a, b, d >
```
```
elt< J | [a, b], d >
```

The point on the Jacobian J defined by the polynomials a and b and the positive integer d; if not specified then d is taken to be $\deg(a)$.

```
P - Q
```
```
J ! [P, Q]
```
```
elt< J | P, Q >
```

For points P and Q on a hyperelliptic curve, this constructs the image of the divisor class $[P - Q]$ as a point on its Jacobian J.

```
J ! [S, T]
```
```
elt< J | S, T >
```

Given two sequences $S = [P_i]$ and $T = [Q_i]$ of points on the hyperelliptic curve with Jacobian J, each of length n, this returns the image of the divisor class $\sum_i [P_i] - \sum_i [Q_i]$ as a point on the Jacobian J.

`JacobianPoint(J, D)`

The point on the Jacobian J (of a hyperelliptic curve C) associated to the divisor D on C. If D does not have degree 0, then a suitable multiple of the divisor at infinity is subtracted. When the divisor at infinity on C has even degree, D is required to have even degree.

The function works for any divisor such that the corresponding point is definable in MAGMA. It is not implemented for characteristic 2.

`J ! P`

Given a point P on a Jacobian J', construct the image of P on J, where J is a base extension of J'.

`Points(J, a, d)`

`RationalPoints(J, a, d)`

Find all points on the Jacobian J with first component a and degree d. Only implemented for genus 2 curves of the form $y^2 = f(x)$.

Example H125E15

Points on $y^2 = x^6 - 3x - 1$ and their images on the Jacobian.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6-3*x-1);
> C;
Hyperelliptic Curve defined by y^2 = x^6 - 3*x - 1 over Rational Field
> J := Jacobian(C);
> J;  // Magma didn't do much work to create J
Jacobian of Hyperelliptic Curve defined by y^2 = x^6 - 3*x - 1 over Rational Field
```

Find some points on C and map them to J (using the first point to define the map $C \to J$):

```
> ptsC := Points(C : Bound := 100);
> ptsC;
{@ (1 : -1 : 0), (1 : 1 : 0), (-1 : -1 : 3), (-1 : 1 : 3) @}
> ptsJ := [ ptsC[i] - ptsC[1] : i in [2,3,4] ];
> ptsJ;
[ (1, x^3, 2), (x + 1/3, x^3, 2), (x + 1/3, x^3 + 2/27, 2) ]
```

We recreate the first of these, giving it in MAGMA's notation (which is read as "the divisor of degree 2 on C determined by $z^2 = y - x^3 = 0$").

```
> pt1 := elt< J | [1,x^3], 2 >;
> pt1 eq ptsJ[1];
true
```

The degree of the divisor must be specified here, otherwise it is assumed to be $\deg(a(x)) = 0$:

```
> pt1 := J! [1,x^3];
> pt1; pt1 eq J!0;
(1, 0, 0)
true
```

Example H125E16

We define the nontrivial 2-torsion point on the Jacobian of $C : y^2 = (x^2 + 1)(x^6 + 7)$.
The divisor $(y = 0, x^2 + 1 = 0)$ should define the only nontrivial 2-torsion point in $J(\mathbf{Q})$.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve( (x^2+1)*(x^6+7) );
> J := Jacobian(C);
```

Define the point corresponding to the divisor given by $x^2 + 1 = 0, y = 0$ on C. We can use the simpler syntax, not specifying that the degree of the divisor is 2, because this equals the degree of $a(x) = x^2 + 1$.

```
> Ptors := J![x^2+1, 0];
> Ptors;
(x^2 + 1, 0, 2)
```

The alternative syntax would be as follows.

```
> Ptors1 := elt< J | [x^2+1, 0], 2 >;
> Ptors eq Ptors1;  // Are they the same?
true
```

Check that Ptors has order 2:

```
> 2*Ptors;
(1, 0, 0)
> $1 eq J!0;  // Is the previous result really the trivial point on J?
true
> Order(Ptors);  // Just to be absolutely sure ...
2
```

The other factor $x^6 + 7$ will give the same point on J:

```
> Ptors2 := J![x^6+7,0];
(x^2 + 1, 0, 2)
```

Note that MAGMA returned the unique reduced triple representing this point, which means we can easily check whether or not it is the same point as `Ptors`.
For alternative ways to obtain 2-torsion points, see the section on torsion.

Example H125E17

A Jacobian with a point not coming from the curve.
Any curve containing the point $(\sqrt{2}, \sqrt{2})$ has a $\mathbf{Q}$-rational divisor

$$D := (\sqrt{2}, \sqrt{2}) + (-\sqrt{2}, -\sqrt{2}).$$

This will give a nontrivial point in $J(\mathbf{Q})$. For instance, take $y^2 = x^6 - 6$.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6-6);
```

```
> J := Jacobian(C);
```

The divisor D has degree 2 and is given by $x^2 - 2 = y - x = 0$.

```
> pt := J![x^2-2, x];
> pt;  // What is pt?
(x^2 - 2, x, 2)
> Parent(pt);  // Where does pt live?
Jacobian of Hyperelliptic Curve defined by y^2 = x^6 - 6 over Rational Field
> pt eq J!0;  // Is pt equal to 0 on J?
false
> Order(pt);
0
```

This means that P has infinite order in $J(\mathbf{Q})$.
Alternatively we can construct the same point by first constructing the divisor, giving it as an ideal in the homogeneous coordinate ring in which C lives. (Note that Y has weight 3).

```
> P<X,Y,Z> := CoordinateRing(Ambient(C));
> D := Divisor(C, ideal<P | X^2-2*Z^2, Y-X*Z^2> );
> pt1 := J!D;
> pt eq pt1;
true
```

125.10.2 Random Points

`Random(J)`

A random point on a Jacobian J of a hyperelliptic curve defined over a finite field.

125.10.3 Booleans and Predicates for Points

For each of the following functions, P and Q are points on the Jacobian of a hyperelliptic curve.

`P eq Q`

Returns `true` if and only if the points P and Q on the same Jacobian are equal.

`P ne Q`

Returns `false` if and only if the two points P and Q on the same Jacobian are equal.

`IsZero(P)`

`IsIdentity(P)`

Returns `true` if and only if P is the zero element of the Jacobian.

125.10.4 Access Operations

`P[i]`

Given an integer $1 \leq i \leq 2$, this returns the i-th defining polynomial for the Jacobian point P. For $i = 3$, this returns the degree d of the associated reduced divisor.

`Eltseq(P)`

`ElementToSequence(P)`

Given a point P on the Jacobian J of a hyperelliptic curve, the function returns firstly, a sequence containing the two defining polynomials for the divisor associated to P and secondly, the degree of the divisor.

125.10.5 Arithmetic of Points

For each of the following functions, P and Q are points on the Jacobian of a hyperelliptic curve.

`-P`

The additive inverse of the point P on the Jacobian.

`P + Q`

The sum of the points P and Q on the same Jacobian.

`P +:= Q`

Given two points P and Q on the same Jacobian, set P equal to their sum.

`P - Q`

The difference of the points P and Q on the same Jacobian.

`P -:= Q`

Given two points P and Q on the same Jacobian, set P equal to the difference $P-Q$.

`n * P`

`P * n`

The n-th multiple of P in the group of rational points on the Jacobian.

`P *:= n`

Set P equal to the n-th multiple of itself.

125.10.6 Order of Points on the Jacobian

`Order(P)`

Returns the order of the point P on the Jacobian J of a hyperelliptic curve defined over a finite field or the rationals, or 0 if P has infinite order. This first computes $\#J$ when J is defined over a finite field.

`Order(P, l, u)`

`Alg`	MonStg	*Default :* "*Shanks*"
`UseInversion`	BoolElt	*Default :* `true`

Returns the order of the point P where u and l are bounds for the order of P or for the order of J the parent of P. This does not compute $\#J$.

If the parameter `Alg` is set to `"Shanks"` then the generic Shanks algorithm is used, otherwise, when `Alg` is `"PollardRho"`, a Pollard-Rho variant is used (see [GH00]).

If `UseInversion` is `true` the search space is halved by using point negation.

`Order(P, l, u, n, m)`

`Alg`	MonStg	*Default :* "*Shanks*"
`UseInversion`	BoolElt	*Default :* `true`

Returns the order of the point P where u and l are bounds for the order of P or for the order of J the parent of P and where n and m are such that the group order is n mod m. This does not compute $\#J$.

The two parameters `Alg` and `UseInversion` have the same use as in the previous function.

`HasOrder(P, n)`

Given a point P on the Jacobian J of a hyperelliptic curve and a positive integer n, this returns `true` if the order of the point is n.

125.10.7 Frobenius

`Frobenius(P, k)`

`Check`	BoolElt	*Default :* `true`

Given a point P that lies on the Jacobian J of a hyperelliptic curve that is defined over the finite field $k = F_q$, determine the image of P under the Frobenius map $x \to x^q$. If `Check` is `true`, Magma verifies that the Jacobian of P is defined over k.

125.10.8 Weil Pairing

`WeilPairing(P, Q, m)`

Computes the Weil pairing of P and Q, where P and Q are m-torsion points on the 2-dimensional Jacobian J defined over a finite field.

Example H125E18

The following illustrates the use of the Weil Pairing in the MOV-reduction of the discrete logarithm problem on a Jacobian.

```
> PP<x>:=PolynomialRing(GF(2));
> h := PP!1;
> f := x^5 + x^4 + x^3 + 1;
> J := Jacobian(HyperellipticCurve(f,h));  // a supersingular curve
> Jext := BaseExtend(J, 41);
> Factorization(#Jext);
[ <7, 1>, <3887047, 1>, <177722253954175633, 1> ]
> m := 177722253954175633;                 // some big subgroup order
> cofact := 3887047*7;
> P := cofact*Random(Jext);
> Q := 876213876263897634*P;               // Q in <P>
```

Say we want to recompute the logarithm of Q in base P.

```
> Jext2 := BaseExtend(Jext, 6);            // go to an ext of deg 6
> NJ := #Jext2;
>
> R := Random(Jext2);
> R *:= NJ div m^Valuation(NJ, m);
>
> eP := WeilPairing(Jext2!P, R, m);
> eQ := WeilPairing(Jext2!Q, R, m);
> assert eP^876213876263897634 eq eQ;
```

So the discrete log problem on the Jacobian has been reduced to a discrete log problem in a finite field.

125.11 Rational Points and Group Structure over Finite Fields

125.11.1 Enumeration of Points

`Points(J)`

`RationalPoints(J)`

Given a Jacobian J of a hyperelliptic curve defined over a finite field, determine all rational points on the Jacobian J.

125.11.2 Counting Points on the Jacobian

Several algorithms are used to compute the order of a Jacobian depending of its size, its genus and its type. In particular, in genus 2 it includes all the techniques described in [GH00]. The best current algorithms are the ones based on p-adic liftings. These are the defaults when they apply (see below) and the characteristic is not too large. In odd characteristic, Kedlaya's algorithm is used as described in [Ked01]. For characteristic 2, we have Mestre's canonical lift method as adapted by Lercier and Lubicz. Details can be found in [LL]. We also now have an implementation of Vercauteren's characteristic 2 version of Kedlaya (described in [Ver02]). As an added bonus, the p-adic methods actually give the Euler factor (see below). A verbose flag can be set to see which strategy is chosen and the progress of the computation.

The latest p-adic methods, faster than Kedlaya in odd characteristic, are those of Alan Lauder based on deformations over parametrised families. Magma incorporates an implementation for hyperelliptic families by Hendrik Hubrechts (see [Hub06] for details). This has a slightly different interface to the other methods (which all run through the same top-level intrinsics) as it can be used to count points on several members of the family at once.

`SetVerbose("JacHypCnt", v)`

Set the verbose printing level for the point-counting on the Jacobians. Currently the legal values for v are `true`, `false`, 0, 1, 2, 3 or 4 (`false` is the same as 0, and `true` is the same as 1).

`#J`

`Order(J)`

Given the Jacobian J of a hyperelliptic curve defined over a finite field, determine the order of the group of rational points.

There are 4 optional parameters which concern every genus.

`NaiveAlg`	BoolElt	*Default :* `false`
`ShanksLimit`	RngIntElt	*Default :* 10^{12}
`CartierManinLimit`	RngIntElt	*Default :* 5×10^5
`UseSubexpAlg`	BoolElt	*Default :* `true`

The parameter `NaiveAlg` can be set to one if one want to use the naive algorithm for point counting, consisting in counting points on the curve over the first g extensions, where g is the genus. Setting this parameter to `true` annihilates the effects of the others. By default, this strategy is used for small groups and Jacobians in characteristic 2 for which no group law is available.

In odd characteristic, Kedlaya's algorithm can be applied to curves of any genus and it is the default when the group is not too small or the characteristic too large.

In contrast, Mestre's characteristic 2 method has several conditions on its applicability. When these are satisfied and the genus is not too large or the group order too small, it is the default.

- Firstly, the Jacobian must be *ordinary*. This is equivalent to the defining polynomial $h(x)$ having degree g or $g+1$ and having distinct roots (ie non-zero discriminant).
- Next, there must be a group law available for a final elimination: the algorithm produces several possibilities for the characteristic polynomial of Frobenius. If no group law is available, we attempt to replace the curve with an isomorphic one for which one is. Note that a group law exists if there is a single point at infinity (degree of $h(x) = g$).

Warning : Even if these conditions are satisfied, the last phase of the algorithm may still fail for $g \geq 4$ in unusual cases. However, this is very rare. Finally, it should be noted that the main algorithm works over the smallest extension of the ground field K over which $h(x)$ splits. It is therefore much faster if $h(x)$ has all its roots in K.

When the genus is > 4 or the canonical lift method doesn't apply, Vercauteren's version of Kedlaya is now used in its place. It is also used for genus 4 when an extension of the base field is required for Mestre: ie, $h(x)$ doesn't split.

`UseGenus2` BoolElt *Default :* `false`

For genus 2 the methods mentioned at the start are applied if the parameter `UseGenus2` is set to `true`. Otherwise they are now only used for large characteristic.

If none of the above apply, the remaining methods are the subexponential algorithm, which uses the generic machinery of the function fields, and general group order algorithms of Shanks and Pollard. The subexponential algorithm will be the first choice if no group law is available or the genus is large and the base field small. It can be disabled by setting `UseSubexpAlg` to `false`.

The parameter `ShanksLimit` determines when we switch from a memory-consuming Shanks' algorithm to a slower Pollard's method. The value of the parameter `CartierManinLimit` is the maximal characteristic for which we may use the Cartier-Manin trick (see function `EulerFactorModChar` below).

The next 2 parameters are used only for the genus 2 methods in odd characteristic.

`UseSchoof` BoolElt *Default :* `true`

`UseHalving` BoolElt *Default :* `true`

When the base field is large enough, it is better to firstly compute the cardinality of the Jacobian modulo some odd primes and some power of two. These two parameters allow the user to disable one or both of these methods.

Example H125E19

In the following sequence of examples the different point counting methods are illustrated. The first example uses direct counting.

```
> SetVerbose("JacHypCnt",true);
> P<x> := PolynomialRing(GF(31));
> f := x^8 + 3*x^7 + 2*x^6 + 23*x^5 + 5*x^4 + 21*x^3 + 29*x^2 + 12*x + 9;
> J := Jacobian(HyperellipticCurve(f));
> time #J;
Using naive counting algorithm.
20014
Time: 0.020
```

Example H125E20

For the second example, we apply Kedlaya's algorithm to a genus curve 2 over $GF(3^{20})$.

```
> K := FiniteField(3,20);
> P<x> := PolynomialRing(K);
> f :=  x^5 + x + K.1;
> J := Jacobian(HyperellipticCurve(f));
> #J;
Using Kedlaya's algorithm.
Applying Kedlaya's algorithm
Total time: 2.310
12158175772023384771
```

Example H125E21

For the third example, we apply Vercauteren's algorithm to a non-ordinary genus curve 2 over $GF(2^{25})$..

```
> K := FiniteField(2,25);
> P<x> := PolynomialRing(K);
> f :=  x^5 + x^3 + x^2 + K.1;
> J := Jacobian(HyperellipticCurve([f,K!1]));
> time #J;
Using Kedlaya/Vercauteren's algorithm.
1125899940397057
Time: 0.680
```

Example H125E22

For the third example, we apply Mestre's algorithm to a genus 3 ordinary curve over $GF(2^{25})$.

```
> K := FiniteField(2,25);
> P<x> := PolynomialRing(K);
> h := x*(x+1)*(x+K.1);
> f :=  x^7 + x^5 + x + K.1;
> C := HyperellipticCurve([f,h]);
> J := Jacobian(C);
> #J;
Using Mestre's method.
Total time: 0.440
3778001771268503789504 0
> SetVerbose("JacHypCnt",false);
```

As the full Euler factor of J has been computed and stored the number of points on C, the Zeta function for C and the Euler factor for C are now immediate.

```
> time #C;
33555396
Time: 0.000
```

Example H125E23

We compare the Shanks and Pollard methods for large prime fields.

```
> // Comparison between Shanks and Pollard:
> P<x> := PolynomialRing(GF(1000003));
> f := x^7 + 123456*x^6 + 123*x^5 + 456*x^4 + 98*x^3 + 76*x^2 + 54*x + 32;
> J := Jacobian(HyperellipticCurve(f));
> curr_mem := GetMemoryUsage(); ResetMaximumMemoryUsage();
> time Order(J : ShanksLimit := 10^15);
1001800207033014252
Time: 19.140
> GetMaximumMemoryUsage()-curr_mem;
133583360
```

The computation took about 100 MB of central memory.

```
> delete J`Order;   // clear the result which has been stored
> curr_mem := GetMemoryUsage();
> ResetMaximumMemoryUsage();
> time Order(J : ShanksLimit := 0);
1001800207033014252
Time: 95.670
> GetMaximumMemoryUsage()-curr_mem;
0
```

Now it takes almost no memory, but it is slower (and runtime may vary a lot).

Example H125E24

In the case of genus 2 curves, the parameters `UseSchoof` and `UseHalving` do help.

```
> // Using Schoof and Halving true is generally best in genus 2
> P<x> := PolynomialRing(GF(100000007));
> f := x^5 + 456*x^4 + 98*x^3 + 76*x^2 + 54*x + 32;
> J := Jacobian(HyperellipticCurve(f));
> time Order(J);
10001648178050390
Time: 7.350
> delete J`Order;
> time Order(J: UseSchoof := false, UseHalving := false);
10001648178050390
Time: 21.080
```

But if the Jacobian is known in advance to be highly non–cyclic, it may be slightly better to switch them off. The Jacobian below is the direct product of two copies of the same supersingular elliptic curve.

```
> // ... but not always for highly non-cyclic Jacobians
> P<x> := PolynomialRing(GF(500083));
> f := x^5 + 250039*x^4 + 222262*x^3 + 416734*x^2 + 166695*x + 222259;
> J := Jacobian(HyperellipticCurve(f));
> time Order(J);
250084007056
Time: 1.920
> delete J`Order;
> time Order(J : UseSchoof:=false, UseHalving := false);
250084007056
Time: 1.870
```

`FactoredOrder(J)`

Given the Jacobian J of a hyperelliptic curve defined over a finite field, the function returns the factorization of the order of the group of rational points.

`EulerFactor(J)`

Given the Jacobian J of a hyperelliptic curve defined over a finite field, the function returns the Euler factor J, i.e. the reciprocal of the characteristic polynomial of Frobenius acting on $H^1(J)$. (see also `ZetaFunction(C)` which is essentially the same function and has the same behaviour).

`EulerFactorModChar(J)`

Given the Jacobian J of a hyperelliptic curve defined over a finite field, the function returns the Euler factor J modulo the characteristic of the base field. This function should not be used in high characteristic (say p should be $\leq 10^6$).

`EulerFactor(J, K)`

Given a Jacobian J of a hyperelliptic curve defined over the rationals and a finite field K at which J has good reduction, the function returns the Euler factor of the base extension of J to K.

125.11.3 Deformation Point Counting

`JacobianOrdersByDeformation(Q, Y)`

`EulerFactorsByDeformation(Q, Y)`

`ZetaFunctionsByDeformation(Q, Y)`

These functions compute the orders of Jacobians (*resp.* Euler factors, *resp.* Zeta functions) of one or more hyperelliptic curves in a 1-parameter family over a finite field using deformation methods.

$Q(x, z)$ should be a 2-variable polynomial in variables x and z over a finite field of odd characteristic k. Currently Q must be monic of odd degree as a polynomial in x. z is the parameter and the familiy of curves is given by $y^2 = Q(x, z)$.

Y should be a sequence of elements in a finite field extension K of k. The function then computes and returns the sequence of orders, Euler factors or Zeta functions associated to the hyperelliptic curves over K obtained by specialising the z parameter of $Q(x, z)$ to the elements of Y.

Over a field of size p^n, for n not too large, it is efficient to compute the results for several curves in the family at once, as roughly half of the computation for an individual curve is taken up in computing a Frobenius matrix that is then specialised to the parameter value. For a sequence of input parameter values, this part of the computation is only performed once at the start. However, as n becomes larger, the time taken for the specialisation at a particular value starts to dominate.

The field k over which the family is defined should be of small degree over the prime field. This is because Kedlaya's algorithm is applied over k to a particular member of the family with the parameter specialised to a k-value to initialise the deformation.

Similarly, the algorithm is much faster when $Q(x, z)$ is of small degree in the parameter z. In practice, the degree of $Q(x, z)$ as a polynomial in z, probably shouldn't exceed 3 or 4 (linear is obviously best).

There are two further conditions on Q and Y which we will try to remove in the near future. The first is that no Y-value is zero. The second is that the generic discriminant of $\hat{Q}$ (resultant of $\hat{Q}$ and $\partial\hat{Q}/\partial x$ w.r.t. x) must have leading coefficient (as a polynomial in z) a unit in $W(k)$. Here, $W(k)$ is the ring of integers of the unramified extension of $\mathbf{Q}_p$ with residue class field k and $\hat{Q}$ is a lift of Q to a 2-variable polynomial over $W(k)$. By translating and scaling the parameter, the user may be able to effect these two conditions if they aren't initially satisfied.

As with the other point-counting functions, the verbose flag `JacHypCnt` can be used to output information during processing.

Example H125E25

The following is a small example where the Euler factors for 4 random members of a linear family of elliptic curves are computed with a single call. The base field is $\mathbf{F}_9$ and the parameter values are taken in $\mathbf{F}_{3^{40}}$ which is the field over which the counting occurs.

```
> Fp := FiniteField(3^2);
> R<X,Y> := PolynomialRing(Fp,2);
> Q  := X^3+X^2-2*X+Fp.1+Y*(X^2-X+1);
> Fq := ext<Fp | 20>;
> values := [Random(Fq) : i in [1..4]];
> EFs := EulerFactorsByDeformation(Q,values);
> EFs;
[
    12157665459056928801*$.1^2 + 852459373*$.1 + 1,
    12157665459056928801*$.1^2 + 1088717005*$.1 + 1,
    12157665459056928801*$.1^2 + 6911064226*$.1 + 1,
    12157665459056928801*$.1^2 - 607949990*$.1 + 1
]
```

125.11.4 Abelian Group Structure

`Sylow(J, p)`

Given the Jacobian J of a hyperelliptic curve defined over a finite field and a prime p, this function returns the Sylow p-subgroup of the group of rational points of J, as an abstract abelian group A. The injection from A to J is also returned as well as the generators of the p-Sylow subgroup.

`AbelianGroup(J)`

`UseGenerators`	BOOL	*Default :* `false`
`Generators`	SETENUM	*Default :*

Given the Jacobian J of a hyperelliptic curve defined over a finite field K, this function returns the group of rational points of J as an abstract abelian group A. The isomorphism from A to $J(K)$ is returned as a second value.

If `UseGenerators` is set then the group structure computation is achieved by extracting relations from the user-supplied set of generators in `Generators`.

`HasAdditionAlgorithm(J)`

Returns true if and only if the Jacobian J has an addition algorithm. This is of interest when trying to construct the (abelian) group structure of J: When no user-supplied generators are given, such an algorithm must be present.

125.12 Jacobians over Number Fields or Q

Some functions in this section work for general number fields (notably `TwoSelmerGroup`), while many are only implemented over **Q**.

125.12.1 Searching For Points

`Points(J)`

`RationalPoints(J)`

Bound RngInt *Default :* 0

Given a Jacobian J of a genus 2 hyperelliptic curve defined by an integral model over the rationals, determine all rational points on the Jacobian J whose naive height on the associated Kummer surface is less than or equal to Bound.

125.12.2 Torsion

`TwoTorsionSubgroup(J)`

Given the Jacobian J of a hyperelliptic curve C which is either of genus 2 or has odd degree defined over a number field K, the function returns $J(K)[2]$ as an abstract group, together with a map sending elements of the abstract group to points on J. The curve C must be given in the simplified form $y^2 = f(x)$.

`TorsionBound(J, n)`

Given the Jacobian J of a hyperelliptic curve defined over the rationals, this function returns a bound on the size of the rational torsion subgroup of the Jacobian. The bound is obtained by examining the group $J(\mathbf{F}_p)$ for the first n good primes p.

`TorsionSubgroup(J)`

Given the Jacobian J of a genus 2 curve defined over the rationals, this function returns the rational torsion subgroup of J, and the map from the group into J. The curve must have the form $y^2 = f(x)$ with integral coefficients.

Example H125E26

For the curve

$$C : y^2 = (x+3)(x+2)(x+1)x(x-1)(x-2),$$

the only Q-rational torsion on the Jacobian is 2-torsion.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(&*[x-n : n in [-3..2]]);
> J := Jacobian(C);
> T, m := TwoTorsionSubgroup(J);
> T;
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/2
Defined on 4 generators
Relations:
```

```
    2*P[1] = 0
    2*P[2] = 0
    2*P[3] = 0
    2*P[4] = 0
> [ m(T.i) : i in [1..4] ];
[ (x^2 - 3*x + 2, 0, 2), (x^2 - 2*x, 0, 2), (x^2 - x - 2, 0, 2),
(x^2 - 4, 0, 2) ]
> #T eq #TorsionSubgroup(J);
true
```

The Jacobian for the following curve has torsion subgroup $Z/24$ over $\mathbf{Q}$.

```
> C := HyperellipticCurve((2*x^2-2*x-1)*(2*x^4-10*x^3+7*x^2+4*x-4));
> J := Jacobian(C);
> T, m := TwoTorsionSubgroup(J);
> T;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*P[1] = 0
> m(T.1);
(x^2 - x - 1/2, 0, 2)
> A,h := TorsionSubgroup(J);
> #T eq #A;
false
> A;
Abelian Group isomorphic to Z/24
Defined on 1 generator
Relations:
    24*P[1] = 0
> P := h(A.1);
> P;
(x^2 - 1/2, -1, 2)
> Order(P);
24
> 12 * P eq m(T.1);
true
```

125.12.3 Heights and Regulator

This section pertains to height functions on the Mordell–Weil group of the Jacobian of hyperelliptic curves over a number field k. However, naive heights and height constants are currently only implemented for Jacobians of genus 2 curves defined over $\mathbf{Q}$.

In the case of genus two curves defined over $\mathbf{Q}$, the canonical height is computed using the algorithm of Flynn and Smart[FS97] with improvements by Stoll[Sto99]. This algorithm computes the canonical height using local error functions on the associated Kummer surface.

In all other cases the algorithm described in chapter 5 of [Mül10a] is used. It is based on a theorem due to Faltings and Hriljac which expresses the canonical height pairing in terms of Arakelov intersection theory and works as follows:

We find divisors D_P and D_Q of degree zero on the curve representing P and Q, respectively. For this we use the canonical representative of P and Q (see Section 125.10); if $P = Q$, then the canonical representatives for P and $-P$ are used. Since the canonical representatives have common support at infinity, we subtract the divisor of a function $x-\lambda$ from one of them. These ideas are due to David Holmes [Hol06]. If there are points at infinity in the positive support of P or Q, then we might have to also subtract the divisor of a function $x - \mu$ from the other representatives.

The actual Arakelov intersection computations are performed locally using regular models of the curve (see Section 114.12.2) at the relevant primes and Groebner bases over p-adic quotient rings in the non-archimedean case. The algorithm requires factorisation of polynomials over non-archimedean local fields. For archimedean places the intersections multiplicities can be expressed using theta functions with respect to the analytic Jacobian. This relies heavily on several functions described in Section 125.18.

If the genus is less than 4, the most expensive archimedean operations are usually applications of the Abel-Jacobi map ToAnalyticJacobian. In larger genus, the computation of theta functions, whose running time grows exponentially in the genus is more expensive.

Regarding the non-archimedean computations, the main bottleneck is integer factorisation which is required to find out which primes may yield non-trivial intersection multiplicities.

Applications: Heights are a useful tool for studying rational points on varieties. The most standard applications concerning points on Jacobians are

- proving independence of points in $J(k)/J_{tors}(k)$ (in particular, the regulator is defined in terms of the canonical height), and
- proving non-divisibility: given $P \in J(k)$ and $n \in \mathbf{Z}$, proving that P is not of the form nR for some $R \in J(k)$.

The heights in this section are logarithmic, and they measure the size of the coordinates of the image of P on the Kummer variety associated to J (embedded in $\mathbf{P}^{2^g-1}$, where g is the genus of the curve). The naive height h is simply the height of the image of P in $\mathbf{P}^{2^g-1}$ using an explicit embedding, which is currently only available for $g = 2$. One can refine this, taking advantage of the group law on J, defining a *canonical height* which has nice properties with respect to the group law, for instance $\hat{h}(nP) = n^2\hat{h}(P)$. In particular, $\hat{h}(P) = 0$ if and only if P is a torsion point. The function $h - \hat{h}$ is bounded on $J(k)$.

Computationally, one generally wants an upper bound on this, because then one can find all points up to a given canonical height by doing a search for points of bounded naive height.

`NaiveHeight(P)`

Given a point P on the Jacobian of a curve of genus 2 (or on the associated Kummer surface), the function returns the logarithmic height of the image of P in $\mathbf{P}^3$ under the maps $J \to K \to \mathbf{P}^3$.

`Height(P: parameters)`

`CanonicalHeight(P: parameters)`

`lambda`	RngIntElt	*Default :* 1
`mu`	RngIntElt	*Default :* 0
`LocalPrecision`	RngIntElt	*Default :* 0
`UseArakelov`	BoolElt	*Default :* `false`
`Precision`	RngIntElt	*Default :* 0

The canonical height of a point P on the Jacobian of a hyperelliptic curve over a number field or over the rationals. If the genus is 2 and the ground field is $\mathbf{Q}$, then this computes the canonical height on the associated Kummer surface. Otherwise this function simply computes the height pairing of P with itself using Arakelov intersection theory.

`HeightConstant(J: parameters)`

`Effort`	RngIntElt	*Default :* 0
`Factor`	BoolElt	*Default :* `false`

Given the Jacobian J of a genus 2 curve over $\mathbf{Q}$ of the form $y^2 = f(x)$ with integral coefficients, this computes a real number c such that $h(P) \leq \hat{h}(P) + c$ for all P in $J(\mathbf{Q})$, where h is the naive height and $\hat{h}$ is the canonical height.

The parameter `Effort` (which can be $0, 1$ or 2) indicates how much effort should be put into finding a good bound. The second value returned is a bound for μ_∞, the contribution from the infinite place. If the parameter `Factor` is `true`, then the discriminant will be factored, and its prime divisors will be considered individually, usually resulting in an improvement of the bound.

`HeightPairing(P, Q: parameters)`

`lambda`	RngIntElt	*Default :* 1
`mu`	RngIntElt	*Default :* 0
`LocalPrecision`	RngIntElt	*Default :* 0
`UseArakelov`	BoolElt	*Default :* `false`
`Precision`	RngIntElt	*Default :* 0

The value of the canonical height pairing for rational points P and Q on the Jacobian of a hyperelliptic curve defined over a number field. The pairing can be defined as $\langle P, Q\rangle := (\hat{h}(P+Q) - \hat{h}(P) - \hat{h}(Q))/2$ and if the genus is 2 and the ground field is $\mathbf{Q}$, the pairing is computed using this definition. Otherwise the pairing is computed using Arakelov intersection theory.

Sometime these fail due to insufficient precision; if this happens, the parameter `LocalPrecision` should be changed accordingly.

Changing the parameters `lambda` and `mu` (see the introduction above) can sometimes speed up the computations because some of the required integer factorisations might be significantly easier for some values of λ and μ than for others. Note that the parameter `mu` is only used if it is nonzero.

The parameter `UseArakelov` indicates whether the algorithm based on Arakelov intersection theory should be used in genus 2.

`HeightPairingMatrix(S: Precision)`

`Precision` RngIntElt *Default :* 0

Given a sequence $[P_1, ...P_n]$ of points on the Jacobian J of a hyperelliptic curve defined over a number field, this function returns the matrix with entries $\langle P_i, P_j\rangle$, where the latter denotes the canonical height pairing between P_i and P_j.

`Regulator(S: Precision)`

`Precision` RngIntElt *Default :* 0

Given a sequence S of points on the Jacobian J of a hyperelliptic curve defined over a number field k, the function returns the determinant of the height pairing matrix of S. The regulator is equal to zero when the points are dependent in the Mordell–Weil group, and otherwise is equal to the square of the volume of the parallelotope spanned by the points in the subgroup of the free quotient of $J(k)$ generated by S.

`ReducedBasis(S: Precision)`

`Precision` RngIntElt *Default :* 0

Given a sequence of points on the Jacobian J of a hyperelliptic curve defined over a number field k, this function returns an LLL- reduced basis for the subgroup of $J(k)/J_{tors}(k)$ generated by the given points (that is,the function reduces the real lattice formed by the points, under the positive definite quadratic form given by the canonical height pairing). The height pairing matrix of the sequence is returned as a second value.

Example H125E27

This example illustrates some basic properties of heights, and proves that a certain point in $J(\mathbf{Q})$ is not a nontrivial multiple of any other point in $J(\mathbf{Q})$. Let J be the Jacobian of $y^2 = x^6 + x^2 + 2$.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+x^2+2);
```

```
> J := Jacobian(C);
```

Find some small points on C and map them to J:

```
> ptsC := Points(C : Bound:=1000);
> ptsJ := [ ptsC[i] - ptsC[1] : i in [2,3,4,5,6] ];
> ptsJ;
[ (1, x^3, 2), (x + 1, x^3 - 1, 2), (x + 1, x^3 + 3, 2), (x - 1, x^3 - 3, 2),
(x - 1, x^3 + 1, 2) ]
```

The canonical heights of these five points:

```
> [ Height(P) : P in ptsJ ];
[ 0.47983979745040515202327954250 2, 0.00000000000000000000000000000000,
0.47983979745040515202327954249 1, 0.47983979745040515202327954249 1,
0.00000000000000000000000000000000 ]
```

We see that two of them are torsion ($\hat{h} = 0$), and the others are probably equal or inverse to each other modulo torsion, because they appear to have the same canonical height. If so, they would generate a subgroup of rank 1 in $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$. The next command verifies this.

```
> ReducedBasis(ptsJ);
[ (x + 1, x^3 + 3, 2) ]
[0.47983979745040515202327954249 1]
> P := ptsJ[3];
> P;
(x + 1, x^3 + 3, 2)
```

So this point (which is the third point in our list) generates the others. We proceed to check that the other two non-torsion points in our list are equal to $P + T$ or $-P + T$ for some torsion point T.

```
> Jtors, maptoJ := TorsionSubgroup(J);
> {ptsJ[1], ptsJ[4]} subset { pt + maptoJ(T) : pt in {P,-P}, T in Jtors };
true
```

Now we check the property $\hat{h}(nP) = n^2\hat{h}(P)$ for $n = 23$.

```
> Height(23*P)/Height(P);
529.00000000000000000000000000
```

Of course, the naive height does not behave so nicely, but at least $h - \hat{h}$ should be bounded by the height constant.

```
> HC := HeightConstant(J : Effort:=2, Factor);
> HC;
3.7365462328830572011347394037 6
```

In particular, all torsion points should have naive height less than this.

```
> for T in Jtors do
>     NaiveHeight(maptoJ(T));
> end for;
0.00000000000000000000000000000000
```

```
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
0.69314718055994530941723212145 8
> // Does the inequality hold for 23*P?
> NaiveHeight(23*P) - Height(23*P) le HeightConstant(J);
true
```

Finally, we show that P is not a nontrivial multiple of another point in $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$ (implying that P generates $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$ if this has rank 1). For suppose that $P = nQ + T$ for some $Q \in J(\mathbf{Q}), T \in J_{tors}(\mathbf{Q})$. Then $\hat{h}(Q) = (1/n^2)\hat{h}(P) < \hat{h}(P)$, and the following search shows there is no Q satisfying this bound.

```
> LogarithmicBound := Height(P) + HeightConstant(J);  // Bound on the naive h(Q)
> AbsoluteBound := Ceiling(Exp(LogarithmicBound));
> PtsUpToAbsBound := Points(J : Bound:=AbsoluteBound );
> ReducedBasis( [ pt : pt in PtsUpToAbsBound ]);
[ (x^2 + 1/2*x + 1/2, 1/4*x - 5/4, 2) ]
[0.47983979745040515202327954249 1]
```

If Q exists, it would have to be in the set `PtsUpToAbsBound`. But the results of the final command indicate that the group generated by `PtsUpToAbsBound` is also generated by a single point of canonical height 0.47983979745040515202327954249 1, so there are no nontorsion points Q in `PtsUpToAbsBound` with $\hat{h}(Q) < \hat{h}(P)$.
This example is continued in Example H125E35, where we prove that $J(\mathbf{Q})$ has rank 1, and then use the fact that P generates $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$ to find all rational points on C.

Example H125E28

We compute a reduced basis for a set of points on the Jacobian J on the genus two curve $C : y^2 = x^6 + x^2 + 1$.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+x^2+1);
> J := Jacobian(C);
```

We construct some points on C:

```
> Z := PointsAtInfinity(C);
> Z;
{@ (1 : -1 : 0), (1 : 1 : 0) @}
> P1 := Z[1];
> P2 := Z[2];
> P3 := C![1/2,9/8,1];
> P4 := C![-1/2,9/8,1];
```

We now map them to J (for example $Q1$ is the divisor $P1 - P2$):

```
> Q1 := J![P1, P2];
```

```
> Q2 := J![P1, P3];
> Q3 := J![P3, P4];
> B, M := ReducedBasis([Q1, Q2, Q3] : Precision := 12);
> B;  // This will be a basis for <Q1, Q2, Q3>
[ (1, -x^3, 2), (x^2, 1, 2) ]
> M;  // The height pairing matrix for the new basis B
[0.27973179336882782876670568 39      -5.005347463630776922E-17]
[     -5.005347463630776922E-17 0.952446212809730769780007795 9]
> Determinant(M);
0.26642948719661422476551649 84
```

Since Det(M) is nonzero, the two generators in B are independent.

125.12.4 The 2-Selmer Group

The principal functions in this section provide information about the Mordell-Weil group $J(K)$ of a hyperelliptic Jacobian defined over the rationals or a number field. Two descent provides an upper bound (since $J(K)/2J(K)$ embeds in the 2-Selmer group of J). Finer information is provided by `HasSquareSha`, which determines the parity of the 2-rank of the Shafarevich–Tate group, and `RankBounds` collects together all the information that is computable in MAGMA.

Starting with MAGMA 2.13, a simpler user interface for computing 2-Selmer groups was introduced. The two implementations that were previously available still exist internally. In MAGMA 2.18-4 a new implementation has been included. When `TwoSelmerGroup` is called, it chooses one of them (or the user may choose).

`BadPrimes(C)`

`BadPrimes(J)`

`Badness` RNGINTELT *Default :* 1

Given a hyperelliptic curve C with integral coefficients defined over a number field (or the Jacobian of such a curve), the function returns a sequence containing the primes where the given model has bad reduction.

`HasSquareSha(J)`

`IsEven(J)`

Given the Jacobian of a hyperelliptic curve over $\mathbf{Q}$ or a number field, and assuming that the Shafarevich-Tate group of J is finite, this returns `true` if and only if the order of the Shafarevich-Tate group is a square. (Otherwise, the order is twice a square, as shown by Poonen and Stoll in [PS99]). The order is square if and only if the number of "deficient" primes for C is even (see below).

`IsDeficient(C, p)`

For a genus 2 curve defined over $\mathbf{Q}$ or a number field, this returns `true` if C is "deficient" at p. By definition, the curve is deficient if there are no points on C defined over any extension of odd degree over $\mathbf{Q}_p$ (when p is a prime) or over $\mathbf{R}$ (when p is 0). Equivalently, C is deficient if there is no $\mathbf{Q}_p$-rational divisor of odd degree on C.

`HasIndexOne(C,p)`

`HasIndexOne(C,p)`

Given a hyperelliptic curve C over $\mathbf{Q}$ or a number field, this returns true if and only if there is a divisor of odd degree on C which is defined over the completion at the prime p. An even genus curve is deficient at p if and only if it does not have index one at p.

`HasIndexOneEverywhereLocally(C)`

Returns true if and only if C has index one over all completions of its base field (including real completions).

`TwoSelmerGroup(J)`

`Al`	MonStgElt	*Default :*
`Fields`	SetEnum	*Default :*
`ReturnFakeSelmerData`	BoolElt	*Default :* `false`
`ReturnRawData`	BoolElt	*Default :* `false`
Verbose	`Selmer`	*Maximum :* 3

The 2-Selmer group of the Jacobian of a hyperelliptic curve defined over $\mathbf{Q}$ or a number field. If the curve is not defined over $\mathbf{Q}$ then it must have a single rational point at infinity (for curves in the simplified form $y^2 = f(x)$, this is equivalent to $f(x)$ having odd degree), The algorithm may work better when an integral model of the curve is given (or better yet, a minimal model).

The Selmer group is returned as a finite abelian group S, together with a map from S to some affine algebra A, which represents the standard map from the Selmer group to $A^*/(A^*)^2$ or to $A^*/(A^*)^2\mathbf{Q}^*$ (depending whether the degree of f is odd or even).

Three separate implementations exist internally in Magma. (Prior to V2.13 two of these were available as the intrinsics `TwoSelmerGroup` and `TwoSelmerGroupData`). The user can specify which implementation is used by setting the optional parameter `Al` to `"TwoSelmerGroupOld"`, `"TwoSelmerGroupNew"` or to `"TwoSelmerGroupData"`; otherwise, an appropriate choice is made automatically.

Much of the computation time is usually spent on class group and unit calculations. These computations can be speeded up by using non-rigorous bounds, and there are two ways to control which bounds are used. The recommended way is to preset them using one of the intrinsics `SetClassGroupBounds` or

SetClassGroupBoundMaps (see 37.6.1). The other way is to precompute the class groups of the fields involved (with the desired optional parameters in ClassGroup), and then pass these fields to TwoSelmerGroup via the optional parameter Fields. The class group data is stored, and if TwoSelmerGroup requires a field that is isomorphic to one of the given Fields, the stored data will automatically be used. The relevant fields are those given by the roots of f, where $y^2 = f(x)$ is the SimplifiedModel of the curve.

When called with ReturnFakeSelmerData, the program returns an additional item, which specifies the "fake Selmer group" in the terminology of [Sto01]. (This is only relevant to the even degree case.) The returned object is a tuple $\langle B_1, B_2, B_3 \rangle$, where B_1 is a sequence of elements in A that span a subgroup S_1 of $A^*/(A^*)^2$, and B_2 and B_3 are sequences of integers that span subgroups S_2 and S_3 of $\mathbf{Q}^*/(\mathbf{Q}^*)^2$. The fake Selmer group S is then determined by the exact sequence $0 \to S_3 \to S_2 \to S_1 \to S \to 0$. See [Sto01] for a full explanation of this.

When called with ReturnRawData, the program additionally returns a third item expvecs and a fourth item factorbase. These specify the images in $A^*/(A^*)^2$ of the Selmer group generators (in unexpanded form). The factorbase is a sequence of elements f_j of A, and expvecs is a sequence of vectors in $\mathbf{Z}^F$, where F is the number of elements in the factorbase. The image in $A^*/(A^*)^2$ of the ith Selmer group generator is then the sum over j of $f_j^{e_j}$ where (e_j) is the ith exponent vector.

RankBound(J)

RankBounds(J)

An upper, or a lower and an upper bound, on the rank of the Mordell-Weil group of J, which should be the Jacobian of a hyperelliptic curve over the rationals or a number field. RankBound can be computed provided both TwoSelmerGroup and TwoTorsionSubgroup are implemented for J, while RankBounds is only implemented for Jacobians defined over $\mathbf{Q}$.

For curves of even degree and odd genus it is not always possible to compute an upper bound for the rank. One can compute instead an upper bound for the rank of the subgroup of the Mordell-Weil group consisting of points which can be represented by rational divisors. When the curve has index one everywhere locally, every rational divisor class can be represented by a rational divisor. RankBound and RankBounds check if this condition is satisfied and print a warning if it is not.

An initial upper bound is furnished by computing the 2-Selmer group. For even degree hyperelliptic curves this can potentially be sharpened by determining if the torsor T parameterizing divisor classes of degree 1 on the curve represents a nontrivial element of Sha[2]. This can be achieved in two ways. If Sha does not have square order (see HasSquareSha) then T is nontrivial and the bound can be decreased by 1. If there are rational divisor classes of degree 1 everywhere locally, then T lies in Sha[2], and RankBounds will attempt to determine whether T is divisible by 2 in Sha using the algorithm described in [Cre12]. When T is not divisible by 2, the bound may be lowered by 2. Examples of both phenomena are given below.

The lower bound is computed by searching for points on the Jacobian, then determining their independence using either the height pairing machinery or by considering their images in $J(\mathbf{Q})/2J(\mathbf{Q})$.

Example H125E29

In this example, we find out as much as we can about the Mordell-Weil group of the Jacobian of

$$y^2 = x(x + 1344^2)(x + 10815^2)(x + 5406^2)(x + 2700^2).$$

First define the curve and its Jacobian:

```
> _<x> := PolynomialRing(Rationals());
> pol := x*(x+1344^2)*(x+10815^2)*(x+5406^2)*(x+2700^2);
> C := HyperellipticCurve( pol );
> J := Jacobian(C);
> J;
Jacobian of Hyperelliptic Curve defined by
y^2 = x^5 + 155285397*x^4 + 4761213301312596*x^3 + 330186894143664707856000*x^2
+ 450122990999339719434240000000*x over Rational Field
```

We can search for points on C (with x-coordinate up to Bound):

```
> ptsC := Points(C : Bound := 10^6);
> ptsC;
{@ (1 : 0 : 0), (0 : 0 : 1), (43264 : -44828581639628800 : 1),
(43264 : 44828581639628800 : 1) @}
> pointAtInfinity := ptsC[1];
```

This `pointAtInfinity` $(1 : 0 : 0)$ might not seem to lie on C, but recall that in MAGMA, a hyperelliptic curve lives in a weighted projective plane. We can also search for points on the Jacobian, which takes longer:

```
> time ptsJ := Points(J : Bound := 2000);
Time: 0.670
> ptsJ;
{@ (1, 0, 0), (x, 0, 1) @}
```

The notation for points on J is explained in the section "Points on the Jacobian" in this chapter. The points appearing above are the trivial point on J, and the point corresponding to the divisor $(0 : 0 : 1) - (1 : 0 : 0)$ on C.

```
> ptsJ[1] eq J!0;  // Is the first point equal to 0 on J?
true
> Order( ptsJ[2] );
2
```

So far, we have only found some trivial points on J. In fact, we can see from the equation that J has full 2-torsion, which we now confirm.

```
> Jtors, map := TorsionSubgroup(J);
> Jtors;
```

```
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/4
Defined on 4 generators
Relations:
2*P[1] = 0
2*P[2] = 0
2*P[3] = 0
4*P[4] = 0
```

`Jtors` is an abstract group, and `map` converts elements of `Jtors` to actual points on J. Here are the generator of the $\mathbf{Z}/4$ and its inverse.

```
> map(Jtors.4);
> map(3*Jtors.4);
(x^2 + 32963094*x - 212161021632000, 94792247622*x - 2005558137487296000, 2)
(x^2 + 32963094*x - 212161021632000, -94792247622*x + 2005558137487296000, 2)
```

Looking at the points on C we found above, the third of them looks nontrivial, so we find its order on J:

```
> P := ptsC[3];
> PJ := J![ P, pointAtInfinity ];
> PJ;
(x - 43264, -44828581639628800, 1)
> Order(PJ);
0
```

This means PJ has infinite order on J. Now we do two-descent on J:

```
> #TwoSelmerGroup(J);
64
```

We already knew that $J(\mathbf{Q})[2]$ has order 16, and that the rank of $J(\mathbf{Q})$ is at least 1, so we now know that the rank is either 1 or 2. We now ask whether the order of $Sha(J)$ is a square or twice a square (assuming it is finite):

```
> HasSquareSha(J);
true
```

It follows (assuming $Sha(J)$ is finite) that $Sha(J)$ has square order, and that $J(\mathbf{Q})$ has rank 2, even though the other generator of $J(\mathbf{Q})$ is probably not easy to find, especially if does not come from a point on C.
For more examples of Selmer group computations, see the next section.

Example H125E30

We produce some Jacobians for which the order of the Tate-Shafarevich group is twice a square (assuming it is finite). We then observe how this affects the rank bounds.
A good source of examples are curves $y^2 = 3(x^6 - x^2 + a)$ for $a = 1 \bmod 3$, since these curves are "deficient" at 3 (for the definition, see above); this can be proved by elementary arguments. We now list those (for a up to 50) which have nonsquare Sha.

```
> _<x> := PolynomialRing(Rationals());
> for a := 1 to 50 do
```

```
>    if a mod 3 eq 1 then
>       Ca :=  HyperellipticCurve( 3*(x^6-x^2+a) );
>       assert IsDeficient(Ca,3);
>          // (This causes a failure if our assertion is wrong.)
>       if not HasSquareSha(Jacobian(Ca)) then print Ca; end if;
>    end if;
> end for;
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 12 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 21 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 30 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 48 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 57 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 66 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 84 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 93 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 102 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 129 over Rational Field
Hyperelliptic Curve defined by y^2 = 3*x^6 - 3*x^2 + 138 over Rational Field
```

Aside: we could have tried simply $y^2 = 3(x^6 + a)$ for $a = 1 \bmod 3$, but this won't produce any examples: it's a cute exercise to show that for these curves, the number of deficient primes is always even.
Now consider the Mordell-Weil rank of the second curve listed (where $a = 7$),

```
> C7 :=  HyperellipticCurve( 3*(x^6-x^2+7) );
> J := Jacobian(C7);
> #TwoTorsionSubgroup(J);
1
> #TwoSelmerGroup(J);
2
> RankBound(J);
0
```

There is no nontrivial 2-torsion in $J(\mathbf{Q})$, and the Selmer group has order 2. The program has checked that the order of the Tate-Shafarevich group is twice a square (hence the 2-rank of Sha is exactly 1), and therefore it has returned a `RankBound` indicating that $J(\mathbf{Q})$ has rank 0. This rank bound is unconditional. In fact, the computation proves that there is a subgroup $\mathbf{Z}/2$ in Sha modulo the subgroup of infinitely divisible elements; therefore one may also deduce unconditionally that the 2-power part of Sha is finite cyclic (since if there was an infinitely 2-divisible part, it would still contribute to the 2-Selmer group).

Example H125E31

We demonstrate a non-trivial Tate-Shafarevich group on the Jacobian of a genus 2 curve. We consider the following Jacobian.

```
> P<x>:=PolynomialRing(Rationals());
> C:=HyperellipticCurve(-x^6 + 2*x^5 + 3*x^4 + 2*x^3 - x - 3);
```

```
> JC:=Jacobian(C);
```

We determine an upper bound on its Mordell-Weil rank

```
> RankBound(JC);
3
```

But we can only find one independent rational point on this Jacobian.

```
> V:=RationalPoints(JC,x^2 + 83/149*x + 313/596,2);
> B:=ReducedBasis(V);
> #B;
1
```

We test if there is a quadratic twist of our curve that does have high Mordell-Weil rank.

```
> d:=-1;
> Cd:=QuadraticTwist(C,d);
> JCd:=Jacobian(Cd);
> Vd:=RationalPoints(JCd:Bound:=100);
> Bd:=ReducedBasis(Vd);
> #Bd;
4
```

This shows that the Mordell-Weil rank of $\mathrm{Jac}(C_d)(\mathbf{Q})$ is at least four. We note that $\mathrm{rankJac}(C)(\mathbf{Q}(\sqrt{d})) = \mathrm{rankJac}(C)(\mathbf{Q}) + \mathrm{rankJac}(C_d)(\mathbf{Q})$, so if we can find an upper bound on the Mordell-Weil rank of $\mathrm{Jac}(C)$ over $\mathbf{Q}(\sqrt{d})$ then we also find an upper bound on $\mathrm{rankJac}(C_d)(\mathbf{Q})$. We first try this with unproven class group data.

```
> SetClassGroupBounds(1000);
> K:=QuadraticField(d);
> CK:=BaseChange(C,K);
> JCK:=Jacobian(CK);
> NumberOfGenerators(TwoSelmerGroup(JCK));
5
```

We find that $\mathrm{rankJac}(C)(\mathbf{Q}(\sqrt{d})) \leq 5$, which means that $\mathrm{Jac}(C)$ must indeed have Mordell-Weil rank 1 over $\mathbf{Q}$. To make the class group computation unconditional, we must check up to the Minkowski bound for each of the number fields utilized in the computation

```
> Aa:=AbsoluteAlgebra(JCK`Algebra);
> L:=Aa[1];
> MinkowskiBound(L);
3763009
```

The command `FactorBasisVerify(IntegerRing(L),1000,MinkowskiBound(L))` would perform the required check, but will take considerable time to complete.

Example H125E32

In this example we compute the Mordell-Weil rank of a genus 3 hyperelliptic Jacobian J with nontrivial 2-torsion in Sha using a different method. Namely we perform a 2-descent on the torsor parameterizing divisor classes of degree one on the curve as described in [Cre12].

```
> f := Polynomial([Rationals()| 30, 10, 30, 20, 10, 10, 10, 30, 10 ]);
> f;
10*x^8 + 30*x^7 + 10*x^6 + 10*x^5 + 10*x^4 + 20*x^3 + 30*x^2 + 10*x + 30
> X := HyperellipticCurve(f);
> J := Jacobian(X);
> SetClassGroupBounds("GRH");
> S := TwoSelmerGroup(J);
> #S;
4
> TorsionBound(J,5);
1
```

Here the 2-Selmer rank is 2 and there is no nontrivial 2-torsion. So the 2-descent on J gives an upper bound of 2 for the Mordell-Weil rank. However, one can do better.

```
>J`TwoSelmerSet;
{}
```

Calling `TwoSelmerGroup` also computes the 2-Selmer set of the torsor T parameterizing rational divisor classes of degree 1 (because C is everywhere locally solvable, the parameter `Al := "TwoSelmerGroupNew"` was used). This extra information allows us to deduce a better bound for the rank.

```
>RankBounds(J);
0 0
```

In this example the 2-Selmer set is empty, which implies that T is not divisible by 2 in Sha. Consequently Sha[2] has rank at least 2 (because of well known properties of the Cassels-Tate pairing). The theory behind these computations is described in [Cre12].

Example H125E33

For hyperelliptic curves of even degree and odd genus it is not always possible to obtain an upper bound for the Mordell-Weil rank. When the curve does not have index one everywhere locally, it may not be the case that every rational divisor class can be represented by a rational divisor. Here we provide an example of an even degree odd genus curve which does not have index one everywhere locally, but for which we can still compute an upper bound for the Mordell-Weil rank. The use of `SetClassGroupBounds` speeds up the computation, but is not necessary.

```
> f := Polynomial([Rationals()|-9, 8, 8, 1, -8, -8, -7, -2, -7 ]);
> C := HyperellipticCurve(f);
> Genus(C);
3
> Degree(C);
8
> J := Jacobian(C);
```

```
> SetClassGroupBounds("GRH");
> RankBound(J);
WARNING: upper bound is only an upper bound for the rank of Pic^0(X).
2
```

The warning appears because C does not have index one everywhere locally. In fact it is easy to see C has no real points. So over the reals it has no rational divisors of odd degree. However C has points locally at all nonarchimedean primes. This means C fails to have index 1 at exactly one prime. The obstruction to a rational divisor class being represented by a rational divisor is an element of the Brauer group. It follows from reciprocity in the Brauer group that every **Q**-rational divisor class is represented by a **Q**-rational divisor. In particular $Pic^0(C) = J(\mathbf{Q})$. So we can disregard the warning.

```
> HasIndexOneEverywhereLocally(C);
false 0
> Roots(f,RealField(50));
[]
> Evaluate(f,0) lt 0;
true
> &and[ HasIndexOne(C,p) : p in BadPrimes(C) ];
true
```

125.13 Two-Selmer Set of a Curve

Let $C : y^2 = f(x)$ be a hyperelliptic curve of genus g over a number field k. We say $\pi_\delta : D_\delta \to C$ is a *two-cover* of C if, over an algebraic closure, π_δ is isomorphic as a cover to the pull-back of an embedding of C into its Jacobian along multiplication by 2. The two-Selmer set classifies the k-isomorphism classes of two-covers of C that have points everywhere locally.

The hyperelliptic involution acts on such covers by pull-back: $\iota^*(\pi_\delta) = \pi_\delta \circ \iota$ (apply ι after π_δ). The *fake* two-Selmer set is the set

$$\{\delta : D_\delta(k_v) \neq \emptyset \text{ for all places } v \text{ of } k\}/\iota^*$$

If this set is empty, then C has no k-rational points. This can happen even if C itself does have points everywhere locally. If the set is non-empty, it gives information about rational points on C. See [BS09] for the underlying theory as well as a description of an algorithm to compute the set.

`TwoCoverDescent(C)`

`Bound`	RngIntElt	*Default :* -1
`Fields`	SetEnum	*Default :*
`Raw`	BoolElt	*Default :* `false`
`PrimeBound`	RngIntElt	*Default :* 0

`PrimeCutoff` RngIntElt *Default :* 0

Computes the fake 2-Selmer set as an abstract set. The map returned as second value can be used to obtain a representation of these abstract elements as ellements in an algebra, which allows explicit construction of the corresponding cover.

The optional parameters `Bound`, `Fields` and `Raw` perform the same function as for `TwoSelmerGroup` and we refer to it for their description. The remaining optional parameters are specific to this routine and we describe them here.

`PrimeBound`: Two covers are of very high genus. Hence, according to the Weil bounds, they can have local obstructions at very large good primes. For instance, for genus 2 one should check all primes up to norm 1153 and for genus 3 one should check all primes up to norm 66553. This is very time consuming. One can use `PrimeBound` to restrict the good primes to be considered to only those whose norm do not exceed the given bound. In principle, this can result in a larger set being returned than the proper two-selmer set.

`PrimeCutoff`: If the curve has bad reduction at some large prime, it can be prohibitively expensive to check the local conditions at this prime. This bound allows a restriction on the norm of bad primes where local conditions are considered. Setting this bound can result in a larger set being returned than the proper two-selmer set.

Example H125E34

As an illustration of `TwoCoverDescent`, we give the Magma-code to perform the computations related to the examples in [BS09]. First we give some examples of genus 2 curves that have points everywhere locally, but have an empty 2-Selmer set and hence have no rational points.

```
> Q:=Rationals();
> Qx<x>:=PolynomialRing( Q );
> C:=HyperellipticCurve(2*x^6+x+2);
> Hk,AtoHk:=TwoCoverDescent(C);
> #Hk;
0
> C:=HyperellipticCurve(-x^6+2*x^5+3*x^4-x^3+x^2+x-3);
> Hk,AtoHk:=TwoCoverDescent(C);
> #Hk;
0
```

In the following we consider a curve of genus 2 that does have rational points. In fact, its Jacobian has Mordell-Weil rank 2. We compute its two-covers with points everywhere locally. There are two. They both cover an elliptic curve over a quadratic extension. We use `Chabauty` following [Bru02] to determine the rational points on C. First we check that we can represent the fake two-Selmer set of the curve with some nice elements.

```
> f:=2*x^6+x^4+3*x^2-2;
> C:=HyperellipticCurve(f);
> Hk,AtoHk:=TwoCoverDescent(C:PrimeBound:=30);
> A<theta>:=Domain(AtoHk);
> deltas:={-1-theta,1-theta};
```

```
> {AtoHk(d): d in deltas} eq Hk;
true
```

Next, we determine a factorisation of f into a quartic and a quadratic polynomial.

```
> L<alpha>:=NumberField(x^2+x+2);
> LX<X>:=PolynomialRing(L);
> g:=(X^2-1/2)*(X^2-alpha);
> h:=2*(X^2+alpha+1);
> g*h eq Evaluate(f,X);
true
```

For some $\gamma = \gamma(\delta)$, we have that a 2-cover D_δ covers the elliptic curve

$$E : y^2 = \gamma\, g(x).$$

This allows us to translate the question about rational points on D_δ into a question about L-rational points on E with the additional property that x is rational. We verify that the two values of δ we found above, correspond to $\gamma = (1 - \alpha)/2$.

```
> LTHETA<THETA>:=quo<LX|g>;
> j:=hom<A->LTHETA|THETA>;
> gamma:=1/2*(-alpha + 1);
> {Norm(j(delta)):delta in deltas} eq {gamma};
true
> E:=HyperellipticCurve( gamma * g );
> P1:=ProjectiveSpace(Rationals(),1);
> EtoP1:=map<E->P1|[E.1,E.3]>;
```

We present E explicitly as an elliptic curve to Magma

```
> P0:=E![1,(1-alpha)/2];
> Eprime,EtoEprime:=EllipticCurve(E,P0);
> Etilde:=EllipticCurve(X^3+(1-alpha)*X^2+(2-9*alpha)*X+(16-2*alpha));
> EprimeToEtilde:=Isomorphism(Eprime,Etilde);
> EtoEtilde:=EtoEprime*EprimeToEtilde;
> EtildeToP1:=Expand(Inverse(EtoEtilde)*EtoP1);
```

We determine a group of finite odd index in $E(L)$.

```
> success,MWgrp,MWmap:=PseudoMordellWeilGroup(Etilde);
> success;
true
> MWgrp;
Abelian Group isomorphic to Z/2 + Z
Defined on 2 generators
Relations:
    2*MWgrp.1 = 0
```

We determine the set of L-rational points on E that have a $\mathbf{Q}$-rational image under `EtildeToP1`.

```
> V,R:=Chabauty(MWmap,EtildeToP1:IndexBound:=2);
> V;
```

```
{
    0,
    MWgrp.1 - MWgrp.2,
    MWgrp.1,
    -MWgrp.2
}
> R;
4
```

Since we found earlier that in this case, there is only one value of γ to consider, we know that any rational point on C must correspond to one of these points on E. The correspondence is given by the fact that E and C both cover the x-line. We determine these points explicitly.

```
> CtoP1 := map< C -> P1 | [C.1,C.3] >;
> pi := Extend( EtildeToP1 );
> { pi( MWmap( v ) ) : v in V };
{ (1 : 1), (-1 : 1) }
> [ RationalPoints( p@@CtoP1 ): p in { P1(Q)| pi( MWmap( v ) ) : v in V } ];
[
    {@ (1 : -2 : 1), (1 : 2 : 1) @},
    {@ (-1 : -2 : 1), (-1 : 2 : 1) @}
]
```

125.14 Chabauty's Method

This is a method for finding the rational points on a curve C of genus at least 2, that applies when the Mordell-Weil group of $Jac(C)$ has rank less than the genus of C. It involves doing local calculations at some prime where C has good reduction.

For (hyperelliptic) curves of genus 2 over $\mathbf{Q}$, two separate routines are available in MAGMA. In the older one, the user specifies the prime, and the results usually do not determine the set of rational points precisely. In the new implementation, which is far more powerful, Chabauty calculations are combined with a "Mordell-Weil sieve" which puts together information obtained using many different primes, to determine precisely the set of rational points on the curve. However, this routine does not apply to curves with no rational points, in fact one rational point must be known, as this plays a role in the algorithm. Both routines require a generator of the Mordell-Weil group of the Jacobian (which must have rank 1) to be provided.

In addition a routine `Chabauty0` is provided to handle the trivial case where the Jacobian has rank 0.

How Chabauty's method works: Under the assumption that the rank of $J = Jac(C)$ is strictly less than the genus of C, the closure V of $J(\mathbf{Q})$ in $J(\mathbf{Q}_p)$ (in the p-adic topology) can be described as the locus where certain power series vanish. The dimension of V is at most the rank of $J(\mathbf{Q})$. The image of C in J (under a natural embedding) will intersect V in a finite set, and this set must contain $C(\mathbf{Q})$. By examining the power series that define this finite intersection, one obtains upper bounds for the number of points on $C(\mathbf{Q})$ in each congruence class modulo p (or any power of p).

`Chabauty0(J)`

Given the Jacobian of a hyperelliptic curve C over $\mathbf{Q}$, the function finds all rational points on C, under the assumption that $J(\mathbf{Q})$ has rank zero.

The assumption is not checked. When it does not hold, the function computes a subset of $C(\mathbf{Q})$ corresponding (in some sense) to the torsion in $J(\mathbf{Q})$.

`Chabauty(P : ptC)`

`ptC` PT *Default :*

For a curve C of genus 2 over $\mathbf{Q}$, this returns the full set of rational points. The algorithm involves Chabauty's method combined with a Mordell-Weil sieve. The argument P should be a rational point on the Jacobian of C, and P is assumed to generate the Mordell-Weil group (which must have rank 1 in order for Chabauty's method to be applicable).

The algorithm requires knowledge of one rational point on the curve. (In particular, it cannot be used to show that a curve has no rational points!) Such a point may be supplied as the optional argument `ptC`; otherwise, one is found by searching.

`Chabauty(P, p: Precision)`

`Precision` RNGINTELT *Default :* 5

Given a point on the Jacobian of a hyperelliptic curve C over $\mathbf{Q}$, the function uses Chabauty's method (at the prime p) to bound the number of rational points on the curve C, The curve must have good reduction at the prime p, and the point P should generate a subgroup of index coprime to p in $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$. The algorithm assumes that C is in the simplified form $y^2 = f(x)$, where f has integral coefficients.

The function returns an indexed set of tuples $\langle x, z, v, k\rangle$ such that there are at most k pairs of rational points on C whose image in P^1 under the x-coordinate map are congruent to $(x : z)$ modulo p^v, and such that the only rational points on C outside these congruences classes are Weierstrass points.

If the optional parameter `Precision` is supplied, then in the returned data each of the v's will be greater than or equal to `Precision`. (This might take some time because the algorithm is not optimised for this.)

Example H125E35

In this example, which continues Example H125E27, we use both implementations of Chabauty to prove that the curve $y^2 = x^6 + x^2 + 2$ has only the obvious six rational points.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+x^2+2);
> ptsC := Points(C : Bound:=1000); ptsC;
{@ (1 : -1 : 0), (1 : 1 : 0), (-1 : -2 : 1), (-1 : 2 : 1),
   (1 : -2 : 1), (1 : 2 : 1) @}
> J := Jacobian(C);
> RankBound(J);
```

```
1
```

So the Jacobian has rank at most 1. Next we ask whether any of the points on C give us points of infinite order on J.

```
> PJ1 := J! [ ptsC[3], ptsC[1] ];
> Order(PJ1);
8
> PJ2 := J! [ ptsC[5], ptsC[1] ];
> Order(PJ2);
0
```

This means $PJ2$ has infinite order in $J(\mathbf{Q})$. In Example H125E27 we proved that $PJ2$ is not divisible in $J(\mathbf{Q})$. Since we now know $J(\mathbf{Q})$ has rank 1, we can conclude that $PJ2$ is a generator of $J(\mathbf{Q})/J(\mathbf{Q})_{tors}$. Therefore we can use it for Chabauty's method.

```
> all_pts := Chabauty(PJ2); all_pts;
{ (1 : -2 : 1), (-1 : -2 : 1), (1 : 2 : 1),
  (1 : -1 : 0), (1 : 1 : 0), (-1 : 2 : 1) }
```

So we find that we already had the full set of rational points. We could have reached the same conclusion using the other implementation of Chabauty, where we specify that the method be applied at the prime 3 (the most natural choice, since it is the smallest prime of good reduction).

```
> BadPrimes(C);
[ 2, 7 ]
> Chabauty(PJ2, 3);
{@ <1, 1, 4, 1>, <80, 1, 4, 1>, <1, 0, 4, 1> @}
```

This tells us that there are at most 3 pairs of rational points on C, apart from Weierstrass points. In fact, one can easily check that there are no rational Weierstrass points. Therefore, the 6 known points are the only rational points on C.

Example H125E36

In this example we show that there are precisely 6 rational points on the curve $y^2 = x^6 + 8$.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+8);
> ptsC := Points(C : Bound:= 1000); ptsC;
{@ (1 : -1 : 0), (1 : 1 : 0), (-1 : -3 : 1), (-1 : 3 : 1),
   (1 : -3 : 1), (1 : 3 : 1) @}
> J := Jacobian(C);
> PJ := J! [ ptsC[5], ptsC[1]];
> Order(PJ);
0
> RankBound(J);
1
```

This shows that $J(\mathbf{Q})$ has rank 1, and PJ has infinite order. Now we check that PJ generates $J(\mathbf{Q})/J_{tors}(\mathbf{Q})$. (For more explanation, see the similar calculation in Example H125E27).

```
> heightconst := HeightConstant(J : Effort:=2, Factor);
```

```
> LogarithmicBound := Height(PJ) + heightconst;  // Bound on h(Q)
> AbsoluteBound := Ceiling(Exp(LogarithmicBound));
> PtsUpToAbsBound := Points(J : Bound:=AbsoluteBound );
> ReducedBasis([ pt : pt in PtsUpToAbsBound ]);
[ (x^2 - x + 1, 3, 2) ]
[0.32661733877148842826007676859 0]
> Height(PJ);
0.32661733877148842826007676859 0
```

This shows there are no points in $J(\mathbf{Q})$ with canonical height smaller than that of PJ, so PJ is a generator modulo torsion and we may use it for Chabauty's method.

```
> all_pts := Chabauty(PJ : ptC:=ptsC[1]); all_pts;
{@ (1 : -1 : 0), (-1 : -3 : 1), (1 : 3 : 1),
   (-1 : 3 : 1), (1 : -3 : 1), (1 : 1 : 0) @}
```

Example H125E37

In Example H125E29 (in the section on 2-Selmer groups) we found a curve of rank 2. Although we cannot apply Chabauty's method to get information about the full set of rational points on C, we can still apply the routines to find all points on C whose images on J lie in a given subgroup of rank 1.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve( x*(x+1344^2)*(x+10815^2)*(x+5406^2)*(x+2700^2) );
> J := Jacobian(C);
> ptsC := Points(C : Bound := 10^6); ptsC;
{@ (1 : 0 : 0), (0 : 0 : 1), (43264 : -44828581639628800 : 1),
   (43264 : 44828581639628800 : 1) @}
> PJ := J! [ ptsC[3], ptsC[1] ]; Order(PJ);
0
```

Now we find all the points $P \in C(\mathbf{Q})$ for which the image $P - P_0 \in J(\mathbf{Q})$ lies in the subgroup generated by PJ, where P_0 denotes `ptsC[1]`.

```
> pts := Chabauty(PJ : ptC:=ptsC[1] ); pts;
{ (-1806336 : 0 : 1), (0 : 0 : 1), (43264 : 44828581639628800 : 1),
  (1 : 0 : 0), (-29224836 : 0 : 1), (-7290000 : 0 : 1),
  (-116964225 : 0 : 1), (43264 : -44828581639628800 : 1) }
```

Example H125E38

We find all rational points on $y^2 = x^6 + 1$, whose Jacobian J has rank 0, ie the group $J(\mathbf{Q})$ is finite.

```
> _<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^6+1);
> J := Jacobian(C);
> RankBound(J);
0
```

```
// So we may use Chabauty0.
> Chabauty0(J);
{@ (1 : -1 : 0), (1 : 1 : 0), (0 : 1 : 1), (0 : -1 : 1) @}
```

This Selmer computation required class/unit computations in the fields given by roots of $x^6 + 1$. In this example, there's clearly an approach requiring less work: to use the self-evident map from C to the elliptic curve $y^2 = x^3 + 1$, which has rank 0.
To define the map, we need to refer to the space where C lives, which is a weighted projective space in which Y has weight 3.

```
> E := EllipticCurve([0,1]);
> Pr2<X,Y,Z> := Ambient(C);
> CtoE := map< C -> E | [X^2*Z,Y,Z^3] >;
```

The map is well-defined (otherwise MAGMA would have already complained).

```
> CtoE;
Mapping from: CrvHyp: C to CrvEll: E
with equations :
X^2*Z
Y
Z^3
```

Now find the rational points on E.

```
> Rank(E);
0
> #TorsionSubgroup(E);
6
> ptsE := Points(E : Bound:=100 ); ptsE;
{@ (0 : 1 : 0), (-1 : 0 : 1), (0 : 1 : 1), (0 : -1 : 1),
(2 : 3 : 1), (2 : -3 : 1) @}
```

So, these are all the rational points on E. We can see with the naked eye that only those with $X = 0$ pull back to rational points on C, giving us the same six points on C that we found before. Of course, we could instead ask MAGMA to pull them back:

```
> for P in ptsE do
>     preimageofP := P @@ CtoE;
>     Points(preimageofP);
> end for;
{@ (1 : -1 : 0), (1 : 1 : 0) @}
{@ @}
{@ (0 : 1 : 1) @}
{@ (0 : -1 : 1) @}
{@ @}
{@ @}
```

125.15 Cyclic Covers of $\mathbf{P}^1$

A q-cyclic cover of the projective line is a curve C which admits a degree q morphism to $\mathbf{P}^1$ such that the associated extension of function fields is (geometrically) cyclic. By Kummer theory, such a curve has an affine model of the form $y^q = f(x)$ (at least when the base field contains the q-th roots of unity). This class of curve includes hyperelliptic curves. Current functionality for cyclic covers includes testing local solubility, searching for points and performing descents on curves and their Jacobians when they are defined over a number field.

Most functionality is implemented in the cases where $f(x)$ is a separable polynomial of arbitrary degree and q is prime. One notable exception is that the method of descent on the curve is available for any $f(x)$ that is q-th power free.

125.15.1 Points

A point on a cyclic cover $C : y^q = f_d x^d + f_{d-1}x^{d-1} + ... + f_0$ is specified by a triple representing a point in the appropriate weighted projective plane.

When $d = \text{Degree}(f(x))$ is divisible by q, we consider points the weighted projective plane $\mathbf{P}^2(1 : d/q : 1)$. In this case a point is represented by a triple $[X, Y, Z]$ satisfying

$$Y^q = f_d X^d + f_{d-1}X^{d-1}Z + ... + f_0 Z^d.$$

When $d = \text{Degree}(f(x))$ is not divisible by q, we consider points in the weighted projective plane $\mathbf{P}^2(q : d : 1)$. In this case a point is represented by a triple $[X, Y, Z]$ satisfying

$$Y^q = f_d X^d + f_{d-1}X^{d-1}Z^q + ... + f_0 Z^{dq}.$$

`RationalPoints(f,q)`

`Bound`	RngIntElt	*Default :* 0
`DenominatorBound`	RngIntElt	*Default :* 0
`NPrimes`	RngIntElt	*Default :* 0

For a polynomial f defined over a number field (or $\mathbf{Q}$) this Searches for rational points on the curve $y^q = f(x)$ in a box bounded by `Bound` (which must be specified). Returns a set of triples (x, y, z) satisfying $y^q = F(x, z)$ where $F(x, z)$ is the homogenisation of $f(x)$ taking x to have weight LCM(q,Degree($f(x)$))/Degree($f(x)$).

The search is by a sieve method described in Appendix A of [Bru02]. The parameter `NPrimes` controls the number of primes which are used and `DenominatorBound` the size of the denominators used.

`HasPoint(f,q,v)`

`HasPoint(f,q,v)`

For a polynomial f defined over a number field k, this checks if the curve defined by $y^q = f(x)$ has any points over the completion k_v. The second return value is a triple of elements in the completion of k at v giving a point on the curve. The triple

(x, y, z) returned satisfies $y^q = F(x, z)$ where $F(x, z)$ is the homogenisation of $f(x)$ taking x to have weight LCM(q,Degree($f(x)$))/Degree($f(x)$).

The current implementation for testing local solubility of cyclic covers is polynomial time in the cardinality of the residue field, making it somewhat impractical for larger primes.

`HasPointsEverywhereLocally(f,q)`

For a polynomial f defined over a number field k, this returns true if and only if the curve $y^q = f(x)$ has points over all nonarchimedean completions of k.

125.15.2 Descent

Let C be a curve with Jacobian J and suppose $\psi : A \to J$ is an isogeny of abelian varieties. We say that a morphism of curves $\pi : D \to C$ is a ψ-covering of C if, over an algebraic closure, π is isomorphic as a cover to the pull-back of an embedding of C into J along ψ.

Now suppose that $C : y^q = f(x)$ is a q-cyclic cover of the projective line defined over a number field k. Any primitive q-th root of unity ζ gives rise to an automorphism: ι sending a point (x, y) to $(x, \zeta y)$. This induces an automorphism of the Jacobian. Hence the endomorphism ring of the Jacobian contains the cyclotomic ring $\mathbf{Z}[\zeta]$, and in particular the endomorphism $\phi = 1 - \zeta$. The ϕ-Selmer set of C classifies isomorphism classes of ϕ-coverings of C which are everywhere locally soluble. There is an action of ι on these coverings. The quotient by this action is known as the fake ϕ-Selmer set of C. If this set is empty, then C has no k-rational points. This can happen even if C itself has points everywhere locally. Even when this set is non-empty, it gives information about rational points on C. When $q = 2$, ϕ is multiplication by 2, in which case the ϕ-Selmer set is the same as the 2-Selmer set described in `TwoCoverDescent`.

`qCoverDescent(f,q)`

`PrimeBound`	RngIntElt	*Default :* 0
`PrimeCutOff`	RngIntElt	*Default :* 0
`KnownPoints`	Set	*Default :*
Verbose	`CycCov`	*Maximum :* 3

Computes the fake ϕ-Selmer set of the cyclic cover $C : y^q = f(x)$ as an abstract set. The first return value is the fake ϕ-Selmer set given as a subset of the cartesian product of number fields having defining polynomials the irreducible factors of f. The map returned is from this cartesian product into the abstract group $A(S, q)$ involved in the computation (the unramified outside S subgroup of the quotient of the etale algebra associated to the ramification points of C by the subgroup generated by scalars and q-th powers).

The input `f` must be a q-th power free polynomial defined over a number field k with class number 1.

The optional parameters `PrimeBound` and `PrimeCutoff` have the same meaning as those used the `TwoCoverDescent` for hyperelliptic curves. Only good primes up to `PrimeBound` and bad primes up to `PrimeCutoff` will be considered in the local

computations. If either of these parameters is not set to default, the set returned might be strictly larger than the fake ϕ-Selmer set.

One can obtain a lower bound for the size of the ϕ-Selmer set by considering the images of known global points on C. This often speeds up the computation considerably as the first few primes might be sufficient to show that the ϕ-Selmer set is equal to the set of images of the known rational points. A set of known points may be passed in using the parameter `KnownPoints`. These should be given as triples of the type returned by `RationalPoints`.

Example H125E39

The following computation shows that the genus 15 curve defined by the equation $y^7 = 2x^7 + 6$ has no rational points even though it is everywhere locally solvable.

```
> _<x> := PolynomialRing(Rationals());
> RationalPoints(3*x^7+6,7 :  Bound := 1000);
{@ @}
> HasPointsEverywhereLocally(3*x^7+6,7);
true
> time Sel := qCoverDescent(3*x^7+6,7 : PrimeBound := 1000);
Time: 0.450
> Sel;
{}
```

125.15.3 Descent on the Jacobian

Suppose J is the Jacobian of the cyclic cover C defined by $y^q = f(x)$ over a field k containing the q-th roots of unity. If k is a number field, then the ϕ-Selmer group of J is a finite group which contains $J(k)/\phi(J(k))$. Computing the ϕ-Selmer group can be used to give an upper bound for the rank of $J(k)$. In the case $q = 2$, this reduces to the 2-Selmer group computed with `TwoSelmerGroup`.

For q prime the ϕ-Selmer group may be computed using an algorithm of Poonen-Schaefer [PS97]. Their algorithm actually computes a fake Selmer group, which is a quotient of the true Selmer group by a subgroup of order dividing q.

When the base field does not contain the q-th roots of unity, one still obtains information by computing the ϕ-Selmer group over the cyclotomic extension. For details see [PS97], or consider the example below.

`PhiSelmerGroup(f,q)`

`ReturnRawData`	BoolElt	*Default :* `false`
Verbose	`Selmer`	*Maximum :* 3

For a polynomial f over a number field k, ths computes the (fake) ϕ-Selmer group of the Jacobian of the curve $y^q = f(x)$ over the field $k(\mu_q)$ obtained by adjoining the q-th roots of unity to k. The polynomial $f(x)$ must be separable and q must be prime.

There are two steps in the algorithm which may require a significant amount of time: the first is the computation of class groups of the extensions of $k(\mu_q)$ given by the irreducible factors of $f(x)$; the second is the computation of the local images of the descent map at the prime(s) above q.

The (fake) Selmer group is returned as a finite abelian group S, together with a map from S to some affine algebra A, which represents the standard map from the Selmer group to $A^*/k^*(A^*)^q$ or to $A^*/(A^*)^q$ correspondingly as the degree of $f(x)$ is or is not divisible by q.

When called with `ReturnRawData` the program will yield three additional return values, `expvecs`, `factorbase` and `selpic1`. The first two are used to specify the images in $A^*/k^*(A^*)^q$ of the (fake) Selmer group generators (in unexpanded form). This is done exactly as for `TwoSelmerGroup`. `selpic1` is an element of the supergroup containing the (fake) Selmer group, or it is the empty set. This specifies the coset of the (fake) Selmer group corresponding to the (fake) Selmer set of the Pic^1 torsor as described in [Cre12]. When the curve has points everywhere locally this determines whether or not the torsor is divisible by ϕ in Sha, which in turn yields more information on the rank.

`RankBound(f,q)`

`RankBounds(f,q)`

`ReturnGenerators`	BoolElt	*Default :* `false`
Verbose	`Selmer`	*Maximum :* 3

An upper (or a lower and upper) bound for the rank of the Jacobian of the cyclic cover defined by $y^q = f(x)$. The upper bound is obtained by performing a descent as described above and incorporates the information on the Pic^1 torsor thus obtained. The lower bound is obtained by a naive (and rather inefficient) search for divisors on the curve.

If the optional parameter `ReturnGenerators` is set to `true`, then a third value will be returned. This will be a list of univariate polynomials defining divisors on $\mathbf{P}^1$ that lift to divisors on the curve. The images of these in the Mordell-Weil group generate a subgroup of rank at least as large as the lower bound provided. Independence of these points is determined by considering their images in the (fake) Selmer group.

Example H125E40

In this example we use descents to determine both the rank of the Mordell-Weil group and the 3-primary part of Sha for the Jacobian J of a genus 4 curve C over the rationals.

```
> _<x> := PolynomialRing(Rationals());
```

```
> f := 3*(x^6 + x^4 + 4*x^3 + 2*x^2 + 4*x + 3);
> k := CyclotomicField(3);
> IsIrreducible(PolynomialRing(k)!f);
true
> SelJ,m,expvecs,fb,SelPic1 := PhiSelmerGroup(f,3 : ReturnRawData);
> Ilog(3,#SelJ);
2
```

In this example the map from the genuine Selmer group to the fake Selmer group has a kernel of order 3. This is because f has degree divisible by $q = 3$ and is irreducible. Hence the ϕ-Selmer group has 3-rank 3. The fact that f is irreducible also implies that there is no nontrivial ϕ-torsion on J defined over k. Thus the ϕ-Selmer group gives an upper bound of $2 * 3 = 6$ for the rank of J over k and an upper bound of 3 for the rank over $\mathbf{Q}$ (see [PS97]). We can use the information about the Pic^1 torsor to get a better bound

```
> HasPointsEverywhereLocally(f,3);
true
> SelPic1;
{}
```

This means that the Pic^1 torsor represents a ϕ-torsion class in the Shafarevich-Tate group of J that is not divisible by ϕ. In particular it is nontrivial, and because the Cassels-Tate pairing is alternating this imples the ϕ-torsion subgroup of Sha contains a nontrivial subgroup with even 3-rank. Hence, we deduce that $J(k)/\phi(J(k))$ has 3-rank at most $3 - 2 = 1$, and consequently that $J(\mathbf{Q})$ has rank ≤ 1. Calling `RankBounds` will deduce these bounds, and search for generators to obtain a lower bound.

```
> r_l, r_u, gens := RankBounds(f,3 : ReturnGenerators);
> [r_l,r_u];
[1,1]
> gens;
[*
    T^3 - T^2 + 4*T + 4
*]
```

This polynomial defines a divisor on $\mathbf{P}^1$ that lifts to a degree 3 divisor D on $C : y^3 = f(x)$. One way to verify this is the following:

```
> K := NumberField(gens[1]);
> IsPower(Evaluate(f,K.1),3);
true 1/4*(-3*K.1^2 + 9*K.1 + 6)
```

Let D_0 denote the pullback of some point $P \in \mathbf{P}^1$ under the degree 3 map $C \to \mathbf{P}^1$. Then $D - D_0$ is a degree 0 defined over the rationals. According to `RankBounds` its class has infinite order in $J(\mathbf{Q})$. This was determined by considering its image under the composition, $J(\mathbf{Q}) \to J(k) \to Sel^{\phi}(J/k)$. Since there is no nontrivial ϕ-torsion, this amounts to saying that the image is nontrivial. We can verify this with the following computations (carried out internally by `RankBounds`).

```
> A<theta> := Domain(m); // the algebra representing Sel
> D := Evaluate(gens[1],theta);
> imD := m(D);
> assert imD ne SelJ!0;
```

```
> assert imD in SelJ;
```

Since the rank over **Q** has been computed unconditionally it follows that the ϕ-torsion subgroup of Sha is isomorphic to $(\mathbf{Z}/3)^2$, and since it contains a element not divisible by ϕ in Sha one can deduce that the 3-primary part of Sha is also isomorphic to $(\mathbf{Z}/3)^2$.

125.15.4 Partial Descent

The (fake) ϕ-Selmer set of the curve $C : y^q = f(x)$ defined over a number field k is computed using a map which sends a point (x, y) of C to $x - \theta$, where θ is a generic root of f. This map takes values in the product of the extensions of k defined by the irreducible factors of $f(x)$. More generally one can specify a partial descent map as follows. For each irreducible factor $f_i(x)$ of $f(x)$, fix an extension K_i/k and an irreducible factor $h_i(x) \in K_i[x]$ of $f_i(x)$. The map sending (x, y) to $(h_1(x), ..., h_n(x))$ induces a well defined map from $C(k)$ to an appropriate quotient of the units in the product of the K_i. A partial descent computes the set of elements which restrict into the image of $C(k_v)$ for every prime v of k. This set gives information on the set of rational points of C. If it is empty, then the curve has no rational points.

Geometrically this set can be understood as follows. The coverings parameterised by the ϕ-Selmer set are Galois covers of C with group isomorphic (as a Galois module) to the ϕ-torsion subgroup of the Jacobian. By Galois theory, any Galois submodule gives rise to intermediate coverings. A partial descent computes a set of everywhere locally solvable intermediate coverings corresponding to some Galois submodule of $J[\phi]$.

`qCoverPartialDescent(f,factors,q)`

`PrimeBound`	RngIntElt	*Default :* 0
`PrimeCutoff`	RngIntElt	*Default :* 0
`KnownPoints`	Set	*Default :*
Verbose	`CycCov`	*Maximum :* 3

Performs a partial descent on the curve $y^q = f(x)$ with respect to the descent map given by `factors`. The map returned is from this cartesian product into the abstract group $A(S, q)$ involved in the computation (the unramified outside S subgroup of the quotient of the etale algebra associated to the orbits of ramification points of C determined by `factors` by the subgroup generated by scalars and q-th powers).

The input `f` must be a separable polynomial defined over a number field k with class number 1. For each irreducible factor $h_i \in k[x]$ of f, the list `factors` must contain an irreducible factor of h_i defined over some (possibly trivial) extension of k. The optional parameters are the same as for `qCoverDescent`.

Example H125E41

Consider the cyclic cover $D : y^3 = 3(x^2+1)(x^2+17)(x^2-17)$.

```
> _<x>:=PolynomialRing(Rationals());
> f := 3*(x^2+1)*(x^2+17)*(x^2-17);
> pts := RationalPoints(f,3 : Bound:=100);
> pts;
{@
    [ -1, -12, 1 ],
    [ 1, -12, 1 ]
@}
```

So this appears to have only two rational points. We now apply partial descent by only factorising the third factor as follows:

```
> K<th> := NumberField(x^2-17);
> factor := Factorisation(x^2-17,K)[1,1];
> time selmerset, algebra:=qCoverPartialDescent(
>  3*(x^2+1)*(x^2+17)*(x^2-17),[*x^2+1,x^2+17,factor*],3
>  : KnownPoints := pts, PrimeBound := 1000 );
Time: 0.530
> selmerset;
{
    <1, 9, $.1 + 9>,
    <1, 9, 2*$.1 + 2>
}
> delta := <1,9,2+2*th>;
```

Each element of `selmerset` corresponds to a covering of D and every rational point on D lifts to one of these two coverings. For example δ corresponds to a covering Y_δ of D with defining equations

$$\lambda^2 y_1^3 = x^2 + 1,$$

$$9\lambda^2 y_2^3 = x^2 + 17,$$

$$(2\theta + 2)\lambda y_3^3 = x - \theta,$$

where θ is a square root of 17. This covering of D also evidently covers the genus one curve defined over $\mathbf{Q}(\theta)$,

$$C : (2\theta + 2)v^3 = (x^2 + 1)(x - \theta)\,.$$

One can now use the method of Elliptic Curve Chabauty to find all points of $Y_\delta(K)$ which map to points of $D(\mathbf{Q})$. Namely any such point gives rise to a point of $C(K)$ with x-coordinate in $\mathbf{Q}$. Provided we can obtain generators for $C(K)$, such points can be determined using `Chabauty`.

```
> P2<x,v,w>:=ProjectivePlane(K);
> C:=Curve(P2, -(delta[3])*v^3 + (x^2+w^2)*(x-th*w) );
> E,CtoE:=EllipticCurve(C);
> twotors := TorsionSubgroup(E);
> #twotors;
1
```

```
> covers,coverstoE:=TwoDescent(E);
> #covers;
1
> cover:=covers[1];
> covertoE:=coverstoE[1];
> pts:={@pt@covertoE : pt in RationalPoints(cover : Bound:=100)@};
> pts;
{@ (1/128*(-153*th + 1377) : 1/1024*(-8109*th + 28917) : 1),
(1/128*(-153*th + 1377) : 1/1024*(6885*th - 17901) : 1),
(1/194688*(-171346689*th + 708942857) : 1/60742656*(-4566609746937*th
    + 18826158509345) : 1), (1/194688*(-171346689*th + 708942857) :
1/60742656*(4566537140481*th - 18825505051241) : 1) @}
> gen := pts[1];
```

This shows that $E(K) \simeq \mathbf{Z}$, so `gen` generates a finite index subgroup.

```
> A:=FreeAbelianGroup(1);
> AtoE:=map<A -> E | elt :-> Eltseq(elt)[1]*gen >;
```

To apply Chabauty, we want to use a map $E \to \mathbf{P}^1$ such that the composition $C \to E \to \mathbf{P}^1$ sends (x, v, w) to x.

```
> P1:=ProjectiveSpace(Rationals(),1);
> CtoE;
Mapping from: CrvPln: C to CrvEll: E
with equations :
1/16*(9*th - 153)*v
1/128*(-729*th + 1377)*x
-1/17*th*x + w
and inverse
th*$.2
1/16*(-9*th + 153)*$.1
$.2 + 1/128*(1377*th - 12393)*$.3
> EtoP1:=map<E -> P1 | [th*E.2,E.2 + 1/128*(1377*th - 12393)*E.3]>;
> Chabauty(AtoE,EtoP1);
{
    -A.1
}
126
> Chabauty(AtoE,EtoP1 : IndexBound:=126);
{
    -A.1
}
126
> pointC:= (-A.1)@AtoE@@CtoE;
> pointC;
(-1 : -1 : 1)
```

Any preimage of this point on Y_δ has $x = -1$, and as such must lie above $(-1, -12) \in D(\mathbf{Q})$. A similar argument proves that the only rational point coming from the other element of the partial Selmer set is $(1, -12)$, proving $D(\mathbf{Q}) = \{(1, 12), (-1, -12)\}$.

125.16 Kummer Surfaces

The Kummer surface K associated to the Jacobian J of a genus 2 curve is the quotient of J by the inverse map. It can be embedded as a quartic hypersurface in projective 3-space whose only singularities are 16 ordinary double points. The Jacobian is a double cover of K ramified at these double points; they are the images of the two-torsion points on J. Resolving the singularities on K yields a $K3$-surface.

Currently, Kummer surfaces in MAGMA are not schemes, but are of type SrfKum. They can be used to perform arithmetic on the Jacobian without the need for reduction of divisors. The other nontrivial functionality that uses them is point searching.

The Kummer surface and arithmetic on it are implemented for Jacobians in arbitrary characteristic following [Mül10b] which extends earlier work by Flynn, described in chapter 3 of [CF96].

125.16.1 Creation of a Kummer Surface

`KummerSurface(J)`

The Kummer surface of the Jacobian J of a genus 2 curve.

125.16.2 Structure Operations

`DefiningPolynomial(K)`

The defining polynomial of the Kummer surface K.

125.16.3 Base Ring

`BaseField(K)`

`BaseRing(K)`

`CoefficientRing(K)`

The base field of the Kummer surface K.

125.16.4 Changing the Base Ring

`BaseChange(K, F)`

`BaseExtend(K, F)`

Extends the base field of the Kummer surface K to the field F.

`BaseChange(K, j)`

`BaseExtend(K, j)`

Extends the base field of the Kummer surface K by the map j, where j is a ring homomorphism with the base field of C as its domain.

`BaseChange(K, n)`

`BaseExtend(K, n)`

Extends the finite base field of the Kummer surface K over a finite field to the degree n extension.

125.17 Points on the Kummer Surface

Points are given by their projective coordinates, normalized depending on the base field.

125.17.1 Creation of Points

`K ! 0`

Returns the image of the identity element on the Kummer surface K, which is normalized to be the origin $(0 : 0 : 0 : 1)$.

`K ! [x1, x2, x3, x4]`

Returns the point on the Kummer surface K defined by the projective coordinates x_1, x_2, x_3, and x_4.

`K ! P`

Given a point P on the Jacobian of K, or on a Kummer surface for which K is a base extension, this returns the point on K.

`IsPoint(K, S)`

Given a sequence $S = [x_1, x_2, x_3, x_4]$ of elements of the base field of K, the function returns `true` if the point specified by the sequence defines the homogeneous coordinates of a point on the Kummer surface K. If so, the corresponding point on K is returned as the second value.

`Points(K,[x1, x2, x3])`

Returns the indexed set of points on the Kummer surface K with first three coordinates given by the sequence $[x_1, x_2, x_3]$.

125.17.2 Access Operations

`P[i]`

Returns the i-th coordinate of the point P, for $1 \leq i \leq 4$.

`Eltseq(P)`

`ElementToSequence(P)`

Given a point P on a Kummer surface, the function returns the coordinates of P as a sequence.

125.17.3 Predicates on Points

`P eq Q`

Given two points on the same Kummer surface, this returns `true` if and only if the points P and Q are equal.

`P ne Q`

Given two points on the same Kummer surface, this returns `false` if and only if the points P and Q are equal.

125.17.4 Arithmetic of Points

`-P`

Returns the negation of the point P on the Kummer surface, equal to P itself.

`n * P`

`P * n`

Returns the n-th multiple of the point P on the Kummer surface K.

`Double(P)`

Returns the double $2 * P$ of the point P.

`PseudoAdd(P1, P2, P3)`

Let P and Q be points on the Jacobian J of a genus 2 curve. Given the images P_1, P_2, and P_3 on the Kummer surface of points P, Q, and $P - Q$ on J, the function returns the image of $P + Q$.

`PseudoAddMultiple(P1, P2, P3, n)`

Let P and Q be points on the Jacobian J of a genus 2 curve. Given the images P_1, P_2, and P_3 on the Kummer surface of points P, Q, $P - Q$ on J, the function returns the image of $P + n * Q$.

125.17.5 Rational Points on the Kummer Surface

`RationalPoints(K, Q)`

Given the Kummer surface of the Jacobian of a genus 2 hyperelliptic curve defined over a ring R and sequence Q of three elements of R, the function returns an indexed set containing those points on K whose first three coordinates correspond to the three terms of Q.

Example H125E42

We search for some points on the Kummer surface of the hyperelliptic curve $y^2 = x^5 - 7$ defined over the rational field.

```
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^5-7);
> Genus(C);
2
> J := Jacobian(C);
> K := KummerSurface(J);
> K;
Kummer surface of Jacobian of Hyperelliptic Curve defined by
    y^2 = x^5 - 7 over Rational Field
> Points(K, [0,1,2]);
{@ (0 : 1 : 2 : 4) @}
> Points(K, [1,3,2]);
{@ @}
> Points(K, [0,1,3]);
{@ (0 : 1 : 3 : 9) @}
```

125.17.6 Pullback to the Jacobian

`Points(J, P)`

`RationalPoints(J, P)`

Given a point P on the Kummer surface associated to the Jacobian J (of a genus 2 curve), the function returns the indexed set of points on J mapping to P.

125.18 Analytic Jacobians of Hyperelliptic Curves

This section contains descriptions of functions pertaining to the creation and use of analytic Jacobians for hyperelliptic curves.

Suppose C is a curve of genus g defined over the complex numbers. The analytic Jacobian of the curve is an abelian torus and is constructed as follows: We view the complex points on the curve, $C(\mathbf{C})$, as a compact Riemann surface of genus g. It is known that the dimension of the vector space of holomorphic differentials is equal to the genus of the curve. So let ϕ_i, $i = 1, 2, \ldots, g$ be a basis for this vector space and set $\overline{\phi} = {}^t(\phi_1, \ldots, \phi_g)$, a vector of holomorphic 1-forms. For a hyperelliptic curve there is a natural choice of holomorphic differentials, namely $\phi_i = x^{i-1}dx/y$. We can now define a mapping $\mathrm{Int} : C \to \mathbf{C}^g$ by

$$P \mapsto \int_P^\infty \overline{\phi}.$$

To remove the dependency of this mapping on the path of integration, we define Λ to be the image of the map from the first homology group of C, $H_1(C, \mathbf{Z})$, to $\mathbf{C}^g$ which sends a closed path, $\sigma \in H_1(C, \mathbf{Z})$, on the Riemann surface to $\int_\sigma \overline{\phi}$. Then Λ turns out to be a lattice in $\mathbf{C}^g$ and so we get the complex torus $\mathbf{C}^g/\Lambda$. We then see that Int is a well-defined mapping from C into $\mathbf{C}^g/\Lambda$. We extend this mapping additively to the divisors of degree zero on C. The Abel part of the Abel-Jacobi theorem states that two divisors map to the same image under Int if and only if they are linearly equivalent. The Jacobi part of the theorem asserts that the map is onto. So there is a bijection between the points of $\mathbf{C}^g/\Lambda$ and the points of the (algebraic) Jacobian.

So far the analytic Jacobian $\mathbf{C}^g/\Lambda$ is just a torus, but it can be made into an abelian manifold by choosing a polarization. Let $A_1, \ldots, A_g, B_1, \ldots, B_g$ be a symplectic homology basis. That is, the A_i and B_i are closed paths on the Riemann surface such that all intersection numbers are 0 except that A_i intersects B_i with intersection number 1 for each i. Let ω_1 and ω_2 be the $g \times g$-matrices with entries

$$\omega_{1ij} = \int_{B_j} \phi_i,$$

and

$$\omega_{2ij} = \int_{A_j} \phi_i.$$

Then the columns of $P = (\omega_1, \omega_2)$ form a $\mathbf{Z}$-basis for the lattice $\Lambda = P\mathbf{Z}^{2g}$. The matrix P is called the (big) period matrix. The space of complex, symmetric $g \times g$ matrices with positive definite imaginary part is called the Siegel upper-half space of degree g. Because we chose a symplectic basis for the homology it follows that $\tau = \omega_2^{-1}\omega_1$ is an element of Siegel upper half-space. We will refer to τ as the small period matrix.

Set

$$J = \begin{pmatrix} 0 & \mathbf{1}_g \\ -\mathbf{1}_g & 0 \end{pmatrix}.$$

If we define

$$E(Px, Py) = {}^t x J y,$$

for any $x, y \in \mathbf{R}^{2g}$, then E is a Riemann form for the torus $\mathbf{C}^g/\Lambda$ and so the torus acquires a polarization. The existence of a Riemann form on a torus is a necessary and sufficient condition for the torus to be embeddable into projective space. The image is isomorphic to the (algebraic) Jacobian.

In order for the theory describing the map from the analytic Jacobian to the algebraic Jacobian (see Mumford [Mum84]) to work we actually need a special symplectic basis linked to a particular ordering of the roots of the hyperelliptic polynomial. For an example of such a basis see Mumford [Mum84, Chap III.5]. The basis used can be obtained using the function `HomologyBasis` and the roots in the corresponding order are stored as the attribute `A'Roots` (where `A` is an analytic Jacobian).

125.18.1 Creation and Access Functions

`AnalyticJacobian(f)`

Given $f \in \mathbf{C}[x]$ where $\mathbf{C}$ is a complex field (see Chapter 25), this function returns the analytic Jacobian of the hyperelliptic curve defined by $y^2 = f(x)$. The polynomial must have degree at least 3 and the complex field precision at least 20 and, for the moment, less than 2000.

`HyperellipticPolynomial(A)`

Returns the polynomial defining the hyperelliptic curve whose Jacobian is A.

`SmallPeriodMatrix(A)`

The small period matrix of the analytic Jacobian A. If A has dimension g or equivalently the hyperelliptic curve has genus g, then this is a symmetric $g \times g$ matrix with positive definite imaginary part. If $P = (\omega_1, \omega_2)$ is the full period matrix (see `BigPeriodMatrix`) then the small period matrix is defined by $\omega_2^{-1}\omega_1$.

`BigPeriodMatrix(A)`

The full period matrix of the hyperelliptic curve of the Jacobian A. If A has dimension g or equivalently the hyperelliptic curve has genus g, then this is a $g \times 2g$ matrix. The analytic Jacobian as a torus equals $\mathbf{C}^g/\Lambda$, where Λ is the $\mathbf{Z}$-lattice spanned by the columns of the period matrix. The period matrix is computed with respect to the holomorphic differentials $\phi_i = x^{i-1}dx/y$ and a symplectic basis for the homology that can be retrieved using `HomologyBasis`.

`HomologyBasis(A)`

The symplectic homology basis used for the computation of the period matrix of the Jacobian A. First assume that `HyperellipticPolynomial(A)` has odd degree. The function `HomologyBasis(A)` returns three values which we label `basepoints`, `loops` and `S`. Then `basepoints` is a list of points in the complex plane. The return value`loops` is a list of $2g$ lists of indices into `basepoints`. So the list `[i1, i2, i3, ...]` corresponds to the loop consisting of joining the straight lines from `basepoints[in]` to `basepoints[in+1]` for `i` $= 1, 2, \ldots$. These closed loops form a

homology basis for the curve but probably not a symplectic basis. The third return value, S, is a matrix giving the linear combinations of the loops that were used to form a symplectic homology basis and to compute the period matrix.

If HyperellipticPolynomial(A) has even degree then the returned homology basis is not for the Riemann surface for this curve, but for the curve of odd degree obtained by sending $a =$ A`InfiniteRoot to infinity through the linear fractional transformation given by $x \mapsto 1/(x-a)$. So one needs to apply the inverse transformation to the returned basis in order to get the basis that was used to compute the period matrix.

Dimension(A)

Genus(A)

The dimension of the Jacobian A as a complex abelian variety. This is equal to the genus of the curve C for which A is the Jacobian.

BaseField(A)

BaseRing(A)

CoefficientRing(A)

The base field of the Jacobian A.

125.18.2 Maps between Jacobians

ToAnalyticJacobian(x, y, A)

Let A be the analytic Jacobian of $y^2 = f(x)$. This function maps the point (x, y) on the curve to the analytic Jacobian. More precisely, let $a = \infty$ when HyperellipticPolynomial has odd degree and $a =$A`InfiniteRoot otherwise. Then it maps the divisor $(x, y) - (a, 0)$ to the analytic Jacobian. As any point on the algebraic Jacobian is simply a sum of such divisors, we can get its image by linearity of the map. The function returns a $g \times 1$ matrix. This should be thought of as an element of $\mathbf{C}^g/\Lambda$ where Λ is the $\mathbf{Z}$-lattice generated by the columns of the BigPeriodMatrix.

FromAnalyticJacobian(z, A)

Let A be an analytic Jacobian of $y^2 = f(x)$, with small period matrix τ. Let z be a $g \times 1$ complex matrix (thought of as an element of $\mathbf{C}^g/\Lambda$ where Λ is the $\mathbf{Z}$-lattice generated by the columns of the BigPeriodMatrix). This function returns a list of g (the dimension of A), or fewer, pairs $P_i = \langle x_i, y_i \rangle$ satisfying $y^2 = f(x)$. This is an element of the algebraic Jacobian when interpreted as the divisor $\sum_{i=1}^{g} P_i - g\infty$.

Example H125E43

We give an example of moving between the algebraic and analytic Jacobians. We take two points on an algebraic Jacobian, map them to the analytic Jacobian, add them there and map the answer back to the algebraic Jacobian. We check that the answer corresponds to adding the points on the algebraic Jacobian.

```
> P<x> := PolynomialRing(RationalField());
> f := -8*x^5 - 14*x^4 + 28*x^3 - 30*x^2 + 6*x;
> C := HyperellipticCurve(f);
> J := Jacobian(C);
> pts := ReducedBasis(RationalPoints(J:Bound:=500)); pts;
[ (x^2 + 1, -3*x + 5, 2), (x^2 - 4/9*x + 1/9, -55/27*x + 43/27, 2) ]
```

This Jacobian has rank 2 and these are two generators. We will use them as our two points.

```
> P1 := pts[1]; P2 := pts[2];
> C<I> := ComplexField(50);
> K<x> := PolynomialRing(C);
> f2 := Evaluate(f,x);
> div1 := [r[1] : r in Roots(Evaluate(ElementToSequence(P1)[1],x))];
> div1 := [<d1,Evaluate(ElementToSequence(P1)[2],d1)> : d1 in div1];
> div2 := [r[1] : r in Roots(Evaluate(ElementToSequence(P2)[1],x))];
> div2 := [<d1,Evaluate(ElementToSequence(P2)[2],d1)> : d1 in div2];
> A := AnalyticJacobian(f2);
```

We are working with 50 decimal places. The sequences `div1` and `div2` are the two points on the algebraic Jacobian represented as pairs of $\langle x, y\rangle$ coordinates.

```
> pt1 := &+[ToAnalyticJacobian(d[1],d[2],A) : d in div1];
> pt2 := &+[ToAnalyticJacobian(d[1],d[2],A) : d in div2];
```

Now `pt1` and `pt2` are the images of the two points `P1` and `P2` on the analytic Jacobian (two 2×1 matrices).

```
> sum := FromAnalyticJacobian(pt1+pt2,A);
> sum;
[ <0.62500000000000000000000000000000000000000000000024 +
-1.49999999999999999999999999999999999999999999992*I,
1.73437500000000000000000000000000000000000000000053 +
-11.71874999999999999999999999999999999999999999985*I>,
<0.62500000000000000000000000000000000000000000000036 +
1.49999999999999999999999999999999999999999999992*I,
1.73437500000000000000000000000000000000000000000075 +
11.71874999999999999999999999999999999999999999986*I> ]
```

Now we have mapped sum back to the algebraic Jacobian where it is given as a sequence of two $\langle x, y\rangle$ coordinates. We compare the polynomial having these two x-coordinates as roots, with the algebraic sum of `P1` and `P2`.

```
> clst := Coefficients((x-sum[1][1])*(x-sum[2][1]));
> xpol := P![BestApproximation(Re(c),1000) : c in clst];
```

```
> xpol;
x^2 - 5/4*x + 169/64
> P1+P2;
(x^2 - 5/4*x + 169/64, 125/16*x - 403/128, 2)
```

125.18.2.1 Isomorphisms, Isogenies and Endomorphism Rings of Analytic Jacobians

In this section we discuss the functionality provided for finding isomorphisms and isogenies between different analytic Jacobians and also for computing the endomorphism ring of an analytic Jacobian.

Suppose we have two abelian varieties $A_1 = \mathbf{C}^g/\Lambda_1$ and $A_2 = C^g/\Lambda_2$ with a morphism $\phi : A_1 \mapsto A_2$. This map lifts to a map $\mathbf{C}^g \mapsto \mathbf{C}^g$, given by some complex $g \times g$ matrix, α. This is called the complex representation of ϕ. Suppose Λ_i is spanned by the columns of the $g \times 2g$ matrix P_i. As $\phi(\Lambda_1) \subset \Lambda_2$, we see that there must exist an integral $2g \times 2g$ matrix M such that $\alpha P_1 = P_2 M$. M is called the rational representation of ϕ. If A_1 and A_2 are isomorphic and P_1 and P_2 are Frobenius bases, that is, they provide a basis with respect to which the polarization is given by the matrix $J = \begin{pmatrix} 0 & \mathbf{1}_g \\ -\mathbf{1}_g & 0 \end{pmatrix}$, then it follows that M must be a symplectic matrix. That is, M must be such that $MJ^tM = J$. The symplectic matrices act on Siegel upper half-space. If $M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ is a symplectic matrix and τ an element of Siegel upper half-space, then the action is given by $\tau \mapsto (a\tau + b)(c\tau + d)^{-1}$. Note that if there is an isomorphism from A_1 to A_2 with rational representation M then τ_1 equals the result of letting ${}^tM$ (not M) act on τ_2.

In the case of finding isomorphisms between abelian surfaces, the code makes use of a fundamental domain for 2-dimensional upper half-space (see [Got59]). This often works well even with relatively low precision. The other functions all rely on the function `LinearRelation` and work with greater reliability if a high precision is chosen. This also means that it can happen that these functions miss finding a map. Even if a map is reported it might be an artifact of insufficient precision causing `LinearRelation` to identify a relation that disappears at higher precision. Of course, every effort was made to make these functions work as well as possible and no cases are known where sufficient precision fails to give correct results.

`To2DUpperHalfSpaceFundamentalDomian(z)`

Given a complex matrix in 2-dimensional Siegel upper half-space (that is a symmetric matrix with positive definite imaginary part), this function returns two matrices. The first is an element of the fundamental domain for 2-dimensional Siegel upper half-space described by Gottschling in [Got59] and the second is a symplectic matrix that takes the input to the first return value. Note that if the input is equivalent to an element on the border of the fundamental domain the returned value might depend heavily on the least significant digits of the input.

`AnalyticHomomorphisms(t1, t2)`

Given two small period matrices t_1 and t_2, this function returns a basis for the **Z**-module of $2g \times 2g$ integer matrices M such that there exists a complex $g \times g$ matrix α such that $\alpha(t_1, 1) = (t_2, 1)M$.

`IsIsomorphicSmallPeriodMatrices(t1,t2)`

For two small period matrices t_1 and t_2, this function finds a $2g \times 2g$ symplectic integer matrix M such that there exists a complex $g \times g$ matrix α such that $\alpha(t_1, 1) = (t_2, 1)M$. Such matrices define isomorphisms between the corresponding analytic Jacobians. The first return value is true if such a matrix is found, false otherwise. The second return value is the matrix, if found. Zero matrix otherwise.

`IsIsomorphicBigPeriodMatrices(P1, P2)`

For two big period matrices P_1 and P_2, this function finds a $2g \times 2g$ symplectic integer matrix M such that there exists a complex $g \times g$ matrix α such that $\alpha P_1 = P_2 M$. Such matrices define isomorphisms between the corresponding analytic Jacobians. The first return value is true if such a matrix is found, false otherwise. The second and third return values are M and α, if found.

`IsIsomorphic(A1, A2)`

For two analytic Jacobians A_1 and A_2 with big period matrices P_1 and P_2, this function finds a $2g \times 2g$ symplectic integer matrix M such that there exists a complex $g \times g$ matrix α such that $\alpha P_1 = P_2 M$. Such matrices define isomorphisms between the analytic Jacobians. The first return value is true if such a matrix is found, false otherwise. The second and third return values are M and α, if found.

`IsIsogenousPeriodMatrices(P1, P2)`

For two period matrices (small or big) P_1 and P_2, this function finds a nonsingular $2g \times 2g$ integer matrix M such that there exists a complex $g \times g$ matrix α such that $\alpha(P_1, 1) = (P_2, 1)M$, in case of small period matrices, or $\alpha P_1 = P_2 M$ for big period matrices. Such a matrix defines an isogeny between the corresponding analytic Jacobians. The first return value is true if such a matrix is found, false otherwise. The second return value is M, if found. In the case of big period matrices α is the third return value.

`IsIsogenous(A1, A2)`

For two analytic Jacobians A_1 and A_2 with big period matrices P_1 and P_2, this function finds a nonsingular $2g \times 2g$ integer matrix M such that there exists a complex $g \times g$ matrix α such that $\alpha P_1 = P_2 M$. Such a matrix defines an isogeny between the analytic Jacobians. The first return value is true if such a matrix is found, false otherwise. The second and third return values are M and α, if found.

`EndomorphismRing(P)`

This function returns the endomorphism ring, as a matrix algebra, of the analytic Jacobian associated to the given period matrix P. If a big period matrix, P, is given then it also returns a list of α-matrices such that $\alpha P = PM$, for each generator, M, of the matrix algebra.

`EndomorphismRing(A)`

This function returns the endomorphism ring, as a matrix algebra, of the given analytic Jacobian A. Suppose the analytic Jacobian has big period matrix P. The second return value is a list of α-matrices such that $\alpha P = PM$, for each generator, M, of the matrix algebra.

Example H125E44

We give an example of how MAGMA can be used to find rational isogenies between the Jacobians of genus 2 curves. Let us consider the two curves

$$y^2 = x^5 - 4x^4 + 8x^2 - 4x,$$

and

$$y^2 = x^5 + 4x^4 + 10x^3 + 12x^2 + x.$$

These are curves 1 and 3 in the twenty second isogeny class of Smart [Sma97]. We compute their analytic Jacobians to 100 decimal places.

```
> K<x> := PolynomialRing(RationalField());
> C<i> := ComplexField(100);
> KC<xc> := PolynomialRing(C);
> f1 := x^5 - 4*x^4 + 8*x^2 - 4*x;
> f1C := Evaluate(f1,xc);
> A1 := AnalyticJacobian(f1C);
> f2 := x^5 + 4*x^4 + 10*x^3 + 12*x^2 + x;
> f2C := Evaluate(f2,xc);
> A2 := AnalyticJacobian(f2C);
```

We now get a basis for the $\mathbf{Z}$-module of isogenies from `A1` to `A2`. Note that `IsIsogenous` returns `true` for these two Jacobians, but it does not return an isogeny defined over $\mathbf{Q}$.

```
> Mlst := AnalyticHomomorphisms(SmallPeriodMatrix(A1),SmallPeriodMatrix(A2));
> Mlst;
[
  [ 1  0 -1  0]
  [ 0  1  0  0]
  [ 1  1  1  0]
  [ 1  1 -1  2],

  [ 1  0  1  0]
  [ 0  0  0 -1]
  [-1  0  1 -1]
```

```
  [ 1  2  1 -1],

  [ 0  1  0 -1]
  [ 1  0  0  0]
  [ 1  1  0  1]
  [ 1  1  2 -1],

  [ 0  1  0  1]
  [ 0  0 -1  0]
  [ 0 -1 -1  1]
  [ 2  1 -1  1]
]
>
```

For each of these four "M" matrices let us find the corresponding α matrices.

```
> P1 := BigPeriodMatrix(A1);
> P2 := BigPeriodMatrix(A2);
> alst := [Submatrix(P2*Matrix(C,M),1,1,2,2)
>          *Submatrix(P1,1,1,2,2)^-1 : M in Mlst];
> alst[1][1,1];
9.498572673182793269164480489911434797891377549198242765578603486437979481059498
481543257426864218501E-101 + -1.414213562373095048801688724209698078569671875376
769480731766797379907324784621070388503875343276415 73*i
>
```

So at least `alst[1]` does not correspond to a rational isogeny. In general none of the four α-matrices might correspond to a rational isogeny. But it is possible that some $\mathbf{Z}$-linear combination of them is defined over the rationals and we want to know whether this actually happens. We can find out by recognizing the entries of the α-matrices as algebraic numbers. This can be done using the `PowerRelation` function.

```
> SetDefaultRealFieldPrecision(100);
> pol := PowerRelation(C!alst[4][1,1],8:Al:="LLL");
> Evaluate(pol,x);
x^4 + 2*x^2 - 1
```

It turns out that every entry of each of the `alst` matrices is in the number field defined by the polynomial $x^8 + 12x^6 + 34x^4 + 52x^2 + 1$. We can use `LinearRelation` to write each entry as a linear combination of the elements of a power basis for this number field. For example:

```
> aroot := C!Roots(Evaluate(x^8 + 12*x^6 + 34*x^4 + 52*x^2 + 1,xc))[1][1];
> basis := [aroot^i : i in [0..7]];
> LinearRelation(Append(basis,alst[1][1,1]));
[ 0, 411, 0, 293, 0, 107, 0, 9, -40 ]
```

So we can write each α-matrix as an algebraic number in the number field defined by $x^8 + 12x^6 + 34x^4 + 52x^2 + 1$. It is then a simple matter to find a linear combination of the α-matrices that is defined over $\mathbf{Q}$. In this particular case we get lucky and `alst[3]` itself is already rational:

```
> alpha := alst[3];
```

```
> alpha;
[1.1429873912822749822157835483053409594519099948227986612151258432276326359067

> Matrix(2,2,[Round(Real(x)) : x in Eltseq(alpha)]);
[ 0  1]
[ 2 -1]
```

So the two Jacobians are **Q**-isogenous. We can use `alpha` to map points from the one Jacobian to the other. We check that it maps rational points to rational points.

```
> C1 := HyperellipticCurve(f1);
> J1 := Jacobian(C1);
> pts1 := RationalPoints(J1:Bound:=500);
> pts1;
{@ (1, 0, 0), (x^2 - 2*x + 1, 1/2*x + 1/2, 2), (x^2 - 2*x + 1, -1/2*x - 1/2, 2),
(x, 0, 1), (x - 1, 1, 1), (x - 1, -1, 1), (x^2 - 2, 0, 2), (x^2 + 2, 4*x, 2),
(x^2 + 2, -4*x, 2), (x^2 - x, x, 2), (x^2 - x, -x, 2), (x^2 - 4*x - 2, 4*x, 2),

```

125.18.3 From Period Matrix to Curve

`RosenhainInvariants(t)`

Given a small period matrix t corresponding to an analytic Jacobian A of genus g, this function returns a set S of $2g-1$ complex numbers such that the hyperelliptic curve $y^2 = x(x-1)\prod_{s\in S}(x-s)$ has Jacobian isomorphic to A. The name of the function comes from the fact that a hyperelliptic curve in the form $y^2 = x(x-1)(x-\lambda_1)...(x-\lambda_{2g-1})$ is said to be in Rosenhain normal form.

Example H125E45

We give an example of how MAGMA can be used to find the equation of a genus 2 curve whose Jacobian has Complex Multiplication by a given field. We use the field $\mathbf{Q}(\sqrt{-2+\sqrt{2}})$.

```
> SetSeed(1);
> Q := RationalField();
> P<x> := PolynomialRing(Q);
> R<s> := NumberField(x^2-2);
> PP<x> := PolynomialRing(R);
> RF := NumberField(x^2-(-2+s));
> CMF<t> := AbsoluteField(RF);
> O := MaximalOrder(CMF);
```

Now, for a CM type Φ, and $\mathcal{O}$ the ring of integers, $\mathbf{C}^2/\Phi(\mathcal{O})$ is a torus with Complex Multiplication by the maximal order of our field $\mathbf{Q}(\sqrt{-2+\sqrt{2}})$. In order for this to be an abelian variety we have to find a principal polarization. This can be done using Algorithm 1 in [Wam99]. In this case it turns out that a principal polarization is essentially given by a generator of the inverse different.

```
> D := Different(O);
> IsPrincipal(D);
true
> xi := -1/8*O.2; // a chosen generator of D^-1
> xi*O eq D^-1;
true
> auts := Automorphisms(CMF : Abelian := true);
> cc := auts[3];
> cc(cc(t)) eq t;
true
> cc(xi^2) eq xi^2;
```

```
true
```

So `cc` is complex multiplication and `xi` squared is in the real subfield. By Theorem 3 of [Wam99] we see that this gives a principal polarization. We now find a Frobenius basis for our lattice with respect to the non-degenerate Riemann form given by `xi`.

```
> Z := IntegerRing();
> E := Matrix(Z,4,4,[Trace(xi*cc(a)*b) : b in Basis(O), a in Basis(O)]);
> D, C := FrobeniusFormAlternating(E); D;
[ 0  0  1  0]
[ 0  0  0  1]
[-1  0  0  0]
[ 0 -1  0  0]
> newb := ElementToSequence(Matrix(O,C)*Matrix(O,4,1,Basis(O)));
> SetKantPrecision(O,100);
> Abs(Re(Conjugate(xi,2))) lt 10^-10 and Im(Conjugate(xi,2)) gt 0;
true
> Abs(Re(Conjugate(xi,4))) lt 10^-10 and Im(Conjugate(xi,4)) gt 0;
true
```

The CM type Φ is given by the second and fourth complex embeddings. We can finally write down a big period matrix and find the element in the Siegel upper half-space corresponding to our CM Jacobian:

```
> C := ComplexField(100);
> BigPM := Matrix(C,2,4,[Conjugate(b,2) : b in newb] cat
>                       [Conjugate(b,4) : b in newb]);
> tau := Submatrix(BigPM,1,3,2,2)^-1*Submatrix(BigPM,1,1,2,2);
```

We can use `EndomorphismRing` to check that the analytic Jacobian corresponding to `tau` does have CM by the correct field:

```
> MA := EndomorphismRing(tau); Dimension(MA);
4
> MAGens := SetToSequence(Generators(MA)); MAGens;
[
    [-1  0  0  0]
    [ 0 -1  0  0]
    [ 0  0 -1  0]
    [ 0  0  0 -1],
    [  0   0 -17  -7]
    [  0   0  -7  -3]
    [  5 -12   0   0]
    [-12  29   0   0]
]
> MP := [MinimalPolynomial(g): g in MAGens];
> IsIsomorphic(NumberField(rep{f: f in MP | Degree(f) gt 1}), CMF);
true
```

Now let us find a curve with this Jacobian.

```
> S := RosenhainInvariants(tau);
```

```
> P<x> := PolynomialRing(C);
> f := x*(x-1)*&*{x-a : a in S};
> IC := IgusaClebschInvariants(f);
> ICp := [BestApproximation(Re(r),10^50) : r in
>          [IC[1]/IC[1], IC[2]/IC[1]^2, IC[3]/IC[1]^3, IC[4]/IC[1]^5]];
> ICp;
[ 1, 5/324, 31/5832, 1/1836660096 ]
> C1 := HyperellipticCurveFromIgusaClebsch(ICp);

Hyperelliptic Curve defined by y^2 = -x^5 - 3*x^4 + 2*x^3 + 6*x^2 - 3*x - 1
over Rational Field
```

Let's check that this curve's analytic Jacobian is isomorphic to the one corresponding to `tau`.

```
> P<x> := PolynomialRing(C);
> f := -x^5 - 3*x^4 + 2*x^3 + 6*x^2 - 3*x - 1;
> A := AnalyticJacobian(f);
> IsIsomorphicSmallPeriodMatrices(tau,SmallPeriodMatrix(A));
true
[ 1 -2  0  0]
[ 0  0  2  1]
[ 1 -2  5  2]
[ 2 -5  4  2]
```

125.18.4 Voronoi Cells

This section describes two functions that are concerned with the computation of Voronoi cells.

`Delaunay(sites)`

This function computes the Delaunay triangulation for the sites given by *sites*. The argument *sites* should be a sequence of pairs (of type `Tup`) of real numbers. The real numbers should all belong to the same real field. For n sites, a sequence of n sequences is returned. The ith sequence contains the list of indices of the sites to which site i should be joined to form the triangulation.

`Voronoi(sites)`

This function computes the Voronoi cells for the sites given by *sites*. A Voronoi cell of a site consists of all those points in the plane closer to that site than to any other. The argument *sites* should be a sequence of pairs (of type `Tup`) of real numbers. The real numbers can be either fixed precision or free reals, but they should all be in the same real field.

Three sequences, *siteedges*, *dualsites* and *cells* are returned. The sequence *siteedges* is what the intrinsic `Delaunay` would have returned (so it defines the Delaunay triangulation). The sequence *dualsites* is a sequence of triples $\langle x, y, m \rangle$,

interpreted as follows: If m is zero the triple represents the point x, y. If m is non-zero the triple represents a point "at infinity" in the direction of the vector x, y. For n sites, *cells* is a sequence of n sequences. The ith sequence is a list $[i1, i2, i3, ..., im]$ such that the cell around site i is formed by connecting *dualsites[i1]* to *dualsites[i2]*, ... If a cell is infinite the first and last indices in the sequence point to infinite points. That is, the two infinite sides are given by the lines $(x_0, y_0) + t(x_1, y_1)$, for $t \geq 0$ where (x_0, y_0) equals *dualsites[i2][1], dualsites[i2][2]* and (x_1, y_1) equals *dualsites[i1][1], dualsites[i1][2]* or (x_0, y_0) equals *dualsites[im-1][1], dualsites[im-1][2]* and (x_1, y_1) equals *dualsites[im][1], dualsites[im][2]*.

126 HYPERGEOMETRIC MOTIVES

Chapter 126
HYPERGEOMETRIC MOTIVES

126.1 Introduction

Let $\vec{\alpha}, \vec{\beta} \in \mathbf{C}^n$ be n-tuples (or multisets) of complex numbers. For arithmetic applications we will eventually take them to be rationals, and for purposes of monodromy will largely need only to consider them modulo 1.

Consider the generalised hypergeometric differential equation

$$z(\theta+\alpha_1)\cdots(\theta+\alpha_n)F(z) = (\theta+\beta_1-1)\cdots(\theta+\beta_n-1)F(z), \qquad \theta = z\frac{d}{dz},$$

whose only singularities are regular at 0, 1, and ∞. For simplicity of exposition, we assume that the β's are distinct modulo 1, when a basis of solutions around $z=0$ is given by

$$z^{1-\beta_i}{}_nF_{n-1}\left(\frac{\alpha_1-\beta_i+1,\ldots,\alpha_n-\beta_i+1}{\beta_1-\beta_i+1,..\vee..,\beta_n-\beta_i+1}\;\middle|\; z\right)$$

for $i = 1\ldots n$, and the ith term $\beta_i-\beta_i+1$ is suppressed. The generalised hypergeometric function ${}_nF_{n-1}$ is given by

$${}_nF_{n-1}\left(\frac{a_1,\ldots,a_n}{b_1,\ldots,b_{n-1}}\;\middle|\; z\right) = \sum_{k=0}^{\infty}\frac{(a_1)_k\cdots(a_n)_k}{(b_1)_k\cdots(b_{n-1})_k}\frac{z^k}{k!},$$

where the Pochhammer symbol is given by $(x)_k = (x)(x+1)\cdots(x+k-1)$; the $k!$ in the denominator of the above display can thus be thought of as $(1)_k$, which was the suppressed term. Note that shifting all the α and β by some fixed amount keeps the ${}_nF_{n-1}$ expression the same, while only modifying the $z^{1-\beta_i}$ term. Also, switching α and β can be envisaged in terms of the map $z \to 1/z$ that swaps 0 and ∞.

A theorem of Pochhammer says that the above differential equation has $(n-1)$ independent *holomorphic* solutions around $z=1$. Let G denote the fundamental group of the thrice punctured Riemann sphere, and $V_{\vec{\alpha},\vec{\beta}}$ the solution space around a base point. We have a monodromy representation $M : G \to GL_n(V_{\vec{\alpha},\vec{\beta}})$. Writing $g_0, g_1, g_\infty \in G$ for loops about 0,1,∞, we find that $M(g_0)$ has eigenvalues $e^{-2\pi i\beta_j}$ and $M(g_\infty)$ has eigenvalues $e^{2\pi i\alpha_j}$, implying that we are mainly concerned with $\vec{\alpha}$ and $\vec{\beta}$ only modulo 1. Indeed, one can note that if we take $F = {}_nF_{n-1}(\vec{a},\vec{b}|z)$ and $\vec{x} \in \mathbf{Z}^n, \vec{y} \in \mathbf{Z}^{n-1}$, then generically ${}_nF_{n-1}(\vec{a}+\vec{x},\vec{b}+\vec{y}|z)$ is a linear combination of rational functions times derivatives of F (this is a contiguity relation). Meanwhile, the above fact from Pochhammer implies that $M(g_1)$ must have $(n-1)$ eigenvalues equal to 1 (all with independent eigenvectors), and so this element is a pseudo-reflection.

It turns out that if $H \subseteq GL_n(\mathbf{C})$ is generated by A and B with AB^{-1} a pseudo-reflection, the H-action on $\mathbf{C}^n$ is irreducible if and only if A and B have disjoint sets of eigenvalues. This is equivalent to all the $\alpha_i - \beta_j$ being nonintegral. Moreover, in his 1961 Amsterdam thesis, Levelt showed that, given any eigenvalues, there are (up to conjugacy) unique A and B realising these eigenvalues with AB^{-1} a pseudo-reflection. (Much of the above comes from notes of Beukers.)

For arithmetic purposes, one usually also desires that the eigenvalues be roots of unity and the sets of them be Galois-invariant. Thus we can specify hypergeometric data H by (say) two products of cyclotomic polynomials, these products being coprime and of equal degree. Given such an H, Rodriguez-Villegas conjectures the existence of a family of pure motives (defined over $\mathbf{Q}$), for which the trace of Frobenius at good primes is given by a hypergeometric sum defined by Katz [Kat90] (see also [Kat96]). For each rational $t \neq 0, 1$, there should be a motive H_t whose L-function satisfies a functional equation of a prescribed type, with the Euler factors at good primes given in terms of Gauss sums (the bad Euler factors are less understood, and depend on deformation theory).

One can also relate such motives to more traditional objects in many cases. For instance, there is one hypergeometric datum in degree 1, which can be specified by $\alpha = [\frac{1}{2}]$ and $\beta = [0]$, these being rationals corresponding to the second and first cyclotomic polynomials respectively (by convention, we take β to contain the smallest such rational). The L-function here corresponds to the quadratic field $\mathbf{Q}(\sqrt{t(t-1)})$. In degree 2 there are 13 such data, of which 3 are of weight 0 (see below) and give Artin representations of number fields, while the other 10 are of weight 1, and yield elliptic curves (explicitly calculated by Cohen). An example in higher degree is $\alpha = [\frac{1}{5}, \frac{2}{5}, \frac{3}{5}, \frac{4}{5}]$ and $\beta = [0, 0, 0, 0]$, corresponding respectively to the 5th cyclotomic polynomial and the 4th power of the first cyclotomic polynomial, and this is associated to the Calabi-Yau quintic 3-fold given by

$$x_1^5 + x_2^5 + x_3^5 + x_4^5 + x_5^5 = 5t x_1 x_2 x_3 x_4 x_5.$$

The weight w of a hypergeometric motive can be defined in terms of how much the α and β interlace (considered as roots of unity). In particular, if they are completely interlacing, then the weight is 0, and the resulting motive corresponds to an Artin representation. Write $D(x) = \#\{\alpha : \alpha \leq x\} - \#\{\beta : \beta \leq x\}$. Then $w + 1 = \max_x D(x) - \min_x D(x)$, so that the above 3-fold has weight 3 (from the four β's at 0). This weight controls how large the coefficients of the Euler factors will be.

The trace at q of a hypergeometric motive (for the parameter t) is given in terms of Gauss sums g_q over $\mathbf{F}_q$. Associated to hypergeometric data is a `GammaArray`, and one defines $G_q(r) = \prod_v g_q(-rv)^{\gamma_v}$, and also the `MValue` by $M = \prod_v v^{v\gamma_v}$. For primes p with $v_p(Mt) = 0$ the hypergeometric trace is then given by

$$U_q(t) = \frac{1}{1-q}\left(\sum_{r=0}^{q-2} \omega_p(Mt)^r Q_q(r)\right),$$

where ω_p is the Teichmüller character and $Q_q(r) = (-1)^{m_0} q^{D+m_0-m_r} G_q(r)$ where m_r is the multiplicity of $\frac{r}{q-1}$ in the β and D is a scaling parameter that involves the Hodge

structure (one expression is $m_0 = w + 1 - 2D$). One uses p-adic Γ-functions to expedite the computation of the above Gauss sums. The Euler factor is given by the standard recipe $E_p(T) = \exp\bigl(-\sum_n U_{p^n}(t)T^n/n\bigr)$, and this is a polynomial that satisfies a local functional equation.

126.2 Functionality

126.2.1 Creation Functions

`HypergeometricData(A, B)`

`HypergeometricData(F, G)`

These are two of the principal ways of specifying hypergeometric data. The first takes two sequences A and B (of the same length) of rationals, which must be disjoint upon reduction modulo 1, and each of which must be Galois-invariant when taking the corresponding roots of unity (for instance, if $\frac{1}{6}$ is specified, $\frac{5}{6}$ is also given). The second takes two products F and G of cyclotomic polynomials, these products being coprime and of the same degree. *NOTE*: the routine will always switch A and B (or f and g) so that the latter has the smallest rational in $[0, 1)$ in it.

`HypergeometricData(G)`

This is a third way to specify hypergeometric data, by giving a sequence of integers G such that $\sum_v vG[v] = 0$. Here we have $P_\alpha(T)/P_\beta(T) = \prod_v (T^v - 1)^{G[v]}$, and the polynomials can be determined via Möbius inversion. Again α and β will be reversed if necessary (which corresponds to negating all the entries of G).

`HypergeometricData(G)`

This is a fourth way to specify hypergeometric data, by giving a *list* G of nonzero integers (with repetition possible) corresponding to the sequence G of the previous intrinsic, with negative integers for those where $G[v]$ is negative. The sum of the members of the list must be 0.

`HypergeometricData(F, G)`

This is a fifth way to specify hypergeometric data, by giving two arrays F and G of integers, corresponding to the cyclotomic polynomials to be used.

`HypergeometricData(E)`

This is a utility intrinsic that take a sequence E of two sequences and then passes these two sequences to the intrinsics above.

`Twist(H)`

This intrinsic takes hypergeometric data H, and adds 1/2 to every element in α and β, returning new hypergeometric data. Note that the new α and β may be switched due to this twisting.

`PrimitiveData(H)`

Given hypergeometric data H, return its primitive associated data. This is most easily described in terms of `GammaList`, where one divides all the elements by the gcd.

`PossibleHypergeometricData(d)`

`Weight`	RngIntElt	*Default :* `false`
`TwistMinimal`	BoolElt	*Default :* `false`
`CyclotomicData`	BoolElt	*Default :* `false`
`Primitive`	RngIntElt	*Default :* 0

Given a degree d, generate all possible examples of hypergeometric data of that degree, returned as a sequence of pairs of sequences, each sequence therein having d rationals. If `Weight` is specified, restrict to data of this weight. If `TwistMinimal` is specified, only give twist-minimal data. If `CyclotomicData` is specified, return the sequences of cyclotomic data rather than rationals. If `Primitive` is `true`, only return data that are primitive; if `Primitive` is a positive integer, return the data that have this imprimitivity.

126.2.2 Access Functions

`Weight(H)`

The weight of the given hypergeometric data H.

`Degree(H)`

The degree of the given hypergeometric data H.

`DefiningPolynomials(H)`

The (products of cyclotomic) polynomials corresponding to α and β corresponding to hypergeometric data H.

`CyclotomicData(H)`

This returns two arrays of integers, specifying which cyclotomic polynomials occur for α and β corresponding to hypergeometric data H. Thus, for example, $\Phi_3\Phi_4^2\Phi_6$ would be represented by [3,4,4,6]).

`AlphaBetaData(H)`

This returns two arrays of rationals, giving the α and β of the hypergeometric data H.

`MValue(H)`

This returns the scaling parameter M of the given hypergeometric data H. This is defined by taking $M_n = \prod_{d|n} d^{d\mu(n/d)}$ for the nth cyclotomic polynomial, and combining these into the products for α and β, and then dividing these. Another definition is $M = \prod_v v^{v\gamma_v}$.

`GammaArray(H)`

This returns an array of integers corresponding to γ_v, where these are defined by $P_\alpha(T)/P_\beta(T) = \prod_v (T^v - 1)^{\gamma_v}$. We also have $\sum_v v\gamma_v = 0$.

`GammaList(H)`

This returns a *list* of integers corresponding to γ_v, where $\mathrm{sign}(\gamma_v) \cdot v$ appears in the list $|\gamma_v|$ times.

`H1 eq H2`

`H1 ne H2`

Two instances of hypergeometric data $H1$ and $H2$ are equal if they have the same α and β.

`IsPrimitive(H)`

Returns `true` if the given hypergeometric data H is primitive, and the index of imprimitivity. The latter is the gcd of the elements in the `GammaList`.

126.2.3 Functionality with L-series and Euler Factors

`EulerFactor(H, t, p)`

`Precision`	RngIntElt	*Default :* 0
`Check`	BoolElt	*Default :* `false`
`Fake`	BoolElt	*Default :* `false`

This intrinsic is the heart of the hypergeometric motive package. It takes hypergeometric data H, a rational $t \neq 0, 1$, and a prime p, and computes the pth Euler factor of the hypergeometric motive at t. This uses p-adic Γ-functions, as indicated by Cohen. The `Precision` vararg specifies how many terms in the Euler factor should be computed – if this is 0, then the whole polynomial is computed. The `Check` vararg allows one to turn off the use of the (local) functional equation that is used to expedite the computation process.

The `Fake` vararg allows one to compute the hypergeometric trace(s) for t with $v_p(Mt) = 0$ (including wild primes). Whether or not this is the actual Euler factor depends on how inertia acts. The use of this vararg inhibits the use of the local functional equation, but one can curtail via `Precision`, and apply it manually (if known).

In general, the given prime must not be wild, that is, it must not divide the denominator of any of the α or β.

At other bad primes, the Euler factor will depend upon the relevant monodromy. The primes for which $v_p(t-1) > 0$ can perhaps be called multiplicative, in that p should divide the conductor only once (this is related to the pseudoreflection). Since $v_p(Mt) = 0$ here, the Euler factor (of degree $d-1$) can be recovered by the p-adic Γ-function methods (even when $p = 2$). Also it is often possible to relate the (presumed) hypergeometric motive to objects from a deformation. When $v_p(t-1)$ is even and the weight is also even, the prime p is actually good and has a degree d Euler factor, even though the hypergeometric trace only gives one of degree $(d-1)$. In such a case, the `EulerFactor` intrinsic with the `Fake` vararg will return the part from the hypergeometric trace.

The p with $v_p(1/t) > 0$ correspond to monodromy at ∞. The associated inertia is given by the roots of unity with the β, with maximal Jordan blocks when eigenvalues are repeated. The same is true for p with $v_p(t) > 0$, where the monodromy is around 0 (so that the α are used). In Example H126E7), an instance is given where the inertia is trivialised due to having $\zeta^{v_p(t)} = 1$.

We can compute the Euler factors at such tame primes as follows. Suppose that $t = t_0 p^{vm}$ with $v > 0$, where m occurs as a denominator of the α (similarly with $v < 0$ and β). Then one takes the smallest $q = p^f$ that is 1 mod m, and from the hypergeometric trace formula extracts the terms

$$\omega_p(Mt_0)^{j(q-1)/m} Q_q\left(\frac{j(q-1)}{m}\right)$$

for $0 \le j < m$ with $\gcd(j,m) = 1$. Denoting these by η, we then have that $\prod_\eta(1-\eta T^f)$ is an fth power (due to repetitions in the above extraction), and the fth root of this is the desired Euler factor of degree $\phi(m)$.

When m does not divide $v_p(t)$, the Euler factor from it is trivial. One then multiplies together all such Euler factors corresponding to the m from the α and β. Each m is only considered once, even if it appears multiple times in the `CyclotomicData`, as the Jordan blocks of the eigenvalues are maximal. Note that the local functional equation is not used for tame primes, though the computation should not be too onerous unless $q = p^f$ is large.

`LSeries(H, t)`

`BadPrimes`	SeqEnum	*Default :* []
`GAMMA`	SeqEnum	*Default :* []
`Identify`	BoolElt	*Default :* `true`

Given hypergeometric data H and a rational $t \neq 0, 1$, try to construct the L-series of the associated motive. This will usually need the Euler factors at wild primes to be specified. Everything else, including tame/multiplicative Euler factors and γ-factors, can be computed automatically by Magma (these can also be given via `BadPrimes` and `GAMMA`). The `Identify` vararg indicates whether an attempt should be made to identify motives of weight 0 as Artin representations, and similarly with (hyper)elliptic curves for weight 1.

126.2.3.1 Identification of Hypergeometric Data as Other Objects

`ArtinRepresentation(H, t)`

`Check` BoolElt *Default :* `true`

Given hypergeometric data H of weight 0 and a rational $t \neq 0, 1$, try to determine the associated Artin representation. This is implemented for all such H of degree 3 or less, and for some of degree 4 and higher. The condition needed is that `GammaList(H)` have cardinality 3. When `Check` is true, good primes up to 100 have their Euler factors checked for correctness.

`EllipticCurve(H)`

`EllipticCurve(H, t)`

Given hypergeometric data H of degree 2 and weight 1 (there are 10 such families) and a rational $t \neq 0, 1$, return the associated elliptic curve, as catalogued by Cohen. When t is not given, return the result over a function field.

For each of the 10 families, the same function can be called for the corresponding imprimitive data of index r, and the result will generically be an elliptic curve over an extension of degree r. However, when the $x^r - 1/Mt$ splits, the intrinsic will return an array of elliptic curves corresponding to this splitting.

`HyperellipticCurve(H)`

`HyperellipticCurve(H, t)`

Given hypergeometric data H of degree 4 and weight 1 and a rational $t \neq 0, 1$, return the associated hyperelliptic curve, if this data is known to correspond to such. When t is not given, return the result over a function field. There are 18 cases where one gets a genus 2 curve from the `CanonicalCurve` (making 36 cases when twisting is considered), and a few others where `CanonicalCurve` gives a higher genus curve and there is a genus 2 quotient. In general, one can try to call `IsHyperelliptic` on the `CanonicalCurve`.

`Identify(H, t)`

Given hypergeometric data H and a rational $t \neq 0, 1$, return any known associated object (else returns `false`). The return value can (currently) be: an Artin representation (weight 0); an elliptic curve over $\mathbf{Q}$ (weight 1 in degree 2); an elliptic curve over a number field (weight 1 in degree $2r$ with imprimitivity r), or possibly multiple such curves; or a hyperelliptic curve over $\mathbf{Q}$ (weight 1 in degree 4).

126.2.4 Associated Schemes and Curves

`CanonicalScheme(H)`

`CanonicalScheme(H, t)`

Given hypergeometric data H, this constructs a canonical associated scheme. When the parameter t is given, the specialization is returned, otherwise the result returned will be a scheme over a function field.

The scheme is determined from the `GammaList`, with a variable (X_i or Y_j) for every element in the list. The scheme is the intersection of $\sum_i X_i = \sum_j Y_j = 1$ with

$$\prod_i X_i^{g_i^+} \prod_j Y_j^{g_j^-} = \frac{1}{Mt},$$

where the g_i^+ are the positive elements in the `GammaList` and the g_j^- are the negative ones (one usually moves the latter to the other side of the equation, to make the exponents positive).

`CanonicalCurve(H)`

`CanonicalCurve(H, t)`

Given suitable hypergeometric data H, this tries to construct an associated plane curve. When the parameter t is given, the specialization at t is returned, otherwise the return value will be a plane curve over a function field. The curve is constructed using the `GammaList` (which indicates the Jacobi sums that need to be taken). When this list has four elements, it is always possible to get a curve. When the list has six elements, it is sometimes possible, depending on whether the largest element (in absolute value) is the negation of the sum of two of the other elements. If it is not possible to construct such a curve, the intrinsic returns `false`.

126.2.5 Utility Functions

`HypergeometricMotiveSaveLimit(n)`

`HypergeometricMotiveClearTable()`

These are utility intrinsics that will cache the pre-computation of p-adic Γ-functions. The first indicates to save all computed values when the prime power is less than n, and the second clears the table. The qth table entry will have $(q-1)$ elements in it.

126.3 Examples

Example H126E1

Our first example constructs some hypergeometric motives, and recognises them as being related to elliptic curves or Artin representations.

```
> H := HypergeometricData([1/2],[0]); // weight 0
> t := 3/5;
> A := ArtinRepresentation(H,t);
> D := Discriminant(Integers(Field(A))); // -24
> assert IsSquare(D/(t*(t-1))); // Q(sqrt(t(t-1)))
> R := ArtinRepresentationQuadratic(-24);
> assert A eq R;
> //
> H := HypergeometricData([1/4,3/4],[0,0]);
> Weight(H);
1
> DefiningPolynomials(H);
y^2 + 1, y^2 - 2*y + 1
> t := 3/2;
> E := EllipticCurve(H,t); E;
Elliptic Curve defined by y^2 + x*y = x^3 + 1/96*x over Q
> P := PrimesInInterval(5,100);
> &and[EulerFactor(E,p) eq EulerFactor(H,t,p) : p in P];
true
> //
> f := CyclotomicPolynomial(6)*CyclotomicPolynomial(2);
> g := CyclotomicPolynomial(1)^3;
> H := HypergeometricData(f,g); H;
Hypergeometric data given by [ 1/6, 1/2, 5/6 ] and [ 0, 0, 0 ]
> Weight(H);
2
> GammaList(H);
[* -1, -1, -1, -3, 6 *]
> GammaArray(H);
[ -3, 0, -1, 0, 0, 1 ]
> [EulerFactor(H,4,p) : p in [5,7,11,13,17,19]];
[ 125*y^3 + 20*y^2 + 4*y + 1, 343*y^3 - 42*y^2 - 6*y + 1,
  -1331*y^3 - 22*y^2 + 2*y + 1, -2197*y^3 - 156*y^2 + 12*y + 1,
  4913*y^3 + 323*y^2 + 19*y + 1, 6859*y^3 - 57*y^2 - 3*y + 1 ]
> //
> _<u> := FunctionField(Rationals());
> H := HypergeometricData([-2,0,0,-1,0,1]); H; // weight 1
Hypergeometric data given by [1/6,1/3,2/3,5/6] and [0,0,1/4,3/4]
> HyperellipticCurve(H); // defined over Q(u)
Hyperelliptic Curve defined by y^2 = 4*x^6 - 8*x^5 + 4*x^4 - 64/729/u
> t := 4;
> C := Specialization($1,t); // only works over Q(u)
```

```
> &and[EulerFactor(C,p) eq EulerFactor(H,t,p) : p in P];
true
> //
> H := HypergeometricData([0,-1,0,1,0,1,0,-1]); H; // weight 1
Hypergeometric data given by [1/6,1/3,2/3,5/6] and [1/8,3/8,5/8,7/8]
> MValue(H);
729/4096
> t := 3; // could alternatively specialize later
> E := EllipticCurve(H,t); aInvariants(E);
[ 0, 0, -s, -s, 0] where s^2 is 4096/2187
> &and[EulerFactor(E,p) eq EulerFactor(H,t,p) : p in P];
true
```

Example H126E2

This is a simple example of twisting hypergeometric data, showing that a related Artin motive is obtained for the given weight 0 data.

```
> f := CyclotomicPolynomial(6);
> g := CyclotomicPolynomial(1)*CyclotomicPolynomial(2);
> H := HypergeometricData(f,g); H; assert(Weight(H)) eq 0;
Hypergeometric data given by [ 1/6, 5/6 ] and [ 0, 1/2 ]
> A := ArtinRepresentation(H,-4/5);
> K := OptimisedRepresentation(Field(A));
> DefiningPolynomial(K);
y^6 - 3*y^5 + 3*y^4 - y^3 + 3*y^2 - 3*y + 1
> T := Twist(H); T;
Hypergeometric data given by [ 1/3, 2/3 ] and [ 0, 1/2 ]
> A := ArtinRepresentation(T,-4/5); // can be 1/t sometimes
> L := OptimisedRepresentation(Field(A));
> IsSubfield(L,K), DefiningPolynomial(L);
true Mapping from: L to K,  y^3 + 3*y - 1
```

The same can be said for twisting for (hyper)elliptic curves.

```
> H := HypergeometricData([2,2],[3]); // Phi_2^2 and Phi_3
> E := EllipticCurve(H,3);
> T := EllipticCurve(Twist(H),1/3); // 1/t here
> IsQuadraticTwist(E,T);
true -4/9
> //
> H := HypergeometricData([5],[8]); // Phi_5 and Phi_8
> C := HyperellipticCurve(H);
> t := 7;
> S := Specialization(C,t);
> T := HyperellipticCurve(Twist(H),1/t);
> Q := QuadraticTwist(T,5*t); // get right parameter
> assert IsIsomorphic(Q,S);
```

Example H126E3

This example exercises the primitivity functionality.

```
> H := HypergeometricData([3],[4]); // Phi_3 and Phi_4
> GammaList(H);
[* -1, 2, 3, -4 *]
> H2 := HypergeometricData([* -2, 4, 6, -8 *]);
> IsPrimitive(H2);
false 2
> PrimitiveData(H2) eq H;
true
> H3 := HypergeometricData([* -3, 6, 9, -12 *]);
> IsPrimitive(H3);
false 3
> PrimitiveData(H3) eq H;
true
> aInvariants(EllipticCurve(H));
[ 0, 0, -64/27/u, -64/27/u, 0 ] where u is FunctionField(Q).1
> aInvariants(EllipticCurve(H2));
[ 0, 0, -s, -s, 0 ] where s^2=(-64/27)^2/u
> aInvariants(EllipticCurve(H3));
[ 0, 0, -s, -s, 0 ] where s^3=(-64/27)^3/u
```

Example H126E4

Here is an example with the canonical schemes and curves associated to various hypergeometric data.

```
> _<u> := FunctionField(Rationals());
> H := HypergeometricData([* -2, 3, 4, -5 *]); // degree 4
> C := CanonicalScheme(H);
> _<[X]> := Ambient(C); C;
Scheme over Univariate rational function field over Q defined by
X[1] + X[2] - 1, X[3] + X[4] - 1,
X[1]^2*X[2]^5 - 3125/1728/u*X[3]^3*X[4]^4
> Dimension(C), Genus(Curve(C)); // genus 2 curve
1 2
> assert IsHyperelliptic(Curve(C));
> CC := CanonicalCurve(H);
> _<x,y> := Ambient(CC); CC;
Curve over Univariate rational function field over Q defined by
x^7 - 2*x^6 + x^5 + 3125/1728/u*y^7 - 3125/576/u*y^6 +
 3125/576/u*y^5 - 3125/1728/u*y^4
> b, C2 := IsHyperelliptic(CC); assert b;
> HyperellipticCurve(H); // in the degree 4 catalogue
Hyperelliptic Curve defined over Univariate function field
 over Q by y^2 = 4*x^5 - 3125/432/u*x^3 + 9765625/2985984/u^2
> assert IsIsomorphic(HyperellipticCurve(H),C2);
```

```
> // and an example where the curve is reducible
> H := HypergeometricData([* 6,6,-8,-4 *]); // weight 1
> C := CanonicalCurve(H);
> A := AlgorithmicFunctionField(FunctionField(C));
> E<s> := ExactConstantField(A);
> CE := BaseChange(C,E);
> I := IrreducibleComponents(CE); assert #I eq 2;
> _<x,y> := Ambient(I[1]); I[1];
Scheme over E defined by [ where s^2 = 1048576/531441/u ]
 x^6 - 2*x^5 + x^4 - s*y^6 + 3*s*y^5 - 3*s*y^4 + s*y^3
> b, C2 := IsHyperelliptic(Curve(I[1])); assert b;
```

Example H126E5

Here is an example in degree 4 and weight 3. It turns out that the motive from $t = -1$ has complex multiplication, and the L-series appears to be the same as that of a Siegel modular form given by [vGvS93, S8.7]. (This was found by Cohen and Rodriguez-Villegas). This L-series also appears in Example H127E28.

```
> H := HypergeometricData([1/2,1/2,1/2,1/2],[0,0,0,0]);
> L := LSeries(H,-1 : BadPrimes:=[<2,9,1>]); // guessed
> CheckFunctionalEquation(L);
-5.916456789157588540587964239 62E-31
> LGetCoefficients(L,100);
[* 1, 0, 0, 0, -4, 0, 0, 0, -6, 0, 0, 0, -84, 0, 0, 0, 36, 0, 0, 0, 0,
   0, 0, 0, 146, 0, 0, 0, 140, 0, 0, 0, 0, 0, 0, 0, 60, 0, 0, 0, -140,
   0, 0, 0, 24, 0, 0, 0, -238, 0, 0, 0, 924, 0, 0, 0, 0, 0, 0, 0, -820,
   0, 0, 0, 336, 0, 0, 0, 0, 0, 0, 0, -396, 0, 0, 0, 0, 0, 0, 0, -693,
   0, 0, 0, -144, 0, 0, 0, -300, 0, 0, 0, 0, 0, 0, 0, -252, 0, 0, 0 *]
> // compare to the Tensor product way of getting this example
> E := EllipticCurve("32a");
> NF := Newforms(ModularForms(DirichletGroup(32).1,3)); // wt 3 w/char
> L1 := LSeries(E); L2 := LSeries(ComplexEmbeddings(NF[1][1])[1][1]);
> TP := TensorProduct(L1, L2, [ <2, 9> ]); // conductor 2^9 (guessed)
> [Round(Real(x)) : x in LGetCoefficients(TP,100)];
[ 1, 0, 0, 0, -4, 0, 0, 0, -6, 0, 0, 0, -84, 0, 0, 0, 36, 0, 0, 0, 0,
  0, 0, 0, 146, 0, 0, 0, 140, 0, 0, 0, 0, 0, 0, 0, 60, 0, 0, 0, -140,
  0, 0, 0, 24, 0, 0, 0, -238, 0, 0, 0, 924, 0, 0, 0, 0, 0, 0, 0, -820,
  0, 0, 0, 336, 0, 0, 0, 0, 0, 0, 0, -396, 0, 0, 0, 0, 0, 0, 0, -693,
  0, 0, 0, -144, 0, 0, 0, -300, 0, 0, 0, 0, 0, 0, 0, -252, 0, 0, 0 ]
```

Example H126E6

Here is an example showing how to handle bad primes in some cases. The Euler factors at $\{3, 5, 17\}$ [where $p|(t-1)$] were determined via a recipe from deformation theory by Rodriguez-Villegas, while at $p = 2$, Roberts suggested a t-value that would trivialise the conductor (from a number field analogy), and Tornaría then computed the full degree 4 factor (at $p = 2$) for $t = 2^8$.

```
> H := HypergeometricData([1/2,1/2,1/2,1/2],[0,0,0,0]);
> Lf := LSeries(Newforms(ModularForms(8,4))[1][1]);
> T := PolynomialRing(Integers()).1; // dummy variable
> f3 := EulerFactor(Lf,3 : Integral)*(1-3*T); // make it a poly
> f5 := EulerFactor(Lf,5 : Integral)*(1-5*T); // via Integral
> f17 := EulerFactor(Lf,17 : Integral)*(1-17*T);
> f2 := 1+T+6*T^2+8*T^3+64*T^4; // determined by Tornaria
> BP := [<2,0,f2>,<3,1,f3>,<5,1,f5>,<17,1,f17>];
> L := LSeries(H,256 : BadPrimes:=BP);
> Conductor(L);
255
> assert Abs(CheckFunctionalEquation(L)) lt 10^(-28);
```

One need not specify all the bad prime information as in the above example. Here is a variation on it, with $t = 1/2^8$ (note that this actually gives the same L-series, as the data is a self-twist, with the character induced by twisting being trivial for this choice of t). Note that only the information at 2 is given to `LSeries`.

```
> H := HypergeometricData([1/2,1/2,1/2,1/2],[0,0,0,0]);
> MValue(H);
256
> t := 1/2^8; // makes v_2(Mt)=0
> f2 := EulerFactor(H,t,2 : Fake);
> f2;
64*T^4 + 8*T^3 + 6*T^2 + T + 1
> L := LSeries(H,t : BadPrimes:=[<2,0,f2>]);
> Conductor(L);
255
> assert Abs(CheckFunctionalEquation(L)) lt 10^(-28);
```

Example H126E7

Here is an example with the quintic 3-fold. The deformation theory at $p = 11$ here is related to the Grössencharacter example over $\mathbf{Q}(\zeta_5)$ given in Example H34E24. The action on inertia at $p = 11$ involves ζ_5 when $11|t$, and here it is raised to the 5th power, thus trivialising it. As with previous example, the deformation theory also involves a weight 4 modular form, here of level 25.

```
> f := CyclotomicPolynomial(5); g := CyclotomicPolynomial(1)^4;
> H := HypergeometricData(f,g); H, Weight(H); // weight 3
Hypergeometric data given by [1/5,2/5,3/5,4/5] and [0,0,0,0]
3
> t := 11^5; // 11 is now good, as is raised to 5th power
> T := PolynomialRing(Rationals()).1;
> f2 := (1-T+8*T^2)*(1+2*T); // could have Magma compute these
> f3221 := (1-76362*T+3221^3*T^2)*(1-3221*T); // wt 4 lev 25
> // degree 4 factor at 11 comes from Grossencharacter
> // in fact, this is the t=0 deformation: sum_i x_i^5 = 0
> K<z5> := CyclotomicField(5);
> p5 := Factorization(5*Integers(K))[1][1]; // ramified
```

```
> G := HeckeCharacterGroup(p5^2);
> psi := Grossencharacter(G.0,[[3,0],[1,2]]);
> f11 := EulerFactor(LSeries(psi),11 : Integral); f11;
1771561*x^4 - 118459*x^3 + 3861*x^2 - 89*x + 1
> BP := [<2,1,f2>,<5,4,1>,<11,0,f11>,<3221,1,f3221>];
> L := LSeries(H,t : BadPrimes:=BP);
> Conductor(L); // 2*5^4*3221, 5^4 is somewhat guessed
4026250
> LSetPrecision(L,5); LCfRequired(L);
12775
> CheckFunctionalEquation(L); // takes about 40s
-3.8147E-6
```

Again one need not specify all the bad prime information, as Magma can automatically compute it at multiplicative and tame primes (however, the local conductor at 5 must be specified).

```
> EulerFactor(H,t,11); // tame
1771561*T^4 - 118459*T^3 + 3861*T^2 - 89*T + 1
> EulerFactor(H,t,2); // multiplicative
16*T^3 + 6*T^2 + T + 1
> EulerFactor(H,t,3221); // multiplicative
-107637325775281*T^3 + 33663324863*T^2 - 79583*T + 1
```

One can also choose t so as to trivialise the wild prime 5.

```
> MValue(H); // 5^5;
3125
> t := 11^5/5^5;
> f5 := EulerFactor(H,t,5 : Fake); // v_5(Mt)=0
> f5;
15625*T^4 - 125*T^3 - 45*T^2 - T + 1
> L := LSeries(H,t : BadPrimes:=[<5,0,f5>]);
> Conductor(L); // 2*3*26321, Magma computes Euler factors
157926
> LSetPrecision(L,9); // about 4000 terms
> CheckFunctionalEquation(L);
-2.32830644E-10
> t := -11^5/5^5; // another choice with v_5(Mt)=0
> f5 := EulerFactor(H,t,5 : Fake); // v_5(Mt)=0
> f5; // four possible Euler factors, one for each Mt mod 5
15625*T^4 + 1750*T^3 + 230*T^2 + 14*T + 1
> L := LSeries(H,t : BadPrimes:=[<5,0,f5>]);
> Conductor(L); // 2*31*331, Magma computes Euler factors
20552
> LSetPrecision(L,9); // about 1300 terms
> CheckFunctionalEquation(L);
4.65661287E-10
```

Example H126E8

Here is an example with tame primes. This derives from comments of Rodriguez-Villegas. The idea is to take hypergeometric data that has weight 0 or 1, and compare it to Artin representations or hyperelliptic curves.

```
> T := PolynomialRing(Rationals()).1; // dummy variable
> H := HypergeometricData([3,4,6,12],[1,1,5,5]); // degree 10
> b, HC := IsHyperelliptic(CanonicalCurve(H)); // genus 5
> assert b; Genus(HC);
5
> EulerFactor(Specialization(HC,13^12),13); // 13 becomes good
371293*T^10 - 285610*T^9 + 125229*T^8 - 31096*T^7 + 4810*T^6
 - 540*T^5 + 370*T^4 - 184*T^3 + 57*T^2 - 10*T + 1
> EulerFactor(H,13^12,13); // use hypergeometric methods
371293*T^10 - 285610*T^9 + 125229*T^8 - 31096*T^7 + 4810*T^6
 - 540*T^5 + 370*T^4 - 184*T^3 + 57*T^2 - 10*T + 1
> assert &and[EulerFactor(Specialization(HC,p^12),p)
>             eq EulerFactor(H,p^12,p) : p in [11,13,17,19]];
> assert &and[EulerFactor(Specialization(HC,t0*13^12),13)
>             eq EulerFactor(H,t0*13^12,13) : t0 in [1..12]];
```

One can take a smaller power than the 12th, but then the curve will not become completely good at the prime. However, the hypergeometric calculations will still be possible.

```
> EulerFactor(H,17^4,17);
17*T^2 + 2*T + 1
> EulerFactor(H,19^9,19); // takes the Phi_3 term
19*T^2 + 7*T + 1
> EulerFactor(H,19^6,19);
361*T^4 + 114*T^3 + 31*T^2 + 6*T + 1
> EulerFactor(H,1/11^5,11); // degree is phi(1)+phi(5)
-T^5 + 1
> EulerFactor(H,4/11^5,11); // degree is phi(1)+phi(5)
-T^5 + 5*T^4 - 10*T^3 + 10*T^2 - 5*T + 1
```

A similar exploration is possible with a weight 0 example. Here the Artin representation machinery is better able to cope with partially good primes.

```
> H := HypergeometricData([2,3,6],[1,5]); // degree 5
> Q := Rationals();
> EulerFactor(ArtinRepresentation(H,7^6),7 : R:=Q);
-T^5 - T^4 - T^3 + T^2 + T + 1
> EulerFactor(ArtinRepresentation(H,7^3),7 : R:=Q);
T^2 + T + 1
> EulerFactor(ArtinRepresentation(H,7^2),7 : R:=Q);
-T + 1
> EulerFactor(ArtinRepresentation(H,2/11^5),11 : R:=Q);
-T^5 + 5*T^4 - 10*T^3 + 10*T^2 - 5*T + 1
> EulerFactor(H,7^6,7); // compute it directly from H
-T^5 - T^4 - T^3 + T^2 + T + 1
```

```
> EulerFactor(H,7^3,7);
T^2 + T + 1
> EulerFactor(H,7^2,7);
-T + 1
> EulerFactor(H,2/11^5,11);
-T^5 + 5*T^4 - 10*T^3 + 10*T^2 - 5*T + 1
```

Example H126E9

Here is an example of the use of `PossibleHypergeometricData`, enumerating the number of possibilities in small degree. A speed test is also done for the save-limit code.

```
> for d in [1..8] do
>    [#PossibleHypergeometricData(d : Weight:=w) : w in [0..d-1]];
>    end for;
[ 1 ]
[ 3, 10 ]
[ 3, 0, 10 ]
[ 11, 74, 30, 47 ]
[ 7, 0, 93, 0, 47 ]
[ 23, 287, 234, 487, 84, 142 ]
[ 21, 0, 426, 0, 414, 0, 142 ]
[ 51, 1001, 1234, 3247, 894, 1450, 204, 363 ]
> D4w1 := PossibleHypergeometricData(4 : Weight:=1);
> D := [HypergeometricData(x) : x in D4w1];
> #[x : x in D | Twist(x) eq x]; // 12 are self-twists
12
> #PossibleHypergeometricData(4 : Weight:=1,TwistMinimal);
43
> #PossibleHypergeometricData(4 : Weight:=1,Primitive);
64
> // speed test for SaveLimit
> H := HypergeometricData([1/2,1/2,1/2,1/2],[0,0,0,0]);
> HypergeometricMotiveSaveLimit(2000);
> time _:=LGetCoefficients(LSeries(H,-1),2000);
Time: 1.040
> time _:=LGetCoefficients(LSeries(H,-1),2000);
Time: 0.540
> HypergeometricMotiveClearTable();
> time _:=LGetCoefficients(LSeries(H,-1),2000);
Time: 1.030
```

127 L-FUNCTIONS

Chapter 127
L-FUNCTIONS

127.1 Overview

A large variety of ζ-functions and L-functions occur in number theory and algebraic geometry. Some well-known L-functions include the Riemann ζ-function, the Dedekind ζ-function of a number field, Dirichlet series associated to characters, and L-series of curves (e.g., elliptic curves) over the rationals. MAGMA provides functionality for constructing such L-functions and computing their values in the complex plane. A typical calculation might go as follows:

```
> L := LSeries(EllipticCurve([0, -1, 1, 0, 0]));
> Evaluate(L,2);
0.546048036215013518334126660433
```

The first line defines an L-series $L(E, s)$ of the elliptic curve

$$E : y^2 + xy = x^3 - x^2$$

while the second line computes its value at $s = 2$. An impatient reader may wish simply to type `LSeries;` at the prompt and look at the various `LSeries` signatures and mimic the code above, thus getting access to much of the functionality.

Topics covered in this chapter include:

- The built-in L-series which include the Riemann ζ-function, the Dedekind ζ-function of a number field, Dirichlet series associated to characters, Artin representations, modular forms, and L-series of elliptic curves;
- The calculation of values, derivatives and Taylor expansions of L-series at a complex point s_0 to desired accuracy;
- A technical description of the L-series object in MAGMA, together with a description of how to construct user-defined L-series with any number of gamma factors, provided that the L-series satisfies a functional equation of the standard type;
- Operations such as division, multiplication and the tensor product of two L-series.

The reader is referred to Manin-Panchishkin [Sha95] Chapter 4, Serre [Ser65] and articles in [JKS94] for a background on L-functions. The algorithms mostly follow Dokchitser [Dok04] and the Pari implementation ComputeL [Dok02]. See also Lavrik [Lav67], Tollis [Tol97] and the exposition in Cohen [Coh00], 10.3.

127.2 Built-in L-series

An *L-series* or an *L-function* is an infinite sum $L(s) = \sum_{n=1}^{\infty} a_n/n^s$ in the complex variable s with complex coefficients a_n. Such functions arise in many places in mathematics and they are usually naturally associated with some kind of mathematical object, for instance a character, a number field, a curve, a modular form or a cohomology group of an algebraic variety. The coefficients a_n are certain invariants associated with that object. For example, in the case of a character $\chi : (\mathbf{Z}/m\mathbf{Z})^* \to \mathbf{C}^*$ they are simply its values $a_n = \chi(n)$ when $\gcd(n, m) = 1$ and 0 otherwise.

MAGMA is able to associate an L-series to various types of object. The intrinsic which provides access to such pre-defined L-series (apart from the Riemann zeta function that is not quite associated with anything) is

`LSeries(`*object: optional parameters*`)`

Every such function returns a variable of type `LSer`. A range of functions may now be applied to this L-series object as described in the following sections, and these are independent of the object to which the L-series was originally associated. In fact, an object of type `LSer` only "remembers" its origin for printing purposes.

`RiemannZeta()`

`Precision`	RNGINTELT	*Default :*

The Riemann zeta function $\zeta(s)$ is returned.

The number of digits of precision to which the values $\zeta(s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted, the precision of the default real field will be used.

Example H127E1

Check that $\zeta(2)$ agrees numerically with $\pi^2/6$.

```
> L := RiemannZeta( : Precision:=40);
> Evaluate(L,2);
1.6449340668482264364724151666460251892 19
> Pi(RealField(40))^2/6;
1.6449340668482264364724151666460251892 19
```

`LSeries(K)`

`Method`	MONSTGELT	*Default :* "*Default*"
`ClassNumberFormula`	BOOLELT	*Default :* `false`
`Precision`	RNGINTELT	*Default :*

Create the Dedekind zeta function $\zeta(K, s)$ of a number field K. The series is defined by $\sum_I \mathrm{Norm}_{K/\mathbf{Q}}(I)^{-s}$, where the sum is taken over the non-zero ideals I of the maximal order of K. For $K = \mathbf{Q}$, the series coincides with the Riemann zeta function.

The optional parameter `Method` may be `"Artin"`, `"Direct"` or `"Default"` and specifies whether the zeta function should be computed as a product of L-series of Artin representations or directly, by counting prime ideals. (The default behaviour depends upon the field.)

For the `"Direct"` method, the Dedekind zeta function has a simple pole at $s = 1$ whose residue must be known in order to compute the L-values. The class number formula gives an expression for this residue in terms of the number of real/complex embeddings of K, the regulator, the class number and the number of roots of unity in K. If the optional parameter `ClassNumberFormula` is set to `true`, then these quantities are computed on initialization (using MAGMA's functions `Signature(K), Regulator(K), #ClassGroup(MaximalOrder(K))` and `#TorsionSubgroup(UnitGroup(K))`) and it might take some time if the discriminant of K is large. If `ClassNumberFormula` is `false` (default) then the residue is computed numerically from the functional equation. This is generally faster, unless the discriminant of K is small and the precision is set to be very high.

The number of digits of precision to which the values $\zeta(K, s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field.

Example H127E2

This code computes the value of $\zeta(\mathbf{Q}(i), s)$ at $s = 2$.

```
> P<x> := PolynomialRing(Integers());
> K := NumberField(x^2+1);
> L := LSeries(K);
> Evaluate(L, 2);
1.5067030099229850308865650 4818
```

This particular example could have been expressed somewhat more succinctly by replacing the first two lines by either `K:=CyclotomicField(4)` or `K:=QuadraticField(-1)`.

Example H127E3

The code computes $\zeta(F, 2)$ for $F = \mathbf{Q}(\sqrt[12]{3})$.

```
> R<x> := PolynomialRing(Rationals());
> F := NumberField(x^12-3);
> L := LSeries(F: Method:="Direct");
Time: 0.078
> Conductor(L), LCfRequired(L);
1579460446107205632 92968955438
```

The set-up time for the direct method is negligible, but the L-value computation will take days for this number of coefficients. On the other hand, the normal closure of F is not too large and has only representations of small dimension:

```
> G := GaloisGroup(F);
> #G, [Degree(ch): ch in CharacterTable(G)];
```

```
24 [ 1, 1, 1, 1, 2, 2, 2, 2, 2 ]
> time L := LSeries(F : Method:="Artin");
Time: 5.234
```

It took longer to define the L-series, but the advantage is that it is a product of L-series with very small conductors, and the L-value calculations are almost instant:

```
> [Conductor(f[1]) : f in Factorisation(L)];
[ 1, 12, 3888, 576, 243, 15552, 15552 ]
> time Evaluate(L, 2);
1.63925427193646882835990708818
Time: 3.250
```

Example H127E4

This code follows an example of Serre and Armitage (see [Ser71, Arm71, Fri76]) where the ζ-function of a field vanishes at the central point.

```
> _<x> := PolynomialRing(Rationals());
> K<s5> := NumberField( x^2-5 );
> L<s205> := NumberField( x^2-205 );
> C := Compositum(K,L);
> e1 := C!(5+s5);
> e2 := C!(41+s205);
> E:=ext<C | Polynomial( [ -e1*e2, 0, 1] )>;
> A:=AbsoluteField(E);
> DefiningPolynomial(A);
x^8 - 820*x^6 + 223040*x^4 - 24206400*x^2 + 871430400
> Signature(A); // totally real
8 0
> L := LSeries(A);
> LCfRequired(L);
2739
> CheckFunctionalEquation(L);
1.57772181044202361082345713057E-30
> Evaluate(L, 1/2); // zero as expected
-9.98707556173617338749102627597E-62
```

So the evaluation of L at $1/2$ is zero as expected. In fact, L is a product, and one factor has odd sign:

```
> L`prod;
[ <L-series of Riemann zeta function, 1>,
  <L-series of Artin representation of Number Field A with
            character ( 1, 1, 1, -1, -1 ) and conductor 41, 1>,
  <L-series of Artin representation of Number Field A with
            character ( 1, 1, -1, -1, 1 ) and conductor 5, 1>,
  <L-series of Artin representation of Number Field A with
            character ( 1, 1, -1, 1, -1 ) and conductor 205, 1>,
  <L-series of Artin representation of Number Field A with
```

```
            character ( 2, -2, 0, 0, 0 ) and conductor 42025, 2> ]
> [ ComplexField(9)!Sign(x[1]) : x in $1 ];
[ 1.00000000, 1.00000000, 1.00000000, 1.00000000, -1.00000000 ]
> Sign(L`prod[5][1]);
-1.0000000000000000000000000000
```

`LSeries(A)`

`Precision` RngIntElt *Default :*

Creates the L-series of an Artin representation A. (For information about Artin representations see Chapter 44.)

Example H127E5

L-series of the two characters of $\mathrm{Gal}(\mathbf{Q}(i)/\mathbf{Q}) \cong C_2$.

```
> K := QuadraticField(-1);
> triv,sign := Explode(ArtinRepresentations(K));
> Evaluate(LSeries(triv), 2);    // zeta(2)=pi^2/6
1.6449340668482264364724151666 5
> Evaluate(LSeries(sign), 2);
0.9159655941772190150546035149 33
```

Example H127E6

We take a polynomial over $\mathbf{Q}$ with Galois group A_7 and the unique 6-dimensional irreducible Artin representation a of this group

```
> load galpols;
> f:=PolynomialWithGaloisGroup(7,6);
> K:=NumberField(f);
> A:=ArtinRepresentations(K);
> a:=A[2];a;
Artin representation of Number Field with defining polynomial
x^7 - 2*x^6 - 7*x^5 + 11*x^4 + 16*x^3 - 14*x^2 - 11*x + 2 over
the Rational Field with character ( 6, 2, 3, 0, 0, 1, -1, -1, -1 )
and conductor 988410721
```

Its L-series with the default precision of 30 digits needs a lot of coefficients to compute with

```
> L:=LSeries(a);
> LCfRequired(L);
1830809
```

We decrease the precision to 8 digits

```
> L:=LSeries(a: Precision:=8);
> LCfRequired(L);
```

```
52584
```

Now it takes under 30 seconds to verify the functional equation of $L(a, s)$ and to compute its value at $s = 2$.

```
> CheckFunctionalEquation(L);
-2.9802322E-7
> Evaluate(L,2);
1.1105970
```

`LSeries(E)`

`Precision` RngIntElt *Default :*

Create the L-series $L(E, s)$ of an elliptic curve E defined over $\mathbf{Q}$ or over a number field.

The number of digits of precision to which the values $L(E, s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field.

Note that the computation time for evaluating an L-series grows roughly like the square root of the conductor (or its norm to $\mathbf{Q}$ if the base field is a number field). Therefore an evaluation might take an unreasonable amount of time if the conductor of E is much larger than, say, 10^{10} or so. If only the leading term at $s = 1$ is required, over $\mathbf{Q}$ it is faster to use `AnalyticRank` or `ConjecturalRegulator`.

Note also for general number fields it is only conjectured that $L(E/K, s)$ has a meromorphic continuation to $\mathbf{C}$ and also possesses a functional equation. This conjecture is implicitly used in the computations.

Example H127E7

Consider the curve $E : y^2 + y = x^3 + x^2$ over $\mathbf{Q}$ of conductor 43. It has Mordell-Weil rank equal to 1, so we expect $L(E/\mathbf{Q}, 1) = 0$ and $L'(E/\mathbf{Q}, 1) \neq 0$ by the Birch-Swinnerton-Dyer conjecture.

```
> E := EllipticCurve([0,1,1,0,0]);
> Conductor(E);
43
> L:=LSeries(E);
> Evaluate(L, 1);
0.00000000000000000000000000000000
> Evaluate(L, 1 : Derivative:=1);
0.34352397461847823061807116392 2
```

Now base change E to $K = \mathbf{Q}(i)$. The Mordell-Weil rank of E over K is 2:

```
> Rank(E) + Rank(QuadraticTwist(E,-1));
2
```

So we expect $L(E/K, s)$ to have a zero of order 2:

```
> K := QuadraticField(-1);
```

```
> EK := BaseChange(E, K);
> L := LSeries(EK);
> Evaluate(L, 1);
0.00000000000000000000000000000000
> Evaluate(L, 1 : Derivative:=1) lt 10^-20;
true
> Evaluate(L, 1 : Derivative:=2);
1.623995450256000307225469103 42
```

`LSeries(E, K)`

`Method`	MonStgElt	*Default :* "*Default*"
`Precision`	RngIntElt	*Default :*

Given an elliptic curve E defined over the rationals and a number field K, create the L-series $L(E/K, s)$ associated with E/K. Note that in general it is only conjectured that $L(E/K, s)$ has an analytic continuation to $\mathbf{C}$ and possesses a functional equation. This conjecture is implicitly used in the computations.

Technically, the resulting L-series is the tensor product of two l-adic representations, the one associated to $E/\mathbf{Q}$ and the one associated to $K/\mathbf{Q}$. `Method` specifies how `LSeries(K)` should be defined. It is the same parameter as for `LSeries(FldNum)`, except that when E and K both have wild ramification at either 2 or 3, `"Direct"` is always used. Note that the conductor of the L-series $L(E/K, s)$ usually increases very rapidly with the discriminant of K. Consequently, if the used method is `"Direct"` or the irreducible constituents of `PermutationCharacter(K)` have large dimension, the computation time may be quite substantial.

The number of digits of precision to which the values $L(E/K, s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field.

Example H127E8

We take the curve $E : y^2 = x^3 + x$ over the rationals and apply base change to obtain a curve over $\mathbf{Q}(\sqrt{5})$. The resulting L-series $L(E, K, s)$ is in fact the product of $L(E/\mathbf{Q}, s)$ and $L(F/\mathbf{Q}, s)$ where F is E twisted by 5.

```
> E := EllipticCurve([0, 0, 0, 1, 0]);
> F := QuadraticTwist(E, 5);
> L := LSeries(E, QuadraticField(5));
> Evaluate(L, 1);
1.5373382847036052245896606919 5
> Evaluate(LSeries(E),1) * Evaluate(LSeries(F),1);
1.5373382847036052245896606919 5
```

Here is another example over a cyclotomic field. The L-value computations are fast, as here they only involve one-dimensional twists:

```
> E := EllipticCurve([0, 0, 0, 1, 0]);
```

```
> L := LSeries(E, CyclotomicField(11));
> time Evaluate(L, 1);
-1.03578452039312258255988860081E-28
Time: 4.797
```

`LSeries(E, A)`

Precision RngIntElt *Default :*

Twisted L-series of an elliptic curve $E/\mathbf{Q}$ by an Artin representation A. Currently does not allow E and A to be simultaneously wildly ramified at either 2 or 3.

Example H127E9

We take the elliptic curve 11A3 and twist it by the characters of $\mathbf{Q}(\zeta_5)/\mathbf{Q}$:

```
> E := EllipticCurve(CremonaDatabase(),"11A3");
> K := CyclotomicField(5);
> art := ArtinRepresentations(K);
> for A in art do Evaluate(LSeries(E,A),1); end for;
0.25384186085591068433775892335 1
0.68597671458851643816988951422 3 + 1.10993363969520543571381847366*$.1
2.83803828204429619496466743334 2
0.68597671458851643816988951422 3 - 1.10993363969520543571381847366*$.1
```

All the L-values are non-zero, so according to the Birch-Swinnerton-Dyer conjecture E has rank 0 over $\mathbf{Q}(\zeta_5)$. Indeed:

```
> #TwoSelmerGroup(BaseChange(E,K));
1
```

Example H127E10

As a higher-dimensional example, we twist $E = X_1(11)/\mathbf{Q}$ by a 2-dimensional Artin representation that factors through a quaternion Galois group.

```
> load galpols;
> E:=EllipticCurve("11a3");           // X_1(11)
> f:=PolynomialWithGaloisGroup(8,5);  // Quaternion Galois group
> K:=NumberField(f);
> A:=ArtinRepresentations(K);
> assert exists(a){a: a in A | Degree(a) eq 2};a;
Artin representation of Number Field with defining polynomial
x^8 - 12*x^6 + 36*x^4 - 36*x^2 + 9 over the Rational Field with
character ( 2, -2, 0, 0, 0 )
> L:=LSeries(E,a: Precision:=10);
> LCfRequired(L);
208818
> time Evaluate(L,1);
1.678012769
```

```
Time: 23.688
> Sign(L);
1.000000002
```

LSeries(C)

Precision	RngIntElt	*Default :*
ExcFactors	SeqEnum	*Default :* []

L-series of a hyperelliptic curve C defined over the rationals.

The number of digits of precision to which the values $L(C, s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field. If the conductor exponents and the local factors at (some of) the bad primes are known in advance, they can be passed as a sequence of tuples `<prime,conductor exponent,local factor>`, e.g. ExcFactors:=$[\langle 2, 11, 1 - x\rangle]$.

Example H127E11

We take the hyperelliptic curve $y^2 = x^5 + 1$

```
> R<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(x^5+1);
> L := LSeries(C: Precision:=18);
> LCfRequired(L);   // need this number of coefficients
1809
> Evaluate(L,1);  // L(C,1)
1.03140710417331775
> Sign(L); // sign in the functional equation
1.00000000000000000
```

The L-value is non-zero, indicating that the Jacobian should have rank 0. In fact, it does:

```
> RankBound(Jacobian(C));
0
```

LSeries(Chi)

Precision	RngIntElt	*Default :*

Given a primitive dirichlet character $\chi : (\mathbf{Z}/m\mathbf{Z})^* \to \mathbf{C}^*$, create the associated Dirichlet L-series $L(\chi, s) = \sum_{n=1}^{\infty} \chi(n)/n^s$. The character χ must be defined so that its values fall in either the ring of integers, the rational field or a cyclotomic field.

The number of digits of precision to which the values $L(\chi, s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field.

For information on Dirichlet characters, see Section 19.8.

Example H127E12

We define a primitive character $\chi : (\mathbf{Z}/37\mathbf{Z})^* \to \mathbf{C}^*$ and construct the associated Dirichlet L-function.

```
> G<Chi> := DirichletGroup(37, CyclotomicField(36));
> L := LSeries(Chi);
> Evaluate(L,1); // depends on the chosen generator of G
1.65325576836885655776002342451 - 0.55160789892291080587553771593 4*$.1
```

`LSeries(hmf)`

Given a cuspidal newform in a space of Hilbert modular forms, this creates the associated L-series.

Example H127E13

```
> K := QuadraticField(5);
> H := HilbertCuspForms(K,7*Integers(K),[2,2]);
> f := NewformDecomposition(NewSubspace(H))[1];
> L := LSeries(Eigenform(f));
> LSetPrecision(L,9);
> LCfRequired(L);
198
> time CheckFunctionalEquation(L);
-2.32830644E-10
Time: 16.590
```

`LSeries(psi)`

`LSeries(psi)`

`Precision` RngIntElt *Default :*

Given a primitive Hecke (Grössen)character on ideals, construct the associated L-series.

For more information on these see Section 34.9.

`LSeries(f)`

`Embedding`	MAP/USERPROGRAM	*Default :*
`Precision`	RNGINTELT	*Default :*

Given a modular form f, construct the L-series $L(f,s) = \sum_{n=1}^{\infty} a_n/n^s$, where f has the q-expansion $\sum_{n=0}^{\infty} a_n q^n$. It is assumed that $L(f,s)$ satisfies a functional equation of the standard kind (see Section 127.5.1 for the precise form of the functional equation).

The optional parameter `embedding` specifies a map which embeds the coefficients of f into the complex field. By default this is the identity map, so that the coefficients of f must be coercible into $\mathbf{C}$. Otherwise, the value of the parameter must either be an object of type `Map` or a user-defined function $e(x)$ each having domain the base ring of f and codomain the complex field (or values than can be coerced into the complex field).

The number of digits of precision to which the values $L(f,s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted the precision is taken to be that of the default real field.

Example H127E14

We define a newform of weight 2 and conductor 16. It is not defined over the integers but rather over $B = \mathbf{Z}[i]$.

```
> f := Newforms("G1N16k2A")[1]; f;
q + (-a - 1)*q^2 + (a - 1)*q^3 + 2*a*q^4 + (-a - 1)*q^5 + 2*q^6 -
2*a*q^7 + O(q^8)
> B:=BaseRing(f); B;
Equation Order with defining polynomial x^2 + 1 over Z
```

The two distinct embeddings of B into the complex numbers give rise to two modular forms, which can be accessed using the `ComplexEmbeddings` function.

```
> f1, f2 := Explode(ComplexEmbeddings(f)[1]);
> Coefficient(f,2), Coefficient(f1,2), Coefficient(f2,2);
-a - 1
-1.0000000000000000000000000000 + 1.0000000000000000000000000000*$.1
-1.0000000000000000000000000000 - 1.0000000000000000000000000000*$.1
```

Thus, f_1 and f_2 have genuine complex coefficients and we can construct the associated L-series and compute their L-values, for instance at $s = 1$.

```
> L1 := LSeries(f1);
> L2 := LSeries(f2);
> CheckFunctionalEquation(L1);
-2.3665827156630354162351856958 5E-30
> CheckFunctionalEquation(L2);
-2.3665827156630354162351856958 5E-30
> v1 := Evaluate(L1,1); v2 := Evaluate(L2,1); v1,v2;
0.35930643700350568406632720 7778 + 0.07147049399911726865884580 66910*$.1
```

```
0.359306437003505684066327207778 - 0.071470493999117268658845806691O*$.1
```

If instead we invoke `LSeries(f)`, MAGMA will note that f is defined over a number field and complain that the coefficients of f are not well-defined complex numbers.

```
> L := LSeries(f);
For f over a number field, you have to specify a complex embedding
```

Instead of using `ComplexEmbeddings`, one can instead explicitly specify an embedding of the coefficients of B into the complex numbers using the parameter `Embedding` with the function `LSeries` The following statements define the same L-function as L_2 above.

```
> C<i> := ComplexField();
> L2A := LSeries(f: Embedding:=hom< B -> C | i > );
> L2B := LSeries(f: Embedding:=func< x | Conjugates(x)[1] > );
> L2C := LSeries(f1: Embedding:=func< x | ComplexConjugate(x) > );
```

Finally, we illustrate the very important fact that MAGMA expects, but does *not* check that the L-function associated to a modular form satisfies a functional equation.

```
> L := LSeries(f1+f2);  // or L:=LSeries(f: Embedding:=func<x|Trace(B!x)>);
```

Although MAGMA is happy with this definition, it is in fact illegal. The modular form f has a character whose values lie in the field of the 4-th roots of unity.

```
> Order(DirichletCharacter(f));
4
```

The two embeddings f_1 and f_2 of f have *different* (complex conjugate) characters and $f_1 + f_2$ does not satisfy a functional equation of the standard kind. MAGMA will suspect this when it tries to determine the sign in the functional equation and thereby print a warning:

```
> Evaluate(L,1);
  |Sign| is far from 1, wrong functional equation?
0.736718188651826073550560964422
> CheckFunctionalEquation(L);
0.008143380371344820260617212212 44
```

The function `CheckFunctionalEquation` should return 0 (to current precision), so the functional equation is not satisfied, and the result of evaluating L will be a random number. So it is the *user's* responsibility to ensure that the modular form does satisfy a functional equation as described in Section 127.5.1. Here are some examples of modular forms that do.

```
> CheckFunctionalEquation(LSeries(f1^2*f2));
1.5777218104420236108234571305 7E-30
> f3 := ModularForm(EllipticCurve([0, -1, 1, 0, 0]));
> CheckFunctionalEquation(LSeries(f3));
0.00000000000000000000000000000
> M := Newforms("37k2");
> f4 := M[1,1]; f5 := M[2,1]; f6 := M[3,1];
> CheckFunctionalEquation(LSeries((f5+2*f6)*f4));
5.916456789157588540587964239 62E-31
```

127.3 Computing L-values

Once an L-series $L(s)$ has been constructed using either a standard zeta- or L-function (Section 127.2), a user defined L-function (Section 127.5.2) or constructed from other L-functions (Section 127.4), MAGMA can compute values $L(s_0)$ for complex s_0, values for the derivatives $L^{(k)}(s_0)$ and Taylor expansions.

`Evaluate(L, s0)`

`Derivative` RNGINTELT *Default :* 0

`Leading` BOOLELT *Default :* `false`

Given the L-series L and a complex number s_0, the intrinsic computes either $L(s_0)$, or if $D > 0$, the value of the derivative $L^{(D)}(s_0)$. If $D > 0$ and it is known that all the lower derivatives vanish,

$$L(s_0) = L'(s_0) = ... = L^{(D-1)}(s_0) = 0\,,$$

the computation time can be substantially reduced by setting `Leading:=true`. This is useful if it is desired to determine experimentally the order of vanishing of $L(s)$ at s_0 by successively computing the first few derivatives.

`CentralValue(L)`

Given an L-function of even weight $2k$ (in the MAGMA sense), the value of L is computed at $s = k$.

`LStar(L, s0)`

`Derivative` RNGINTELT *Default :* 0

Given the L-series L and a complex number s_0, the intrinsic computes either the value $L^*(s_0)$ or, if $D > 0$, the value of the derivative $L^{*(D)}(s_0)$. Here $L^*(s) = \gamma(s)L(s)$ is the modified L-function that satisfies the functional equation (cf. Section 127.5.1)

$$L^*(s) = \text{sign} \cdot \bar{L}^*(\text{weight} - s)$$

(cf. Section 127.5.1).

`LTaylor(L,s0,n)`

`ZeroBelow` RNGINTELT *Default :* 0

Compute the first $n + 1$ terms of the Taylor expansion of the L-function about the point $s = s_0$, where s_0 is a complex number:

$$L(s_0) + L'(s_0)x + L''(s_0)x^2/2! + \ldots + L^{(n)}(s_0)x^n/n! + O(x^{n+1})\ .$$

If the first few terms $L(s_0), ..., L^{(k)}(s_0)$ of this expansion are known to be zero, the computation time can be reduced by setting `ZeroBelow:=`$k + 1$.

Example H127E15

We define an elliptic curve E of conductor 5077 and compute derivatives at $s = 1$ until a non-zero value is reached:

```
> E := EllipticCurve([0, 0, 1, -7, 6]);
> L := LSeries(E : Precision:=15);
> Evaluate(L, 1);
0.000000000000000
> Evaluate(L, 1 : Derivative:=1, Leading:=true);
-1.69522909186553E-17
> Evaluate(L, 1 : Derivative:=2, Leading:=true);
6.27623031179552E-17
> Evaluate(L, 1 : Derivative:=3, Leading:=true);
10.3910994007158
```

This suggests that $L(E, s)$ has a zero of order 3 at $s = 1$. In fact, E is the rational elliptic curve of smallest conductor with Mordell-Weil rank 3:

```
> Rank(E);
3
```

Consequently, a zero of order 3 is predicted by the Birch–Swinnerton-Dyer conjecture. We can also compute a few terms of the Taylor expansion about $s = 1$, with or without specifying that the first three terms vanish.

```
> time LTaylor(L, 1, 5 : ZeroBelow:=3);
1.73184990011930*$.1^3 - 3.20590558844390*$.1^4 + 2.93970849657696*$.1^5
Time: 11.070
> time LTaylor(L, 1, 5);
-1.69522909186553E-17*$.1 + 3.13811515589776E-17*$.1^2 +
1.73184990011930*$.1^3 - 3.20590558844390*$.1^4 + 2.93970849657696*$.1^5
Time: 20.320
```

And this is the leading derivative, with the same value as `Evaluate(L,1:D:=3)`.

```
> c := Coefficient($1,3)*Factorial(3);c;
10.3910994007158
```

Finally, we compute the 3rd derivative of the modified L-function $L^*(s) = \gamma(s)L(s)$ at $s = 1$. For an elliptic curve over the rationals, $\gamma(s) = (N/\pi^2)^{s/2}\Gamma(s/2)\Gamma((s+1)/2)$, where N is the conductor. So, by the chain rule, $L^{*\prime\prime\prime}(1) = \gamma(1)L'''(1) = \sqrt{N/\pi}L'''(1)$.

```
> LStar(L, 1 : Derivative:=3);
417.724689268266
> c*Sqrt(Conductor(E)/Pi(RealField(15)));
417.724689268267
```

127.4 Arithmetic with L-series

With the exception of some modular forms, all the built-in L-series have weakly multiplicative coefficients, so that $L(s) = \sum a_n/n^s$ with $a_{mn} = a_m a_n$ for m, n coprime. For two such L-series, MAGMA allows the user to construct their product and, provided that it makes sense, their quotient.

`L1 * L2`

`Poles`	SEQENUM	*Default :* []
`Residues`	SEQENUM	*Default :* []
`Precision`	RNGINTELT	*Default :*

Let $L_1(s)$ and $L_2(s)$ be two L-series of the same weight whose coefficients are weakly multiplicative, that is, they satisfy $a_{mn} = a_m a_n$ for m, n coprime. This function constructs their product $L(s) = L_1(s)L_2(s)$.

If one of the L-series has zeros that cancel the poles of the other L-series, the user should specify the list of poles for $L_1^*(s)L_2^*(s)$ using the `Poles` parameter and the corresponding residues using the `Residues` parameter. See Section 127.5.1 for the terminology and Section 127.5.2 for the format of the poles and residues parameters.

The number of digits of precision to which the values $L(s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted, the precision is taken to be that of the default real field.

`L1 / L2`

`Poles`	SEQENUM	*Default :* []
`Residues`	SEQENUM	*Default :* []
`Precision`	RNGINTELT	*Default :*

Let $L_1(s)$ and $L_2(s)$ be two L-series whose coefficients a_{mn} are weakly multiplicative, that is, they satisfy $a_{mn} = a_m a_n$ for m, n coprime. This function constructs their quotient $L(s) = L_1(s)/L_2(s)$.

This function assumes (but does not check!) that this quotient exists and is a genuine L-function with finitely many poles.

If $L_2(s)$ happens to have zeros that give poles in the quotient, the user must specify the list of poles of $L_1^*(s)/L_2^*(s)$ using the `Poles` parameter and the corresponding residues using the `Residues` parameter. See Section 127.5.1 for the terminology and Section 127.5.2 for the format of `Poles` and `Residues`.

The number of digits of precision to which the values $L(s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted, the precision is taken to be that of the default real field.

`TensorProduct(L1, L2, ExcFactors)`

`TensorProduct(L1, L2)`

`TensorProduct(L1, L2, ExcFactors, K)`

`TensorProduct(L1, L2, K)`

`Precision`	RngIntElt	*Default :*
`Sign`	FldComElt	*Default :*

Let L_1 and L_2 be L-functions such that $L_1(s) = L(V_1, s)$ and $L_2(s) = L(V_2, s)$ are associated to systems of l-adic representations V_1 and V_2 (à la Serre). This function computes their tensor product $L(s) = L(V_1 \otimes V_2, s)$. This can be used, for example, to twist an L-function by characters or higher-dimensional Artin representations (see Examples H127E24, H127E25).

Note that, in particular, both $L_1(s)$ and $L_2(s)$ must have integer conductor, weakly multiplicative coefficients and an underlying Hodge structure (which is computed from the γ-shifts). The argument `ExcFactors` is a list of tuples of the form $\langle p, v\rangle$ or $\langle p, v, F_p(x)\rangle$ that give, for each of the primes p where V_1 and V_2 both have bad reduction, the valuation v of the conductor of $V_1 \otimes V_2$ at p and the inverse local factor at p. If the data is not provided for such a prime p, Magma will attempt to compute the local factors by assuming that the inertia invariants behave well at p,

$$(V_1 \otimes V_2)^{I_p} = V_1^{I_p} \otimes V_2^{I_p}.$$

It will also compute the conductor exponents by predicting the tame and wild degrees from the degrees of the local factors, but this does not work if both V_1 and V_2 are wildly ramified at p.

The sign in the functional equation of $L(V_1 \otimes V_2, s)$ cannot be determined from the signs of the factors, so it will be calculated numerically from the functional equation. If the sign is known, the user may specify it by means of the `Sign` parameter.

The number of digits of precision to which the values $L(s)$ are to be computed may be specified using the `Precision` parameter. If it is omitted, the precision is taken to be that of the default real field.

If L_1 and L_2 have Euler products over the same field K, this field can be given as an additional argument, and the tensor product will be taken with respect to that field.

See Examples H127E18 and H127E24, H127E25, and Section 127.9.7.

127.5 General L-series

In addition to the built-in L-series for the standard objects, Magma provides machinery that allows the user to define L-series for arbitrary objects, provided that they admit a meromorphic continuation to the whole complex plane and satisfy a functional equation of the standard kind. To describe how this may be done, we need to introduce some terminology.

127.5.1 Terminology

Recall that an *L-series* is a sum

$$L(s) = \sum_{n=1}^{\infty} \frac{a_n}{n^s},$$

where the coefficients a_n are complex numbers, known as the Dirichlet coefficients of the L-series. For example, the Dirichlet coefficients of the classical Riemann zeta function are $a_n = 1$ for all n. We assume that, as in the case of Riemann zeta function, every $L(s)$ has a meromorphic continuation to the complex plane and has a functional equation. Technically, our assumptions are as follows:

Assumption 1. The defining series for $L(s)$ converges for $\mathrm{Re}(s)$ sufficiently large. Equivalently, the *coefficients* a_n grow at worst as a polynomial function of n.

Assumption 2. $L(s)$ admits a meromorphic continuation to the entire complex plane.

Assumption 3. The following exist: real positive *weight*, complex *sign* of absolute value 1, real positive *conductor* and the Γ-*factor*

$$\gamma(s) = \Gamma\Big(\frac{s+\lambda_1}{2}\Big) \cdots \Gamma\Big(\frac{s+\lambda_d}{2}\Big)$$

of *dimension* $d \geq 1$ and rational γ-*shifts* $\lambda_1, \ldots \lambda_d$, such that

$$L^*(s) = \Big(\frac{\text{conductor}}{\pi^d}\Big)^{s/2} \gamma(s)\, L(s)$$

satisfies the *functional equation*

$$L^*(s) = \text{sign} \cdot \bar{L}^*(\text{weight} - s).$$

Here $\bar{L}$ is the *dual* L-series with complex conjugate coefficients $L(s) = \sum_{n=1}^{\infty} \overline{a_n}/n^s$. Note that the "weight" here is one more than the usual motivic notion of weight.

Assumption 4. The series $L^*(s)$ has finitely many simple *poles* and no other singularities.

Assumption 1 will almost certainly be true for any naturally arising L-function and Assumptions 2–4 are expected (but not proven) to be satisfied for most of the L-functions arising in geometry and number theory. In fact, there is a large class of so-called *motivic L-functions* for which all of the above assumptions are conjectured to be true. Essentially this class consists of L-functions associated to cohomology groups of varieties over number fields. This is an extremely large class of L-functions that includes all of the standard examples.

127.5.2 Constructing a General L-Series

When computing the values $L(s)$ for a complex number s, MAGMA relies heavily on the functional equation. This means that the *emphasized* parameters in Assumptions 1–4 (coefficients, weight, conductor, poles, etc.) must be known before the computations can be carried out.

The generic `LSeries` function allows the user to construct an L-series for a new object by specifying values for these parameters. In fact, this function is used to construct all of the built-in L-series in MAGMA and some of these will be used as examples to illustrate its use (see the advanced examples section).

`LSeries(weight, gamma, conductor, cffun)`

`Sign`	FLDCOMELT	*Default :* 0
`Poles`	SEQENUM	*Default :* []
`Residues`	SEQENUM	*Default :* []
`Parent`	ANY	*Default :*
`CoefficientGrowth`	USERPROGRAM	*Default :*
`Precision`	RNGINTELT	*Default :*
`ImS`	FLDREELT	*Default :* 0
`Asymptotics`	BOOLELT	*Default :* `true`

The function takes four arguments: real positive *weight*, sequence of rational numbers *gamma*, real positive *conductor* and a coefficient function $cffun$ together with a number of optional parameters. It constructs an L-series with specified coefficients and the form of the functional equation.

Compulsory arguments (see Section 127.5.1 for terminology):

weight — weight of the L-series.

Specifies the functional equation; for instance, it is `1` for the Riemann zeta function, `2` for curves over the rationals and `Weight(f)` for modular forms f.

Note that the "weight" in this sense is the w such that $s \to w - s$ satisfies a functional equation. The usual motivic notion of weight is thus one less than this – for instance, a weight k modular form has weight k in Magma, but weight $k-1$ for motives, as its coefficients are typically of size $(\sqrt{p})^{k-1}$.

gamma — gamma shifts/parameters.

List (of type `SeqEnum`) of rational numbers that specify the gamma factor. For instance, this is `[0]` for the Riemann zeta function, `[0,1]` for an elliptic curve over $\mathbf{Q}$ and `[0,...,0,1,...,1]` with $r_1 + r_2$ zeros and r_2 ones for the Dedekind zeta function of a number field K with r_1 real and r_2 pairs of complex embeddings.

conductor — conductor of the L-series.

Part of the exponential factor $(\frac{\text{conductor}}{\pi^d})^{s/2}$ in the functional equation. It is usually an integer and is 1 for the Riemann zeta function, the level for a modular form,

|Discriminant(K)| for the Dedekind zeta of a number field K and the conductor of the Jacobian for an algebraic curve over the rationals.

cffun — specifies the coefficients a_n. The following possibilities are allowed:

- A finite sequence $[a_1, ..., a_n]$;
- A function $f(n)$ that returns a_n;
- A function $f(p, d)$ that computes the inverse of the local factor at p up to degree d;
- The value `0`, signifying that the coefficients will be provided later with a call to `LSetCoefficients`.

See Section 127.5.3 for a detailed explanation and examples.

Optional parameters for `Lseries:`:

`Sign` — the sign appearing in the functional equation.

This is the sign that enters the functional equation and is usually ± 1. It must be a complex number of absolute value 1. Alternatively, this can be set to 0 (default), in which case MAGMA will determine it numerically from the functional equation.

Instead of providing the actual sign, the user may also use an option `Sign:=s` where s is the name of a function $s(p)$ or $s(L, p)$ that computes the sign to precision p.

`Poles` — the poles z of $L^*(s)$ with Re $z \geq$weight/2 and

`Residues` — the residues at these poles

If $L^*(s)$ happens to have poles, there are only finitely many of them and each must be simple by Assumption 4 of the previous subsection. The poles have to be known and specified here when the L-function is created. The poles are symmetric about the point $s =$weight/2 by the functional equation and only the "right half" of the set of them has to be supplied in the form of a sequence as the value of the parameter `Poles`. The default setting is that $L^*(s)$ has no poles.

The residues at the poles of $L^*(s)$ are also required and they can be specified using the `Residues` parameter, which also takes a sequence as its value. It can be either a sequence of the same length as `Poles` or left to its default setting `[]`. In that case, MAGMA will attempt to determine the residues numerically using the functional equation. However, this is only possible if `Sign` is known and will not work to full precision if there is more than one pair of poles.

As an example, the Riemann zeta function has weight 1 and the modified function $\zeta^*(s)$ has poles at $s = 0$ and $s = 1$ with residues 1 and -1 respectively. So the parameter assignments `Poles:=[1], Residues:=[-1]` would be used in its definition.

As in the case of `Sign`, instead of providing the actual residues, the user may give the name of a function $r(p)$ or $r(L, p)$ that computes the residues up to precision p and returns them as a sequence.

`Parent` — any MAGMA object.

This is only used for printing purposes. When a variable type `LSer` is printed, MAGMA prints "L-series of" and then prints the parent object.

`Precision` — the precision to which L-values are to be computed (default is 0, use current precision).

`CoefficientGrowth` — name f of a function $f(x)$ or $f(L, x)$ such that $|a_n| < f(n)$.

`ImS` — the largest imaginary part of s for which $L(s)$ will be evaluated.

`Asymptotics` — whether to use asymptotic expansions (default is yes).

These four settings are related to the precision to which values are calculated in L-series computations. They are the same as for the `SetPrecision` function and are described in detail in Section 127.7.

As an illustration, the following code creates the Riemann zeta function from its invariants. This is essentially what `RiemannZeta()` does:

```
> Z := LSeries(1, [0], 1, func<n|1>
>                         : Sign:=1, Poles:=[1], Residues:=[-1]);
> CheckFunctionalEquation(Z);
0.00000000000000000000000000000000
```

For more examples, see the "Advanced Examples" Section 127.9.

It is strongly advised that the user apply the function `CheckFunctionalEquation` whenever a generic L-series is defined. If one of the specified parameters (conductor, sign, etc.) happens to be incorrect, the resulting L-series will not have a functional equation and the values returned by the evaluation functions will be nonsense. Only by checking the functional equation will the user have an indication that something is wrong.

`CheckFunctionalEquation(L)`

`t` FldReElt *Default :* 1.2

Given an L-series L, this function tests the functional equation numerically and should ideally return 0 (to the current precision), meaning that the test was passed. If the value returned is a significant distance from 0, either the L-function does not have a functional equation or some of the defining parameters (conductor, poles etc.) have been incorrectly specified or not enough coefficients have been given. In the latter case, `CheckFunctionalEquation` is likely to return a number reasonably close to 0 that measures the accuracy of computations.

As already mentioned, Magma can only work with L-functions that satisfy the functional equation as in Section 127.5.1. Whenever an L-function is constructed, its functional equation is implicitly used in all the L-series evaluations, even when L is evaluated in the region where the original Dirichlet series is absolutely convergent.

If either the sign in the functional equation or the residues of $L^*(s)$ have not yet been computed, this function will first compute them. If the sign was undefined, it returns $|\texttt{Sign}| - 1$ which, again, must be 0.

The optional technical parameter `t` is a point on the real line where Magma evaluates the two Theta functions associated to the L-series and subtracts one from the other to get the value returned by `CheckFunctionalEquation`. The parameter

`t` must be a real number satisfying $1.05 < t < 1.2$ and for every such number the function should return 0, provided that the functional equation is indeed correct.

Example H127E16

We attempt to define a truncated L-series of a quadratic character mod 3 (so $\chi(n) = 0, 1, -1$ if n is 0,1 or 2 mod 3 respectively.)

```
> L := LSeries(1, [0], 3, [1,-1,0,1,-1,0] : Sign:=-1);
> CheckFunctionalEquation(L);
1.15245561556037369749660548 1547
```

This does not look right. In fact, the γ-shifts are 0 for even quadratic characters, but 1 for odd ones,

```
> L := LSeries(1, [1], 3, [1,-1,0,1,-1,0] : Sign:=-1);
> CheckFunctionalEquation(L);
1.06372623587922089871296822 6243
```

This still does not look right. We gave the wrong sign in the functional equation.

```
> L := LSeries(1, [1], 3, [1,-1,0,1,-1,0] : Sign:=1);
> CheckFunctionalEquation(L);
3.32817107758805778728258386 3548E-15
```

This certainly looks better but it indicates that we did not give enough coefficients to our L-series. We determine how many coefficients are needed to do computations with default precision (30 digits),

```
> LCfRequired(L);
11
```

So 11 coefficients are needed and we provide them in the code below.

```
> L := LSeries(1, [1], 3, [1,-1,0,1,-1,0,1,-1,0,1] : Sign:=1);
> CheckFunctionalEquation(L);
9.86076131526264756764660706 6035E-32
```

This a correct way to define our L-series. Even better is the following variant:

```
> L := LSeries(1, [1], 3, func<n|((n+1) mod 3)-1> : Sign:=1);
> CheckFunctionalEquation(L);
9.86076131526264756764660706 6035E-32
```

This allows MAGMA to calculate as many a_n as it deems necessary using the provided function.

127.5.3 Setting the Coefficients

`LSetCoefficients(L,cffun)`

This function defines the coefficients a_n of the L-series L. The argument $cffun$ can be one of the following:

- A sequence $[a_1, ..., a_n]$;
- A function $f(n)$ that returns a_n;
- A function $f(p, d)$ that computes the inverse of the local factor at p up to degree d.

When a user-defined L-series is constructed by invoking the function

```
> L := LSeries(weight,gamma,conductor,cffun: <optional parameters>);
```

this is actually equivalent to invoking the pair of functions

```
> L := LSeries(weight,gamma,conductor,0: <optional parameters>);
> LSetCoefficients(L,cffun);
```

where the first line indicates that the coefficients will be supplied later and the second line actually specifies the coefficients. So the following description of the `cffun` parameter for the function `LSetCoefficients(L,cffun)` applies to the main `LSeries` signature as well.

The first two ways to specify the a_n are either to give a pre-computed sequence of coefficients up to a certain bound or to give the name of a function $f(n)$ that computes the a_n. (The other two ways are described in the two subsections that follow.) For instance, the following both define the Riemann zeta function with weight 1, one γ-shift 0, conductor 1, sign 1, pole at $s = 1$ with residue -1, all $a_n = 1$:

```
> V := [ 1 : k in [1..100] ];
> L := LSeries(1, [0], 1, V : Sign:=1, Poles:=[1], Residues:=[-1]);
```

or

```
> f := func<n|1>;
> L := LSeries(1, [0], 1, f : Sign:=1, Poles:=[1], Residues:=[-1]);
```

Of the two possibilities, the second one is safer to use in a sense that it lets MAGMA decide how many coefficients it needs in order to perform the calculations to the required precision. However, if the computation of a_n is costly and it involves previous coefficients, then it is probably better to write a function that computes a_n recursively, storing them in a sequence and then passing it to `LSeries`.

127.5.4 Specifying the Coefficients Later

When specifying a finite list of coefficients it is necessary to know in advance how many coefficients have to be computed. For this, MAGMA provides a function `LCfRequired(L)` (see Section 127.6).

Example H127E17

We define L to be our own version of the Riemann zeta function (weight 1, one γ-shift 0, conductor 1, sign 1, pole at $s = 1$ with residue -1), but tell MAGMA that we will specify the coefficients later with the 4th parameter set to 0. Then we ask how many coefficients it needs to perform computations:

```
> L := LSeries(1, [0], 1, 0: Sign:=1, Poles:=[1], Residues:=[-1]);
> N := LCfRequired(L); N;
6
```

Now we compute the coefficient vector $[a_1, ..., a_N]$.

```
> vec := [1, 1, 1, 1, 1, 1];
> LSetCoefficients(L,vec);
```

Now we can evaluate our ζ-function

```
> Evaluate(L,2);
1.64493406684822643647241516665
> Pi(RealField())^2/6;
1.64493406684822643647241516665
```

If we provide fewer coefficients, the computations will not have full precision but we can use `CheckFunctionalEquation` to get an indication of the resulting accuracy

```
> LSetCoefficients(L, [1,1]);
> CheckFunctionalEquation(L);
4.94876281053441137266582049650 8E-9
> Evaluate(L, 2);
1.64493406684811250127872978182
> $1 - Pi(RealField(28))^2/6;
-1.13935193685384864674677434 0E-13
```

Note that such good accuracy with just two coefficients is a singular phenomenon that only happens for L-functions with very small conductors. Normally, at least hundreds of coefficients are needed to compute L-values to this precision.
Note also that the last value `Evaluate(L,2)` in the example is much more precise than what one would get with the truncated version of the original defining series $\zeta_{trunc}(s) = 1 + 1/2^s$ at $s = 2$. The reason for this is that even in the region where the original Dirichlet series converges, the use of the functional equation usually speeds up the convergence.

127.5.5 Generating the Coefficients from Local Factors

The final and, in many cases, mathematically the most natural way to supply the coefficients is by specifying the so-called *local factors*. Recall that the coefficients for most L-series are *weakly multiplicative*, meaning that $a_{mn} = a_m a_n$ for m coprime to n. For such L-series, $L(s)$ admits a *product formula*

$$L(s) = \prod_{p \text{ prime}} \frac{1}{F_p(p^{-s})},$$

where $F_p(x)$ is a formal power series in x with complex coefficients. For example, if $L(s)$ arises from a variety over a number field (and this, as we already mentioned, essentially covers everything), then such a product formula holds. In this case the $F_p(x)$ are polynomials of degree d for those primes p not dividing the conductor and are of smaller degree otherwise. Moreover, their coefficients lie in the ring of integers of the field of definition of the variety.

For L-functions with weakly multiplicative coefficients, MAGMA allows the coefficients to be defined by specifying the local factors, using the function `LSetCoefficients(L,f)` where f is a user-defined function with two arguments p and d that computes $F_p(x)$, either as a full polynomial in x or as a power series in x of precision $O(x^{d+1})$. For example, the Riemann zeta function has $F_p(x) = 1 - x$ for all p, so we can define it as follows,

```
> Z := LSeries(1, [0], 1, 0 : Poles:=[1], Residues:=[-1], Sign:=1);
> P<x> := PolynomialRing(Integers());
> LSetCoefficients(Z, func<p,d | 1-x> );
```

or as

```
> P<x> := PowerSeriesRing(Integers());
> Z := LSeries(1, [0], 1, func<p,d|1-x+O(x^(d+1))> :
               Poles:=[1], Residues:=[-1], Sign:=1);
```

127.6 Accessing the Invariants

`LCfRequired(L)`

The number of Dirichlet coefficients a_n that have to be calculated in order to compute the values $L(s)$. This function can be also used with a user-defined L-series before its coefficients are set, see Section 127.5.4.

`LGetCoefficients(L, N)`

Compute the vector of first N coefficients `[*` $a_1, ..., a_N$ `*]` of the L-series given by L.

`EulerFactor(L, p)`

Given an L-series and a prime p, this computes the pth Euler factor, either as a polynomial or a power series. The optional parameter `Degree` will truncate the series to that length, and the optional parameter `Precision` is of use when the series is defined over the complex numbers.

`Conductor(L)`

Conductor of the L-series (real number, usually an integer). This invariant enters the functional equation and measures the 'size' of the object to which the L-series is associated. Evaluating an L-series takes time roughly proportional to the square root of the conductor.

`Sign(L)`

Sign in the functional equation of the L-series. This is a complex number of absolute value 1, or 0 if the sign has not been computed yet. (Calling `CheckFunctionalEquation(L)` or any evaluation function sets the sign.)

`GammaFactors(L)`

A sequence of Gamma factors $\lambda_1, \ldots, \lambda_d$ for $L(s)$. Each one represents a factor $\Gamma((s+\lambda_i)/2)$ entering the functional equation of the L-function.

`LSeriesData(L)`

Given an L-series L, this function returns the weight, the conductor, the list of γ-shifts, the coefficient function, the sign, the poles of $L^*(s)$ and the residues of $L^*(s)$ as a tuple of length 7. If Sign $= 0$, this means it has not been computed yet. Residues= [] means they have not yet been computed. From this data, L can be re-created with a general `LSeries` call (see Section 127.5.2).

Example H127E18

For a modular form, the q-expansion coefficients are the same as the Dirichlet coefficients of the associated L-series:

```
> f := Newforms("30k2")[1,1];
> qExpansion(f,10);
q - q^2 + q^3 + q^4 - q^5 - q^6 - 4*q^7 - q^8 + q^9 + O(q^10)
> Lf := LSeries(f);
> LGetCoefficients(Lf,20);
[* 1, -1, 1, 1, -1, -1, -4, -1, 1, 1, 0, 1, 2, 4, -1, 1, 6, -1, -4, -1*]
```

The elliptic curve of conductor 30 that corresponds to f has, of course, the same L-series.

```
> E := EllipticCurve(f); E;
Elliptic Curve defined by y^2 + x*y + y = x^3 + x + 2 over Rational Field
> LE := LSeries(E);
> LGetCoefficients(LE,20);
```

```
[* 1, -1, 1, 1, -1, -1, -4, -1, 1, 1, 0, 1, 2, 4, -1, 1, 6, -1, -4, -1*]
```

Now we change the base field of E to a number field K and evaluate the L-series of E/K at $s = 2$.

```
> P<x> := PolynomialRing(Integers());
> K := NumberField(x^3-2);
> LEK := LSeries(E,K);
> i := LSeriesData(LEK); i;
<2, [ 0, 0, 0, 1, 1, 1 ], 8748000, ... >
```

The conductor of this L-series (second entry) is very large and this is an indication that the calculations of $L(E/K, 2)$ to the required precision (30 digits) will take some time. We can also ask how many coefficients will be used in this calculation.

```
> LCfRequired(LEK); // a lot!
280632
```

Decreasing the precision will help somewhat.

```
> LSetPrecision(LEK,9);
> LCfRequired(LEK);
17508
```

And realizing that our L-series has a piece that can be factored out will certainly help (see the Arithmetic section).

```
> Q := LEK/LE;
> LSetPrecision(Q,9);
> LCfRequired(Q);
3780
> time Evaluate(Q,2) * Evaluate(LE,2);  // = L(E/K,2)
0.892165947
Time: 8.020
```

`Factorization(L)`

If an L-series is represented internally as a product of other L-series, say $L(s) = \prod_i L_i(s)^{n_i}$, return the sequence `[...<`L_i`,`n_i`>...]`.

Example H127E19

```
> L := RiemannZeta();
> Factorization(L);
[
    <L-series of Riemann zeta function, 1>
]
> R<x> := PolynomialRing(Rationals());
> K := SplittingField(x^3-2);
> L := LSeries(K);
> Factorization(L);
[
```

```
    <L-series of Riemann zeta function, 1>,
    <L-series of Artin representation of Number Field with
      defining polynomial x^6 + 108 over the Rational Field
      with character ( 1, -1, 1 ) and conductor 3, 1>,
    <L-series of Artin representation of Number Field with
      defining polynomial x^6 + 108 over the Rational Field
      with character ( 2, 0, -1 ) and  conductor 108, 2>
]
```

127.7 Precision

The values of an L-series are computed numerically and the precision required in these computations can be specified using the `Precision` parameter when an L-function is created. For example,

```
> K := CyclotomicField(3);
> L := LSeries(K: Precision:=60);
> Evaluate(L,2);
1.285190955484149402917511798699574603969178397028921243951 33
```

computes $\zeta(K, 2)$ to 60 digits precision. The default value `Precision:=0` is equivalent to the precision of the default real field at the time of the `LSeries` initialization call. If the user only wants to check numerically whether an L-function vanishes at a given point s and the value itself is not needed, it might make sense to decrease the precision (to 9 digits, say) to speed up the computations.

```
> E := EllipticCurve([0,0,1,-7,6]);
> RootNumber(E);
-1
> L := LSeries(E: Precision:=9);
> Evaluate(L, 1: Derivative:=1);
1.50193628E-11
> Rank(E);
3
```

This example checks numerically that $L'(E, 1) = 0$ for the elliptic curve E of conductor 5077 from Example H127E15.

The precision may be changed at a later time using `LSetPrecision`.

`LSetPrecision(L,precision)`

`CoefficientGrowth`	UserProgram	*Default :*
`ImS`	FldReElt	*Default :* 0
`Asymptotics`	BoolElt	*Default :* `true`

Change the number of digits to which the L-values are going to be computed to *precision*. The parameter `CoefficientGrowth` is described below in Section 127.7.1.

127.7.1 L-series with Unusual Coefficient Growth

The parameter `CoefficientGrowth` is the name f of a function $f(x)$ (or $f(L, x)$, where L is an L-series) which is an increasing function of a real positive variable x such that $|a_n| \leq f(n)$. This is used to truncate various infinite series in computations. It is set by default to the function $f(x) = 1.5 \cdot x^{\rho-1}$ where ρ is the largest real part of a pole of $L^*(s)$ if $L^*(s)$ has poles and $f(x) = 2x^{(weight-1)/2}$ if $L^*(s)$ has no poles. The user will most likely leave this setting untouched.

127.7.2 Computing $L(s)$ when $\mathrm{Im}(s)$ is Large (`ImS` Parameter)

If s is a complex number having a large imaginary part, a great deal of cancellation occurs while computing $L(s)$, resulting in a loss of precision. (The time when all the precision-related parameters are pre-computed is when the function `LSeries` is invoked, and at that time MAGMA has no way of knowing whether $L(s)$ is to be evaluated for complex numbers s having large imaginary part.) If this happens, a message is printed, warning of a precision loss. To avoid this, the user may specify the largest $\mathrm{Im}(s)$ for which the L-values are to be calculated as the value of the `ImS` parameter at the time of the L-series initialization or, later, with a call to `LSetPrecision`:

```
> C<i> := ComplexField();
> L := RiemannZeta();
> Evaluate(L, 1/2+40*i);            // wrong
Warning: Loss of 13 digits due to cancellation
0.79304495256192867198212885 1045 - 1.041274614651065020074521950 86*i
> LSetPrecision(L, 30: ImS:=40);
> Evaluate(L, 1/2+40*i);            // right
0.79304495256192867196489258 8898 - 1.041274614651065020051890595 39*i
```

127.7.3 Implementation of L-series Computations (`Asymptotics` Parameter)

The optional parameter `Asymptotics` in `LSetPrecision` and in the general `LSeries` function specifies the method by which the special functions needed for the L-series evaluation are computed.

If set to `false`, MAGMA will use only Taylor expansions at the origin and these are always known to be convergent. With the default behaviour (`Asymptotics:=true`) MAGMA will use both the Taylor expansions and the continued fractions of the asymptotic expansions at infinity. This is much faster, but these continued fractions are not proved to be convergent in all cases.

127.8 Verbose Printing

There is one verbose printing variable, called "LSeries" that controls verbose printing for all of the functions in this chapter.

```
> SetVerbose("LSeries",n);
```

It accepts verbosity levels n such that $0 \leq n \leq 3$. The values are as follows:

$n = 0$ is the (default) quiet mode. The functions do not print anything apart from loss-of-precision warnings.

$n = 1$ is possibly the most useful setting. The sign and the residues of $L^*(s)$ are printed whenever they are determined from the functional equation.

$n = 2$ generates messages that allow the user to keep track of what is currently happening. So messages are printed when a new L-function is constructed, when coefficients are generated or when expansions of special functions are computed.

$n = 3$ is a "keep-alive" setting that basically informs the user that the computer has not crashed yet and, yes, something is still happening. For L-functions of large conductor or very high precision that require a large number of coefficients, MAGMA will print a "progress indicator" every time 1000 new coefficients are generated and every 5000 terms in the series computations that test the functional equation or compute the L-values. (The frequencies 1000 and 5000 are stored in the attributes L`vprint_coeffs and L`vprint_series of a variable L of type LSeries and may be changed at the user's desire.)

127.9 Advanced Examples

127.9.1 Handmade L-series of an Elliptic Curve

Example H127E20

This is an example of how the general LSeries function can be used to define the L-series for elliptic curves. This is essentially what LSeries(E) does:

```
> E := EllipticCurve([1,2,3,4,5]);
> N := Conductor(E);N;
10351
> P<x> := PolynomialRing(Integers());
```

The easiest way to define the coefficients is to provide the local factors.

```
> cf := func< p,d|1 - TraceOfFrobenius(E,GF(p,1))*x
>                   +(N mod p ne 0 select p else 0)*x^2 >;
> L := LSeries(2,[0,1],N,cf : Parent:=E, Sign:=RootNumber(E));
```

Compare this with the built-in function LSeries(E)

```
> Evaluate(L,2);
0.97743186689450050867903912764 7
> Evaluate(LSeries(E),2);
0.97743186689450050867903912764 7
```

127.9.2 Self-made Dedekind Zeta Function

Example H127E21

This is an example of how the general `LSeries` function may be used to define the Dedekind zeta function of a number field K. This is essentially what the function `LSeries(K)` does:

```
> function DedekindZeta(K)
>   M := MaximalOrder(K);
>   r1,r2 := Signature(K);
>   gamma := [0: k in [1..r1+r2]] cat [1: k in [1..r2]];
>   disc := Abs(Discriminant(M));
>   P<x> := PolynomialRing(Integers());
```

The coefficients are defined by means of local factors; for a prime p we take the product of $1 - x^{f_k}$ where the f_i are the residue degrees of primes above p. Note that this local factor has (maximal) degree $[K : \mathbf{Q}]$ if and only if p is unramified or, equivalently, if and only if p does not divide the discriminant of K which is (up to sign) the conductor of our zeta-function.

```
>   cf := func<p,d|&*[1-x^Degree(k[1]): k in Decomposition(M,p)]>;
```

Finally, the Dedekind zeta function has a pole at $s = 1$ and we need its residue (or, rather, the residue of $\zeta^*(s)$) which we compute using the class number formula.

```
>   h := #ClassGroup(M);
>   reg := Regulator(K);
>   mu := #TorsionSubgroup(UnitGroup(M));
>   return LSeries(1, gamma, disc, cf: Parent:=K, Sign:=1, Poles:=[1],
>     Residues := [-2^(r1+r2)*Pi(RealField())^(r2/2)*reg*h/mu]);
> end function;
> Z := DedekindZeta(CyclotomicField(5)); Z;
L-series of Cyclotomic Field of order 5 and degree 4
> Evaluate(Z,1);
L*(s) has a pole at s = 1
> L := Z/RiemannZeta();
> Evaluate(L,1);
0.33983727824052353546427878 1159
```

127.9.3 L-series of a Genus 2 Hyperelliptic Curve

Example H127E22

We compute an L-series of a hyperelliptic curve of genus 2.

```
> P<x> := PolynomialRing(Integers());
> C := HyperellipticCurve([x^5+x^4,x^3+x+1]); C;
Hyperelliptic Curve defined by y^2 + (x^3 + x + 1)*y = x^5 + x^4
```

```
over Rational Field
```

There is an L-series attached to $\mathrm{H}^1(C)$ or, equivalently, the H^1 of the Jacobian J of C. To define this L-series, we need its local factors which, for primes p of good reduction of C, are given by `EulerFactor(J,GF(p,1))`. Let us look at the primes of bad reduction:

```
> Abs(Discriminant(C));
169
> Factorization(Integers()!$1);
[ <13, 2> ]
```

There is one prime $p = 13$ where the curve has bad reduction. There the fibre is a singular curve whose normalization is elliptic.

```
> A<X,Y> := AffineSpace(GF(13,1),2);
> C13 := Curve(A,Equation(AffinePatch(C,1)));
> GeometricGenus(C), GeometricGenus(C13);
2 1
> SingularPoints(C13);
{@ (9, 1) @}
> p := $1[1]; IsNode(p), IsCusp(p);
false true
> C13A := Translation(C13,p)(C13);
> C13B := Blowup(C13A); C13B;
Curve over GF(13) defined by
X^3 + 12*X^2*Y + 7*X^2 + 12*X*Y + 12*Y^2 + 3*Y + 1
> E := EllipticCurve(ProjectiveClosure(C13B));
```

The local factor of C at $p = 13$ is given by the Euler factor of this elliptic curve

```
> EulerFactor(E);
13*x^2 + 5*x + 1
```

The conductor of $L(C, s)$ is 13^2, the same as the discriminant in this case. So, we define $L(C, s)$:

```
> J := Jacobian(C);
> loc := func<p,d|p eq 13 select EulerFactor(E) else EulerFactor(J, GF(p,1))>;
> L := LSeries(2,[0,0,1,1],13^2,loc);
```

Now we check the functional equation and compute a few L-values. (Most of the execution time will be spent generating coefficients, so the first call takes some time. After that, the computations are reasonably fast.)

```
> CheckFunctionalEquation(L);
-2.95822839457879427029398211981 0E-31
> Evaluate(L,1);
0.090490390832429629 1135897572580
> Evaluate(L,2);
0.364286342944364068154291450139
```

127.9.4 Experimental Mathematics for Small Conductor

Example H127E23

This example shows how one may construct the first 20 coefficients of the L-series of an elliptic curve of conductor 11 without knowing anything about either the curve or modular form theory. The point is that for an L-series $L(s) = \sum a_n/n^s$, the associated theta function (used in `CheckFunctionalEquation`) is a series with a_n as coefficients and terms that decrease very rapidly with n. This means that if we truncate the series to, for instance, just $a_1 + a_2/2^s$ and call `LSeries` with the same parameters (weight, sign, etc.) as those for $L(s)$ but just $[a_1, a_2, 0, 0, 0, 0, ...]$ as the coefficient vector, then `CheckFunctionalEquation` will return a number reasonably close to 0, because the coefficients a_n for $n > 2$ only make a small contribution.
With this in mind, we create an L-series that looks like that of an elliptic curve with conductor 11 and sign 1, that is, we take weight = 2, conductor = 1, gamma = [0,1], sign = 1 and no poles:

```
> L := LSeries(2, [0,1], 11, 0 : Sign:=1);
```

Then taking $a_1 = 1$, and recalling the requirement that all the coefficients must be weakly multiplicative, we try various a_2 to see which of the truncated L-series $1 + a_2/2^s$ is closest to satisfying a functional equation. Using the knowledge that a_2 (and every other a_n) is an integer together with the Hasse-Weil bound, $|a_p| < 2\sqrt{p}$, we find just 5 choices:

```
> for a_2 := -2 to 2 do
>   LSetCoefficients(L,[1,a_2]);
>   print a_2, CheckFunctionalEquation(L);
> end for;
-2 0.00844809870747809018757958838063 5
-1 0.07557498328782515608604001309880
0 0.14270186786817222198450043781 69
1 0.20982875244851928788296086253 50
2 0.27695563702886635378142128725 32
```

It seems that $a_2 = -2$ is the best choice, so we set it. Note that this also determines a_4, a_8, etc. We next proceed to find a_3 in the same way. It might come as a surprise, but in this way we can find the first 30 or so coefficients correctly. (Actually, by using careful bounds, it is even possible to prove that these are indeed uniquely determined.) Here is code that finds $a_1, ..., a_{20}$:

```
> N := LCfRequired(L); N;
48
> V := [0 : k in [1..N] ];   // keep a_p in here
> P<x> := PolynomialRing(Integers());
> function Try(V,p,a_p)  // set V[p]=a_p and try functional equation
>   V[p] := a_p;
>   LSetCoefficients(L, func<p,d | 1-V[p]*x+(p eq 11 select 0 else p)*x^2 >);
>   return Abs(CheckFunctionalEquation(L));
> end function;
> for p := 2 to 20 do     // try a_p in Hasse-Weil range and find best one
>   if IsPrime(p) then
>     hasse := Floor(2*Sqrt(p));
>     _,V[p] := Min([Try(V,p, a_p): a_p in [-hasse..hasse]]);
```

```
>     V[p] -:= hasse+1;
>   end if;
> end for;
> LSetCoefficients(L, func<p,d | 1-V[p]*x+(p eq 11 select 0 else p)*x^2 >);
```

We list the coefficients that we found and apply CheckFunctionalEquation to them:

```
> LGetCoefficients(L,20);
[* 1, -2, -1, 2, 1, 2, -2, 0, -2, -2, 1, -2, 4, 4, -1, -4, -2, 4, 0, 2*]
> CheckFunctionalEquation(L);
4.1865797906741233744189856688l6E-16
```

Compare this with the actual truth:

```
> qExpansion(Newforms("11A")[1],21);
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 - 2*q^9 - 2*q^10 + q^11
    - 2*q^12 + 4*q^13 + 4*q^14 - q^15 - 4*q^16 - 2*q^17 + 4*q^18 +
    2*q^20 + O(q^21)
```

Such methods have been used by Stark in his experiments with L-functions of number fields, and by Mestre to find restrictions on possible conductors of elliptic curves. In fact, by modifying our example (changing 11 to $1 \ldots 10$ and sign $= 1$ to sign $= \pm 1$) one can show that for $N < 11$ there are no modular elliptic curves of conductor N.

127.9.5 Tensor Product of L-series Coming from l-adic Representations

Example H127E24

This is an example of using the tensor product for L-functions coming from l-adic representations. This is what `LSeries(E,K)` uses to construct L-series of elliptic curves over number fields.

```
> E := EllipticCurve([ 0, 0, 0, 0, 1]); // Mordell curve
> P<x> := PolynomialRing(Integers());
> K := NumberField(x^3-2);
> LE := LSeries(E);
> LK := LSeries(K);
```

We have now two L-functions, one associated to an elliptic curve and one to a number field. They both come from l-adic representations, and we can try to construct their tensor product. Actually, the function `TensorProduct` requires us to specify exponents of the conductor and the bad local factors of the tensor product representation, but we can try and let MAGMA do it, hoping that nothing unusual happens. We take the tensor product of the two L-series and divide it by $L(E, s)$ to speed up the computations. Remember that $L(K, s)$ has a copy of the Riemann zeta function as a factor.

```
> L := TensorProduct(LE, LK, []) / LE;
> CheckFunctionalEquation(L);
  |Sign| is far from 1, wrong functional equation?
```

```
0.023406257100607511430153563640 1
```

The resulting L-function does not satisfy the required functional equation, so something unusual does happen at a prime where both E and K have bad reduction, which in this case must be either $p = 2$ or $p = 3$.
Let us check $p = 2$. We change the base field of E to K and look at its reduction at the unique prime above 2:

```
> EK := BaseChange(E,K);
> p := Decomposition(MaximalOrder(K),2)[1,1];
> LocalInformation(E,2);
<2, 4, 2, 3, IV>
> loc, model:=LocalInformation(EK,p);loc,model;
<Principal Prime Ideal
Generator:
    [0, -1, 0], 0, 0, 1, I0>
Elliptic Curve defined by y^2 - y = x^3 over K
```

We see that E has acquired good reduction at $p|2$. This means that the inertia invariants at 2 of the l-adic representation associated to L, namely $\rho_E \otimes (\rho_K - \rho_{\mathbf{Q}})$ are *larger* than the tensor product of the corresponding inertia invariants, which is zero. Thus the local factor of L at 2 is not $F_p(x) = 1$ (which is what `TensorProduct` assumed), but a polynomial of higher degree. In fact, it is the characteristic polynomial of Frobenius of the reduced curve E/K mod p, so $F_p(x) = 1 - a_2x + 2x^2$ with a_2 given by

```
> TraceOfFrobenius(Reduction(model, p));
0
```

This is now the correct L-function (at $p = 3$ the default procedure works) and the functional equation is satisfied

```
> L := TensorProduct(LE,LK,[<2,4,1+2*x^2>])/LE;
> CheckFunctionalEquation(L);
3.155443620884047221646914261 13E-30
```

In fact, our L-series is the same as that constructed by `LSeries(E,K)/LE`.

127.9.6 Non-abelian Twist of an Elliptic Curve

Example H127E25

In this example we illustrate how to use `LSeries(E,K)` to construct non-abelian twists of elliptic curves.

```
> E := EllipticCurve([0, 0, 0, 0, 1]);
> P<x> := PolynomialRing(Integers());
> K := NumberField(x^3-2);
> L := LSeries(E,K) / LSeries(E);
> lval := Evaluate(L, 1); lval;
```

```
0.65537155216497443571237884249 1
```

The series L is the L-function of non-abelian twist of E and it appears that $L(1)$ is non-zero. In other words, the analytic rank of $L(E/K, s)$ at $s = 1$ is the same as that of $L(E/\mathbf{Q}, s)$. Tate's version of the Birch-Swinnerton-Dyer conjecture then predicts that the Mordell-Weil rank of E/K is the same as the rank over $\mathbf{Q}$, so the elliptic curve has not acquired new independent points. This is something that can be confirmed by a Selmer group computation:

```
> EK := BaseChange(E,K);
> twoE := MultiplicationByMMap(E, 2);
> #SelmerGroup(twoE);
2
> twoEK := MultiplicationByMMap(EK, 2);
> #SelmerGroup(twoEK);
2
```

Indeed, the 2-Selmer rank is 1 in both cases, as expected. Also, the second part of the Birch-Swinnerton-Dyer conjecture predicts that the following quotient should be rational:

```
> p1, p2 := Explode(Periods(E));
> lval*Sqrt(Abs(Discriminant(K))) / (p1*Im(p2));
1.33333333333333333333333333334
```

Finally, the same L-series can be defined via the Artin representation machinery:

```
> triv,sign,rho:=Explode(ArtinRepresentations(K));
> L:=LSeries(E,rho);
> CentralValue(L);
0.65537155216497443571237884249 2
```

127.9.7 Other Tensor Products

We take two L-functions with Euler products over a field K:

$$L_1(M,s) = \prod_{\mathfrak{p}} \prod_{i=1}^{m} \big(1 - \alpha_i(\mathfrak{p})/\mathrm{N}\mathfrak{p}^s\big)^{-1} \quad \text{and} \quad L_2(N,s) = \prod_{\mathfrak{p}} \prod_{j=1}^{n} \big(1 - \beta_j(\mathfrak{p})/\mathrm{N}\mathfrak{p}^s\big)^{-1},$$

where M and N are of degrees m and n respectively, and we ignore bad Euler factors in the above. Their tensor product is an L-function of degree mn given by

$$L(A \otimes B, s) = \prod_{\mathfrak{p}} \prod_{i=1}^{m} \prod_{j=1}^{n} \big(1 - \alpha_i(\mathfrak{p})\beta_j(\mathfrak{p})/\mathrm{N}\mathfrak{p}^s\big)^{-1}.$$

It is not clear in general how to compute bad Euler factors, and even the gamma factors can be tricky. Internally, the functionality tries to compute a "Hodge structure" corresponding to the gamma factors of each object, with the "Hodge structure" for the tensor product then following via combinatorics, before passing back to the gamma factors.

Some tensor products can induce poles, particularly when tensoring an L-series with itself. Also in some cases, the tensor product will be taken over $\mathbf{Q}$ unless the user specifies otherwise.

Example H127E26

A tensor product of two elliptic curves over $\mathbf{Q}$.

```
> E1 := EllipticCurve("11a");
> E2 := EllipticCurve("17a");
> L1 := LSeries(E1);
> L2 := LSeries(E2);
> L := TensorProduct(L1, L2, []);
> LSeriesData(L); // level is 11^2 * 17^2
<3, [ 0, 1, -1, 0 ], 34969, ... >
> CheckFunctionalEquation(L);
-2.83989925879564249948222283502E-29
```

Example H127E27

A tensor product of two modular forms of level 1.

```
> f1 := ModularForms(1,12).2;
> f2 := ModularForms(1,26).2;
> L1 := LSeries(f1);
> L2 := LSeries(f2);
> L := TensorProduct(L1, L2, []);
> LSeriesData(L); // weight is (12-1)+(26-1)+1 -- motivic weight is 11+25
<37, [ 0, 1, -11, -10 ], 1, ... >
> CheckFunctionalEquation(L);
-5.75014913311889483177106362349E-25
> Pi(RealField(30))^2 * Evaluate(L,24) / Evaluate(L,25);
9.87142857142857142857142857136
> 691/70.; // Ramanujan congruence
9.87142857142857142857142857142
```

Example H127E28

An example related to Siegel modular forms (see [vGvS93, S8.7]).

```
> E := EllipticCurve("32a"); // congruent number curve
> chi := DirichletGroup(32).1; // character of conductor 4 lifted
> MF := ModularForms(chi, 3); // weight 3 modular forms on Gamma1(32,chi)
> NF := Newforms(MF);
> NF[1][1]; // q-expansion of the desired form
q + a*q^3 + 2*q^5 - 2*a*q^7 - 7*q^9 - a*q^11 + O(q^12)
> Parent(Coefficient(NF[1][1], 3)); // defined over Q(i)
Number Field with defining polynomial x^2 + 16 over the Rational Field
> f1, f2 := Explode(ComplexEmbeddings(NF[1][1])[1]);
> L1 := LSeries(E);
> L2 := LSeries(f1); // first complex embedding
> L := TensorProduct(L1, L2, [ <2, 9> ]); // conductor 2^9 (guessed)
> time CheckFunctionalEquation(L);
```

```
-3.1554436208840472216469142611 3E-30
Time: 2.090
```

Example H127E29

An example of a tensor product over a field larger than the rationals.

```
> K<s> := QuadraticField(-3);
> I := Factorization(3 * IntegerRing(K))[1][1];
> H := HeckeCharacterGroup(I^2);
> G := Grossencharacter(H.0, [[1, 0]]); // canonical character
> E := EllipticCurve([1, (3+s)/2, 0, (1+s)/2, 0]);
> Norm(Conductor(E));
73
> LG := LSeries(G);
> LE := LSeries(E);
> TP := TensorProduct(LE, LG, [<I, 5>], K); // ensure 3-part correct
> LSetPrecision(TP, 9); // there is another factor of 3 from K
> LCfRequired(TP);
1642
> CheckFunctionalEquation(TP);
4.65661287E-10
```

127.9.8 Symmetric Powers

Symmetric power L-functions form a natural analogue to tensor products. Here we essentially tensor an L-function with itself repeatedly, but remove redundant factors.

In the case of $GL(1)$, the kth symmetric power is simply the L-function associated to the kth power of the underlying character, though we must be careful to ensure primitivity (this disregards the bad primes). Explicitly, we have

$$L(\mathrm{Sym}^k \psi, s) = \prod_{\mathfrak{p}} \Big(1 - \psi(\mathfrak{p})^k / \mathrm{N}\mathfrak{p}^s\Big)^{-1},$$

(again ignoring bad primes) and so the eigenvalues are just the kth powers of the original. It is relatively easy to compute the bad Euler factors, given those for $L(\psi, s)$.

In the case of $GL(2)$, the kth symmetric power is an L-function of degree $(k+1)$ over the field of definition, given by

$$L(\mathrm{Sym}^k A, s) = \prod_{\mathfrak{p}} \prod_{i=0}^{k} \Big(1 - \alpha_1(\mathfrak{p})^{k-i} \alpha_2(\mathfrak{p})^i / \mathrm{N}\mathfrak{p}^s\Big)^{-1},$$

where $\alpha_1(\mathfrak{p})$ and $\alpha_2(\mathfrak{p})$ are the eigenvalues at the prime $\mathfrak{p}$. In the case of elliptic curves, one can use the fact that $\alpha_1(p)\alpha_2(p) = p$ to rewrite these via symmetric functions.

A similar definition can be made for higher degree L-functions, yielding that the kth symmetric power of an L-function of degree d will have degree $\binom{k+d-1}{d-1}$.

If the object itself has a natural powering operation (as with, say, Hecke characters), Magma will simply take the primitivization therein. The bad Euler factors have been explicitly calculated for elliptic curves over the rationals in [MW06] and [DMW09]. In other cases, the user will likely have to provide them. Furthermore, the full ability to take symmetric powers over fields other than the rationals is not yet fully implemented.

`SymmetricPower(L, m)`

`BadEulerFactors` SeqEnum *Default :* []

Return the L-series corresponding to the mth symmetric power of L. The `BadEulerFactors` consists of $\langle p, f, E\rangle$ triples, where p is a prime, f the conductor exponent, and E a polynomial that gives the Euler factor at that prime.

Example H127E30

Some basic code, showing the special cases where Magma will just take the power of the underlying object.

```
> G := FullDirichletGroup(3*5*7);
> chi := G.1*G.2*G.3; // Random now gives an imprimitive character
> L := LSeries(chi);
> LS3 := SymmetricPower(L, 3);
> Lc3 := LSeries(chi^3);
> Evaluate(LS3, 1);
0.84396449805350779437298478447 0 + 0.19923299213711678303364580375 3*i
> Evaluate(Lc3, 1);
0.84396449805350779437298478447 0 + 0.19923299213711678303364580375 3*i
```

Example H127E31

```
> K := QuadraticField(-23);
> I := Factorization(23 * IntegerRing(K))[1][1];
> G := HeckeCharacterGroup(I);
> psi := G.1^14; // Random now gives an imprimitive character
> L := LSeries(psi);
> LS5 := SymmetricPower(L, 5);
> Lp5 := LSeries(psi^5);
> Evaluate(LS5, 1);
0.87080188482438164758363114981 4 + 0.62258929156395483122972653081 3*i
> Evaluate(Lp5, 1);
0.87080188482438164758363114981 4 + 0.62258929156395483122972653081 3*i
```

Example H127E32

In this example we take symmetric powers of the L-function of a Grossencharacter.

```
> GR := Grossencharacter(psi, [[1,0]]);
> L := LSeries(GR);
> LS4 := SymmetricPower(L, 4);
> Lp4 := LSeries(GR^4);
> Evaluate(LS4, 3);
0.35465127571691531343026809804 2 - 0.14751987727745317365661305654 8*i
> Evaluate(Lp4, 3);
0.35465127571691531343026809804 2 - 0.14751987727745317365661305654 8*i
```

Example H127E33

An example with symmetric powers of elliptic curves. In the case of the symmetric square of 389A, the `ModularDegree` code will do the same calculation, but more efficiently.

```
> E := EllipticCurve("389a");
> L := LSeries(E);
> L2 := SymmetricPower(L, 2);
> LSeriesData(L2);
<3, [ 0, 1, 0 ], 389^2, function(p, d) ... end function, 1, [], []>
> LSetPrecision(L2, 9);
> Evaluate(L2, 2);
3.17231145
> ($1 * Conductor(E)) / (2 * Pi(RealField()) * FundamentalVolume(E));
40.0000000
> ModularDegree(E);
40
```

Example H127E34

This in an example where a higher symmetric power has a vanishing central value, here a zero of (presumably) order 4. It comes from work of Buhler, Schoen, and Top [BST97].

```
> E := EllipticCurve("73a");
> L := LSeries(E);
> L3 := SymmetricPower(L, 3);
> LSeriesData(L3); // Magma knows the Sign is +1
<4, [ 0, -1, 1, 0 ], 73^3, function(p, d) ... end function, 1, [], []>
> LSetPrecision(L3, 9);
> CentralValue(L3);
-2.16367048E-12
```

127.10 Weil Polynomials

The characteristic polynomial of the Frobenius on the etale cohomology is called a Weil polynomial. This section contains some auxiliary routines for simpler handling of these polynomials. All routines make frequently use of `PowerSumToCoefficients`, `CoefficientsToElementarySymmetric` and `ElementarySymmetricToPowerSums`.

`SetVerbose("WeilPolynomials", v)`

Set the verbose printing level for the analysis of weil polynomials. Maximal value 2.

`HasAllRootsOnUnitCircle(f)`

Given a polynomial f with rational coefficients this routine checks that the complex roots of the polynomial are all of absolute value 1. The algorithm does not use floating point approximations.

`FrobeniusTracesToWeilPolynomials(tr, q, i, deg)`

`KnownFactor`	RngUPolElt	*Default :* 1
Verbose	`WeilPolynomials`	*Maximum :* 2

Given the sequence of Frobenius traces on the i-th etale cohomology this function returns a list of possible characteristic polynomials. Here q is the order of the basefield and *deg* is the degree of the characteristic polynomial. In the case of even i the sign in the functional equation has to be determined. This is done by checking the absolute values of the roots of the hypothetical polynomials. In the case that this does not work both candidates are returned. In the case of contradictory data an empty sequence is returned.

If a factor of the characteristic polynomial is known it can be given as optional argument.

`WeilPolynomialToRankBound(f, q)`

Given a polynomial f this routine counts the zeros (with multiplicity) of f that are q times a root of unity. This is an upper bound for the Picard rank of the corresponding algebraic surface; according to the Tate conjecture, it is precisely the Picard rank.

`ArtinTateFormula(f, q, h20)`

Given a Weil polynomial corresponding to H^2 of an algebraic surface with Hodge number $h^{2,0}$ this routine evaluates the Artin-Tate formula. If the Tate conjecture holds, the two values returned are the arithmetic Picard rank, and the absolute value of the discriminant of the Picard group times the order of the Brauer group of the surface.

`WeilPolynomialOverFieldExtension(f, deg)`

Given the characteristic polynomial f of the Frobenius on an etale cohomology group. This routine returns the characteristic polynomial of the *deg* times iterated Frobenius.

`CheckWeilPolynomial(f, q, h20)`

`SurfDeg` RngIntElt *Default :* -1

Given a polynomial f this routine checks several conditions that must be satisfied by the characteristic polynomial of the Frobenius on H^2 of an algebraic surface. Here q is the size of the basefield, $h20$ is the Hodge number $h^{2,0}$ and `SurfDeg` is the degree of the surface (-1 means degree unknown). For example, this routine can be used to determine the sign in the functional equation.

The routine checks the valuation of the roots at all places (including p and ∞). It also checks the functional equation and the Artin-Tate conditions (see [EJ10] for details).

Example H127E35

```
> q1<t> := PolynomialRing(RationalField());
> z4<x,y,z,w> := PolynomialRing(IntegerRing(),4);
> f := x^4 + x^3*z + x^2*y^2 + x^2*y*w + x^2*z^2 + x^2*z*w +
>      x*y^3 + x*y*z*w + x*y*w^2 + x*z^2*w + y^3*w + y^2*z^2 +
>      y^2*z*w + y^2*w^2 + y*z^2*w + z^4 + z*w^3;
> Tr := [];
> for i := 1 to 10 do
>    P3 := ProjectiveSpace(GF(2^i),3);
>    S := Scheme(P3,f);
>    time
>    Tr[i] := #Points(S) - 1 - 2^(2*i);
> end for;
> cpl := FrobeniusTracesToWeilPolynomials(Tr, 2, 2, 22: KnownFactor := t-2);
> cpl;
[
    t^22 - t^21 - 2*t^20 - 4*t^19 + 16*t^17 + 32*t^16 - 64*t^15
         + 16384*t^7 - 32768*t^6 - 65536*t^5 + 262144*t^3
         + 524288*t^2 + 1048576*t - 4194304,
    t^22 - t^21 - 2*t^20 - 4*t^19 + 16*t^17 + 32*t^16 - 64*t^15
         - 16384*t^7 + 32768*t^6 + 65536*t^5 - 262144*t^3
         - 524288*t^2 - 1048576*t + 4194304
]
```

Here the sign in the functional equation can not be determined by the absolute values of roots test. Further point counting would be very slow, as the coefficients of t^{11}, t^{10}, t^9, t^8 are zero, thus point counting over $\mathbf{F}_{2^{15}}$ would be necessary to determine the sign in this way. Instead, we can try to use more invariants of the surface.

```
> cpl_2 := [wp : wp in cpl | CheckWeilPolynomial(wp,2,1: SurfDeg := 4)];
> cpl_2;
[
    t^22 - t^21 - 2*t^20 - 4*t^19 + 16*t^17 + 32*t^16 - 64*t^15
         + 16384*t^7 - 32768*t^6 - 65536*t^5 + 262144*t^3
         + 524288*t^2 + 1048576*t - 4194304
```

```
]
> WeilPolynomialToRankBound(cpl_2[1],2);
2
> ArtinTateFormula(cpl_2[1],2,1);
1 4
> ArtinTateFormula(WeilPolynomialOverFieldExtension(cpl_2[1],2),2^2,1);
2 68
```

Thus the minus sign in the functional equation is correct. The surface has arithmetic Picard rank 1 and relative to the Tate conjecture the geometric Picard group has rank 2 and discriminant either -17 or -68 (depending on the order of the Brauer group).
Advanced example: Bounding Picard rank with less point counting:
The computation is based on the same equation as the example above. Now we do not use the most costly Frobenius trace, but we assume additional cyclotomic factors.

```
> Tr := [ 1, 5, 19, 33, 11, -55, 435, -31, -197]; /* First 9 Frobenius traces */
> cycl := [ Evaluate(CyclotomicPolynomial(i),t/2)*2^EulerPhi(i)
>         : i in [1..100] | EulerPhi(i) lt 23];
> cycl[1] := cycl[1]^2;
> cycl[2] := cycl[2]^2; /* linear factors need multiplicity two */
> hyp := &cat [FrobeniusTracesToWeilPolynomials(Tr, 2, 2, 22 :
>                       KnownFactor := (t-2)*add) : add in cycl];
> hyp := SetToSequence(Set(hyp));
> hyp;
[
    t^22 - t^21 - 2*t^20 - 4*t^19 + 16*t^17 + 32*t^16 - 64*t^15
         - 16384*t^7 + 32768*t^6 + 65536*t^5 - 262144*t^3
         - 524288*t^2 - 1048576*t + 4194304
]
```

Using only the number of point over $\mathbf{F}_2, \ldots, \mathbf{F}_{2^9}$ we can prove that either the Picard rank is bounded by 2 or the correct Weil polynomial is in the list.

```
> CheckWeilPolynomial(hyp[1],2,1:SurfDeg := 4);
false
```

The invariants of the surface and the hypothetical Weil polynomial are contradictory. Thus the Picard rank is at most 2.

PART XVII
MODULAR ARITHMETIC GEOMETRY

128 MODULAR CURVES

Chapter 128
MODULAR CURVES

128.1 Introduction

Modular curves in MAGMA are a special type `CrvMod` of plane curve. A modular curve X is defined in terms of standard affine modular polynomials which are stored in precomputed databases. Those modular curves presently available are defined by bivariate polynomials relating the j-invariant and one of several standard functions on $X_0(N)$. These give singular models for $X_0(N)$ designed for computing isogenies of elliptic curves.

128.2 Creation Functions

Several different models for modular curves are available. The possible model types are "Atkin", "Canonical", and "Classical", each giving affine models defined by the modular polynomial databases of the same names. For more details on these polynomials see Section 128.4 on modular polynomials and databases.

128.2.1 Creation of a Modular Curve

`ModularCurve(X,t,N)`

Returns a model of the modular curve $X_0(N)$, in an affine plane specified by X. The string t must be one of "Atkin", "Canonical", or "Classical", with N a level in the corresponding modular curve database.

`ModularCurve(D, N)`

Returns an affine model of the modular curve $X_0(N)$ of level N from a database D of modular curves.

128.2.2 Creation of Points

Points on modular curves can be created in the same way as points on curves or schemes in general. In addition, there exist several specific constructors, defined in terms of the moduli structure, which take a parameterized elliptic curve as an argument.

`ModuliPoints(X,E)`

Given a modular curve $X = X_0(N)$ and an elliptic curve E, with compatible base rings, returns the sequence of points over the base field of E, corresponding to E with additional level structure.

Example H128E1

Below we give an example of the use of the moduli interpretation of modular curves in order to construct the corresponding subgroup scheme structures defined over a finite field.

```
> FF := FiniteField(NextPrime(10^6));
> A2 := AffineSpace(FF,2);
> X0 := ModularCurve(A2,"Canonical",17);
> E := EllipticCurve([FF|1,23]);
> mp := ModuliPoints(X0,E); mp;
[ (259805, 350390), (380571, 350390) ]
```

We will see later that it is possible to construct the structure of an elliptic curve parameterized by the corresponding moduli points.

```
> P, Q := Explode(mp);
> SubgroupScheme(E,P);
Subgroup of E defined by x^8 + 377217*x^7 + 190510*x^6 + 872850*x^5
  + 816054*x^4 + 457629*x^3 + 64955*x^2 + 361795*x + 460146
> SubgroupScheme(E,Q);
Subgroup of E defined by x^8 + 796070*x^7 + 308587*x^6 + 62023*x^5
  + 976430*x^4 + 380273*x^3 + 200328*x^2 + 892738*x + 536749
```

In this example we see that the prime 17 splits in the endomorphism ring of E, so we have exactly two parameterized isogenies defined over the base field of E.

128.3 Invariants

The defining data and invariants of the curves are accessed through standard functions.

`Level(X)`

Returns the level of the modular curve X as an integer.

`Genus(X)`

Returns the genus of the modular curve X .

`ModelType(X)`

Returns the type of the model for the modular curve X, presently limited to "Atkin", "Canonical", or "Classical". This is used to determine the algorithm by which parameterized isogenies are determined.

`Indices(X)`

Returns a sequence of integers, of the form $[N, M, P]$, classifying the class of the modular curve X. The integer sequence defines a congruence subgroup of $\mathrm{PSL}_2(\mathbf{Z})$ defined by

$$\Gamma(N, M, P) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \;\middle|\; c \equiv 0 \bmod N,\ b \equiv 0 \bmod P,\ a \equiv 1 \bmod M \right\},$$

where M divides $\mathrm{LCM}(N, P)$. For the models presently available, this will be the sequence $[N, 1, 1]$, where is the level of $X = X_0(N)$.

128.4 Modular Polynomial Databases

MAGMA contains several databases of standard defining polynomials for modular curves which are used throughout the system for the construction of isogenies of elliptic curves, and which are made available to the user. These define singular models for modular curves $X_0(N)$, in terms for standard functions on the curves.

The classical model for $X_0(N)$ is in terms of the polynomial $\Phi_N(X, Y)$ such that $\Phi_N(j(\tau), j(N\tau)) = 0$, where $j(\tau)$ is the j-function. The bivariate polynomial $\Phi_N(X, Y)$ is defined to be the *classical modular polynomial*. The classical modular polynomial has the property of being symmetric in X and Y, and moreover, the canonical involution is defined by $(X, Y) \mapsto (Y, X)$.

Suppose that N is a prime and set $s = 12/\text{GCD}(N-1, 12)$. Using the property that the Dedekind η-function is holomorphic with no zeros on the upper half plane $\mathbf{H}$, the function

$$f(\tau) = N^s \left(\frac{\eta(N\tau)}{\eta(\tau)} \right)^{2s},$$

is a holomorphic function whose reciprocal is also holomorphic on $\mathbf{H}$. The transformation properties of the η-function imply that $f(\tau)$ is invariant under $\Gamma_0(N)$. Together $j(\tau)$ and $f(\tau)$ generate the function field for $X_0(N)$. The polynomial $\Psi_N(X, Y)$ such that $\Psi_p(f(\tau), j(\tau)) = 0$ is called the *canonical modular polynomial*. The Atkin–Lehner involution sends $f(\tau)$ to $N^s/f(\tau)$, so that the relation $\Psi_N(N^s/f(\tau), j(N\tau)) = 0$ also holds.

The third distinguished class of modular polynomials are the *Atkin modular polynomials* $\Xi_N(X, Y)$, satisfying the property that $\Xi_N(f(\tau), j(\tau)) = 0$ for a modular function $f(\tau)$ on $X_0(N)$ invariant under the Atkin-Lehner involution. Since the function $f(\tau)$ is well-defined as a function on the Atkin-Lehner quotient curve $X_0^+(N)$, sometimes denoted $X_0^*(N)$, these polynomials are also referred to as *star* modular polynomials in the literature. The construction of $f(\tau)$ and the modular polynomial $\Xi_N(X, Y)$ is described in articles of Elkies [Elk98] and Morain [Mor95]. The database of Atkin modular polynomials were provided by A.O.L. Atkin.

`AtkinModularPolynomial(N)`

Given a prime number N, represented in the database of Atkin modular curves, this function returns the Atkin modular polynomial $\Xi_N(X, Y)$.

`CanonicalModularPolynomial(N)`

Given a prime number N represented in the database of canonical modular curves, this function returns the canonical modular polynomial $\Psi_N(X, Y)$.

`ClassicalModularPolynomial(N)`

Given an integer N represented in the database of classical modular curves, this function returns the defining classical modular polynomial $\Phi_N(X, Y)$.

`ModularCurveDatabase(t)`

`ModularCurveDatabase(t,i)`

Given an identifier string t, which must be one of "Atkin", "Canonical", or "Classical", this function returns the corresponding database object of modular curves $X_0(N)$.

Because of its size, the Atkin database is split into database objects of levels $200(i-1)+1 \leq N < 200i$ for i in $1, 2, 3, 4, 5$, of which only the first two are provided by default. Additional datafiles are available from the MAGMA website. The canonical database contains a subset of the curves for prime levels below 200, and only curves for levels below 60 are present in the classical modular curve database.

`N in D`

Returns `true` if and only if N is a level represented in the given modular curve database D.

`ExistsModularCurveDatabase(t)`

`ExistsModularCurveDatabase(t,i)`

Returns `true` if and only if the data file given by the string t and integer i exists

Example H128E2

Here we compare the defining polynomials for the Atkin, Canonical, and Classical models for the modular curves $X_0(N)$. For the modular curve $X_0(3)$ we list the corresponding polynomial.

```
> P2<x,j> := PolynomialRing(Integers(),2);
> P2!AtkinModularPolynomial(3);
x^4 - x^3*j + 744*x^3 + 193752*x^2 + 2348*x*j + 19712160*x + j^2
  + 24528*j + 538141968
> P2!CanonicalModularPolynomial(3);
x^4 + 36*x^3 + 270*x^2 - x*j + 756*x + 729
> P2!ClassicalModularPolynomial(3);
x^4 - x^3*j^3 + 2232*x^3*j^2 - 1069956*x^3*j + 36864000*x^3 +
    2232*x^2*j^3 + 2587918086*x^2*j^2 + 8900222976000*x^2*j +
    452984832000000*x^2 - 1069956*x*j^3 + 8900222976000*x*j^2 -
    770845966336000000*x*j + 1855425871872000000000*x + j^4 +
    36864000*j^3 + 452984832000000*j^2 + 1855425871872000000000*j
```

For larger values of N the Atkin modular polynomials tend to have smaller coefficients.

```
> P2!CanonicalModularPolynomial(11);

    24576000*j + 150994944000000
```

In general the Atkin modular polynomials have coefficients of a smaller size when $N \equiv 11 \bmod 12$ and are largest when $N \equiv 1 \bmod 13$, while the opposite is true for the canonical modular polynomials.

128.5 Parametrized Structures

The modular curves $X_0(N)$ parametrize elliptic curves together with the structure of a cyclic isogeny, or equivalently, a cyclic subgroup scheme of the N-torsion of the elliptic curve. over the modular curve, singularities of the chosen surface may obstruct the construction of the corresponding isogeny.

`Isogeny(E,P)`

Given an elliptic curve E and a point P on some $X_0(N)$ corresponding to a cyclic level structure on E, the function returns an isogeny $f : E \to F$ corresponding to P. The isogeny is defined by the formulae of Velu in such a way that the pull-back of the invariant differential of F is the invariant differential on E.

`SubgroupScheme(E,P)`

Given an elliptic curve E and a point P on some $X_0(N)$ corresponding to a cyclic level structure on E, the function returns the subgroup scheme of E parameterized by $X_0(N)$.

Example H128E3

In this example we create the function field of the modular curve and compute the corresponding parameterized subgroup scheme for the canonical model of the modular curve $X_0(7)$.

```
> A2 := AffineSpace(RationalField(),2);
> X0 := ModularCurve(A2,"Canonical",7);
> K0<u,j> := FunctionField(X0);
> j;
(u^8 + 28*u^7 + 322*u^6 + 1904*u^5 + 5915*u^4 + 8624*u^3 + 4018*u^2 +
   748*u + 49)/u
```

We can now create an elliptic curve with this j-invariant and compute the corresponding subgroup scheme.

```
> E := EllipticCurveFromjInvariant(j);
> E;
Elliptic Curve defined by y^2 + x*y = x^3 - 36*u/(u^8 + 28*u^7 + 322*u^6 +
 1904*u^5 + 5915*u^4 + 8624*u^3 + 4018*u^2 - 980*u + 49)*x - u/(u^8 +
 28*u^7 + 322*u^6 + 1904*u^5 + 5915*u^4 + 8624*u^3 + 4018*u^2 - 980*u + 49)
 over Function Field of Modular Curve over Rational Field defined by
 $.1^8 + 28*$.1^7*$.3 + 322*$.1^6*$.3^2 + 1904*$.1^5*$.3^3 +
 5915*$.1^4*$.3^4 + 8624*$.1^3*$.3^5 + 4018*$.1^2*$.3^6 - $.1*$.2*$.3^6 +
 748*$.1*$.3^7 + 49*$.3^8
> ModuliPoints(X0,E);
[ (u, (u^8 + 28*u^7 + 322*u^6 + 1904*u^5 + 5915*u^4 + 8624*u^3 +
  4018*u^2 + 748*u + 49)/u) ]
> P := $1[1];
> SubgroupScheme(E,P);
Subgroup of E defined by x^3 + (-u^3 - 13*u^2 - 47*u - 14)/(u^4 + 14*u^3 +
 63*u^2 + 70*u - 7)*x^2 + (u^5 + 19*u^4 + 133*u^3 + 373*u^2 + 271*u + 49)/
 (u^8 + 28*u^7 + 322*u^6 + 1904*u^5 + 5915*u^4 + 8624*u^3 + 4018*u^2 -
 980*u + 49)*x + (-u^6 - 21*u^5 - 166*u^4 - 569*u^3 - 750*u^2 - 349*u -
 49)/(u^12 + 42*u^11 + 777*u^10 + 8246*u^9 + 54810*u^8 + 233730*u^7 +
 628425*u^6 + 999306*u^5 + 801738*u^4 + 159838*u^3 - 93639*u^2 +
 10290*u - 343)
```

We now replay the same computation for the Atkin model for $X_0(7)$.

```
> X0 := ModularCurve(A2,"Atkin",7);
> K0<u,j> := FunctionField(X0);
> j;
j
> E := EllipticCurveFromjInvariant(j);
> E;

128.6 Associated Structures

`FunctionField(X)`

Returns the function field of the modular curve X.

`jFunction(X)`

Given a modular curve X over a field, returns the j-invariant as a function on the curve.

`BaseCurve(X)`

Given one of the standard models X for the modular curve $X_0(N)$, returns the base model curve $X(1)$ and the morphism $\pi : X_0(N) \to X(1)$.

Example H128E4

In this example we demonstrate the relation of a modular curve with its base curve $X(1)$.

```
> D := ModularCurveDatabase("Atkin");
> X0 := ModularCurve(D,17);
> X1, pi := BaseCurve(X0);
```

The discriminants -4, -8, -16, -19, -43, and -67 are the class number 1 discriminants in which 17 is a split prime. We use this to construct the corresponding moduli points on the curve $X_0(17)$ and map these back down to the curve $X(1)$. Refer to Section 128.8 for a description of the function `HilbertClassPolynomial`.

```
> discs := [ -4, -8, -16, -19, -43, -67 ];
> jinvs := [ Roots(HilbertClassPolynomial(D))[1][1] : D in discs ];
> jinvs;
[ 1728, 8000, 287496, -884736, -884736000, -147197952000 ]
> pnts := &cat[ ModuliPoints(X0, EllipticCurveFromjInvariant(j))
>               : j in jinvs ];
> pnts;
[ (-2, 1728), (-3, 8000), (-4, 287496), (-1, -884736), (2, -884736000),
(7, -147197952000) ]
> [ pi(P) : P in pnts ];
[ (1728, 1728), (8000, 8000), (287496, 287496), (-884736, -884736),
(-884736000, -884736000), (-147197952000, -147197952000) ]
```

We note that $X(1)$ is defined to be the classical modular curve, defined by the diagonal image of the j-line in $\mathbf{P}^2$.

128.7 Automorphisms

`CanonicalInvolution(X)`

`AtkinLehnerInvolution(X,N)`

Given a projective modular curve $X = X_0(N)$, the function returns the Atkin-Lehner involution of the modular curve as a map of schemes. Currently, the only Atkin-Lehner involution returned is that for N equal to the level of X.

128.8 Class Polynomials

Class polynomials are invariants of elliptic curves with complex multiplication by an imaginary quadratic order of discriminant D. As such the Hilbert class polynomials can be interpreted as defining a subscheme or divisor on the modular curve $X(1) \cong \mathbf{P}^1$, while the Weber variants define a subscheme of a modular curve of higher level.

`HilbertClassPolynomial(D)`

Given a negative discriminant D, returns the Hilbert class polynomial, defined as the minimal polynomial of $j(\tau)$, where $\mathbf{Z}[\tau]$ is an imaginary quadratic order of discriminant D.

`WeberClassPolynomial(D)`

Given a negative discriminant D not congruent to 5 modulo 8, returns the Weber class polynomial, defined as the minimal polynomial of $f(\tau)$, where $\mathbf{Z}[\tau]$ is an imaginary quadratic order of discriminant D and f is a particular normalized Weber function generating the same class field as $j(\tau)$. The particular $f(\tau)$ used depends on whether D is odd ($\equiv 1 \bmod 8$) or even, in which case it also depends on $D/4 \bmod 8$, as well as whether 3 divides D or not. A root $f(\tau)$ of the Weber class polynomial is an algebraic integer (a unit in most cases and always a unit outside of 2) generating the ring class field related to the corresponding root $j(\tau)$ of the Hilbert class polynomial by an expression $j(\tau) = F(f(\tau))$. Here F is a rational function of the form $A(Bx^r + C)^3/x^r$ with $r|24$ and A,B,C rational integers which are positive or negative powers of 2. The function F is also returned. For example, if $D \equiv 1 \bmod 8$ then

$$j(\tau) = \frac{(f(\tau)^{24} - 16)^3}{f(\tau)^{24}},$$

where $\mathrm{GCD}(D, 3) = 1$, and

$$j(\tau) = \frac{(f(\tau)^{8} - 16)^3}{f(\tau)^{8}},$$

if 3 divides D and $f(\tau)$ is a unit.

In fact, $f(\tau)$ can only be a non-unit when $4|D$ and $D/4 \equiv 0, 4$ or $5 \bmod 8$. For further details, consult Yui and Zagier [YZ97] for the case of odd D and Schertz [Sch76] for the case of even D.

`WeberToHilbertClassPolynomial(f,D)`

`Al`	MonStgElt	*Default :* "*Roots*"

Given a negative discriminant D, and the corresponding Weber class polynomial f, returns the Hilbert class polynomial for D. The default algorithm, as specified by the `Al` parameter, is to compute complex approximations to the roots of the latter polynomial from approximations to the roots of the Weber polynomial and the rational function F linking the two. The other method is algebraic and uses resultants and the function F which was discussed in the description of the intrinsic `WeberClassPolynomial`.

Example H128E5

Class polynomials are typically used for constructing elliptic curves with a known endomorphism ring or known number of points over some finite field. The Weber (and other) variants of the class polynomials were introduced as a means of obtaining class invariants – defining the j-invariant of curves with given CM discriminant – with much smaller coefficients. In this example we give the classical example of $D = -71$, where the

```
> HilbertClassPolynomial(-71);
x^7 + 313645809715*x^6 - 3091990138604570*x^5 + 98394038810047812049302*x^4
- 823534263439730779968091389*x^3 + 513880036645397678032372632944 6*x^2 -
425319473946139603274605151187659*x + 737707086760731113357714241006081263
> WeberClassPolynomial(-71);
x^7 + x^6 - x^5 - x^4 - x^3 + x^2 + 2*x - 1
```

As indicated by the constant term -1, the roots of the WeberClassPolynomial are units in a particular ring class order.

128.9 Modular Curves and Quotients (Canonical Embeddings)

`ModularCurveQuotient(N,A)`

`Raw`	BoolElt	*Default :* `false`
`Reduce`	BoolElt	*Default :* `false`

Given a level N and a (possibly empty) set of Atkin-Lehner involutions represented as a sequence of integers A, this function computes a model for a quotient of $X_0(N)$ by A. When `Raw` is not set to `true`, an initial "semi-reduction" is not performed. If the `Reduce` option is `true`, then a complete `LLL`-reduction is performed on the resulting equations (this is impractical for genus greater than 50 or so). The returned curve can be: P^1 for a genus 0 curve, an elliptic or hyperelliptic curve, or the canonical embedding of the curve in P^{g-1} where g is the genus of the quotient curve (in this general case, the coordinates correspond to cusp forms invariant under the specified Atkin-Lehner involutions).

Example H128E6

We compute a model for $X_0(13 \cdot 29)$ quotiented by the Atkin-Lehner involutions w_{13} and w_{29}.

```
> C := X0NQuotient(13*29,[13,29]); C; // defined by cubics in P^4
Curve over Rational Field defined by
-x[1]*x[2]^2 + x[1]*x[2]*x[3] - x[2]^2*x[3] + x[1]*x[2]*x[4] +
    x[2]^2*x[4] + x[2]*x[4]^2 + x[1]*x[2]*x[5],
x[1]*x[2]^2 - x[2]^3 - x[2]^2*x[3] + x[1]*x[2]*x[5] + x[2]^2*x[5] +
    x[2]*x[4]*x[5],
x[1]*x[2]*x[3] - x[2]^2*x[3] - x[2]*x[3]^2 + x[1]*x[3]*x[5] +
    x[2]*x[3]*x[5] + x[3]*x[4]*x[5],
x[1]*x[2]*x[5] - x[2]^2*x[5] - x[2]*x[3]*x[5] + x[1]*x[5]^2 +
    x[2]*x[5]^2 + x[4]*x[5]^2,
-x[1]^2*x[2] + x[1]*x[2]^2 + x[1]*x[2]*x[3] - x[1]^2*x[5] -
    x[1]*x[2]*x[5] - x[1]*x[4]*x[5],
x[1]*x[2]*x[3] + x[2]^2*x[4] + x[2]*x[3]*x[4] + x[2]*x[4]*x[5] +
    x[3]*x[4]*x[5] + x[2]*x[5]^2 + x[4]*x[5]^2,
x[1]*x[2]*x[3] + x[1]*x[2]*x[4] + x[1]*x[2]*x[5] - x[1]*x[3]*x[5] -
    x[3]^2*x[5] + x[1]*x[4]*x[5] - x[2]*x[4]*x[5] - x[3]*x[4]*x[5] +
    x[1]*x[5]^2 + x[3]*x[5]^2,
-x[1]*x[2]*x[4] + x[1]*x[3]*x[4] - x[2]*x[3]*x[4] + x[1]*x[4]^2 +
    x[2]*x[4]^2 + x[4]^3 + x[1]*x[4]*x[5],
-x[1]*x[2]*x[3] + x[1]*x[3]^2 - x[2]*x[3]^2 + x[1]*x[3]*x[4] +
    x[2]*x[3]*x[4] + x[3]*x[4]^2 + x[1]*x[3]*x[5],
-x[1]*x[2]*x[5] + x[1]*x[3]*x[5] - x[2]*x[3]*x[5] + x[1]*x[4]*x[5] +
    x[2]*x[4]*x[5] + x[4]^2*x[5] + x[1]*x[5]^2,
x[1]*x[2]*x[4] - x[2]^2*x[4] - x[2]*x[3]*x[4] + x[1]*x[2]*x[5] -
    x[1]*x[3]*x[5] + x[2]*x[3]*x[5] - x[1]*x[5]^2,
-x[1]^2*x[3] - x[1]*x[2]*x[3] + x[1]*x[3]^2 - x[2]*x[3]^2 -
    x[1]*x[2]*x[4] - x[3]^2*x[4] - x[2]*x[4]^2 + x[1]*x[3]*x[5] -
    x[2]*x[4]*x[5] - x[4]^2*x[5] - x[1]*x[5]^2,
-x[1]^2*x[2] + x[1]*x[2]^2 + x[2]^2*x[3] + x[1]^2*x[4] -
    x[1]*x[3]*x[4] + x[2]*x[3]*x[4] + x[3]*x[4]^2 + x[1]^2*x[5] -
    x[1]*x[3]*x[5] - x[3]^2*x[5] - x[1]*x[4]*x[5] - x[3]*x[4]*x[5] +
    x[2]*x[5]^2 + x[3]*x[5]^2 + x[4]*x[5]^2,
-x[1]^2*x[2] + x[1]^2*x[3] - x[1]*x[2]*x[3] + x[1]^2*x[4] +
    x[1]*x[2]*x[4] + x[1]*x[4]^2 + x[1]^2*x[5],
x[1]^2*x[2] + x[1]^2*x[3] - x[1]*x[2]*x[3] + x[2]^2*x[3] - x[1]*x[3]^2
    - x[3]^3 - x[1]*x[2]*x[4] + x[1]*x[3]*x[4] - x[2]*x[3]*x[4] -
    x[3]^2*x[4] + x[1]^2*x[5] + x[1]*x[3]*x[5] - x[2]*x[3]*x[5] +

128.10 Modular Curves of Given Level and Genus

The intrinsics described in this section are designed to construct curves C over $\mathbf{Q}$ of genus at least 2 which are images of $X_1(N)$ (or $X_0(N)$) under a morphism $\pi : X_1(N) \to C$ defined over $\mathbf{Q}$. Such curves will be referred to as modular curves. The code uses some of the ideas and methods from the papers [GJG03], [BGJGP05] and [GJO10].

The morphism π induces an isogeny π^* from the Jacobian of C, $Jac(C)$ onto a $\mathbf{Q}$-rational abelian subvariety B of $J_1(N)$ (or $J_0(N)$), i.e. a $\mathbf{Q}$-rational modular abelian variety of dimension g, the genus of C. The space of holomorphic differentials of $Jac(C)$ identified with those of C pull back under π^* to the holomorphic differentials of B which can be identified with the space of weight 2 cusp forms associated to B.

If $f_1, \ldots, f_g$ is a $\mathbf{Q}$-basis of this space, then these forms will satisfy the canonical relations for some canonical embedding of C in the non-hyperelliptic case. Conversely, if a basis of the space of cusp forms for a $\mathbf{Q}$-rational modular abelian variety B of dimension g satisfies the polynomial relations defining a canonical curve C of genus g, then C is a modular curve, but the pullback of the space of holomorphic differentials under the obvious map $\pi : z \mapsto [f_1(z) : f_2(z) : \ldots : f_g(z)]$ from $X_1(N)$ to C may NOT give the space of differentials $\langle f_1, \ldots, f_g \rangle$ and $Jac(C)$ may be isogenous to a different modular abelian subvariety of $J_1(N)$ to B.

In the hyperelliptic case, criteria for the pullback of the differentials of the curve C to give precisely the space of forms of a particular modular abelian variety B are given in [GJG03] and [BGJGP05], provided that B lies in the new part of $J_1(N)$. In the genus 3 non-hyperelliptic case, a simple explicit criterion for $Jac(C)$ to pull back to B is given in [GJO10].

Modular curves C such that the pullback $\pi^*(Jac(C))$ lies in the *new* part of $J_1(N)$ (or $J_0(N)$) are referred to as *new* modular curves.

Intrinsics are provided that determine all of the new modular hyperelliptic curves or all of the new modular genus 3 non-hyperelliptic curves of $X_1(N)$ (or $X_0(N)$) for a given level N. There are also intrinsics that determine whether a given modular abelian subvariety B corresponds to a hyperelliptic or genus 3 non-hyperelliptic curve C and give the equations of C (as a Weierstrass model or canonical model, respectively) in the affirmative case.

In future releases it is planned to add intrinsics to deal with non-hyperelliptic modular curves of genus greater than 3 and to add more functionality to cover non-new cases.

`SetVerbose("ModularCurve", v)`

Set the printing level for verbose output for the following intrinsics. Currently the legal values for v are `true`, `false`, 0, 1, 2 (`false` is the same as 0, and `true` is the same as 1).

`NewModularHyperellipticCurves(N, g)`

`check`	BoolElt	*Default :* `false`
`prec`	RngIntElt	*Default :* 100
`gamma`	RngIntElt	*Default :* 1

For level N, this function returns a list of all hyperelliptic curves of genus $g \geq 2$ which are new modular curves for $X_1(N)$ if parameter `gamma` equals 1 (the default) or $X_0(N)$, if `gamma` equals 0.

A hyperelliptic curve is returned as a univariate polynomial $f(x)$ such that $y^2 = f(x)$ is a Weierstrass equation of the actual curve.

The parameter `prec` (default 100) is the precision to which modular forms are expanded in the computations. If parameter `check` (default `false`) is `true`, the forms are actually computed to a precision slightly in excess of the precision $prec_1$ needed to guarantee that polynomial relations on them (of the degrees that are used in the computations) vanish if they vanish to precision $prec_1$.

`NewModularHyperellipticCurve(B)`

`check`	BoolElt	*Default :* `false`
`prec`	RngIntElt	*Default :* 100
`gamma`	RngIntElt	*Default :* 1

Given a sequence B of distinct modular abelian subvarieties of $J_1(N)^{new}$, presented as subspaces of modular symbols, this function `true` if the modular abelian variety M which is the direct sum of the B corresponds exactly to a hyperelliptic curve C as described in the introduction (M is isogenous to $Jac(C)$). If so, a univariate polynomial $f(x)$ is also returned such that $y^2 = f(x)$ is a Weierstrass equation for C.

The parameters `check` and `prec` have the same meaning as in the previous intrinsic. The parameter `gamma` is only relevant if `check` is `true`, is 1 by default, and should only be set to 0 if all of the B are abelian subvarieties of $J_0(N)$. It is then used to get sharper bounds for the precision required for the q-expansions.

`NewModularHyperellipticCurve(F)`

This is a variant on the intrinsic directly above where, instead of the sequence of modular abelian subvarieties as argument, the sequence of q-expansions of the basis of weight 2 forms for the modular abelian subvariety M is given instead.

`ModularHyperellipticCurve(B)`

`prec`	RngIntElt	*Default :* 100

Given a sequence B of distinct modular abelian subvarieties of $J_1(N)^{new}$, where the direct sum modular abelian variety M that B defines does not have to lie in the new part $J_1(N)^{new}$, the function determines whether the basis of the differentials (forms) of M satisfy the correct relations so as to arise from a hyperelliptic curve C of genus g. If so, the intrinsic also returns a univariate polynomial $f(x)$, such that $y^2 = f(x)$ is a Weierstrass equation for C. The difference between this and the new case is that, although C is a modular curve, it is not guaranteed that $Jac(C)$ is isogenous to M: it may be isogenous to a different modular abelian subvariety of $J_1(N)$.

The parameter `prec` (default 100) is the precision to which modular forms are expanded in the computations.

`ModularHyperellipticCurve(F)`

This is a variant on the intrinsic immediately above where, instead of a sequence of modular abelian varieties B with direct sum M passed as the argument, a sequence of q-expansions of the basis of weight 2 cusp forms of such an M is given instead.

`NewModularNonHyperellipticCurvesGenus3(N)`

`check`	BoolElt	*Default :* `false`
`prec`	RngIntElt	*Default :* 100
`gamma`	RngIntElt	*Default :* 1

Given an integer N, this function returns a list of all non-hyperelliptic curves of genus 3 which are new modular curves, for $X_1(N)$ if the parameter `gamma` equals 1 (the default), or for $X_0(N)$ if `gamma` equals 0.

The parameter `prec` (default 100) is the precision to which modular forms are computed to in the computations. If parameter `check` (default `false`) is `true`, the forms are actually computed to a little over the precision $prec_1$ needed to check that polynomial relations on them (of the degrees that are used in the computations) are definitely guaranteed to vanish if they vanish to precision $prec_1$.

`NewModularNonHyperellipticCurveGenus3(B)`

`check`	BoolElt	*Default :* `false`
`prec`	RngIntElt	*Default :* 100
`gamma`	RngIntElt	*Default :* 1

Given a sequence B of distinct modular abelian subvarieties of $J_1(N)^{new}$, where the direct sum modular abelian variety M that B defines does not have to lie in the new part $J_1(N)^{new}$, the function determines whether the basis of the differentials (forms) of M satisfy the correct relations so as to arise from a non-hyperelliptic curve C of genus 3. If so, the intrinsic also returns a a defining polynomial for the canonical image of C. The parameters `check` and `prec` have the same meaning as for the intrinsic `NewModularHyperellipticCurves`. The parameter `gamma`, which is only relevant if `check` is `true`, and is 1 by default, may be set to 0 if M is an abelian subvariety of $J_0(N)$ when sharper bounds for the required precision of q-expansions will be used. This intrinsic is similar to `NewModularHyperellipticCurve(B)`.

`NewModularNonHyperellipticCurveGenus3(F)`

This is a variant on the intrinsic `NewModularNonHyperellipticCurveGenus3(B)` above where, instead of the sequence of modular abelian varieties B with direct sum M passed as the argument, a sequence F of q-expansions of the basis of weight 2 cusp forms of such an M is given instead.

`ModularNonHyperellipticCurveGenus3(F)`

This is the same as the intrinsic `NewModularNonHyperellipticCurveGenus3(F)` immediately preceding except that it is not required that the modular abelian variety M which corresponds to F lies in the new part $J_1(N)^{new}$. This may be used to search for non-new non-hyperelliptic genus 3 curves.

Example H128E7

We give some examples of the use of these intrinsics.
The modular curve $X_1(13)$ is of genus 2, therefore hyperelliptic, and the space of modular forms of weight 2 for $\Gamma_1(13)$ is generated by an unique newform f of nebentype a Dirichlet character of order 6, such that the modular abelian variety attached to f, A_f, is $\mathbf{Q}$-isogenous to $J_1(13)$:

```
> chi := DirichletGroup(13,CyclotomicField(6)).1; //order 6 character mod 13
> A13:=Af(chi)[1];
> NewModularHyperellipticCurve([A13]);
true x^6 + 4*x^5 + 6*x^4 + 2*x^3 + x^2 + 2*x + 1
> f13:=qIntegralBasis(A13,100);
> NewModularHyperellipticCurve(f13);
true x^6 + 4*x^5 + 6*x^4 + 2*x^3 + x^2 + 2*x + 1
> SetVerbose("ModularCurve",1);
> NewModularHyperellipticCurve([A13]:check:=true);
Checking ...
          ... bound =113
true x^6 + 4*x^5 + 6*x^4 + 2*x^3 + x^2 + 2*x + 1
```

Let us compute all the new modular hyperelliptic curves parameterized by $X_0(80)$:

```
> NewModularHyperellipticCurves(80,0: gamma:=0);
     Candidates:=3
     All the curves
1 2 3
[
    x^5 + 2*x^4 - 26*x^3 - 132*x^2 - 231*x - 142
]
```

Finally, we calculate the new modular hyperelliptic curves parameterized by $X_1(80)$ (the default):

```
> SetVerbose("ModularCurve",0);
> NewModularHyperellipticCurves(80,0);
[
    x^5 + 2*x^4 - 26*x^3 - 132*x^2 - 231*x - 142,
    x^5 - 2*x^4 - 2*x^3 + 20*x^2 - 47*x + 30,
    x^7 - 4*x^6 - 4*x^5 + 39*x^4 - 64*x^3 + 40*x^2 - 8*x,
    x^7 + 2*x^5 + 7*x^4 - 4*x^3 - 20*x^2 - 16*x - 4
]
```

Example H128E8

In this exercise, an interesting example from [JK07] is presented.

```
> S:=CuspidalSubspace(ModularSymbolsH(21,[1,8,13,20],2,+1));
> S;
Modular symbols space of level 21, weight 2, and dimension 3 over Rational Field
(multi-character)
> ModularHyperellipticCurve([S]);
true x^8 - 6*x^6 + 4*x^5 + 11*x^4 - 24*x^3 + 22*x^2 - 8*x + 1
```

The above curve is the unique hyperelliptic intermediate modular curve $X_\Delta(N)$ between $X_1(N)$ and $X_0(N)$, where Δ is a subgroup of $(\mathbf{Z}/N\mathbf{Z})^*/\{\pm 1\}$ and $X_\Delta(N)$ is the modular curve associated to some congruence subgroup of $PSL_2(\mathbf{Z})$ attached to Δ. In fact, the above hyperelliptic curve is the new modular curve denoted by $C^A_{21A_{\{0,2\}}}$ in [BGJGP05].

Example H128E9

Given a modular abelian subvariety of $J_0(97)$, we determine whether it corresponds to a new modular non-hyperelliptic curve of genus 3 and level 97:

```
> M:=ModularSymbols(97,2,1);
> NN:=SortDecomposition(NewformDecomposition(NewSubspace(CuspidalSubspace(M))));
> NN;
[
    Modular symbols space for Gamma_0(97) of weight 2 and dimension 3 over
    Rational Field,
    Modular symbols space for Gamma_0(97) of weight 2 and dimension 4 over
    Rational Field
]
> A97:=NN[1];
> NewModularNonHyperellipticCurveGenus3([A97]);
true -x^2*y^2 + x*y^3 + x^3*z + x*y^2*z - 5*x^2*z^2 + 3*x*y*z^2 - 3*y^2*z^2 +
  6*x*z^3 - y*z^3 - 2*z^4
```

Example H128E10

We calculate all of the new modular non-hyperelliptic curves of genus 3 parameterized by $X_1(20)$:

```
> NewModularNonHyperellipticCurvesGenus3(20);
[
    -x^2*y^2 + x*y^3 + x^3*z - 3*x^2*z^2 + 4*x*z^3 - 2*z^4
]
```

We now construct an example of a non-new modular non-hyperelliptic curve of genus 3:

```
> S1:=ModularSymbols(178,2,1);
> N1:=SortDecomposition(NewformDecomposition(NewSubspace(CuspidalSubspace(S1))));
> A:=N1[3];A;
Modular symbols space for Gamma_0(178) of weight 2 and dimension 2 over
Rational Field
```

```
> S2:=ModularSymbols(89,2,1);
> N2:=SortDecomposition(NewformDecomposition(NewSubspace(CuspidalSubspace(S2))));
> B:=N2[1];B;
Modular symbols space for Gamma_0(89) of weight 2 and dimension 1 over
Rational Field
> fA:=qIntegralBasis(A,100);
> fB:=qIntegralBasis(B,100);
> q := Universe(fB).1;
> fB2:=&+[Coefficient(fB[1],k)*q^(2*k) : k in [1..99]];
> g:=fB[1]+2*fB2;
> ModularNonHyperellipticCurveGenus3([g,fA[1],fA[2]]);
true -x^4 + 2*x^2*y^2 - y^4 + 8*x^2*y*z + 8*y^3*z - 6*x^2*z^2 - 38*y^2*z^2 +
    24*y*z^3 + 7*z^4
>
```

The above curve is denoted by C_{178C}^{89A} in [GJO10]. Its jacobian is $\mathbf{Q}$-isogenous to $A \times B$.

129 SMALL MODULAR CURVES

Chapter 129
SMALL MODULAR CURVES

129.1 Introduction

The Small Modular Curve database is a database of simple models over the rational numbers for the $X_0(N)$ modular curves along with the standard automorphisms, cusps and non-cuspidal rational points in the positive genus cases, the various projection maps from $X_0(N) \to X_0(M)$ when M divides N and expressions for standard functions $(j(z), j(Nz))$ and forms (e.g. E_4, E_6) in terms of rational functions or k-differentials on the model. We refer to them as "small", because the models are of low degree, are defined by reasonably sparse polynomials with small integer coefficients, and are non-singular or have only a few simple singularities.

Because the MAGMA type of the model may be `CrvEll`, `CrvHyp`, `CrvPln` or just general `Crv` and it is not possible for a type to extend different subtypes of `Crv`, we have not introduced a special type like `CrvMod` (or used this type) for small modular curves. The modular curve component of the arguments to most of the intrinsics consists of a projective curve, which should be a base change of the model over $\mathbf{Q}$ to a field of characteristic zero, and the level N. This is a little "clunky" but hopefully the user won't find it too awkward. For efficiency, there is currently no initial check that the curve argument really is a base change of the database model, which the user can obtain via the `SmallModularCurve` call. The call will almost certainly result in an error if this is not the case.

For simplicity, in the initial implementation, the intrinsics require the modular curve to be defined over a field of characteristic zero, although the models are all defined by polynomials with integral coefficients which reduce nicely for primes not dividing the level. Again, we do not check this condition in all intrinsics: the user may find that if he carries out a mod p reduction on the database model himself and uses it as the argument to some of the intrinsics, they may still work.

129.2 Small Modular Curve Models

The models are projective models of the complete curve $X_0(N)$ over $\mathbf{Q}$. In the genus 0 case, we simple take the projective line $\mathbf{P}^1$ with the point at infinity corresponding to the cusp at infinity ∞. In the genus 1 case, we take a `CrvEll` which is the standard minimal Weierstrass model of the elliptic curve $(X_0(N), \infty)$ with the cusp ∞ as the 0 point for the group law. In the hyperelliptic cases (see [Ogg74]), we take a minimal Weierstrass model with two rational points at infinity, the cusp ∞ (which is never a hyperelliptic Weierstrass point) and its image under the hyperelliptic involution.

In all other cases (non-subhyperelliptic), we have followed the rule of taking a plane model (in $\mathbf{P}^2$) or a non-singular model in $\mathbf{P}^3$. In fact, we have only used $\mathbf{P}^3$ models in the genus 4 cases. For genus 3 and 4, we take a canonical model (non-singular plane quartic

and non-singular complete intersection of a quadric and a cubic respectively). For genus 5 and 6, we find a smallest degree singular birational plane model. These plane curves are of degree 6 in all cases. The singularities are mainly nodes (type A_2) and simple cusps (type A_3) and often under cuspidal points, though there are some more complex ones of higher A_n type. All of the non-singular models that we have produced reduce mod p to non-singular models of the reduction of $X_0(N)$ for p not dividing the level N. The singular plane models reduce mod p (p not dividing N again) to singular plane models of the reduction of $X_0(N)$ with singularities of the same type, except for a few cases with small p where nodes become cusps or two singularities coalesce into a more complex one.

The initial version of the database contains data for all subhyperelliptic $X_0(N)$ and all other cases with genus ≤ 6 (with a few genus 5 and 6 cases not yet added). This covers all $N < 60$ along with about half of the N between 60 and 80 and $N = 81, 121$.

We briefly indicate how the models were arrived at. Equations in the genus 0 and elliptic cases and modular functions giving the coordinate generators are reasonably well-known (see [Lig75] for the elliptic cases), though we found them again anyway as part of our general procedure of searching for small degree rational functions on $X_0(N)$. We considered functions generated by Dedekind eta products and weight 2 integral forms coming from eta products, various types of theta series and Eisenstein series. For the hyperelliptic cases with genus g, functions x and y with poles at ∞ giving a $y^2 = f(x)$ type Weierstrass equation are determined from constructing weight two cusp forms G and F with q-expansions $q^{g-1} + ..$ and $q^g + ..$ respectively. These were found in terms of eta products and theta forms and the results were checked against the output of MAGMA's modular forms package.

In the non-subhyperelliptic cases, we started from a canonical image simplified by applying LLL as output by `ModularCurveQuotient`, occasionally slightly adapting this to get good reduction at 2. In the genus 5 and 6 cases, we determined minimal degree (singular) plane models from these. Genus 5 is fairly straightforward. For the method to find degree 6 plane images in the genus 6 case, see [Hara] where the genus 5 case is also discussed.

Having determined a model as the image of the mapping $X_0(N)$ into $\mathbf{P}^{r-1}$ by $z \mapsto [f_1(z) : \ldots : f_r(z)]$, $r = 3$ or 4, we then found expressions for the weight 2 forms f_i of the type described above (eta products etc.). For more information on this, see the subsection 129.8 where we also give intrinsics to return a symbolic description of the construction of the generating modular functions/forms and to return q-expansions up to a desired precision. We wished to have concrete expressions for these functions/forms in terms of certain basic types, independent of the generic modular symbol method of generating q-expansions for bases of forms. It also allows for slightly faster reconstruction of q-expansions.

`SmallModularCurve(N)`

`SmallModularCurve(N,K)`

The first intrinsic returns the model for $X_0(N)$ over the rationals from the small modular curve database. The second returns the base change of this to K, which should be a characteristic zero field.

If there is no database entry yet for level N, a runtime error results.

`IsInSmallModularCurveDatabase(N)`

Returns whether or not there is a data for level N in the small modular curves database.

Example H129E1

```
> IsInSmallModularCurveDatabase(79);
false
> IsInSmallModularCurveDatabase(35);
true
> SmallModularCurve(35);
Hyperelliptic Curve defined by y^2 + (-x^4 - x^2 - 1)*y = -x^7 - 2*x^6 - x^5 -
    3*x^4 + x^3 - 2*x^2 + x over Rational Field
> C<x,y,z> := SmallModularCurve(63);
> C;
Curve over Rational Field defined by
x^5*y - 2*x^4*y^2 + 3*x^3*y^3 - 2*x^2*y^4 + x*y^5 - 2*x^3*z^3 + x^2*y*z^3 +
    x*y^2*z^3 - 2*y^3*z^3 + z^6
```

129.3 Projection Maps

The database contains information allowing the reconstruction of the standard projection maps between the models of the level N and level M curves for any M dividing N.

`ProjectionMap(CN,N,CM,M)`

CN and CM should be base changes to the same characteristic zero field K of the small modular database curves of levels N and M with $M|N$.

Returns the natural projection map $CN \to CM$ that corresponds to $z \mapsto z$ in terms of the upper half-plane quotient models and to $(E, C) \mapsto (E, (N/M)C)$ in the moduli space interpretation where non-cuspidal points correspond to isomorphism classes of an elliptic curves E with a cyclic subgroup C of order N.

`ProjectionMap(CN,N,CM,M,r)`

CN and CM should be base changes to the same characteristic zero field K of the small modular database curves of levels N and M with $M|N$ and r should be a positive integer divisor of N/M.

Returns the projection map $CN \to CM$ that corresponds to $z \mapsto rz$ in terms of the upper half-plane quotient models and to

$$(E, C) \mapsto (E/(N/r)C, (N/(Mr))C/(N/r)C)$$

in the moduli space interpretation where non-cuspidal points correspond to isomorphism classes of an elliptic curves E with a cyclic subgroup C of order N.

Example H129E2

We use a 3-projection (case $r = 3$ in the above) in our extended example at the end of the section. Here, we just give some simple examples of the calls.

129.4 Automorphisms

For modular curves $X_0(N)$, there is a finite group of automorphisms $B_0(N)$ which come from matrices acting on the complex upper half-plane. This group is isomorphic to $\mathrm{Nm}_{\mathrm{SL}_2(\mathbf{R})}(\Gamma_0(\mathrm{N}))/\Gamma_0(\mathrm{N})$ where $\mathrm{Nm}_{\mathrm{SL}_2(\mathbf{R})}(\Gamma_0(\mathrm{N}))$ is the normaliser of $\Gamma_0(N)$ in $\mathrm{SL}_2(\mathbf{R})$. It is generated by Atkin-Lehner involutions and, if 4 or 9 divides N, a transformation of the form $z \mapsto z + (1/r)$ for some $1 < r \,|\, 24$ (see [AL70] and also [Bar08] for the correct structure in all cases). We denote the latter transformations by S_r and write w_d for the d-th Atkin-Lehner involution ($d|N$, $(d, N/d) = 1$). These transformations have a natural modular interpretation.

A famous result of Kenku and Momose [KM88], completed by Elkies for $N = 63$ [Elk90], says that $B_0(N)$ gives the *full* group of algebraic automorphisms of $X_0(N)$ (in characteristic zero) when the genus of $X_0(N)$ is at least 2, except for $N = 37$ and 63. In fact, there is a slight error in their analysis, and $N = 108$ is also an exception [Harb]. In these three cases $B_0(N)$ is of index two in the full automorphism group $A_0(N)$ of $X_0(N)$.

We have precomputed and stored the w_d and S_r curve isomorphisms in the database. Let $g(N)$ denote the genus of $X_0(N)$. There are intrinsics to return these individual isomorphisms and a special intrinsic to compute and return the automorphism group $B_0(N)$, when $g \leq 1$, or $A_0(N)$, when $g \geq 2$, over various fields as a `GrpAutCrv`. We sometimes refer to the elements of these groups as modular automorphisms to emphasise that they are not all of the curve automorphisms in the $g(N) = 0$ or 1 cases (when the automorphism group is infinite).

Except in the $N = 108$ case, all automorphisms are defined over the cyclotomic field $\mathbf{Q}(\mu_r)$ where r is the largest divisor of 24 such that $r^2|N$ (for this field of definition, r can be replaced by $r/2$ if r is twice an odd number). Specifically, the w_d are all defined over $\mathbf{Q}$ and S_r has $\mathbf{Q}(\mu_r)$ as its field of definition.

The automorphism group intrinsics include in various ways an integer n that specifies a cyclotomic level and they return the subgroup of $A_0(N)$, or $B_0(N)$ for $g \leq 1$, containing all elements defined over $\mathbf{Q}(\mu_n)$. In all cases, the group of automorphism returned is a semi-direct product of groups, one for each prime p dividing N. For $p > 3$ this group is just C_2, generated by an Atkin-Lehner involution. For $p = 2$ or 3, if $p^2|N$ and n is appropriately divisible, the p-component is more complex. We build up the automorphism group in the various cases from the known structure. This is much faster than using the generic algorithm to compute it. The only real time goes into building up the total set of function field automorphisms (starting from the stored data for the generators) that is cached in the `GrpAutCrv` object.

`AtkinLehnerInvolution(CN,N,d)`

CN should be a base change of the small modular database curve of level N to a field of characteristic 0. d is a divisor of N with $(d, N/d) = 1$. Returns the Atkin-Lehner involution w_d as a scheme automorphism of CN. If the full automorphism group G of CN has already been computed and cached with CN (see the intrinsics below and the section in the Algebraic Curves chapter on automorphism groups) then the intrinsic will return w_d as a `GrpAutCrvElt` in G. Note that the intrinsic should terminate immediately in the first case, when it is just retrieving the equations from the database file, but has to do a little bit of work in the second case.

`SrAutomorphism(CN,N,r,u)`

CN should be a base change of the small modular database curve of level N to a field K of characteristic 0. r is a divisor of 24 such that $r^2|N$. u is a primitive r-th root-of-unity in K. Returns S_r as a scheme automorphism of CN that corresponds to $z \mapsto z+(1/r)$ if K is embedded into $\mathbf{C}$ so that u maps to $e^{2\pi i/r}$. If the full automorphism group G of CN has already been computed and cached with CN (see the intrinsics below and the section in the Algebraic Curves chapter on automorphism groups) then the intrinsic will return S_r as a `GrpAutCrvElt` in G. Note that the intrinsic will usually terminate more quickly in the first case, when it is just retrieving equations from the database file and maybe performing a composition, whereas in the second case it is doing an extra little bit of work.

`ExtraAutomorphism(CN,N,u)`

CN should be a base change of the small modular database curve of level N to a field K of characteristic 0. N is 37, 63 or 108. u is a primitive r-th root-of-unity in K where $r = 1$ (so $u = 1$) when $N = 37$ and $r = 3$ in the other cases. Returns an automorphism of CN in $A_0(N)$ that is not in $B_0(N)$ (i.e. not given by the action of a matrix on the complex upper half-plane: see the introduction). This "extra" automorphism generates $A_0(N)$ over $B_0(N)$ and is an involution when $N = 37$ (the hyperelliptic involution) or $N = 108$ and is of order 4 when $N = 63$ with square equal to the Atkin-Lehner involution w_9. If the full automorphism group G of CN has already been computed and cached with CN (see the intrinsics below and the section in the Algebraic Curves chapter on automorphism groups) then the intrinsic will return the extra automorphism as a `GrpAutCrvElt` in G. Note that the intrinsic should terminate immediately in the first case, when it is just retrieving the equations from the database file, but has to do a little bit of work in the second case.

`AutomorphismGroupOverQ(CN,N)`

`Install` BoolElt *Default :* `true`

CN should be a base change of the small modular database curve of level N to a field K of characteristic 0. Computes and returns the full group of automorphisms of CN (automorphisms in $B_0(N)$ if the genus of $X_0(N)$ is ≤ 1: see the introduction)

defined over **Q**. If the parameter `Install` has the value `true`, which is the default, the return value is internally installed and cached as the (full) automorphism group of CN, so the user should be careful that K doesn't contains roots of unity which generate a field over which some extra modular automorphisms are defined (viz. roots of unity of exact order r where $2 < r|24$ and $r^2|N$).

`AutomorphismGroupOverCyclotomicExtension(CN,N,n)`

`Install` BoolElt *Default :* `true`

CN should be a base change of the small modular database curve of level N to a field K which is the cyclotomic extension of **Q** obtained by adjoining the n-th roots of unity (the precise condition is that $K.1$ should be a primitive n-th root of unity). Computes and returns the full group of automorphisms of CN (automorphisms in $B_0(N)$ if the genus of $X_0(N)$ is ≤ 1: see the introduction) defined over K. If the parameter `Install` has the value `true`, which is the default, the return value is internally installed and cached as the (full) automorphism group of CN.

`AutomorphismGroupOverExtension(CN,N,n,u)`

`Install` BoolElt *Default :* `true`

CN should be a base change of the small modular database curve of level N to a field K which is an extension of **Q** containing the n-th roots of unity. u should be a primitive n-th root of unity in K. Computes and returns the full group of automorphisms of CN (automorphisms in $B_0(N)$ if the genus of $X_0(N)$ is ≤ 1: see the introduction) defined over the cyclotomic field $\mathbf{Q}(\mu_n)$. If the parameter `Install` has the value `true`, which is the default, the return value is internally installed and cached as the (full) automorphism group of CN. In that case, the user should be careful that n is well-chosen so that K doesn't contain higher order roots of unity which generate a subfield over which some modular automorphisms are defined that are not defined over $\mathbf{Q}(\mu_n)$.

Example H129E3

```
> C := SmallModularCurve(37);
> C;

129.5 Cusps and Rational Points

Letting H^* denote the extended complex upper half-plane $\{z \in C|\mathrm{Im(z)} > 0\} \cup \mathbf{Q} \cup \infty$, $X_0(N)(\mathbf{C})$ identifies with the quotient space $H^*/\Gamma_0(N)$ and the cusps are the images of $\mathbf{Q} \cup \infty$. A complete set of representatives of cusps are the images of the points a/d where d runs through positive divisors of N and, for each d, a runs through a set of integer representatives of $(\mathbf{Z}/(d, N/d)\mathbf{Z})^\times$ relatively prime to d. In particular, if $(d, N/d) \leq 2$, we just get $1/d$. The image of the cusp at ∞ identifies with the image of $1/N$.

With respect to the rational structure of $X_0(N)$, the cusps are all algebraic points defined over cyclotomic fields. Specifically, for a given $d|N$, the a/d are a set of Galois-conjugate points, each one having $\mathbf{Q}(\mu_{(d,N/d)})$ as the field of definition, and the Galois group of $\mathbf{Q}(\mu_{(d,N/d)})$ over $\mathbf{Q}$ acts simply transitively on this set. In particular, if $(d, N/d) \leq 2$, the cusp $1/d$ is a $\mathbf{Q}$-rational point on $X_0(N)$. Thus, $\infty \sim 1/N$ and $0 = 0/1 \sim 1/1$ are always rational cusps.

The cuspidal points on the models for small modular curves are stored in the database. More precisely, for each $d|N$, the database stores either a rational point for the cusp $1/d$, if $(d, N/d) \leq 2$, or a cluster that defines the $\mathbf{Q}$-conjugate set of cusps a/d, if $(d, N/d) > 2$. The user can access these through an intrinsic. If the model C for $X_0(N)$ is singular, some cusps may correspond to singular points on C. There may be two cusps that lie over the same node of C. In any case, the *place* over each conjugate class of cusps a/d is unique (different for different d) and the database contains information to determine which place belongs to which cusp for places above a singular cuspidal point on the model. There is an intrinsic to return the curve place above each $\mathbf{Q}$-conjugate set of cusps a/d.

Non-cuspidal rational points are of particular interest since they correspond to classes of elliptic curves defined over $\mathbf{Q}$ with a cyclic N-isogeny also defined over $\mathbf{Q}$ up to twist. On the complete set of curves $X_0(N)$ of genus > 0, there are very few non-cuspidal rational points and all such were determined by Mazur and others in the 1970s. The database

stores the list of non-cuspidal rational points for each level N. These are never singular points on the chosen models.

`Cusp(CN,N,d)`

CN should be a base change of the small modular database curve of level N to a field K of characteristic 0. d is a positive divisor of N. Returns the point on CN corresponding to the cusp $1/d$, if $(d, N/d) \leq 2$, or returns the cluster (zero-dimensional scheme) defined over K that is the reduced subscheme of CN consisting of the $\phi((d, N/d))$ cusps a/d, if $(d, N/d) > 2$ where ϕ is Euler's totient function.

`CuspIsSingular(N,d)`

Returns whether the points lying under the cusps a/d for $d|N$ on the small modular curve database model for $X_0(N)$ are singular. For a given d, they either all are or all are not.

`CuspPlaces(CN,N,d)`

CN should be a base change of the small modular database curve of level N to a field K of characteristic 0. d is a positive divisor of N. Returns the sequence of places of CN that correspond to the $\phi((d, N/d))$ cusps a/d. If $(d, N/d) \leq 2$ or $K = \mathbf{Q}$ there will only be one place. However, if K is a proper extension of $\mathbf{Q}$, the $\mathbf{Q}$-conjugate cusps a/d may split into several Galois orbits over K.

`NonCuspidalQRationalPoints(CN,N)`

CN should be a base change of the small modular database curve of level N of genus > 0 to a field K of characteristic 0. Returns the sequence of points on CN that correspond to non-cuspidal points in $X_0(N)(\mathbf{Q})$. There are only a small number of N for which this is a non-empty set and the rational points are non-singular ones on all of our models.

Example H129E4

```
> C := SmallModularCurve(32);
> C;
Elliptic Curve defined by y^2 = x^3 + 4*x over Rational Field
> Cusp(C,32,32); //cusp at infinity
(0 : 1 : 0)
> Cusp(C,32,8);
Cluster over Rational Field defined by
$.1^2 + 4*$.3^2,
$.2
> Degree($1);
2
> C<x,y,z> := SmallModularCurve(63);
> Cusp(C,63,1); // cusp at 0
(1 : 1 : 1)
```

```
> Cusp(C,63,7); // cusp at 1/7
(1 : 1 : 1)
> CuspIsSingular(63,1);
true
> CuspIsSingular(63,7);
true
> CuspPlaces(C,63,1);
[
    Place (2) at (1 : 1 : 1)
]
> CuspPlaces(C,63,7);
[
    Place (1) at (1 : 1 : 1)
]
> Cusp(C,63,3);
Cluster over Rational Field defined by
x - y,
y^2 + y*z + z^2
> Cusp(C,63,21);
Cluster over Rational Field defined by
x - y,
y^2 + y*z + z^2
> CuspPlaces(C,63,3)[1];
Place at ($.1 : $.1 : 1)
> CuspPlaces(C,63,21)[1];
Place at ($.1 : $.1 : 1)
> $1 eq $2;
false
```

129.6 Standard Functions and Forms

This section contains intrinsics that return the j-invariant as a rational function and normalised Eisenstein forms as meromorphic k-differentials on the small database models of $X_0(N)$. Standard variants of these can be obtained by pulling back by Atkin-Lehner involutions or pulling back the corresponding objects from lower level curves by the projection or r-projection maps.

The database actually only contains precomputed expressions for $E_2^{(N)}$ (see below), E_4 and E_6 for prime levels N and reconstructs everything else from these objects using projection maps.

`jInvariant(CN,N)`

`jFunction(CN,N)`

CN should be a base change of the small modular database curve of level N to a field of characteristic 0. These intrinsics return the j-invariant $j(z)$ as a rational function on CN. The second returns it as an element of the function field of CN. The first returns it as an element in the field of fractions of the coordinate ring of the ambient of CN, which is sometimes more convenient to use.

`jInvariant(p,N)`

p is a non-cuspidal point or a non-cuspidal place on a base change CN of the small modular database curve of level N to a field of characteristic 0. Returns the value of $j(z)$ at p, the value lying in L if p is a point in $CN(L)$ or in the residue class field of p if p is a place of CN. If p is a point, it should be non-singular. However, if the j function is defined at p, the intrinsic will still return a value.

`jNInvariant(p,N)`

Exactly as `jInvariant` above, except that the intrinsic gives the value of rational function $j(Nz)$ at the point or place. This is equivalent to computing the j-invariant value on the image of p under the Fricke involution w_N.

`E2NForm(CN,N)`

CN should be a base change of the small modular database curve of level N to a field of characteristic 0. $E_2^{(N)}(z) = NE_2(Nz) - E_2(z)$ is a weight 2 integral form for $\Gamma_0(N)$ where $E_2(z) = 1 - 24e^{2\pi iz} + \ldots$ is the normalised weight 2 Eisenstein series. $E_2^{(N)}(z)$ corresponds to a meromorphic differential (defined over $\mathbf{Q}$) on $X_0(N)$. The intrinsic returns $E_2^{(N)}(z)$ as a meromorphic differential in the function field of CN.

`E4Form(CN,N)`

CN should be a base change of the small modular database curve of level N to a field of characteristic 0. Returns a rational function f and a differential form ω in the function field of CN such that the Eisenstein series $E_4(z) = 1 + 240e^{2\pi iz} + \ldots$ as a meromorphic 2-differential on CN is given by $f\omega^2$.

`E6Form(CN,N)`

CN should be a base change of the small modular database curve of level N to a field of characteristic 0. Returns a rational function f and a differential form ω in the function field of CN such that the Eisenstein series $E_6(z) = 1 - 504e^{2\pi iz} + \ldots$ as a meromorphic 3-differential on CN is given by $f\omega^3$. Note that the same differential ω is returned by the `E4Form` intrinsic.

129.7 Parametrized Structures

As with the other modular equation databases in MAGMA there is functionality to explicitly compute a cyclic N-isogeny or cyclic subgroup of order N on an elliptic curve that is represented by a non-cuspidal point or place on the $X_0(N)$ models with the usual moduli space interpretation of the modular curves. The points represent equivalence classes of these structures (elliptic curve E with cyclic subgroup C, (E, C), or cyclic N-isogeny $\phi : E \to F$) up to isomorphism. In particular, if (E, C) is an elliptic curve with cyclic subgroup with both E and C defined over a field K, then any quadratic twist E_1 of E with the twisted subgroup C_1, which is the image of C under the isomorphism from E to E_1 over a quadratic extension, is represented by the same point on $X_0(N)$. If $j \neq 0, 1728$, any two elliptic curves over a field K with j-invariant j are quadratic twists of each other. Because of this, if $j(p) \neq 0, 1728$, any elliptic curve E over the field of definition K of the point p and j-invariant $j(p)$ will have a cyclic subgroup C defined over K such that (E, C) is represented by p or, equivalently, there is a cyclic N-isogeny defined over K and with domain E that is represented by p. We allow the user to pass in his choice of E for the base elliptic curve.

If z is a non-real complex number, let Λ_z be the two dimensional complex lattice $\mathbf{Z} \oplus \mathbf{Z}z$. Under the identification of the complex points of our model of $X_0(N)$ with $H^*/\Gamma_0(N)$ which follows from the identifcation of coordinate functions with specific modular functions or forms (see the next section), if a non-cuspidal point p corresponds to a point z in the upper halfplane H, the point p in the moduli intepretation is represented by (E_z, C), where $E_z = \mathbf{C}/\Lambda_z$ and C is the cyclic subgroup generated by $(1/N) \bmod \Lambda_z$, or the cyclic N-isogeny $\phi : E_z \to E_{Nz}$, $t \mapsto Nt$.

The computation of structures uses well-known methods. If d is a suitable differential on $X_0(N)$, we start with the data

$$p_1 = (N/12)(E_2^{(N)}/d)(p) \qquad E_4 = (E_4/d^2)(p) \qquad E_6 = (E_6/d^3)(p)$$

$$\tilde{E}_4 = N^2((E_4/d^2)(w_N(p))(w_N^*(d)/d)(p)^2 \qquad \tilde{E}_6 = N^3((E_6/d^3)(w_N(p))(w_N^*(d)/d)(p)^3$$

p is represented by (E, C) where E is given by $y^2 = x^3 - (E_4/48)x - (E_6/864)$ and the monic polynomial in x that defines C is computed from $p_1, E_4, E_6, \tilde{E}_4, \tilde{E}_6$ by the same algorithm as used in the SEA Elkies variant of Schoof's algorithm. The corresponding isogeny $\phi : E \to F$ with kernel C can then be computed using Velu's formulae.

```
SubgroupScheme(p,N)
```

```
SubgroupScheme(p,N,E)
```

Here p is a non-cuspidal point or place on C_N, a base change of the curve from the small modular curve database of level N to a field of characteristic zero. When p is given as a point, it should be non-singular point on C_N. The function returns an elliptic curve E_1 and a subgroup scheme G of E_1, both defined over the field of definition K of p (K if p is a point in $C_N(K)$; the residue class field of p if p is a place) such that G gives a cyclic subgroup of order N on E_1 and (E_1, G) represents p in the moduli space interpretation.

In the second version, when $j(p)$ should not be 0 or 1728, E should be an elliptic curve over a subfield of K with j-invariant $j(p)$. In this case, E_1 is taken as E or the base change of E to K, and only G is returned.

`Isogeny(p,N)`

`Isogeny(p,N,E)`

Here p is a non-cuspidal point or place on C_N, a base change of the curve from the small modular curve database of level N to a field of characteristic zero. When p is given as a point, it should be non-singular point on C_N. The function returns a cyclic N-isogeny of elliptic curves $\phi : E_1 \to F_1$, all defined over the field of definition K of p (K if p is a point in $C_N(K)$; the residue class field of p if p is a place), which represents p in the moduli space interpretation.

In the second version, when $j(p)$ should not be 0 or 1728, E should be an elliptic curve over a subfield of K with j-invariant $j(p)$. In this case, E_1 is taken as E or the base change of E to K.

Example H129E5

```
> C := SmallModularCurve(14);
> rats := NonCuspidalQRationalPoints(C,14);
> rats;
[ (2 : 2 : 1), (9 : -33 : 1) ]

```

129.8 Modular Generators and q-Expansions

In the genus 0 cases, the database model is just the projective line $\mathbf{P}^1$ and the uniformising parameter $t = x/y$ (where x, y are the projective coordinates of $\mathbf{P}^1$) is a modular function on $X_0(N)$. We have normalised so that this function has a simple zero at the cusp 0 and a simple pole at the cusp ∞ with q-expansion of the form $q^{-1} + \ldots$ when $N > 1$. For $N = 1$ we just take the j-invariant as our parameter.

In the elliptic and hyperelliptic cases, the model is a minimal Weierstrass equation $y^2 + h(x)y = f(x)$ and the x and y coordinate functions are modular functions on $X_0(N)$. We have normalised so that one of the points at infinity of the model is the cusp ∞, so x and y have poles there. In the elliptic cases, there is only one point at infinity. In the hyperelliptic cases, the other point at infinity is always the image of ∞ under the hyperelliptic involution: ∞ is never a Weierstrass point in these cases.

We sometimes refer to genus zero, elliptic and hyperelliptic curves by the semi-standard term subhyperelliptic. The models in the non-subhyperelliptic cases are ordinary projective and are sub-canonical images of $X_0(N)$. This means that there are linearly-independent weight 2 cusp forms $f_1, \ldots, f_r$ (which correspond to holomorphic differentials on $X_0(N)$) such that our model is the image of $X_0(N)$ under the map $z \mapsto [f_1(z) : \ldots : f_r(z)]$ into $\mathbf{P}^{r-1}$.

As stated earlier, although we sometimes used MAGMA's modular symbols machinery to compute a basis for forms when deriving models, we also worked out expressions for the modular functions t, x and y and the forms f_i in terms of certain basic types. This gives the models a degree of independence from the modular symbol machinery and also allows for faster reconstruction of q-expansions of the generating functions/forms. We describe the basic types here. There is an intrinsic that the user may call to retrieve the information as to how the forms are built up and one to return the actual q-expansions up to any desired precision. In some cases, we have used the cusp forms associated to an

elliptic curve of conductor N. We would have liked to avoid this and maybe with a bit more work we may be able to find alternative expressions that avoid using them. In fact, we should be using more of the theta series associated to quaternion algebras (this was an oversight only discovered recently: we are currently only using the theta series attached to one isomorphism class of maximal order for each quaternion algebra). Leaving aside the forms associated to elliptic curves, the basic types that we have looked at are all classical. We could also have tried to use some other basic types like the generalised eta products of Y. Yang.

The basic types fall into a number of categories:

(i) Dedekind eta products.

(ii) Theta series of binary quadratic forms of various kinds and theta series of quaternion algebras.

(iii) Weight 2 Eisenstein series of prime level.

(iv) Weight two cusp forms of elliptic curves.

Dedekind eta products for level N are of the form $\eta(d_1z)^{r_1}\eta(d_2z)^{r_2}\dots\eta(d_nz)^{r_n}$ where the d_i run over a subset of the positive divisors of N, the r_i are integers and $\eta(z)$ is the Dedekind η-function which has q-expansion $q^{1/24}\prod_{n=1}^{\infty}(1-q^n)$. If $\sum r_i$ is even and $\sum r_id_i$ and $\sum r_i(N/d_i)$ are divisible by 24, the product gives a modular form of weight $(1/2)\sum r_i$ for $\Gamma_0(N)$ with a certain character mod N. The form only has zeroes and poles at cusps with order given by a formula depending on N, r_i and d_i. We use these products to give modular functions and weight 2 forms and occasionally weight one forms to be used in combination with weight one forms coming from theta series.

The theta series associated to binary quadratic forms come in several flavours.

If $Q(x,y)=ax^2+bxy+cz^2$ (with $a,b,c\in\mathbf{Z}, a>0$) has discriminant $-N$, then the usual theta series $\theta_Q(z)=\sum_{(x,y)\in\mathbf{Z}^2}q^{Q(x,y)}$ is a weight one form of level N for the quadratic character given by the Jacobi symbol $(\frac{-N}{\cdot})$. The product of two of these gives a weight 2 integral form for $\Gamma_0(N)$.

If $N\equiv 1 \bmod 4$ and $Q(x,y)=ax^2+bxy+cz^2$ is a form with discriminant $-4N$ with a odd and b,c even, the function $\theta_Q^{(1)}(z)=\sum_{(x,y)\in\mathbf{Z}^2,xodd}(-1)^y q^{Q(x,y)/4}$ is a weight one form of level N for the character $(\frac{\cdot}{N})\chi^a$ where χ is the quartic character giving the action of $\Gamma_0(1)$ on $\eta(z)^6$. If Q_1,Q_2 are two such forms, one of which has $a\equiv 1 \bmod 4$ and $a\equiv 3 \bmod 4$ for the other, then $\theta_{Q_1}^{(1)}\theta_{Q_2}^{(1)}$ is a weight 2 integral form for $\Gamma_0(N)$. Additionally, the function $\theta_Q^{(2)}(z)=\sum_{(x,y)\in\mathbf{Z}^2,xodd}q^{Q(x,y)/4}$ is a weight one form of level $2N$ for the character $(\frac{\cdot}{N})\chi^a\delta$ where δ is the unique non-trivial character that factors through the quotient $\Gamma_0(2N)/\Gamma_0(4N)$. Again, $\theta_{Q_1}^{(2)}\theta_{Q_2}^{(2)}$ is a weight 2 form for $\Gamma_0(2N)$ if the as for Q_1 and Q_2 are non-congruent mod 4.

If $N\equiv 3 \bmod 8$ and $Q(x,y)=ax^2+bxy+cz^2$ is a form with discriminant $-N$ (here a,b,c must all be odd), the function $\theta_Q^{(3)}(z)=\sum_{(x,y)\in\mathbf{Z}^2,xodd}(-1)^y q^{Q(x,y)/2}$ is a weight one form of level N for the character $(\frac{-N}{\cdot})\chi$ where χ is the quadratic character giving the action of $\Gamma_0(1)$ on $\eta(z)^{12}$. The product of any two of these gives a weight 2 integral form for $\Gamma_0(N)$.

If $N = p_1 \dots p_r$ is a product of an odd number of distinct primes, let H_N be the quaternion algebra over $\mathbf{Q}$ which is ramified precisely at ∞ and the primes p_i. Let O_N be a maximal order of H_N, which is a $\mathbf{Z}$-lattice of rank 4, and Q_N the positive-definite quadratic form on it given by the reduced norm Nm of H_N. Then the theta function $\theta_{Q_N}(z) = \sum_{x \in O_N} q^{Nm(x)}$ is a weight two integral form for $\Gamma_0(N)$.

The weight 2 Eisenstein series of prime level p is the form $pE_2(pz) - E_2(z)$, which is an integral form of weight 2 for $\Gamma_0(p)$. Here $E_2(z)$ is the usual normalised weight 2 Eisenstein series (which isn't a modular form for any level) with q-expansion $1 - 24q - 72q^2 - \dots$. We usually normalise the prime level Eisenstein series by dividing by $GCD(24, p-1)$ which is the GCD of its integral coefficients.

If E is an elliptic curve over Q of conductor N, then the modular form $f_E(z)$ associated to E, which is returned by the call `ModularForm(E)`, is a weight 2 cusp form for $\Gamma_0(N)$.

We also use three standard operations on forms/functions.

If $f(z)$ is a modular function on $X_0(N)$ then $D(f) = (1/2\pi i)(df/dz)$ is a weight 2 form for $\Gamma_0(N)$.

If $f(z)$ is a form/function on $X_0(M)$ and d is a positive integer dividing N/M then $f(dz)$ is a form/function on $X_0(N)$.

If f is a form for $\Gamma_0(N)$ and χ is the quadratic character with conductor d where $|d|^2$ divides N, then the twisted form $f \otimes \chi$ is also a form for $\Gamma_0(N)$ where if f has the q-expansion $\sum a_n q^n$ then $f \otimes \chi$ has q-expansion $\sum a_n \chi(n) q^n$.

The basic types are forms or functions of types (i)-(iv), possibly operated on by one of the above 3 operations. Basic functions are functions of basic type or quotients of forms of basic type of the same weight. We build modular functions as rational functions of basic functions. We build modular forms of weight 2 as linear combinations of weight 2 forms of basic type or products of modular functions with weight 2 forms of basic type. We give some examples below.

`qExpansionExpressions(N)`

This procedure prints out a mini-program that is used to compute the modular functions that correspond to t or to x, y on $X_0(N)$ in the subhyperelliptic cases or the weight 2 cusp forms $f_1, \dots, f_r$ on $X_0(N)$ in the other cases. These give expressions for the forms/functions in terms of forms/functions of basic type. The format of the mini-program is as follows.

There are a sequence of statements. Each except the last is of the form $v = \langle expr \rangle$ where v is a variable name, $\langle expr \rangle$ is an expression and the statement assigns the value of the expression (a modular form or function on $X_0(N)$) to variable v. Each expression is a string of terms separated by binary arithmetic operators $\hat{} \; * \; / \; + \; -$ which have their usual meaning, are listed in precedence order and evaluate left to right for operators of the same precedence. There may also be subexpressions in () brackets. Subexpressions in brackets are evaluated first and replaced with their value, inner bracketed subexpressions being evaluated before outer ones. Terms are of one of the following types, possibly modified by an operator:

(i) An integer. This either multiplies a form/function, is an exponent for powering or gives a constant function.

(ii) q. This is just $e^{2\pi iz}$, the 'q' of the q-expansion.

(iii) A variable that has previously been assigned to.

(iv) An eta product. $e\{\langle d_1\ r_1\rangle\langle d_2\ r_2\rangle\dots\langle d_n\ r_n\rangle\}$ represents the eta product $\eta(d_1z)^{r_1}\eta(d_2z)^{r_2}\dots\eta(d_nz)^{r_n}$.

(v) Binary theta functions as described in the introduction. For a positive-definite binary quadratic form $Q(x,y)=Ax^2+Bxy+Cy^2$,
$th0\{A\ B\ C\}$ is the usual theta series of Q.
$th1\{A\ B\ C\}$ is $(1/2)q^{-a/4}\theta_Q^{(1)}$ where a is A mod 4. This has q-integral q-expansion.
$th2\{A\ B\ C\}$ is $(1/2)q^{-a/4}\theta_Q^{(2)}$ where a is A mod 4. This has q-integral q-expansion.
$th3\{A\ B\ C\}$ is $(1/2)q^{-1/2}\theta_Q^{(3)}$. This has q-integral q-expansion.

(vi) Theta functions of quaternion algebras as described in the introduction. $thQ\{N\}$ represents the weight 2 theta function attached to a maximal order of the quaternion algebra of level N, where N is a product of an odd number of distinct primes. The notation is deficient here. The theta series depends on the isomorphism class of the maximal order chosen. Currently, we are only using the maximal order returned by MAGMA in the call `MaximalOrder(QuaternionAlgebra(N))`.

(vii) Eisenstein series. $E\{p\}$ represents the weight 2 normalised Eisenstein series of prime level p, $(pE_2(pz)-E_2(z))/GCD(24,p-1)$.

(viii) Cusp forms from elliptic curves. $f\{a_1\ a_2\ a_3\ a_4\ a_6\}$ represents the weight two newform associated to the elliptic curve over $\mathbf{Q}$ with equation $y^2+a_1xy+a_3y=x^3+a_2x^2+a_4x+a_6$.

Modifying operators are

(i) D. $D(f)$ is $(1/2\pi i)(df/dz)$, where f is a modular function on $X_0(N)$.

(ii) $[d]$. d is a positive integer. If f represents a form or function $f(z)$, then $f[d]$ represents $f(dz)$.

(iii) $\langle d\rangle$. If f is a form, $f\langle d\rangle$ represents the form twisted by the quadratic character of conductor d.

The last line of the mini-program is of the form $[t,1]$ if $X_0(N)$ is of genus 0, $[x,y,1]$ if $X_0(N)$ is elliptic or hyperelliptic, and $[f_1,\dots,f_r]$ otherwise, where t,x,y,f_i are variables that were assigned to in earlier lines. These give the generating functions/forms for the $X_0(N)$ model.

`qExpansionsOfGenerators(N,R,r)`

Returns q-expansions to precision r as Laurent series in the Laurent series ring R over $\mathbf{Q}$ for the sequence of modular forms/functions of level N that define the small modular curve database model of $X_0(N)$. As described in the introduction, the

return sequence is of the form $[t]$ if $X_0(N)$ is of genus 0, $[x, y]$ if $X_0(N)$ is elliptic or hyperelliptic, and $[f_1, \ldots, f_r]$ otherwise. Here t, x and y are Laurent series giving the q-expansions of functions which will have poles at the cusp ∞, so have negative power terms, and the f_i will actually be power series giving the q-expansions of weight 2 cusp forms.

The q-expansions are computed from the expressions which are given in the mini-program output by `qExpansionExpressions(N)`, generating the forms/functions from ones of basic type for which there are fast routines to compute q-expansions.

Example H129E6

We give some examples of the mini-programs for various levels

```
> qExpansionExpressions(8); //genus 0 case
x=e{<1 4><2 -2><4 2><8 -4>}
[x,1]
> qExpansionExpressions(15); //genus 1 case
F=e{<1 1><3 1><5 1><15 1>}

        + q^11 + 2*q^13 + q^15 + q^16 - 2*q^20 - q^22 - q^23 - 2*q^24 - q^25 -
        q^29 + q^30 + O(q^31)
]
```

129.9 Extended Example

We give an example that combines functionality for small modular curves with MAGMA's machinery for curve quotients and elliptic curves to compute the j-invariant of a special class of elliptic curves over $\mathbf{Q}$ up to quadratic twist. This class of curves arose in Wiles' original paper on Fermat's Last Theorem and the Shimura-Tanayama-Weil (STW) conjecture.

Example H129E7

In the Breuil-Conrad-Diamond-Taylor-Wiles proof of the STW conjecture, a couple of special cases arise that lead to a finite number of classes of elliptic curves up to $\bar{\mathbf{Q}}$-isomorphism that have to be determined and then checked directly for modularity. If $E[p]$ is the p-torsion subgroup of E considered as a $\mathrm{Gal}(\bar{\mathbf{Q}}/\mathbf{Q})$-module, these are cases where $E[3]$ and $E[5]$ are both reducible, $E[3]$ is reducible and $E[5]$ is irreducible but absolutely reducible as a $\mathrm{Gal}(\bar{\mathbf{Q}}/\mathbf{Q}(\sqrt{5}))$-module, or $E[5]$ is reducible and $E[3]$ is irreducible but absolutely reducible as a $\mathrm{Gal}(\bar{\mathbf{Q}}/\mathbf{Q}(\sqrt{-3}))$-module. The first case corresponds to non-cuspidal rational points on $X_0(15)$ and leads, up to isogeny, to one class of twists with $j = -25/2$ as may easily be verified using the intrinsics here. The second case corresponds to non-cuspidal rational points on a quotient of $X_0(75)$ and leads to curves with $j = 0$. We consider the third case in this example, showing that, up to isogeny, there is one class (up to quadratic twist) with j-invariant $(11/2)^3$.

The curves we want are precisely those that have a cyclic subgroup of order 5 rational over $\mathbf{Q}$ and for which the image of $\mathrm{Gal}(\bar{\mathbf{Q}}/\mathbf{Q})$ in $GL_2(\mathbf{F}_3)$, giving the action on $E[3]$, is the normaliser of a split Cartan subgroup.

Curves just satisfying the $E[3]$ condition are classified by non-cuspidal rational points on $X_0(9)/w_9$ that are not the image of a rational point of $X_0(9)$. Such a point p lifts to a point p_1 on $X_0(9)$ defined over some quadratic field K such that $p_1^\sigma = w_9(p_1)$ where σ is the nontrivial automorphism of K over $\mathbf{Q}$. If (E, C) is an elliptic curve/K with cyclic subgroup $C = \langle P \rangle$ rational over K that is represented by the moduli point p_1, then $E_1 = E/\langle 3P \rangle$ can be defined over $\mathbf{Q}$ so that the order 3 subgroups $C/\langle 3P \rangle$ and $(C/\langle 3P \rangle)^\sigma$ generate $E_1[3]$, are rational over K and are swapped by σ.

In the same way, adding the extra condition that there is a rational subgroup of order 5 leads to curves classified by non-cuspidal rational points of $X_0(45)/w_9$. These do not lift to rational points because $X_0(45)$ has no non-cuspidal rational points. $X_0(45)/w_9$ is $\mathbf{Q}$-isogenous to the rank 0 elliptic curve $X_0(15)$ so only has finitely many rational points. If p_1 is a lift, the image of p_1 under the 3-projection map $X_0(45) \to X_0(5)$ ($z \mapsto 3z$ on complex points) is a rational point that corresponds to the desired curve E_1 (with its cyclic 5-subgroup). We could apply the 3-projection

all the way down to $X_0(1)$ of course, but it is slightly more efficient to just project to level 5 and remove duplicate images before computing j-invariants.

```
> X45<x,y,z> := SmallModularCurve(45);
> w9 := AtkinLehnerInvolution(X45,45,9);
> G := AutomorphismGroup(X45,[w9]);
> C,prjC := CurveQuotient(G);
> c_inf := Cusp(X45,45,45);
> ptE := prjC(c_inf);
> E1,mp1 := EllipticCurve(C,ptE);
> E,mp2 := MinimalModel(E1);
> prjE := Expand(prjC*mp1*mp2);
```

E is a minimal model for $X_0(45)/w_9$ and $prjE$ is the projection from $X_0(45)$ to E that takes the cusp ∞ to the zero point of E. We compute the image of the cusps under $prjE$ so as to discount these when we find all the rational points on E. Since p and $w_9(p)$ map to the same point under $prjE$, we only need consider cusps up to w_9 equivalence. The non-rational conjugate cusps $\pm 1/3$ are defined over $\mathbf{Q}(\sqrt{-3})$ and are swapped by w_9, so map to the same rational point. The same holds for the cusps $\pm 1/15$.

```
> i0 := prjE(Cusp(X45,45,1));
> K := QuadraticField(-3);
> c3 := Cusp(X45,45,3);
> c3p := X45(K)!Representative(Support(c3,K));
> i3 := E!(prjE(c3p));
> c15 := Cusp(X45,45,15);
> c15p := X45(K)!Representative(Support(c15,K));
> i15 := E!(prjE(c15p));
> Ecusps := [E!0,i0,i3,i15];
```

E has rank zero, so we can recover all of its rational points using `TorsionSubgroup`. There are 8 in all, 4 of which are images of cusps. We find the 4 non-cuspidal ones and compute the pullbacks of them to $X_0(45)$. In each case, the pull back is a pair of conjugate points defined over a quadratic field. It is easiest to work with places here (and we don't have to worry about the base scheme of $prjE$). The pullback of each point gives a single place corresponding to the two conjugate points.

```
> T,mp := TorsionSubgroup(E);
> Epts := [mp(g) : g in T];
> Eptsnc := [P : P in Epts | P notin Ecusps];
> plcs := [Support(Pullback(prjE,Place(p)))[1] : p in Eptsnc];
```

We now perform the 3-projection to $X_0(5)$ on these places and discard duplicate images.

```
> X5 := SmallModularCurve(5);
> prj3 := ProjectionMap(X45,45,X5,5,3);
> prj3 := Expand(prj3);
> plcs5 := [Support(Pushforward(prj3,p))[1] : p in plcs];
```

```
> plcs5 := Setseq(Seqset(plcs5));
```

We compute the j-invariants of the two images and verify that they represent isogenous curves under the cyclic 5-isogeny coming from the rational 5-subgroup (i.e. they are images of each other under w_5).

```
> js := [jInvariant(p,5) : p in plcs5];
> js;
[ -1680914269/32768, 1331/8 ]
> w5 := AtkinLehnerInvolution(X5,5,5);
> Pullback(w5,plcs5[1]) eq plcs5[2];
true
```

Finally, we can use MAGMA intrinsics to check that the elliptic curves with these j-invariants actually do satisfy the property that the image of the action of Galois on 3-torsion is the normaliser of a split Cartan subgroup (D_8). As this property remains true for quadratic twists and is unchanged by images under a rational 5-isogeny, we only need check it for one curve over $\mathbf{Q}$ with one of the j-invariants. We also check that a minimal twist has conductor 338 from which modularity can be checked explicitly.

```
> Ej := EllipticCurveWithjInvariant(js[2]);
> Ej := MinimalModel(MinimalTwist(Ej));
> Conductor(Ej);
338
> ThreeTorsionType(Ej);
Dihedral
```

130 CONGRUENCE SUBGROUPS OF $\mathrm{PSL}_2(\mathbf{R})$

Chapter 130
CONGRUENCE SUBGROUPS OF $\mathrm{PSL}_2(\mathbf{R})$

130.1 Introduction

The group $GL_2^+(\mathbf{R})$ of 2 by 2 matrices defined over $\mathbf{R}$ with positive determinant acts on the upper half complex plane $\mathbf{H} = \{x \in \mathbf{C} | \mathrm{Im(x)} > 0\}$ by fractional linear transformation:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} : z \mapsto \frac{az+b}{cz+d}.$$

Any subgroup Γ of $GL_2^+(\mathbf{R})$ also acts on $\mathbf{H}$. To compactify the quotient $\Gamma\backslash\mathbf{H}$ it is necessary to adjoin the cusps, which are points in $\mathbf{P}^1(\mathbf{Q}) = \mathbf{Q} \cup \{\infty\}$. We set $\mathbf{H}^* := \mathbf{H} \cup \mathbf{P}^1(\mathbf{Q})$.

A fundamental domain for the action of Γ is a region of $\mathbf{H}^*$ containing a representative of each orbit of the action. The fundamental domain is most useful when it can be taken to be compact with finite area under the hyperbolic metric on $\mathbf{H}$. This is the situation for congruence subgroups.

This chapter gives a description of how to work in Magma with $\mathbf{H}^*$ and with congruence subgroups and their action on $\mathbf{H}^*$. This allows the computation of generators for congruence subgroups, and various other information, such as coset representatives. Farey symbols are used for this computation, and can be computed and manipulated by the user. Procedures are provided for producing graphical images, in the form of postscript files, which illustrate the fundamental domains. These procedures can be used to draw geodesics and polygons in the upper half plane.

This package has been written by Helena Verrill, and is partly based on a java program for drawing fundamental domains ([Ver00]). The Farey sequence algorithm used here is that described by Kulkarni [Kul91].

Example H130E1

An example of what can be computed with this package.

```
> G := CongruenceSubgroup(0,35);
> G;
Gamma_0(35)
> Generators(G);
[
    [1 1]
    [0 1],
    [ 11  -3]
    [ 70 -19],
    [ 13  -8]
    [ 70 -43],
    [  8  -3]
```

```
    [ 35 -13],
    [ 29 -21]
    [105 -76],
    [ 11  -6]
    [ 35 -19],
    [ 29 -17]
    [ 70 -41],
    [ 16 -11]
    [ 35 -24],
    [ 22 -17]
    [ 35 -27]
]
> C := CosetRepresentatives(G);
> H := UpperHalfPlaneWithCusps();
> triangle := [H|Infinity(),H.1,H.2];
> triangle_translates := [g*triangle : g in C];
>  DisplayPolygons(triangle_translates,"/tmp/Gamma035.ps": Show := false);
[ 0.E-57, 1.0000000000000000000000000000, 1.5000000000000000000000000000, 300 ]
```

In the example the command `DisplayPolygons` produces a postscript file "/tmp/Gamma035.ps" of a drawing of all the translates of the given triangle under the cosets of $\Gamma_0(35)$. If the `Show` option is set to `true`, a system command is issued and a window pops up for viewing the file created. Continuing with the above example, one can also find the vertices of a polygon defining the Fundamental domain of the group:

```
> FD := FundamentalDomain(G);
> // Print a FD in a reasonable format:
> &cat[Sprintf(" %o ",c) : c in FD];
 oo  0  1/6  1/5  1/4  3/11  2/7  1/3  2/5  3/7  1/2  4/7  3/5  5/8  2/3  5/7
3/4  1  oo
>  DisplayPolygons([FD],"/tmp/Gamma0_35_Domain.ps": Show := false);
[ 0.E-28, 1.0000000000000000000000000000, 1.5000000000000000000000000000, 300 ]
```

130.2 Congruence Subgroups

We denote by $\mathrm{SL}_2(\mathbf{Z})$ the group of 2 by 2 matrices with integer coefficients and determinant 1. The group $\mathrm{PSL}_2(\mathbf{Z})$ is the projectivization of $\mathrm{SL}_2(\mathbf{Z})$. For any integer N we have groups

$$\Gamma_0(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbf{Z}) \;\middle|\; \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} * & * \\ 0 & * \end{pmatrix} \bmod N \right\}$$

$$\Gamma_1(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbf{Z}) \;\middle|\; \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & * \\ 0 & 1 \end{pmatrix} \bmod N \right\}$$

$$\Gamma(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbf{Z}) \;\middle|\; \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \bmod N \right\}$$

$$\Gamma^1(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbf{Z}) \;\middle|\; \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 \\ * & 1 \end{pmatrix} \bmod N \right\}$$

$$\Gamma^0(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbf{Z}) \;\middle|\; \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} * & 0 \\ * & * \end{pmatrix} \bmod N \right\}$$

A *congruence subgroup* is any discrete subgroup Γ of $\mathrm{SL}_2(\mathbf{R})$ which is commensurable with $\mathrm{SL}_2(\mathbf{Z})$, that is, $\Gamma \cap \mathrm{SL}_2(\mathbf{Z})$ has finite index in Γ and in $\mathrm{SL}_2(\mathbf{Z})$, and such that $\Gamma(N)$ is contained in G for some N. The *level* N of a congruence subgroup G is the greatest integer N such that $\Gamma(N)$ is contained in Γ. We will abuse notation and also refer to the projectivizations of these groups by the same names.

130.2.1 Creation of Subgroups of $\mathrm{PSL}_2(\mathbf{R})$

`PSL2(R)`

Returns $\mathrm{PSL}_2(R)$, the projective linear group over the ring R.

`Gamma0(N)`

The group $\Gamma_0(N)$ for any positive integer N.

`Gamma1(N)`

The group $\Gamma_1(N)$ for any positive integer N.

`GammaUpper0(N)`

The group $\Gamma^0(N)$ for any positive integer N.

`GammaUpper1(N)`

The group $\Gamma^1(N)$ for any positive integer N.

`CongruenceSubgroup(N)`

The group $\Gamma(N)$ for any positive integer N.

`CongruenceSubgroup(i,N)`

For a positive integer N and $i = 0, 1, 2, 3$, or 4, this is the group $\Gamma_0(N)$, $\Gamma_1(N)$, $\Gamma(N)$, $\Gamma^1(N)$ or $\Gamma^0(N)$ respectively.

`CongruenceSubgroup([N,M,P])`

This is the congruence subgroup consisting of 2 by 2 matrices with integer coefficients $[a, b, c, d]$ with $b = 0 \pmod P$, $c = 0 \pmod N$, and $a = d = 1 \pmod M$. It is required that M divides NP.

`Intersection(G,H)`

`G meet H`

The intersection of congruence subgroups G and H.

Example H130E2

Examples of defining different congruence subgroups:

```
> G := PSL2(Integers());
> H := CongruenceSubgroup([2,3,6]);
> H;
Gamma_0(2) intersection Gamma^1(3) intersection Gamma^0(2)
> K := CongruenceSubgroup(0,5);
> K meet H;
Gamma_0(10) intersection Gamma^1(3) intersection Gamma^0(2)
```

130.2.2 Relations

`G eq H`

Returns `true` if and only if the congruence subgroups G and H are equal.

`H subset G`

For congruence subgroups G and H contained in $\mathrm{PSL}_2(\mathbf{Z})$, returns `true` if and only if H is a subgroup of G.

`Index(G,H)`

For congruence subgroups G and H, returns the index of G in H provided G is a subgroup of H.

`Index(G)`

For G a congruence subgroup in $\mathrm{PSL}_2(\mathbf{Z})$, returns the index in $\mathrm{PSL}_2(\mathbf{Z})$.

130.2.3 Basic Attributes

`Level(G)`

The level of a congruence subgroup G.

`IsCongruence(G)`

Returns `true` if and only if G is a congruence subgroup.

`IsGamma0(G)`

Returns `true` if and only if G is equal to $\Gamma_0(N)$ for some integer N.

`IsGamma1(G)`

Returns `true` if and only if G is equal to $\Gamma_1(N)$ for some integer N.

`BaseRing(G)`

Returns the base ring over which matrices of the congruence subgroup G are defined.

`Identity(G)`

Returns the identity matrix in the congruence subgroup G.

130.3 Structure of Congruence Subgroups

`CosetRepresentatives(G)`

If G is a subgroup of finite index in $\mathrm{PSL}_2(\mathbf{Z})$, then returns a sequence of coset representatives of G in $\mathrm{PSL}_2(\mathbf{Z})$.

`Generators(G)`

Returns a sequence of generators of the congruence subgroup G.

`FindWord(G,g)`

For a congruence subgroup G, and an element g of G, this function returns a sequence of integers corresponding to an expression for g in terms of a fixed set of generators for G. Let L be the list of generators for G output by the function `Generators`. Then the return sequence $[e_1n_1, e_2n_2, \ldots, e_mn_m]$, where n_i are positive integers, and $e_i = 1$ or -1, means that $g = L[n_1]^{e_1}L[n_2]^{e_2}\ldots L[n_m]^{e_m}$. Note that since the computation is in $PSL_2(\mathbf{R})$, this equality only holds up to multiplication by ± 1.

`Genus(G)`

The genus of the upper half plane quotiented by the congruence subgroup G.

`FundamentalDomain(G)`

For G a subgroup of $\mathrm{PSL}_2(\mathbf{Z})$ returns a sequence of points in the Upper Half plane which are the vertices of a fundamental domain for G.

Example H130E3

In this example we compute a set of generators for $\Gamma_0(12)$.

```
> G := CongruenceSubgroup(0,12);
> Generators(G);
[
    [1 1]
    [0 1],
    [ 5 -1]
    [36 -7],
    [  5  -4]
    [ 24 -19],
    [  7  -5]
    [ 24 -17],
    [ 5 -3]
    [12 -7]
]
> C := CosetRepresentatives(G);
> H<i,r> := UpperHalfPlaneWithCusps();
> triangle := [H|Infinity(),r,r-1];
> translates := [g*triangle : g in C];
```

Example H130E4

This example illustrates how any element of a congruence subgroup can be written in terms of the set of generators output by the `generators` function.

```
> N := 34;
> characters := DirichletGroup(N,CyclotomicField(EulerPhi(N)));
> char := Elements(characters)[5];
> G := CongruenceSubgroup([N,Conductor(char),1],char);
>
> // We can create a list of generators:
> gens := Generators(G);
> #gens;
21
> // given an element of G,
> g := G![ 21, 4, 68, 13 ];;
> // we can find g in terms of these generators:
> FindWord(G,g);
[ -8, 1 ]
> // This means that up to sign, g = gens[8]^(-1)*gens[1],
> // which can be verified as follows:
> gens[8]^(-1)*gens[1];
[-21  -4]
[-68 -13]
```

130.3.1 Cusps and Elliptic Points of Congruence Subgroups

`Cusps(G)`

Returns a sequence of inequivalent cusps of the congruence subgroup G.

`CuspWidth(G,x)`

Returns the width of x as a cusp of the congruence subgroup G.

`EllipticPoints(G)`

`EllipticPoints(G,H)`

Returns a list of inequivalent elliptic points for the congruence subgroup G. A second argument may be given to specify the upper half plane H containing these elliptic points.

Example H130E5

We can compute a set of representative cusps for $\Gamma_1(12)$, and their widths as follows:

```
> G := CongruenceSubgroup(0,12);
> Cusps(G);
[
    oo,
    0,
    1/6,
    1/4,
    1/3,
    1/2
]
> Widths(G);
[ 1, 12, 1, 3, 4, 3 ]
> // Note that the sum of the cusp widths is the same as the Index:
> &+Widths(G);
24
> Index(G);
24
```

In the following example we find which group $\Gamma_0(N)$ has the most elliptic points for N less than 20, and list the elliptic points in this case.

```
> H := UpperHalfPlaneWithCusps();
> [#EllipticPoints(Gamma0(N),H) : N in [1..20]];
[ 2, 1, 1, 0, 2, 0, 2, 0, 0, 2, 0, 0, 4, 0, 0, 0, 2, 0, 2, 0 ]
> // find the index where the maximal number of elliptic points is attained:
> Max($1);
4 13
> // find the elliptic points for Gamma0(13):
> EllipticPoints(Gamma0(13));
[
    5/13 + (1/13)*root(-1),
    8/13 + (1/13)*root(-1),
    7/26 + (1/26)*root(-3),
    19/26 + (1/26)*root(-3)
]
```

130.4 Elements of $\mathrm{PSL}_2(\mathbf{R})$

130.4.1 Creation

`G ! x`

If x is a sequence $x = [a, b, c, d]$ of elements in the base ring of G, this function returns $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$, provided this is an element of G. If x is an integer the identity matrix is returned. If x is a matrix, it is coerced into G if possible.

`Random(G,m)`

Returns a random element of the projective linear group G, with m determining the size of the coefficients.

130.4.2 Membership and Equality Testing

`g eq h`

For g and h elements of $\mathrm{PSL}_2(\mathbf{Z})$, returns `true` if g, h have compatible coefficient rings and if $g = h$, `false` otherwise. Since the group is projective, returns `true` if the matrices are equal up to a nonzero scalar multiple.

`IsEquivalent(g,h,G)`

For g and h elements of $\mathrm{PSL}_2(\mathbf{Z})$, returns `true` if g and h are defined of the same field, and if $Gg = Gh$, i.e. if $gh^{-1} \in G$.

`g in G`

For g an elements of $\mathrm{PSL}_2(\mathbf{Z})$, returns `true` if g is in the congruence subgroup G, `false` otherwise.

130.4.3 Basic Functions

For a matrix g in a congruence subgroup, and an integer n, returns g^n.

`Eltseq(g)`

Returns the sequence of four numbers which are the entries of the matrix g.

`g * h`

If g and h have the same parent then this returns their product.

`g ^ n`

For a matrix g and integer n returns g^n.

Example H130E6

Define congruence subgroups as in the following examples:

```
> // examples of defining matrix elements of congruence subgroups:
>
> G := PSL2(Integers());
> G![2,0,0,2];
[1 0]
[0 1]
> H := CongruenceSubgroup([2,3,6]);
> H![7,6,8,7];
[7 6]
[8 7]
```

130.5 The Upper Half Plane

The *upper half complex plane* is defined by $\mathbf{H} := \{z \in \mathbf{C} \mid \mathrm{Im(z)} > 0\}$. The group $\mathrm{SL}_2(\mathbf{Z})$ acts on H by fractional linear transformations. The space $\mathbf{H}/SL_2(\mathbf{Z})$ is not compact; it is compactified by adding the cusps, which are points of $\mathbf{Q}$, together with ∞. Thus we define $\mathbf{H}^*$ to be the upper half plane union the cusps. Then $\mathbf{H}^*/\mathrm{SL}_2(\mathbf{Z})$ is compact. Thus we define a function which will return the space of points in the upper half complex plane, together with the set of cusps.

In $\mathbf{H}^*$ we define two distinguished points, the elliptic points $\sqrt{-1}$ and $(1+\sqrt{-3})/2$. In general, points constructed in $\mathbf{H}^*$ are allowed to come from at most quadratic extensions of $\mathbf{Q}$, since in this case there is a canonical embedding in $\mathbf{C}$.

130.5.1 Creation

`UpperHalfPlane()`

Creates a copy of the upper half complex plane, with the cusps included. As a set this consists of all complex numbers with positive imaginary part, together with all rational numbers, and the point at infinity.

`H ! x`

Returns x as a point in $\mathbf{H}$. Here x can be a cusp, rational, integer, in a quadratic extension of $\mathbf{Q}$, or a complex number with positive imaginary part.

Example H130E7

Example of creating some points in the upper half plane.

```
> H := UpperHalfPlaneWithCusps();
> // coerce a cusp into H:
> c := Cusps()!(1/2);
> H!c;
1/2
> // coerce an element of a quadratic extension of Q into H
> K := QuadraticField(-7);
> K<u> := QuadraticField(-7);
> H!(u+5);
5 + root(-7)
> // refer to the two distinguished elliptic points:
> H.1;
root(-1)
> H.2;
1/2 + (1/2)*root(-3)
> // Defining the names of the elliptic points when constructing H:
> H<i,rho> := UpperHalfPlaneWithCusps();
> i;
root(-1)
> rho;
1/2 + (1/2)*root(-3)
```

130.5.2 Basic Attributes

`Imaginary(z)`

Returns the imaginary part of the argument as an element of `RealField`.

`Real(z)`

Returns the real part of the argument as an element of `RealField`.

`IsReal(z)`

Returns `true` if and only if the element z of the upper half plane lies on the real line (and is not the infinite cusp).

`IsCusp(z)`

Returns `true` if and only if the element z of the upper half plane is a cusp.

`IsInfinite(z)`

Returns `true` if and only if the element z of the upper half plane is the cusp at infinity.

`IsExact(z)`

Returns `true` if and only if the element z of the upper half plane is a cusp or has an exact value defined in a quadratic extension of the rationals.

`ExactValue(z)`

For x an element of the upper half plane, if x is a cusp, returns the value of x as an object of type `SetCspElt`; if x has an exact value in a quadratic extension, returns this value, as an object of type `FldQuadElt`; otherwise returns a complex value of type `FldComElt`.

`ComplexValue(x)`

`Precision`	RngIntElt	*Default :*
`MaxValue`	RngIntElt	*Default :* 600

For x an element of the upper half place, this returns x as a complex number. When x is the cusp at infinity, the value returned is `MaxValue + i*MaxValue`.

`x eq y`

Returns `true` if and only if the points x and y in the upper half plane are equal.

130.6 Action of $\mathrm{PSL}_2(\mathbf{R})$ on the Upper Half Plane

`g * z`

For z of type `SpcHypElt, SetCspElt` or `[SpcHypElt]`, and when g is an element of a projective linear group, returns the image of z under the action of g. The type of the image is the same as the type of z. If g is a positive integer, returns return az, which his is equivalent to acting on z with the matrix $\begin{pmatrix} a & 0 \\ 0 & 1 \end{pmatrix} \in \mathrm{PGL}_2(\mathbf{R})$.

`FixedPoints(g,H)`

Returns a sequence of points in H fixed by the action of g.

`IsEquivalent(G,a,b)`

If points a, b in the upper half plane are equivalent under the action of the group G, returns `true`, and the matrix g in G such that $g \cdot a = b$. Otherwise returns `false` and the identity.

`EquivalentPoint(x)`

For the point x in the upper half plane, returns a point z in the region with $-1/2 < z \leq 1/2$ and $|z| \geq 1$, and a matrix g in $\mathrm{PSL}_2(\mathbf{Z})$ with g*x = z

`Stabilizer(a,G)`

Returns a generator of the subgroup of G stabilizing a.

`FixedArc(g,H)`

If g is an element of $\mathrm{PSL}_2(\mathbf{Z})$ which is an involution, this returns the end points in the real line of the arc fixed by g, with mid point of the arc also fixed by g. Note that for any point b, the arc from b to $g \cdot b$ is fixed by g.

130.6.1 Arithmetic

`z + a`
`z + a`
`z - a`
`z - a`

For any integer a, and element z in the upper half plane, this returns the element $z + a$ in the same copy of the upper half plane.

`a * z`
`z * a`
`a * z`
`a * z`
`a * seq`
`a * z`
`a * z`
`z * a`
`z * a`
`z * a`
`z * a`
`z * a`
`z / a`

Given an element z (or a sequence of elements) in the upper half plane, and a positive rational number a, this returns the product (or products) in the same copy of the upper half plane.

130.6.2 Distances, Angles and Geodesics

`Distance(z,w)`

`Precision` RngIntElt *Default :*

Returns the hyperbolic distance between z and w.

`TangentAngle(x,y)`

`Precision` RngIntElt *Default :*

Returns the angle of the tangent at x of the geodescic from x to y, with given precision.

`Angle(e1,e2)`

`Precision` RngIntElt *Default :*

Given two sequences $e_1 = [z_1, z_2]$ and $e_2 = [z_1, z_3]$, where $z1, z2, z3$ are elements of the upper half plane, this returns the angle between the geodesics at z_1.

`ExtendGeodesic([z1,z2], H)`

Given elements $z1, z2$ in the upper half plane H, this extends the geodesic between $z1$ and $z2$ to a semicircle with endpoints on the real line, and returns the two real endpoints as elements of H.

`GeodesicsIntersection(x1,x2)`

`GeodesicsIntersection(x1,x2)`

The intersection in the upper half plane of the two geodesics whose endpoints are given by the sequences x_1 and x_2. If the geodesics intersect along a line, the empty sequence is returned.

130.7 Farey Symbols and Fundamental Domains

One method of finding fundamental domains for congruence subgroups is the method of Farey Symbols, as described by Kulkarni [Kul91].

A *generalized Farey sequence* is a sequence of rationals

$$\frac{a_1}{b_1} < \frac{a_2}{b_2} < \ldots < \frac{a_n}{b_n}$$

such that for a consecutive pair of fractions $\frac{b}{d}, \frac{a}{c}$ in the sequence, written in lowest terms, we have $ad - bc = 1$. We extend the rationals to $\mathbf{Q} \cup \{-\infty, \infty\}$, where we use the convention $-\infty = \frac{-1}{0}$ and $\infty = \frac{1}{0}$.

A *Farey Symbol* is a Farey sequence of length n starting with $\frac{-1}{0}$, and ending with $\frac{1}{0}$, together with a sequence of $n-1$ labels. We use the convention that labels can be any elements of $\mathrm{N}_{>0} \cup \{-2, -3\}$. The sequence of labels must satisfy the condition that each element of $\mathrm{N}_{>0}$ appears in the sequence either exactly twice or not at all. For example, the sequences $\left[\frac{-1}{0}, \frac{0}{1}, \frac{1}{2}, \frac{2}{3}, \frac{5}{7}, \frac{3}{4}, \frac{1}{1}, \frac{1}{0}\right]$ and $[1, 2, 2, -3, -2, -2, 1]$ define a Farey symbol, which is generally written in the following format:

$$\left\{ \frac{-1}{0}, \overset{1}{\frac{0}{1}}, \overset{2}{\frac{1}{2}}, \overset{2}{\frac{2}{3}}, \overset{-3}{\frac{5}{7}}, \overset{-2}{\frac{3}{4}}, \overset{-3}{\frac{1}{1}}, \overset{1}{\frac{1}{0}} \right\}.$$

Farey symbols are used to define certain fundamental domains for congruence subgroups of $\mathrm{PSL}_2(\mathbf{Z})$. The sequence of fractions gives cusps which are vertices of the domain, and the labels give edge identifications. For a_i, a_{i+1} in the Farey sequence, with corresponding label l_i not -3, the corresponding edge of the domain is a geodesic between a_i and a_{i+1}. If the label is -3, there is an extra elliptic point of order 3 on the boundary of the domain between the two cusps, and the two edges between these cusps are identified. The label $l_i = -2$ indicates an elliptic point of order 2 on the boundary between the two cusps a_i and a_{i+1}. This point is on the geodesic between a_i and a_{i+1}, and the two halves of the geodesic are identified.

`FareySymbol(G)`

Computes the Farey Symbol of a congruence subgroup G in $\mathrm{PSL}_2(\mathbf{Z})$.

`Cusps(FS)`

Returns the cusp sequence of the Farey symbol FS. Note, this is not a sequence of inequivalent cusps of the corresponding group.

`Labels(FS)`

Returns the sequence of edge labels of a Farey symbol FS.

`Generators(FS)`

Returns the generators of the congruence subgroup corresponding to the Farey symbol FS.

`Group(FS)`

Returns the congruence subgroup corresponding to the Farey Symbol FS.

`Widths(FS)`

Returns the sequence of integers giving twice the widths of the cusp list of the Farey symbol FS.

`Index(FS)`

Returns the index of `Group(FS)` in $\mathrm{PSL}_2(\mathbf{Z})$.

`FundamentalDomain(FS)`
`FundamentalDomain(FS,H)`

Returns the vertices in the upper half plane of the fundamental domain described by the Farey Sequence FS. A second argument may be given to specify the upper half plane H.

`CosetRepresentatives(FS)`

Returns the coset representatives of the congruence subgroup of $\mathrm{PSL}_2(\mathbf{Z})$ corresponding to the Farey symbol FS.

`InternalEdges(FS)`

Returns a sequence of pairs of cusps which are cusps of the Farey Symbol FS, and which are not adjacent in FS but which are images of 0 and infinity under some matrix in $\mathrm{PSL}_2(\mathbf{Z})$.

130.8 Points and Geodesics

In this section we describe some functions involving points and geodesics. Geodesics in the upper half plane are given by circles or lines which intersect the real axes at right angles. A geodesic is defined by its two end points. Points and geodesics can be drawn using the graphics functions described in the next section.

`GeodesicsIntersection(x,y)`

Computes the intersection in the upper half plane of the two geodesics x, y, where x and y are specified by their end points, which must be cusps. If the geodesics intersect along a line the empty sequence is returned.

Example H130E8

In the following example we find and display the intersection points of some geodesics:

```
> H := UpperHalfPlaneWithCusps();
> g1 := [H|-1,2];
> g2 := [H|0,6];
> g3 := [H|1,5];
> g4 := [H|2,Infinity()];
> lines := [g1,g2,g3,g4];
> points := [GeodesicsIntersection(x,y,H) : x in lines,y in lines];
>  DisplayPolygons(lines cat points,"/tmp/pic.ps":
>  Labels := [-1,0,1,2,5,6],Colours := [1,0,0],Show := true);
[ -1.0000000000000000000000000000, 6.0000000000000000000000000000,
3.3284271247461900976033774484, 91 ]
```

130.9 Graphical Output

When working with a particular congruence subgroup it is often useful to be able to produce a picture of a fundamental domain of the group. Also when considering images of geodesics in $\mathbf{H}^*$ it can be useful to draw the images. The following graphics functions provide a useful tool for this purpose.

`DisplayPolygons(P,file)`

`Colours`	SeqEnum	*Default :* $[1,1,0]$
`Outline`	BoolElt	*Default :* `true`
`Fill`	BoolElt	*Default :* `true`
`Show`	BoolElt	*Default :* `false`
`Labels`	SeqEnum	*Default :* $[0,1]$
`Fontsize`	RngIntElt	*Default :* 2
`Size`	SeqEnum	*Default :* [ ]
`Pixels`	RngIntElt	*Default :* 300

`Overwrite`	BoolElt	*Default :* `false`
`Radius`	FldReElt	*Default :* 0.5
`PenColours`	SeEnum	*Default :* $[0, 0, 0]$

Given a sequence of polygons, each of which is defined by a sequence of points in the upper half plane, produce the postscript drawing of these polygons, and write the result to the named file. The function returns a sequence of 4 real numbers, `[x0,x1,h,S]`, where `(x0,0)` are the coordinates of the lower left corner, `(x1,h)` are the coordinates of the upper right corner, and the scale is such that there are `S` pixels per unit. These values are either given by the user, or computed automatically.

`Colours` : Either a sequence of 3 numbers, or a sequence of such sequences, one for each polygon in the sequence of polygons given. A colour is represented by 3 real numbers between 0 and 1, giving the red, green and blue components of the colour. This colour is used for the filling of the polygon.

`PenColours` : A sequence of 3 numbers, or a sequence of such sequences, one for each polygon in the sequence of polygons given. A colour is represented by 3 real numbers between 0 and 1, giving the red, green and blue components of the colour. This colour is used for drawing the outline of the polygon.

`Labels` : A sequence of elements of type `SetCspElt`, `FldRatElt` or `RngIntElt`, which will be labeled on the real axis in the diagram.

`Fontsize` : The size of the font used in labeling the diagram.

`Pixels` : When using Autoscale, the scale is computed so that the width of the resulting diagram is given by `Pixels` in pixels, plus a 20 pixel border. The minimal possible value for `Pixels` is 10, and if any smaller value is given it will be set to 10.

`Size` : If `Size` is not the empty sequence, the values in the sequence `Size` are used to determine the size of the image. When `Size` is given by `[x0,x1,y,S]`, the picture is draw with coordinates `(x0,0)` in the lower left corner, `(x1,h)` in the upper right corner, and the scale is such that there are `S` pixels per unit. If `Size` is not given, then an appropriate size for the image is computed automatically.

`Overwrite` : If `Overwrite` is set to `true`, then if the name of the file given names a file which already exists, it will be overwritten. Otherwise the user will be asked whether they want to overwrite the file or not.

`Show` : If `Show` is set to `true` a System command is issued to make a window pop up showing the file just created. The system command is `System("gv file &")`. In future other options may be possible. If `Show` is `false` then

`Fill` : A boolean or sequence of booleans, determining whether the polygon is drawn filled in with a colour, the colour coming from the sequence

`Colours`. If both `Fill` and `Outline` are set to `false` outline is reset to `true`.

`Outline` : A boolean or sequence of booleans, determining whether the polygon is drawn with an outline. If both `Fill` and `Outline` are set to `false` outline is reset to `true`.

`Radius` : A real number giving the radius of points marked on the diagram. A point will be marked for any polygon given by a single point.

`DisplayFareySymbolDomain(FS,file)`

`DisplayFareySymbolDomain(G,file)`

`Colour`	SeqEnum	*Default :* $[1, 1, 0]$
`Show`	BoolElt	*Default :* `false`
`Fontsize`	RngIntElt	*Default :* 2
`Labelsize`	RngIntElt	*Default :* 3
`Autoscale`	BoolElt	*Default :* `true`
`Size`	SeqEnum	*Default :* []
`Pixels`	RngIntElt	*Default :* 300
`Overwrite`	BoolElt	*Default :* `false`
`ShowInternalEdges`	BoolElt	*Default :* `false`

`Display` : a fundamental domain corresponding to the Farey Symbol FS, or a group G, for which the Farey symbol will be computed, with edge identifications and cusps labeled. This function returns a sequence of 4 real numbers, `[x0,x1,h,S]`, where `(x0,0)` are the coordinates of the lower left corner, `(x1,h)` are the coordinates of the upper right corner, and the scale is such that there are `S` pixels per unit. These values are either given by the user, or computed automatically. A polygon can be a sequence of any number of points of type `HypSpcElt` or `SetCspElt`. When at least 3 points are given a polygon is drawn. For two points, a geodesic between them is drawn. For one point a small circle is drawn to mark the point.

`Colour` : This colour is used in colouring the domain drawn. A colour is represented by a sequence of 3 real numbers between 0 and 1, giving the red, green and blue components of the colour.

`Fontsize` : The size of the font used in labeling the cusps on the diagram.

`Labelsize` : The size of the font used in labeling the identification labels on the diagram.

`Autoscale` : If `true`, the scale is computed and the file is created so that all the polygons listed can be seen in the diagram, if this is feasible. if `Autoscale` is set to `false`, then the variable `Size` must be given.

`Pixels` : When using `Autoscale`, the scale is computed so that the width of the resulting diagram is given by `Pixels` in pixels, plus a 20 pixel border. The minimal possible value for `Pixels` is 10, and if any smaller value is given it will be set to 10.

`Size` : When `Autoscale` is `false`, the values in the sequence `Size` are used to determine the size of the image. When `Size` is given by `[x0,x1,y,S]`, the picture is draw with coordinates `(x0,0)` in the lower left corner, `(x1,h)` in the upper right corner, and the scale is such that there are `S` pixels per unit.

`Overwrite` : If `Overwrite` is set to `true`, then if the name of the file given names a file which already exists, it will be overwritten. Otherwise the user will be asked whether they want to overwrite the file or not.

`Show` : If `Show` is set to `true` a System command is issued to make a window pop up showing the file just created. The system command is `System("gv file &")`. In future other options may be possible. If `Show` is `false` then

`ShowInternalEdges` : If this is set to `true` then internal edges are drawn dividing the domain into fundamental domains for $\Gamma_0(2)$.

Example H130E9

In the first example we draw a fundamental domain for $\Gamma_0(12)$.

```
> G := Gamma0(24);
> FS := FareySymbol(G);
> C := Cusps(FS);
> Domain := FundamentalDomain(G);
> red := [1,0,0];
>  DisplayPolygons(Domain,"/tmp/Gamma0N12.ps":
>      Colours := red, Labels := C, Show := true, Fontsize := 1);
[ 0.E-28, 1.0000000000000000000000000000, 1.5000000000000000000000000000, 300 ]
```

The user could write a procedure as follows for drawing the fundamental domain as a union of fundamental domains for $\mathrm{PSL}_2(\mathbf{Z})$.

```
> procedure draw_fundamental_domain(Group,file)
>     cosets := CosetRepresentatives(Group);
>     H<i,r> := UpperHalfPlaneWithCusps();
>     tri := [H|Infinity(),0,r];
```

```
>     red := [1,0,0];
>     yellow := [1,1,0];
>     cyan := [0,1,1];
>     cols := &cat[[red,yellow,cyan] : i in [1..(Ceiling(#cosets/3))]];
>     trans := [g*tri : g in cosets];
>     Outlines := [false : g in cosets];
>     DisplayPolygons(trans,file:
>         Colours := cols, Outline := Outlines, Show := true);
> end procedure;
>
> // use the procedure to draw a domain for Gamma_0(19):
>  draw_fundamental_domain(Gamma0(19),"/tmp/gamma019.ps");
[ 0.E-28, 1.0000000000000000000000000000, 1.5000000000000000000000000000, 300 ]
```

In the following example, we use the cosets of $\Gamma_0(11)$ to draw a fundamental domain for $\Gamma_0(11)$, divided up into fundamental domains for the group of automorphisms of $\mathbf{H}^*$ generated by $\mathrm{PSL}_2(\mathbf{Z})$ together with the map $z \mapsto -\overline{z}$.

```
> G := Gamma0(11);
> H<i,rho> := UpperHalfPlaneWithCusps();
> tri := [H|Infinity(),i,rho];
> tri1 := [H|0,i,rho];
> C11 := CosetRepresentatives(G);
> Colours := [[0.6,0.2,0.9] : i in [1..#C11]] cat [[1,1,0] : i in [1..#C11]];
> triangles := [g*tri : g in C11] cat [g*tri1 : g in C11];
>  DisplayPolygons(triangles,"/tmp/Gamma_0_11.ps":
>      Colours := Colours, Show := false);
[ 0.E-57, 1.0000000000000000000000000000, 1.5000000000000000000000000000, 300 ]
```

Continuing from the above example, we can take any other polygon we wish, and look at it's translates under the action of the cosets of $\Gamma_0(11)$.

```
> tri2 := [H|Infinity(),2*i + 1,i,rho];
>  DisplayPolygons([g*tri2 : g in C11],"/tmp/pic.ps":
>      Colours := Colours, Show := true);
[ 0.E-57, 1.0000000000000000000000000000, 2.5000000000000000000000000000, 300 ]
```

In the next example we define three different triangles. Each of these is a fundamental domain for $\Gamma^0(2)$, though MAGMA currently does not verify this. For each choice we use a set of generators of $\Gamma^0(2)$ to draw a partial tiling of the upper half plane with equivalent fundamental domains.

```
> G := CongruenceSubgroup(4,2);
> H<i,r> := UpperHalfPlaneWithCusps();
> generators := Generators(G);
> M := generators cat [g^(-1) : g in generators] cat [G!1];
> tri1 := [H|Infinity(),r-1,0,r,r+1];
> tri2 := [H|Infinity(),i-1,0,i+1];
> tri3 := FundamentalDomain(G);
> X := [1..#M];
> L := [G!m : m in Set([Matrix(M[i]*M[j]*M[k]) : i in X, j in X, k in X])];
>  DisplayPolygons([g*tri1 : g in L],"/tmp/picture1.ps": Show := true);
```

```
[ -4.000000000000000000000000000, 3.500000000000000000000000000,
1.500000000000000000000000000, 200 ]
>  DisplayPolygons([g*tri2 : g in L],"/tmp/picture2.ps": Show := true);
[ -4.000000000000000000000000000, 3.000000000000000000000000000,
1.500000000000000000000000000, 200 ]
>  DisplayPolygons([g*tri3 : g in L],"/tmp/picture3.ps": Show := true);
[ -4.000000000000000000000000000, 3.000000000000000000000000000,
1.500000000000000000000000000, 200 ]
```

Edges and Polygons with different numbers of sides can be included in the same picture, as in the following example.

```
> H<i,r> := UpperHalfPlaneWithCusps();
> cosets := CosetRepresentatives(Gamma0(19));
> polygons := [g*tri : g in cosets, tri in [[H|i,r],[H|i,2*r,3*r-1]]];
> outlines := [true : i in cosets] cat [false : i in cosets];
> cyan := [0,1,1];
>  DisplayPolygons(polygons,"/tmp/pic.ps":
>      Colours := cyan, Outline := outlines, Labels := [], Show := false);
[ 0.E-57, 1.000000000000000000000000000, 3.098076211353315940291169512, 300 ]
```

In the following example a function is defined to determine the colouring of the polygons in terms of which Farey sequence pairs of end points of the polygons belong to.

```
> frac := func<a | a[1]/a[2]>;
>
> function FareyValue(m)
>   mat := Matrix(m);
>   Denominators := [mat[2,1],mat[2,2],mat[2,1]+mat[2,2]];
>   values := [Abs(v) : v in Denominators];
>   return &+ContinuedFraction(frac(Sort(values)));
> end function;
>
> procedure drawDomain(cosets)
>    H<i,r> := UpperHalfPlaneWithCusps();
>    tri := [H|Infinity(),0,r];
>    cols := [[0.5,0.2*FareyValue(c),1-0.2*FareyValue(c)] : c  in cosets];
>    trans := [g*tri : g in cosets];
>    DisplayPolygons(trans,"/tmp/pic.ps":
>        Outline := false, Colours := cols, Show := true);
> end procedure;
>
> // Now we can use the above functions and procedure, for example
> // take the cosets as follows:
> C := CosetRepresentatives(Gamma0(41));
> // Then draw the picture:
>  drawDomain(C);
[ 0.E-28, 1.000000000000000000000000000, 1.500000000000000000000000000, 300 ]
```

Example H130E10

Functions are provided for drawing pictures coming from Farey symbols and fundamental domains. These functions provide short cuts for producing some of the pictures in the previous examples, but are not so flexible.

```
> G := CongruenceSubgroup(5);
> FS := FareySymbol(G);
> FS;
[ 2, 2, 7, 8, 8, 10, 9, 3, 3, 9, 4, 1, 1, 4, 5, 5, 10, 11, 11, 7, 6, 6 ]
[ oo, 0, 1/5, 2/9, 1/4, 3/11, 5/18, 2/7, 1/3, 3/8, 5/13, 2/5, 1/2, 3/5, 5/8, 2/3,
5/7, 8/11, 3/4, 7/9, 4/5, 1, oo ]
> // The following command graphically displays the information contained in FS:
>  DisplayFareySymbolDomain(FS,"/tmp/Gamma5b.ps": Show := false);
[ 0, 1.0000, 0.50000, 800 ]
> // This picture represents a modular curve with genus 0:
> Genus(G);
0
```

Example H130E11

In the following example we show how to create a postscript file and include the resulting file in a latex file.
The example in question is $\Gamma_0(37)$. A simple question is to find what is the fundamental domain, and to give a list of inequivalent elliptic points of the group, and display this information graphically. First we create the group and find the information we are interested in:

```
> G := Gamma0(37);
> // To draw a picture of the fundamental domain we need to define
> // the upper half plane.
> H<i,r> := UpperHalfPlaneWithCusps();
> D := FundamentalDomain(G,H);
> E := EllipticPoints(G,H);
```

We can now take a look at the picture:

```
> // We need to make sure the polygons we want to display all
> // have the same type, so we have t create the following object:
> HH:=Parent(D);
> // now we make a list of polygons and points:
> P1:=[HH|D] cat [HH|[e] : e in E];
> // we take a look at the default picture of the situation:
>  DisplayPolygons(P1,"/tmp/pic.ps": Show := true);
[ 0.E-28, 1.0000, 1.5000, 300 ]
```

The points have been displayed in yellow, the default colour, but we'd prefer a different colour. Also the picture is not quite the right size. It has been shown with the real axis shown from 0 to 1, which is reasonable, but we'd prefer less height, and the scale 300 could be changed, as in this example:

```
> // use different colours:
```

```
> yellow := [1,1,0];
> red := [1,0,0];
> green := [0,1,0];
> cyan := [0,1,1];
> black := [0,0,0];
> Colours := [yellow] cat [red : e in E];
> // use a different size and scale:
> Size := [0,1,0.2,400];
> // view the result:
>  DisplayPolygons(P1,"/tmp/pic.ps":
>      Show := true, Colours := Colours, Size := Size);
[ 0, 1, 0.19999999999999999999999999999, 400 ]
```

After more experimenting we reach the following:

```
> // We use a slightly different list of polygons, to show more
> // structure.
> tri := [H|Infinity(),0,H.2];
> cosets := CosetRepresentatives(G);
> P := [HH|g*tri : g in cosets] cat [HH|[e] : e in E] cat [HH|D];
> // Choosing some colours:
> LotsOfColours := &cat[[yellow,green,cyan] : c in cosets];
> Colours := [LotsOfColours[i] : i in [1..#cosets]]
>            cat [black]
>            cat [red : e in E];
> // choose which polygons are filled, and which have outlines:
> outlines := [false : i in cosets] cat [false : i in E] cat [true];
> fill := [true : i in cosets] cat [true : i in E] cat [false];
> labels := Cusps(FareySymbol(G));
> // Create a file of the result:
>  DisplayPolygons(P,"/tmp/pic.ps":
>      Colours := Colours, Show := false, Size := [0,1,1,200],
>      Labels := labels, Outline := outlines, Fill := fill,
>      Fontsize := 1, Radius := 0.3);
[ 0, 1, 1, 200 ]
```

If we are satisfied with the resulting picture then we can include the resulting picture in a latex file as in the following example, where we use the Latex `graphicx` package to include the diagram.

```
\documentclass{article}
\usepackage[dvips]{graphicx}
\begin{document}
Here is a picture of a
fundamental domain for $\Gamma_0(37)$:
$${\includegraphics{/tmp/pic.ps}}$$
In the picture we have marked $4$ inequivalent
elliptic points.
```

```
\end{document}
```

Note that currently, given a list of points to draw, the postscript file will include all of the points, even if they are not in the area of the bounding box, which can produce bad results some times. This should be changed in a future version. Sometimes using the Fundamental domain function can produce results in a more reliable way, as in the following example, which produces a similar picture to the above, and a latex file can be written in the same way.

```
> G := Gamma0(37);
> H<i,r> := UpperHalfPlaneWithCusps();
> D := FundamentalDomain(G,H);
> HH:=Parent(D);
> E := EllipticPoints(G,H);
> P:=[HH|D] cat [HH|[e] : e in E];
> labels := Cusps(FareySymbol(G));
> yellow := [1,1,0];
> red := [1,0,0];
> Colours := [yellow] cat [red : e in E];
>  DisplayPolygons(P,"/tmp/pic.ps":
>      Colours := Colours, Show := false, Size := [0,1,0.2,200],
>      Labels := labels,
>      Fontsize := 1, Radius := 0.3);
[ 0, 1, 0.19999999999999999999999999999, 200 ]
```

131 ARITHMETIC FUCHSIAN GROUPS AND SHIMURA CURVES

Chapter 131
ARITHMETIC FUCHSIAN GROUPS AND SHIMURA CURVES

In this chapter, we document algorithms for arithmetic Fuchsian groups. Let F be a totally real number field. Let A be a *quaternion algebra* over F, a central simple algebra of dimension 4 (see Chapter 86), such that A is split at exactly one real place, corresponding to the injective map $\iota_\infty : A \to M_2(\mathbf{R})$. Let $\mathcal{O}$ be a maximal order in A (see also Section 81.4), let $\mathcal{O}^*$ denote the group of elements of $\mathcal{O}$ of reduced norm 1, and let $\Gamma(1) = \iota_\infty(\mathcal{O}^*)/\{\pm 1\} \subset PSL_2(\mathbf{R})$. An *arithmetic Fuchsian group* Γ is a discrete subgroup of $PSL_2(\mathbf{R})$ which is commensurable with $\Gamma(1)$ (for some choice of F and A).

The classical case of the modular groups corresponds to $F = \mathbf{Q}$, $A = M_2(\mathbf{Q})$, $\mathcal{O} = M_2(\mathbf{Z})$, and $\Gamma(1) = \mathrm{PSL}_2(\mathbf{Z})$. Specialized algorithms for this case apply, and they are treated in detail in Chapter 130. To exclude this case, we assume throughout that A is a division ring, or equivalently $A \ncong M_2(\mathbf{Q})$.

The group Γ acts properly and discontinuously on the upper half-plane $\mathbf{H}$, and the quotient $\Gamma\backslash\mathbf{H} = X(\Gamma)$ can be given the structure of a compact Riemann surface, called a *Shimura curve*.

We exhibit methods for computing with arithmetic Fuchsian groups Γ, including the basic invariants of Γ and a fundamental domain for $X(\Gamma)$. We provide further specialized algorithms for triangle groups. Along the way, we also present an interface for computing with the unit disc, parallel to that for the upper half-plane (see Chapter 130).

The algorithm used to compute fundamental domains is described in [Voi09]. We recommend the following additional reading concerning the algorithms in this section. For an introduction to Fuchsian groups, see Katok [Kat92] and Beardon [Bea77], and for their relationship to quaternion algebras, see also Vignéras [Vig80]. For a computational perspective on arithmetic Fuchsian groups and Shimura curves, see Alsina-Bayer [AB04], Elkies [Elk98], and Voight [Voi05], and for a discussion of triangle groups, see Voight [Voi06].

131.1 Arithmetic Fuchsian Groups

In this section, we computing the basic invariants of an arithmetic Fuchsian group Γ.

131.1.1 Creation

We begin by giving the basic constructors for arithmetic Fuchsian groups.

`FuchsianGroup(O)`

Returns the arithmetic Fuchsian group Γ corresponding to the group $\mathcal{O}^*$ of units of reduced norm 1 in the quaternion order $\mathcal{O}$.

`FuchsianGroup(A)`

Returns the arithmetic Fuchsian group Γ corresponding to the group $\mathcal{O}^*$ of units of reduced norm 1 in a maximal order $\mathcal{O}$ in the quaternion algebra A.

`FuchsianGroup(A, N)`

Returns the arithmetic Fuchsian group Γ corresponding to the group $\mathcal{O}^*$ of units of reduced norm 1 in an order $\mathcal{O}$ of level $\mathfrak{N}$ in the quaternion algebra A.

Example H131E1

In this example, we construct arithmetic Fuchsian groups in three ways. First, we construct the group associated to the quaternion algebra of discriminant 6 over $\mathbf{Q}$.

```
> A := QuaternionAlgebra(6);
> G := FuchsianGroup(A);
> G;
Arithmetic Fuchsian group arising from order of Quaternion Algebra with base
ring Rational Field
> O := BaseRing(G);
> O;
Order of Quaternion Algebra with base ring Rational Field
with coefficient ring Integer Ring
> Discriminant(O);
6
> Algebra(O) eq A;
true
```

Next, we construct a group "by hand", associated to the quaternion algebra over the totally real subfield $F = \mathbf{Q}(\zeta_9)^+$ of $\mathbf{Q}(\zeta_9)$ ramified only at two of the three real infinite places.

```
> K<z> := CyclotomicField(9);
> F := sub<K | z+1/z >;
> Degree(F);
3
> Z_F := MaximalOrder(F);
> Foo := InfinitePlaces(F);
> A := QuaternionAlgebra(ideal<Z_F | 1>, Foo[2..3]);
> Discriminant(A);
Principal Ideal of Z_F
Generator:
    [1, 0, 0]
[ 2nd place at infinity, 3rd place at infinity ]
> O := MaximalOrder(A);
> G := FuchsianGroup(O);
> G;
Arithmetic Fuchsian group arising from order of Quaternion Algebra with base
ring Field of Fractions of Maximal Equation Order with defining polynomial x^3 -
```

```
3*x - 1 over its ground order
```

Lastly, we construct the group of level 3 inside a quaternion algebra ramified at $2\infty_1$ over $\mathbf{Q}(\sqrt{5})$.

```
> F<x> := NumberField(Polynomial([-5,0,1]));
> Z_F := MaximalOrder(F);
> A := QuaternionAlgebra(ideal<Z_F | 2>, InfinitePlaces(F)[1..1]);
> G := FuchsianGroup(A, ideal<Z_F | 3>);
> O := BaseRing(G);
> O;
Order of Quaternion Algebra with base ring Field of Fractions of Z_F
with coefficient ring Maximal Order of Equation Order with defining polynomial
x^2 - 5 over its ground order
> Discriminant(O);
Principal Ideal of Z_F
Generator:
    6/1*Z_F.1
> Discriminant(A);
Principal Prime Ideal of Z_F
Generator:
    [2, 0]
[ 1st place at infinity ]
> Level(G);
Principal Ideal of Z_F
Generator:
    3/1*Z_F.1
```

131.1.2 Quaternionic Functions

In this section, we provide some functions related quaternion algebras which underlie the other functions in this chapter.

Let A be a quaternion algebra over a totally real field F, represented in standard form by $\alpha, \beta \in A$ satisfying $\alpha^2 = a$, $\beta^2 = b$, and $\beta\alpha = -\alpha\beta$. Suppose that A has a unique split real place v; we then take this place to be the identity and consider F as a subfield of $\mathbf{R}$. Then at least one of $a, b > 0$, and without loss of generality we may assume that $a > 0$.

We then define the embedding $\iota : A \to M_2(\mathbf{R})$, given by

$$\alpha \mapsto \begin{pmatrix} \sqrt{a} & 0 \\ 0 & -\sqrt{a} \end{pmatrix}, \quad \beta \mapsto \begin{pmatrix} 0 & \sqrt{|b|} \\ \mathrm{sgn}(b)\sqrt{|b|} & 0 \end{pmatrix}.$$

This particular choice of embedding is governed by the following. The reduced norm $\mathrm{nrd} : A \to \mathbf{R}$ given by

$$\gamma = x + y\alpha + z\beta + w\alpha\beta \mapsto \mathrm{nrd}(\gamma) = x^2 - ay^2 - bz^2 + abw^2$$

is not a Euclidean norm, so it is natural to instead take

$$\gamma \mapsto \mathrm{nrd}'(\gamma) = x^2 + |a|y^2 + |b|z^2 + |ab|w^2,$$

which corresponds to

$$\mathrm{nrd}'(\gamma) = x^2 + y^2 + z^2 + w^2 \text{ if } \iota(\gamma) = \begin{pmatrix} x & y \\ z & w \end{pmatrix}.$$

Combining this new norm, defined for the identity real place, with the ones corresponding to the nonidentity real places σ, we may then define the definite norm

$$N(\gamma) = \mathrm{nrd}'(\gamma) + \sum_{\sigma \neq \mathrm{id}} \sigma(\mathrm{nrd}(\gamma)).$$

This norm (and the corresponding Gram matrix) on A are used in the application to fundamental domains (see the next section).

`QuaternionOrder(G)`

`BaseRing(G)`

The order in some quaternion algebra that was used to define the Fuchsian group G.

`QuaternionAlgebra(G)`

The quaternion algebra used to define the Fuchsian group G.

`SplitRealPlace(A)`

Returns the unique real place at which A is split, if it exists.

`FuchsianMatrixRepresentation(A)`

Returns the map $A \to M_2(\mathbf{R})$ when A has a unique split place, as defined above.

`DefiniteNorm(gamma)`

Returns the definite norm of $\gamma \in A$ for A a quaternion algebra with a unique split real place, as defined above.

`DefiniteGramMatrix(B)`

Returns the definite Gram matrix for the basis B of a quaternion algebra A with a unique split real place, as defined above.

Example H131E2

We begin by defining the quaternion algebra over $F = \mathbf{Q}(\sqrt{5})$ which is ramified at the prime ideal 2 and the second real place ∞_2, as indexed by MAGMA.

```
> F<w> := QuadraticField(5);
> Z_F := MaximalOrder(F);
> Foo := InfinitePlaces(F);
> A<alpha,beta> := QuaternionAlgebra(ideal<Z_F | 2>, [Foo[2]]);
> a, b := StandardForm(A);
> F!a, F!b;
-1 w + 2
> Norm(a);
1
```

We see that A is isomorphic to the algebra represented in standard form by

$$\alpha^2 = a,\ \beta^2 = b,\ \beta\alpha = -\alpha\beta$$

where $a = -1$, $b = 2 + \sqrt{5}$. (Note that the algorithm used to construct A is probabilistic, so a and b are not canonically given.)
We now demonstrate the real embedding corresponding to the split real place ∞_1.

```
> v := SplitRealPlace(A);
> v;
1st place at infinity
> iota := FuchsianMatrixRepresentation(A);
> iota(alpha);
[0.00000000000000000000000000000000000000000000000000000000000000000000000000000000000000000000

89255422971041469683941
> DefiniteNorm(alpha);
3.00000000000000000000000000000000000000000000000000000000000000000000000000000000000000000000
000000000000000000000
```

We see indeed that

$$\alpha \mapsto \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \beta \mapsto \begin{pmatrix} \sqrt{2+\sqrt{5}} & 0 \\ 0 & -\sqrt{2+\sqrt{5}} \end{pmatrix}$$

and

$$N(\alpha) = \mathrm{nrd}'(\alpha) + \sigma(\mathrm{nrd}(\alpha)) = (0^2 + 1^2 + (-1)^2 + 0^2) + 1 = 3.$$

`MultiplicativeOrder(gamma)`

`PlusMinus` BoolElt *Default :* `true`

Computes the order of the element γ of a quaternion algebra; either a finite number or 0 if the element has infinite order. If `PlusMinus` eq `true`, then compute the order in the group of units modulo ± 1.

`Quaternion(g)`

For g an element of an arithmetic Fuchsian group, return the underlying element of the quaternionic order.

131.1.3 Basic Invariants

In this section, we compute the basic invariants associated to an arithmetic Fuchsian group Γ.

The first is the hyperbolic volume $\mathrm{vol}(X)$ of the orbit space $X = \Gamma\backslash\mathbf{H}$, which can be computed via a formula of Shimizu:

$$\mathrm{vol}(X) = \left(\frac{1}{2}\right)^{d-2} \zeta_F(-1) \prod_{\mathfrak{p}|\mathrm{disc}A} (N(\mathfrak{p}) - 1)$$

where $d = [F : \mathbf{Q}]$. This volume is normalized so that an ideal triangle (i.e. a triangle with all vertices on the boundary of $\mathbf{H}$) has volume $1/2$. With this normalization, $\mathrm{vol}(X)$ takes rational values.

The next invariant is the signature of Γ. A point $z \in \mathbf{H}$ is an *elliptic point* of order $k \geq 2$ if the stabilizer of z under Γ, which is a finite cyclic group, has order k. There are only finitely many Γ-conjugacy classes of elliptic points, also known as *elliptic cycles*. If Γ has t elliptic cycles of order $m_1, \ldots, m_t$, and X has genus g, then we say that Γ has *signature* $(g; m_1, \ldots, m_t)$.

We compute the number of elliptic cycles of order k by a formula (too complicated to state here) which requires the computation of the relative class group of a CM extension of number fields. The genus g can then be calculated by the Riemann-Hurwitz formula:

$$\mathrm{vol}(X) = 2g - 2 + \sum_{i=1}^{t} \left(1 - \frac{1}{m_i}\right).$$

`ArithmeticVolume(G)`

Returns the hyperbolic volume of the quotient of the upper half-plane by G for an arithmetic Fuchsian group G. The volume is normalized arithmetic volume, so the "usual" volume is divided by 2π; this gives an ideal triangle volume $1/2$.

`EllipticInvariants(G)`

Returns the number of elliptic cycles of the arithmetic Fuchsian group G as a sequence of elliptic orders and their multiplicities.

`Signature(G)`

Returns the signature of the arithmetic Fuchsian group G.

131.1.4 Group Structure

We now compute a finite presentation for an arithmetic Fuchsian group Γ.

If Γ has signature $(g; m_1, \ldots, m_t)$, then there exists a standard presentation for Γ, generated (freely) by $\alpha_1, \beta_1, \ldots, \alpha_g, \beta_g, \gamma_1, \ldots, \gamma_t$ with the relations

$$\gamma_1^{m_1} = \ldots = \gamma_t^{m_t} = [\alpha_1, \beta_1] \cdots [\alpha_g, \beta_g] \gamma_1 \cdots \gamma_t = 1$$

where $[\alpha_i, \beta_i] = \alpha_i \beta_i \alpha_i^{-1} \beta_i^{-1}$ is the commutator. In the special case where $g = 0$, there exists an algorithm to reconstruct the standard presentation; if $g > 0$, we only obtain a finite presentation, and it is possible that the construction of a standard presentation may be algorithmically impractical.

Our algorithm uses a fundamental domain F for Γ (see section 131.3). In brief, we compute the set of elements which pair the sides of F; these elements are provably generators for the group Γ, and the relations between them are given as the set of minimal loops in a graph which records the side pairings.

`Group(G)`

Returns a presentation U for the arithmetic Fuchsian group G, a map $U \to G$, and a map $U \to \mathcal{O}$ where $\mathcal{O}$ is the quaternion order corresponding to G.

Example H131E3

In this example, we compute the basic invariants of the arithmetic Fuchsian group associated to a maximal order in the quaternion algebra of discriminant 6 over $\mathbf{Q}$.

```
> A := QuaternionAlgebra(6);
> O := MaximalOrder(A);
> G := FuchsianGroup(O);
> ArithmeticVolume(G);
1/3
> EllipticInvariants(G);
[ <2, 2>, <3, 2> ]
> Genus(G);
0
> Signature(G);
<0, [2, 2, 3, 3]>
```

We verify the Riemann-Hurwitz formula $1/3 = 2 \cdot 0 - 2 + 2(1 - \frac{1}{2}) + 2(1 - \frac{1}{3})$.

We can also compute a finite presentation of this group.

```
> U, m := Group(G);
> U;
Finitely presented group U on 3 generators
Relations
    U.1^2 = Id(U)
    U.2^3 = Id(U)
    U.3^3 = Id(U)
    (U.2 * U.1 * U.3)^2 = Id(U)
> [Matrix(m(U.i)) : i in [1..2]];
[
    [-0.44721359549995793928183473374634344441856698198020262470211905349191088

]
> [A!Quaternion(m(U.i)) : i in [1..2]];
[ -1/5*j + 1/5*k, -1/2 - 1/2*i + 3/10*j - 3/10*k ]
```

Next we compute a more complicated example, exhibiting an elliptic cycle of order 11. The group Γ corresponds to $F = \mathbf{Q}(\zeta_{11})^+$ and A the quaternion algebra only at real places. (See also the section on triangle groups.)

```
> K<z> := CyclotomicField(11);
> F := sub<K | z+1/z >;
> Foo := InfinitePlaces(F);
> Z_F := MaximalOrder(F);
> A := QuaternionAlgebra(ideal<Z_F | 1>, Foo[1..4]);
> G := FuchsianGroup(A);
> Signature(G);
<0, [ 2, 3, 11 ]>
> U, m := Group(G);
> U;
Finitely presented group U on 2 generators
Relations
    U.1^2 = Id(U)
    U.2^3 = Id(U)
```

```
    (U.1 * U.2^-1)^11 = Id(U)
```

As a final example, we show that the finite presentation of G may indeed be quite complicated. Here, we exmaine the (torsion-free) group associated to the quaternion algebra over $\mathbf{Q}$ with discriminant 35.

```
> G := FuchsianGroup(QuaternionOrder(35));
> Signature(G);
<3, []>;
> time U := Group(G);
Time: 78.870
> U;
Finitely presented group U on 6 generators
Relations
    U.5 * U.4^-1 * U.5^-1 * U.1 * U.3 * U.2^-1 * U.3^-1 * U.6 * U.4 *
    U.2 * U.1^-1 * U.6^-1 = Id(U)
```

131.2 Unit Disc

Let D denote the Poincaré unit disc,

$$D = \{z \in \mathbf{C} : |z| < 1\}$$

equipped with the hyperbolic metric

$$d(z, w) = \log\left(\frac{|1 - z\bar{w}| + |z - w|}{|1 - z\bar{w}| - |z - w|}\right).$$

We mimic the existing functionality for working with the upper half-plane (see Chapter 130) to compute in a similar way with the geometry of the unit disc, including computation of angles, intersections, areas, and so on.

131.2.1 Creation

`UnitDisc()`

`Center`	RngElt	*Default :* (9/10)i
`Precision`	RngElt	*Default :* 0

The hyperbolic unit disc, mapped conformally to the upper half-plane by mapping 0 in D to `Center`, with given `Precision`.

131.2.2 Basic Operations

`D ! x`

Coerces x into D, if possible.

`x eq y`

Returns `true` if and only if $x = y$.

`a * x`

Returns $a \cdot x$.

`x + y`

Returns $x + y$.

`x - y`

Returns $x - y$.

`x / a`

Returns $(1/a) \cdot x$.

131.2.3 Access Operations

`IsExact(z)`

Returns `true` (and the exact value of z) if and only if z is exact.

`ExactValue(z)`

Returns the exact value of z; if it does not exist, returns an error.

`ComplexValue(z)`

`Precision` RngIntElt *Default :* 0

Returns the complex value z, with given precision.

`Im(z)`
`Imaginary(z)`

`Precision` RngIntElt *Default :* 0

Returns the imaginary part of z, with given precision.

`Re(z)`
`Real(z)`

`Precision` RngIntElt *Default :* 0

Returns the real part of z, with given precision.

`Argument(z)`

`Precision` RngIntElt *Default :* 0

Returns the argument of z, with given precision.

`Abs(z)`

`AbsoluteValue(z)`

`Precision` RngIntElt *Default :* 0

Returns the absolute value of z, with given precision.

Example H131E4

In this example, we exhibit basic functions for the unit disc.

```
> D := UnitDisc();
> D;
Hyperbolic unit disc
> CC<I> := ComplexField();
> w := D ! ((1+I)/2);
> w;
0.50000000000000000000000000000 + 0.50000000000000000000000000000*I
> Re(w), Abs(w);
0.50000000000000000000000000000 0.70710678118654752440084436210 5
```

Note that since D does not form a ring, when binary operations are performed, we return elements according to the base ring in which they belong; if desired, they can be coerced back into D.

```
> z := D ! 0;
> z;
0
> IsExact(z);
true 0
> ComplexValue(z : Precision := 100);
0.00000000000000000000000000000000000000000000000000000000000000000000000000000000000000000000000000
00000000000000000000000
> 2*z;
0
> Type($1);
FldRatElt
> D!(z+w) eq w;
true
```

131.2.4 Distance and Angles

`Distance(z,w)`

`Precision` RngIntElt *Default :* 0

Returns the hyperbolic distance between z and w.

`Geodesic(z,w)`

`Precision` RngIntElt *Default :* 0

Returns the center and radius of the geodesic containing z and w, with given precision.

`TangentAngle(x,y)`

`Precision` RngIntElt *Default :* 0

Returns the angle of the tangent at x of the geodescic from x to y, with given precision.

`Angle(e1,e2)`

`Precision` RngIntElt *Default :* 0

Given two sequences $e_1 = [z_1, z_2]$ and $e_2 = [z_1, z_3]$, returns the angle between the geodesics at z_1.

`ArithmeticVolume(P)`

`Precision` RngIntElt *Default :* 0

The volume of the convex region specified the sequence of elements of the unit disc. The elements must be specified in counterclockwise order by their arguments. The volume is normalized "arithmetic" volume, so the "usual" volume is divided by 2π; this gives an ideal triangle volume $1/2$.

Example H131E5

In this example, we compute geodesics in the unit disc.

```
> D := UnitDisc();
> CC<I> := ComplexField();
> z0 := D!0;
> z1 := D!(1/2*I);
> z2 := D!(1/2);
> Distance(z0,z1);
1.0986122886681096913952452369 2
> Geodesic(z0,z1);
Infty 0.00000000000000000000000000000
> Geodesic(z1,z2);
1.25000000000000000000000000000 + 1.25000000000000000000000000000*I
1.4577379737113251177185382193 9
> TangentAngle(z0,z1);
```

```
1.5707963267948966192313216916 4
> TangentAngle(z1,z2);
-1.0303768265243124637877433270 3
> Angle([z1,z2],[z1,z0]);
2.6011731533192090830190650186 7
> ArithmeticVolume([D | 1/2+1/2*I, -1/2+1/2*I, -1/2-1/2*I, 1/2-1/2*I]);
0.5903344706017330967016043048 99
```

131.2.5 Structural Operations

`T * x`

Returns $T(x)$, using the identification of the unit disc with the upper half-plane.

`Center(D)`

Returns the element in the upper half-plane which maps to 0 in D.

`DiscToPlane(H,z)`

Maps z in a unit disc to $\mathbf{H}$.

`PlaneToDisc(D,z)`

Maps z in an upper half-plane to D.

`Matrix(g,D)`

Returns the matrix representation of g acting on the unit disc D.

`FixedPoints(g,D)`

Returns the fixed points of g acting on D.

`IsometricCircle(g)`

`IsometricCircle(g,H)`

Returns the center and radius of the set of points in the upper half-plane H where g acts as a Euclidean isometry.

`IsometricCircle(g,D)`

Returns the center and radius of the set of points in the unit disc D where g acts as a Euclidean isometry.

`GeodesicsIntersection(x1,x2)`

Returns the intersection in the unit disc of the two geodesics x_1, x_2, where x and y are specified by their end points. If more than one intersection exists, returns a sequence.

`BoundaryIntersection(x)`

Computes the intersection of the geodesic x with the boundary of the unit disc.

Example H131E6

In this example, we illustrate the use of the structural operations on the unit disc. We begin by declaring a Fuchsian group over the totally real subfield $F = \mathbf{Q}(\zeta_9)^+$ of $\mathbf{Q}(\zeta_9)$.

```
> K<z> := CyclotomicField(9);
> F := sub<K | z+1/z >;
> b := F! (z+1/z);
> A<alpha,beta> := QuaternionAlgebra<F | -3, -b>;
> G := FuchsianGroup(A);
> O := BaseRing(G);
> A<alpha,beta> := Algebra(O);
```

Next, we compute the fixed point of the element $g = (1 + \alpha)/2$.

```
> g := G!((1+alpha)/2);
> H := UpperHalfPlane();
> FixedPoints(g, H);
[
    root(-1)
]
> Matrix(g);
[0.500000000000000000000000000000000000000000000000000000000000000000000000000000000000
    000000000000000000000 0.866025403784438646763723170752936183471402626905
    190314027903489725966508454400018540573093378624287 8]
[-0.866025403784438646763723170752936183471402626905190314027903489725966508454
    400018540573093378624287 8 0.500000000000000000000000000000000000000000000000
    000000000000000000000000000000000000000000000000000]
> g*H.1;
root(-1);
```

The fixed point is at $z = i$. Next, we compute the isometric circle $C(g)$ of g,

$$C(g) = \{z \in \mathbf{C} : |g(z)| = |z|\}.$$

(See also the next section on fundamental domains.)

```
> cH, rH := IsometricCircle(g);
> cH;
0.577350269189625764509148780501957455647601751270126876018602326483977672302933
3345693715395585749525 2
> rH;
1.154700538379251529018297561003914911295203502540253752037204652967955344605866
6691387430791171499050
```

The cirlce $C(g)$ has radius $r_H = 1.154\ldots$ and center $c_H = 0.577\ldots$. We verify that g acts by a Euclidean isometry at the point $c_H + r_H i \in C(g)$.

```
> CC<I> := ComplexField();
> Abs(Matrix(g)[2,1]*(cH+rH*I)+Matrix(g)[2,2]);
```

```
1.000000000000000000000000000
```

We now repeat these same steps, with g acting on the unit disc D.

```
> D := UnitDisc(: Center := 9/10*H.1);
> Matrix(g, D);
[0.500000000000000000000000000000000000000000000000000000000000000000000000000000000000
    000000000000000000000000 + 0.870836656027685528134632743923817879053886967119

```

131.3 Fundamental Domains

Let D denote the unit disc and Γ an arithmetic Fuchsian group. A *fundamental domain* in D for Γ is a closed, hyperbolically convex region $P \subset D$ such that the translates of P by Γ cover D and such that the interiors of all translates P are disjoint, i.e. $D = \bigcup_{\gamma\in\Gamma} \gamma P$ and $\mathrm{int}(P) \cap \mathrm{int}(\gamma P) = \emptyset$ for $\gamma \neq 1$, where $\mathrm{int}(P)$ denotes the interior of P.

Choosing a point $p \in D$ not fixed by any element of $\Gamma \setminus \{1\}$, we obtain a fundamental domain by letting

$$P = \{z \in D : d(z,p) \leq d(z,\gamma(p)) \text{ for all } \gamma \in \Gamma\}.$$

Typically, one takes $p = 0$.

One can similarly define a fundamental domain in the upper half-plane $\mathbf{H}$, and one can bijectively map fundamental domains in D to those in $\mathbf{H}$ via a choice of conformal map between them. The unit disc is a more natural setting for our algorithms.

For each $\gamma \in \Gamma \setminus \{1\}$, we define the *isometric circle* of γ to be the circle

$$C(\gamma) = \{z \in \mathbf{C} : |\gamma(z)| = |z|\}.$$

Then in fact P is the closure of the intersection of half-spaces given by

$$\bigcap_{\gamma\in\Gamma\setminus\{1\}} C(\gamma)^o$$

where $C(\gamma)^o$ denotes the exterior of $C(\gamma)$. Our algorithm recursively finds elements in Γ to decrease the hyperbolic volume of this intersection until the volume $\mathrm{vol}(X)$ is reached; it relies upon a "reduction theory" with respect to a set of generators of Γ.

`FundamentalDomain(G,D)`

Computes a fundamental domain in the unit disc D for the action of G.

`FundamentalDomain(G)`

Computes a fundamental domain in the upper half-plane for the action of G.

Example H131E7

We first compute a fundamental domain for a quaternion algebra defined over $\mathbf{Q}(\zeta_7)^+$ which turns out to be the $(2,3,7)$-triangle group.

```
> K<z> := CyclotomicField(7);
> F := sub<K | z+1/z >;
> b := F! (z+1/z);
> A<i,j,k> := QuaternionAlgebra<F | b, b>;
> O := MaximalOrder(A);
> G := FuchsianGroup(O);
> P := FundamentalDomain(G, UnitDisc());
> P;
[
    0.056346691761945477319557812463 9 -
      0.265288162495691167957067899257*$.1,
    0.056346691761945477319557812463 9 +
      0.265288162495691167957067899257*$.1,
    -0.088650485594770026461525429450 0 -
      4.571949565129099928863134193 22E-100*$.1
]
> P := FundamentalDomain(G);
> P;
[
    0.496970425395180896221180392445 +
      (0.867767478235116240951536665696)*root(-1),
    -0.496970425395180896221180392445 +
      (0.867767478235116240951536665696)*root(-1),
    6.943796662033680246332406840 73E-100 +
      (0.753423227948677598725236624130)*root(-1)
]
> ArithmeticVolume(P);
0.023809523809523809523809523809 2
> ArithmeticVolume(G);
1/42
> ($1)*1.0;
0.023809523809523809523809523809 5
```

We can visualize the domain P by using the postscript plotting tools of Chapter 130.

```
>  DisplayPolygons(P, "/tmp/quat237triang.ps" : Show := true);
[ -0.496970425395180896221180392445, 0.496970425395180896221180392445,
```

```
1.0500000000000000000000000000, 302.0000000000000000000000000000 ]
```

We repeat this with the quaternion algebra over $\mathbf{Q}$ of discriminant 10.

```
> G := FuchsianGroup(QuaternionOrder(10));
> P := FundamentalDomain(G);
>  DisplayPolygons(P, "/tmp/quat10.ps" : Show := true);
[ -1.3144841297278098202363616814O, 0.158113883008418966599944677206,
1.279124762273123946981795500S6, 235.0000000000000000000000000000 ]
> U, m := Group(G);
> U;
Finitely presented group U on 3 generators
Relations
    U.1^3 = Id(U)
    U.2^3 = Id(U)
    U.3^3 = Id(U)
    (U.1^-1 * U.2^-1 * U.3^-1)^3 = Id(U)
```

`ShimuraReduceUnit(delta, gammagens, G, D)`

`CreateWord`	BoolElt	*Default :* `false`
`NextSmallest`	BoolElt	*Default :* `false`
`z0`	SpcHydElt	*Default :* 0
`z1`	SpcHydElt	*Default :* 0

Reduce the unit delta moving z_0 to z_1 with respect to the generators in γ_{gens} by multiplying on the left or right by elements of γ_{gens} inside the arithmetic Fuchsian group G to minimize the distance to the origin in the unit disc D. Returns a sequence of triples containing reduced elements and the sequence on the left and right to obtain them. The argument `CreateWord` reduces δ even if δ is in γ_{gens}, disallowing the trivial word.

131.4 Triangle Groups

We now look at a certain class of arithmetic Fuchsian groups of particular interest. We assume that $\Gamma(1)$ is a *triangle group*, i.e. Γ has signature $(0; p, q, r)$ for $p, q, r \in \mathbf{Z}_{\geq} 2$. Hence there exists a presentation

$$\Gamma(1) \cong \langle \gamma_p, \gamma_q, \gamma_r \mid \gamma_p^p = \gamma_q^q = \gamma_r^r = \gamma_p\gamma_q\gamma_r = 1 \rangle.$$

Since $g = 0$, there exists a map j from $X(1)_{\mathbf{C}}$ to the projective line over $\mathbf{C}$ which is ramified only above the three *elliptic points*, the fixed points of $\gamma_p, \gamma_q, \gamma_r$, which we may take to be $0, 1, \infty$.

There are only finitely many such triples (p, q, r), and we have implemented a constructor for these triples which yields the group Γ as well as the arithmetic data including the maximal order $\mathcal{O}$ and the quaternion algebra A. We also compute the analytic map j for each of these groups, which includes methods for evaluating the ${}_2F_1$-hypergeometric series to extremely high precision at complex arguments.

131.4.1 Creation of Triangle Groups

We begin with the basic constructors.

`ArithmeticTriangleGroup(p,q,r)`

Returns the arithmetic triangle group of signature (p, q, r).

`AdmissableTriangleGroups()`

Returns the list of arithmetic triangle groups currently implemented.

`IsTriangleGroup(G)`

Returns `true` if and only if G was created as an arithmetic triangle group.

131.4.2 Fundamental Domain

`ReduceToTriangleVertices(G,z)`

Returns points in the G-orbit of z which are nearest to the vertices of the fundamental domain for G a triangle group.

131.4.3 CM Points

For triangle groups, we can compute CM points analytically. By work of Shimura, the curve $X(1)$ has an interpretation as a moduli space for certain abelian varieties and has a canonical model defined over $\mathbf{Q}$. Let K be a totally imaginary quadratic extension of F, and let $O_D \subset K$ be a quadratic order. Suppose that K splits A, i.e. $A \otimes_F K \cong M_2(K)$. Then there exists an embedding $\iota_K : K \hookrightarrow A$ such that $\iota_K(K) \cap \mathcal{O} = O_D$, given by an element $\mu \in \mathcal{O}$ such that $\mathbf{Z}_F[\mu]$ is isomorphic to O_D. The unique fixed point of $\iota_\infty(\mu)$ in $\mathbf{H}$ yields a *CM point* on $X(1)$ that is defined over an abelian extension H of F, and there is a reciprocity law which describes the action of $\mathrm{Gal}(H/K)$.

We exhibit algorithms for computing with these objects. Explicitly, given the data of a quadratic order O_D contained in a imaginary quadratic extension K of F, we compute the set of $\mathrm{Gal}(H/K)$-conjugates of a CM-point for O_D on $X(1)$. Our algorithm first computes representatives for the ring class group in terms of the Artin map. It then applies the Shimura reciprocity law for each of these representatives, which uses our architecture for principalization of ideals of quaternionic orders, to compute the conjugates. Given these points to high enough precision, we can recognize the CM point as a putative algebraic number.

`HypergeometricSeries2F1(A,B,C,z)`

Returns the value of the 2F1-hypergeometric function with parameters (A, B; C) at the complex number z.

Example H131E8

Although programmed for use by the hypergeometric reversion procedure, involved in the calculation of CM points, the `HypergeometricSeries2F1` function can also be called independently to evaluate the series at any complex number at any precision.

```
> HypergeometricSeries2F1(1/2, 1/2, 1, 1);
0.31830988618379067153776752674
> CC<I> := ComplexField(100);
> HypergeometricSeries2F1(1/2, 1/3, 1/4, 1+I);
0.18914889986718938009890989889270323251621296927695426144398500333164293730405
5659151692186899720481 9 + 1.3516500011026082918038421690042816399520000054582828
7705534621378149655804166701124643888726219267520*I
```

`ShimuraConjugates(mu)`

Returns the set of conjugates of the quaternion order element μ under the Shimura reciprocity law.

`jParameter(G,z)`

`Bound`	RngIntElt	*Default :* 200
`Precision`	RngIntElt	*Default :* 100

Returns the value of the map $j : X(G) \to \mathbf{P}^1$ at z, for G an arithmetic triangle group.

Example H131E9

We begin by constructing the $(2, 3, 9)$-triangle group.

```
> G := ArithmeticTriangleGroup(2,3,9);
> O := BaseRing(G);
> Z_F := BaseRing(O);
```

Next, we compute the CM point corresponding to the imaginary quadratic extension K/F of discriminant -7. First, we define the extension.

```
> Z_K := ext<Z_F | Polynomial([2,-1,1])>;
> Discriminant(Z_K);
Principal Ideal of Z_F
Generator:
    [-7, 0, 0]
> IsMaximal(Z_K);
true
> ClassNumber(AbsoluteOrder(Z_K));
1
```

Since $\mathbf{Z}_K$ has class number 1, the corresponding CM point will be a rational number. We now embed $\mathbf{Z}_K$ into $\mathcal{O}$.

```
> mu := Embed(Z_K, O);
```

```
> MinimalPolynomial(mu);
$.1^2 - $.1 + 2/1*Z_F.1
```

Finally, we compute the fixed point z of μ in the upper half-plane, and compute the value of the uniformizing parameter $j(z)$.

```
> z := FixedPoints(G!mu, UpperHalfPlane())[1];
> j := jParameter(G, z);
> j;
-9594.703124999999999999999999999999999999999999999999999999999999999999999999999
998082712686344925455 41 - 8.607499388211909042811249895070271789213361939086074
091584429508486426059712018492327398804638684615E-77*I
> BestApproximation(Re(j), 10^50);
-614061/64
> Factorization(Numerator($1)), Factorization(Denominator($1));
[ <3, 5>, <7, 1>, <19, 2> ]
[ <2, 6> ]
```

We recognize the value $j(z) = \frac{3^5 7^1 19^2}{2^6}$ as a smooth rational number.

`CMPoints(G,mu)`

Returns the minimal polynomial of the Galois conjugates of the CM points corresponding to μ and their complex values for G a triangle group. The element μ must be Galois-stable, i.e. $F(\mu)$ must be Galois over F, where F is the defining base field of G. The polynomial returned is the "best guess" rational approximation to the polynomial with the CM points as roots.

Example H131E10

We now compute the minimal polynomial for CM points which generate a nontrivial extension: we again take the $(2, 3, 9)$-triangle group and now consider K of discriminant -11.

```
> G := ArithmeticTriangleGroup(2,3,9);
> O := BaseRing(G);
> Z_F := BaseRing(O);
> Z_K := ext<Z_F | Polynomial([3,-1,1])>;
> Discriminant(Z_K);
Principal Ideal of Z_F
Generator:
    [-11, 0, 0]
> IsMaximal(Z_K);
true
> ClassNumber(AbsoluteOrder(Z_K));
3
> mu := Embed(Z_K, O);
> time f, js := CMPoints(G, mu);
Time: 18.120
> f;
```

```
-127332762814175510528*x^3 + 297798194745682427904*x^2 - 545543748833233386651*x
    + 443957770932571793051
```

The number field $H = K(\alpha)$, where α is a root of f, is the Hilbert class field of K, which we have computed analytically!

```
> D := Discriminant(f);
> Denominator(D);
1
> Factorization(Numerator(D));
[ <2, 32>, <3, 18>, <11, 1>, <17, 6>, <19, 12>, <73, 2>, <107, 6>, <109, 2>,
<197, 2>, <271, 2>, <431, 2>, <701, 2> ]
> K := AbsoluteField(NumberField(Z_K));
> H := ext<K | f>;
> Factorization(Discriminant(MaximalOrder(H)));
[]
> IsAbelian(GaloisGroup(H));
true
```

132 MODULAR FORMS

Chapter 132
MODULAR FORMS

132.1 Introduction

132.1.1 Modular Forms

This theoretically-oriented section serves as a guide to the rest of the chapter. We recall the definition of modular forms, then briefly discuss q-expansions, Hecke operators, eigenforms, congruences, and modular symbols.

Fix positive integers N and k, let $\mathbf{H}$ denote the complex upper half plane. Denote by $M_k(\Gamma_1(N))$ the space of modular forms on $\Gamma_1(N)$ of weight k. This is the complex vector space of holomorphic functions $f : \mathbf{H} \to \mathbf{C}$ such that

$$f\left(\frac{az+b}{cz+d}\right) = (cz+d)^k f(z) \qquad \text{for all} \qquad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma_1(N),$$

and $f(z)$ is holomorphic at each "cusp" in $\mathbf{P}^1(\mathbf{Q}) = \mathbf{Q} \cup \{\infty\}$ (see, e.g., [DI95] for a more precise definition.)

A *Dirichlet character* is a homomorphism $\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to \mathbf{C}^*$ of abelian groups. Dirichlet characters are of interest because they decompose $M_k(\Gamma_1(N))$ into more manageable chunks. If V is any complex vector space equipped with an action $\rho : (\mathbf{Z}/N\mathbf{Z})^* \to \mathrm{Aut}(V)$ and ε is a Dirichlet character, we set

$$V(\varepsilon) = \{x \in V : \rho(a)x = \varepsilon(a)x \quad \text{all} \quad a \in (\mathbf{Z}/N\mathbf{Z})^*\}.$$

The space $M_k(\Gamma_1(N))$ is equipped with an action of $(\mathbf{Z}/N\mathbf{Z})^*$ by the diamond-bracket operators $\langle d \rangle$, which are defined as follows. Given $\overline{d} \in (\mathbf{Z}/N\mathbf{Z})^*$, choose a matrix $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma_0(N)$ such that $d \bmod N = \overline{d}$. Then

$$\langle d \rangle f(z) = (cz+d)^{-k} f\left(\frac{az+b}{cz+d}\right).$$

We call $M_k(\Gamma_1(N))(\varepsilon)$ the space of modular forms of weight k, level N, and character ε. This is the complex vector space of holomorphic functions $f : \mathbf{H} \to \mathbf{C}$ such that

$$f\left(\frac{az+b}{cz+d}\right) = \varepsilon(a)(cz+d)^k f(z) \qquad \text{for all} \qquad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma_0(N),$$

and which is holomorphic at the cusps. We let $M_k([\varepsilon])$ denote the direct sum of the spaces $M_k(\Gamma_1(N))(\varepsilon)$ *as* ε *varies over the* $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$*-conjugates* of ε. It is unnecessary to specify the level because it is built into ε.

To summarize, for any integer k and positive integer N, there is a finite-dimensional $\mathbf{C}$-vector space $M_k(\Gamma_1(N))$. Moreover,

$$M_k(\Gamma_1(N)) = \bigoplus_{\text{all } \varepsilon} M_k(\Gamma_1(N))(\varepsilon) = \bigoplus_{\text{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})\text{-class reps. } \varepsilon} M_k([\varepsilon]).$$

In Section 139.2, we describe how to create the spaces $M_k(\Gamma_1(N))$ and $M_k([\varepsilon])$ in MAGMA, for any $k \geq 1$, $N \geq 1$, and character ε.

Let f be a modular form, and observe that since $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \in \Gamma_1(N)$, we have $f(z) = f(z+1)$. If we set $q = \exp(2\pi i z)$, there is a *q-expansion* representation for f:

$$f = a_0 + a_1 q + a_2 q^2 + a_3 q^3 + a_4 q^4 + \cdots.$$

The a_n are called the *Fourier coefficients* of f. MAGMA contains an algorithm for computing a basis of q-expansions for any space of modular forms of weight $k \geq 2$ (see Section 135.3).

Fix a positive integer N and let M be a sum of spaces $M_k(N, \varepsilon)$. Let $q{-}\exp : M \to \mathbf{C}[[q]]$ denote the map that associates to a modular form f its q-expansion. One can prove that there is a basis $f_1, \ldots, f_d$ of M that maps to a basis for the free $\mathbf{Z}$-module $q{-}\exp(M) \cap \mathbf{Z}[[q]]$. See Section 132.4 for how to compute such a basis in MAGMA. Let $M_{\mathbf{Z}}$ be the $\mathbf{Z}$-module spanned by $f_1, \ldots, f_d$. For any ring R, we define the *space of modular forms over* R to be $M_R = M_{\mathbf{Z}} \otimes_{\mathbf{Z}} R$. Thus M_R is a free R-module of rank d with basis the images of $f_1, \ldots, f_d$ in $M_{\mathbf{Z}} \otimes_{\mathbf{Z}} R$. The computation of M_R is discussed in Section 132.2.2.

Any space M of modular forms is equipped with an action of a commutative ring $\mathbf{T} = \mathbf{Z}[\ldots T_n \ldots]$ of Hecke operators. The computation of Hecke operators T_n and their characteristic polynomials is described in Section 136.14.

An *eigenform* is a simultaneous eigenvector for every element of the Hecke algebra $\mathbf{T}$. A *newform* is an eigenform that doesn't come from a space of lower level and is normalized so that the coefficient of q is 1. Section 132.13 describes how to find newforms. Computation of the mod p reductions and p-adic and complex embeddings of a newform is described in Section 132.14.

Computation of congruences is discussed in Section 132.15.

Modular symbols are closely related to modular forms. See Section 132.19 for the connection between the two.

132.1.2 About the Package

The modular forms package is in many ways an interface to the modular symbols machinery (Section 132.19). It also contains additional functionality (such as Eisenstein series), and features that are implemented independently (such as Hecke operators). In some situations however, it is better to work with modular symbols directly. In particular, spaces of modular forms are required to be Galois-stable over the rationals, while spaces of modular symbols are not. Moreover some features, such as Hecke operators of certain spaces, are

unavailable for a given space of modular forms but can be obtained using the corresponding modular symbols.

In MAGMA version 2.14 modular forms of weight one, and of half-integral weight, were added. Most of the existing functions now also work for these weights, however some are not implemented (for instance `Newforms`). Further functionality for half-integral weight will be added in future releases (including Hecke operators).

132.1.3 Categories

In MAGMA, spaces of modular forms belong to the category `ModFrm`, and the elements of spaces of modular forms belong to `ModFrmElt`.

132.1.4 Verbose Output

To set the verbosity level use the command `SetVerbose("ModularForms",n)`, where `n` is 0 (silent), 1 (verbose), or 2 (very verbose). The default verbose level is 0.

Example H132E1

In this example, we illustrate categories and verbosity for modular forms.

```
> M := ModularForms(11,2); M;
Space of modular forms on Gamma_0(11) of weight 2 and dimension 2 over
Integer Ring.
> Type(M);
ModFrm
> B := Basis(M); B;
[
    1 + 12*q^2 + 12*q^3 + 12*q^4 + 12*q^5 + 24*q^6 + 24*q^7 + O(q^8),
    q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
]
> Type(B[1]);
ModFrmElt
```

Using `SetVerbose`, we get some information about what is happening during computations.

```
> SetVerbose("ModularForms",2);
> M := ModularForms(30,4);
> EisensteinSubspace(M);
ModularForms: Computing eisenstein subspace.
ModularForms: Computing dimension.
Space of modular forms on Gamma_0(30) of weight 4 and dimension 8 over
Integer Ring.
> SetVerbose("ModularForms",0);   // turn off verbose mode
```

132.1.5 An Illustrative Overview

In this section, we give a longer example that serves as an overview of the modular forms package. It illustrates computations of modular forms of level 1, and illustrates the exceptional case of Serre's conjecture with a level 13 example.

Example H132E2

First, we compute the two-dimensional space of modular forms of weight 12 and level 1 over **Z**.

```
> M := ModularForms(Gamma0(1),12); M;
Space of modular forms on Gamma_0(1) of weight 12 and dimension 2 over
Integer Ring.
```

The default output precision is 8:

```
> Basis(M);
[
    1 + 196560*q^2 + 16773120*q^3 + 398034000*q^4 + 4629381120*q^5 +
    34417656000*q^6 + 187489935360*q^7 + O(q^8),
    q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 - 16744*q^7
    + O(q^8)
]
> [PowerSeries(f,10) : f in Basis(M)];
[
    1 + 196560*q^2 + 16773120*q^3 + 398034000*q^4 + 4629381120*q^5 +
        34417656000*q^6 + 187489935360*q^7 + 814879774800*q^8 +
        2975551488000*q^9 + O(q^10),
    q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 - 16744*q^7
        + 84480*q^8 - 113643*q^9 + O(q^10)
]
> f := Basis(M)[1];
> Coefficient(f,2);
196560
```

The `Newforms` command returns a list of the Galois-orbits of newforms.

```
> NumberOfNewformClasses(M);
2
> f := Newform(M,1); f;
q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 - 16744*q^7 +
O(q^8)
```

We can call the "q" in the q-expansion anything we want and also compute forms to higher precision.

```
> Mf<w> := Parent(f); Mf;
Space of modular forms on Gamma_0(1) of weight 12 and dimension 1 over
Rational Field.
> f + O(w^12);
w - 24*w^2 + 252*w^3 - 1472*w^4 + 4830*w^5 - 6048*w^6 - 16744*w^7 +
```

```
84480*w^8 - 113643*w^9 - 115920*w^10 + 534612*w^11 + O(w^12)
```

Typing `f + O(w^12)` is equivalent to typing `PowerSeries(f,12)`. The second newform orbit contains an Eisenstein series.

```
> E := Newform(M,2); PowerSeries(E,2);
691/65520 + q + O(q^2)
```

Next we compute the two conjugate newforms in $S_2(\Gamma_1(13))$:

```
> M := ModularForms(Gamma1(13),2);
> S := CuspidalSubspace(M); S;
Space of modular forms on Gamma_1(13) of weight 2 and dimension 2 over
Integer Ring.
> NumberOfNewformClasses(S);
1
> f := Newform(S, 1); f;
q + (-a - 1)*q^2 + (2*a - 2)*q^3 + a*q^4 + (-2*a + 1)*q^5 + (-2*a +
4)*q^6 + O(q^8)
```

Here a is a root of the polynomial $x^2 - x + 1$.

```
> Parent(f);
Space of modular forms on Gamma_1(13) of weight 2 and dimension 2 over
Number Field with defining polynomial x^2 - x + 1 over the Rational
Field.
```

The Galois-conjugacy class of f has two newforms in it.

```
> Degree(f);
2
> g := Newform(S, 1, 2); g;
q + (-b - 1)*q^2 + (2*b - 2)*q^3 + b*q^4 + (-2*b + 1)*q^5 + (-2*b +
4)*q^6 + O(q^8)
> BaseRing(Parent(g));
Number Field with defining polynomial x^2 - x + 1 over the Rational
Field
```

The parents of f and g are isomorphic (but distinct) abstract extensions of $\mathbf{Q}$ both isomorphic to $\mathbf{Q}(\sqrt{-3})$.

```
> Parent(f) eq Parent(g);
false
```

We can also list all of the newforms at once, gathered into Galois orbits, using the `Newforms` command:

```
> N := Newforms(M);
> #N;
8
> N[3];
[*
1/13*(-7*zeta_6 - 11) + q + (2*zeta_6 + 1)*q^2 + (-3*zeta_6 + 1)*q^3 +
```

```
(6*zeta_6 - 3)*q^4 - 4*q^5 + (-7*zeta_6 + 7)*q^6 + (-7*zeta_6 + 8)*q^7
+ O(q^8),
1/13*(7*zeta_6 - 18) + q + (-2*zeta_6 + 3)*q^2 + (3*zeta_6 - 2)*q^3 +
(-6*zeta_6 + 3)*q^4 - 4*q^5 + 7*zeta_6*q^6 + (7*zeta_6 + 1)*q^7 +
O(q^8)
*]
```

The "Nebentypus" or character of f has order 6.

```
> e := DirichletCharacter(f); Parent(e);
Group of Dirichlet characters of modulus 13 over Cyclotomic Field of
order 6 and degree 2
> Order(e);
6
```

This shows that there are no cuspidal newforms with Dirichlet character of order 2. As we see below, the mod-3 reduction of f has character $\overline{\varepsilon}$ that takes values in $\mathbf{F}_3$ and has order 2. The minimal lift of $\overline{\varepsilon}$ to characteristic 0 has order 2, while there are no newforms of level 13 with character of order 2. (This example illustrates the "exceptional case of Serre's conjecture".)

```
> f3 := Reductions(f,3); f3;
[* [*
q + 2*q^3 + 2*q^4 + O(q^8)
*] *]
> M3<q> := Parent(f3[1][1]);
> f3[1][1]+O(q^15);
q + 2*q^3 + 2*q^4 + q^9 + q^12 + 2*q^13 + O(q^15)
```

The modular forms package can also be used to quickly compute dimensions of spaces of modular forms.

```
> M := ModularForms(Gamma0(1),2048);
> Dimension(M);
171
> M := ModularForms(Gamma1(389),2);
> Dimension(M);
6499
> Dimension(CuspidalSubspace(M));
6112
```

Don't try to compute a basis of q-expansions for M!

```
> M := ModularForms(Gamma0(123456789),6);
> Dimension(CuspidalSubspace(M));
68624152
> Dimension(EisensteinSubspace(M));
16
```

132.2 Creation Functions

132.2.1 Ambient Spaces

The following are used for creating spaces of modular forms. For information on Dirichlet characters, see Section 19.8.

`ModularForms(N)`

The space $M_2(\Gamma_0(N), \mathbf{Z})$ of modular forms on $\Gamma_0(N)$ of weight 2. See the documentation for `ModularForms(N,k)` below, with $k = 2$.

`ModularForms(N, k)`

The space $M_k(\Gamma_0(N), \mathbf{Z})$ of weight k modular forms on $\Gamma_0(N)$ over $\mathbf{Z}$.

`ModularForms(eps, k)`

Given a Dirichlet character `eps` and an integer k, this returns a space of modular forms over the integers, of weight k, which under base extension becomes equal to the direct sum of the spaces $M_k(\Gamma_1(N), eps1)$ of weight k and nebentypus character `eps1`, where `eps1` runs over all Galois conjugates `eps`.

`ModularForms(chars, k)`

The space of modular forms of weight k over the integers, formed as the direct sum of spaces `ModularForms(eps,k)`, summing over all `eps` in the given sequence `chars` of Dirichlet characters.

`ModularForms(G)`

This is the same as `ModularForms(G,2)` (see below).

`ModularForms(G, k)`

The space $M_k(G, \mathbf{Z})$, where G is a congruence subgroup. The groups $\Gamma_0(N)$ and $\Gamma_1(N)$ are currently supported, and can be created using the commands `Gamma0(N)` and `Gamma1(N)`, respectively.

`CuspForms(x)`

`CuspForms(x,y)`

These commands are a shortcut, and return the `CuspidalSubspace` of the corresponding full space of modular forms.

Example H132E3

In this example, we illustrate each of the above constructors in turn. First we create $M_2(\Gamma_0(65))$.

```
> M := ModularForms(65); M;
Space of modular forms on Gamma_0(65) of weight 2 and dimension 8 over
Integer Ring.
> Dimension(M);
8
> Basis(CuspidalSubspace(M));
[
    q + q^5 + 2*q^6 + q^7 + O(q^8),
    q^2 + 2*q^5 + 3*q^6 + 2*q^7 + O(q^8),
    q^3 + 2*q^5 + 2*q^6 + 2*q^7 + O(q^8),
    q^4 + 2*q^5 + 3*q^6 + 3*q^7 + O(q^8),
    3*q^5 + 5*q^6 + 2*q^7 + O(q^8)
]
```

Next we create $M_4(\Gamma_0(8))$.

```
> M := ModularForms(8,4); M;
Space of modular forms on Gamma_0(8) of weight 4 and dimension 5 over
Integer Ring.
> Dimension(M);
5
> Basis(CuspidalSubspace(M));
[
    q - 4*q^3 - 2*q^5 + 24*q^7 + O(q^8)
]
```

Now we create the space $M_3(N, \varepsilon)$, where ε is a character of level 20, conductor 5 and order 4.

```
> G := DirichletGroup(20,CyclotomicField(EulerPhi(20)));
> chars := Elements(G); #chars;
8
> [Conductor(eps) : eps in chars];
[ 1, 4, 5, 20, 5, 20, 5, 20 ]
> eps := chars[3];
> IsEven(eps);
false
> M := ModularForms([eps],3); M;
Space of modular forms on Gamma_1(20) with character all conjugates of
[$.2], weight 3, and dimension 12 over Integer Ring.
> Dimension(EisensteinSubspace(M));
6
> Dimension(CuspidalSubspace(M));
6
```

Next we create the direct sum of the spaces $M_k(20, \varepsilon)$ as ε varies over the four mod 20 characters of order at most 2, for $k = 2$ and 3.

```
> G := DirichletGroup(20, RationalField());   // (Z/20Z)^* --> Q^*
```

```
> chars := Elements(G); #chars;
4
> M := ModularForms(chars,2); M;
Space of modular forms on Gamma_1(20) with characters all
conjugates of [1, $.1, $.2, $.1*$.2], weight 2, and dimension 12
over Integer Ring.
> M := ModularForms(chars,3); M;
Space of modular forms on Gamma_1(20) with characters all
conjugates of [1, $.1, $.2, $.1*$.2], weight 3, and dimension 16
over Integer Ring.
```

Now we create the spaces $M_k(\Gamma_1(20))$ for $k = 2, 3$.

```
> ModularForms(Gamma1(20));
Space of modular forms on Gamma_1(20) of weight 2 and dimension 22
over Integer Ring.
> ModularForms(Gamma1(20),3);
Space of modular forms on Gamma_1(20) of weight 3 and dimension 34
over Integer Ring.
```

We can also create the subspace of cuspforms directly:

```
> CuspForms(Gamma1(20));
Space of modular forms on Gamma_1(20) of weight 2 and dimension 3
over Integer Ring.
> CuspForms(Gamma1(20),3);
Space of modular forms on Gamma_1(20) of weight 3 and dimension 14
over Integer Ring.
```

132.2.1.1 Half-integral Weight Forms

Spaces of modular forms of half-integral weight can now be constructed. For these spaces, `CuspidalSubspace` and `qExpansionBasis` are available, as well as basic functionality such as element arithmetic. More functionality will be added in future releases.

The algorithm for determining the q-expansion basis involves computing those of related integral-weight spaces (of weight either one half smaller or one half larger, and appropriate level and character).

`HalfIntegralWeightForms(N, w)`

The space of half-integral weight forms on `Gamma0(N)` and weight w. Here N should be a multiple of 4 and w a positive element of $\mathbf{Z} + 1/2$.

`HalfIntegralWeightForms(chi, w)`

The space of half-integral weight forms on `Gamma1(N)` with character `chi` and weight w. The modulus of `chi` should be a multiple of 4, and w a positive element of $\mathbf{Z}+1/2$.

`HalfIntegralWeightForms(G, w)`

The space of half-integral weight forms on the congruence subgroup G and weight w. Here G must be contained in `Gamma0(4)`, and w is a positive element of $\mathbf{Z}+1/2$.

132.2.2 Base Extension

If M is a space of modular forms created using one of the constructors in Section 132.2.1, then the base ring of M is $\mathbf{Z}$. Thus we can base extend M to any ring R. The examples below illustrate some simple applications of `BaseExtend`.

`BaseExtend(M, R)`

The base extension of the space M of modular forms to the ring R and the induced map from M to `BaseExtend(M,R)`. The only requirement on R is that there is a natural coercion map from the base ring of M to R. For example, when `BaseRing(M)` is the integers, any ring R is allowed.

`BaseExtend(M, phi)`

The base extension of the space M of modular forms to the ring R using the map ϕ : `BaseRing(M)` $\to R$, and the induced map from M to `BaseExtend(M,R)`

Example H132E4

We first illustrate an Eisenstein series in $M_{12}(1)$ that is congruent to 1 modulo 3.

```
> M<q> := EisensteinSubspace(ModularForms(1,12));
> E12 := M.1; E12 + O(q^4);
691 + 65520*q + 134250480*q^2 + 11606736960*q^3 + O(q^4)
> M3<q3> := BaseExtend(M,GF(3));
> Dimension(M3);
1
> M3.1+O(q3^20);
1 + O(q3^20)
```

This congruence can be proved by noting that the coefficient of q^n in the q-expansion of $E_{12}/65520$, for any $n \geq 1$, is an eigenvalue of a Hecke operator, hence an integer, and that 65520 is divisible by 3. Because E_{12} is defined over $\mathbf{Z}$ the command `"E12Q/65520"` would result in an error, so we first base extend to $\mathbf{Q}$.

```
> MQ, phi := BaseExtend(M,RationalField());
> E12Q := phi(E12);
> E12Q/65520;
691/65520 + q + 2049*q^2 + 177148*q^3 + 4196353*q^4 + 48828126*q^5 +
362976252*q^6 + 1977326744*q^7 + O(q^8)
```

It is possible to base extend to almost any silly commutative ring.

```
> M := ModularForms(11,2);
> R := PolynomialRing(GF(17),3);
> MR<q> := BaseExtend(M,R); MR;
Space of modular forms on Gamma_0(11) of weight 2 and dimension 2 over
Polynomial ring of rank 3 over GF(17)
Lexicographical Order
Variables: $.1, $.2, $.3.
> f := MR.1;  f + O(q^5);
```

```
1 + 12*q^2 + 12*q^3 + 12*q^4 + O(q^5)
> f*(R.1+3*R.2) + O(q^4);
$.1 + 3*$.2 + (12*$.1 + 2*$.2)*q^2 + (12*$.1 + 2*$.2)*q^3 + O(q^4)
```

132.2.3 Elements

`M . i`

The ith basis vector of the space of modular forms M.

`M ! f`

The coercion of f into the space of modular forms M. Here f can be a modular form, a power series with absolute precision, or something that can be coerced into `RSpace(M)`.

`ModularForm(E)`

The modular form associated to the elliptic curve E over $\mathbf{Q}$. (See Section 132.18.)

Example H132E5

```
> M := ModularForms(Gamma0(11),2);
> M.1;
1 + 12*q^2 + 12*q^3 + 12*q^4 + 12*q^5 + 24*q^6 + 24*q^7 + O(q^8)
> M.2;
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
> R<q> := PowerSeriesRing(Integers());
> f := M!(1 + q + 10*q^2 + O(q^3));
> f;
1 + q + 10*q^2 + 11*q^3 + 14*q^4 + 13*q^5 + 26*q^6 + 22*q^7 + O(q^8)
> Eltseq(f);
[ 1, 1 ]
```

`Eltseq` gives f as a linear combination of `M.1` and `M.2`. Next we coerce f into $M_2(\Gamma_0(22))$.

```
> M22 := ModularForms(Gamma0(22),2);
> g := M22!f; g;
1 + q + 10*q^2 + 11*q^3 + 14*q^4 + 13*q^5 + 26*q^6 + 22*q^7 + O(q^8)
> Eltseq(g);
[ 1, 1, 10, 11, 14 ]
```

The elliptic curve E below defines an element of $M_2(\Gamma_0(11))$.

```
> E := EllipticCurve([ 0, -1, 1, -10, -20 ]);
> Conductor(E);
11
> f := ModularForm(E);
> f;
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
```

```
> f + M.1;
1 + q + 10*q^2 + 11*q^3 + 14*q^4 + 13*q^5 + 26*q^6 + 22*q^7 + O(q^8)
```

Note, however, that the ambient space of the parent of f is not equal to M, despite the fact that both are isomorphic to $M_2(\Gamma_0(11))$. This is because they were created independently. The above operations are defined because there is a canonical way to coerce f into M using its q-expansion.

```
> f in M;
false
> AmbientSpace(Parent(f)) eq M;
false
```

132.3 Bases

Any space of modular forms that can be created in MAGMA is of the form $M_{\mathbf{Z}} \otimes_{\mathbf{Z}} R$ for some ring R and some space $M_{\mathbf{Z}}$ of modular forms defined over $\mathbf{Z}$. The basis of M is the image in M of `Basis(M_Z)`, and `Basis(M_Z)` is in Hermite normal form.

Note that in order to determine this basis over $\mathbf{Z}$, it is necessary to compute q-expansions up to a "Sturm bound" for M (see `PrecisionBound`). The precision used internally will therefore be at least as large as this bound. If desired, however, one can compute q-expansions to lower precision by working directly with spaces of modular symbols.

`Basis(M)`

The canonical basis of the space of modular forms or half-integral weight forms M.

`Basis(M, prec)`

`qExpansionBasis(M, prec)`

A sequence containing q-expansions (to the specified precision) of the elements of `Basis(M)`.

`PrecisionBound(M : parameters)`

`Exact` BOOLELT *Default :* `false`

An integer b such that $f+O(q^b)$ determines any modular form f in the given space M of modular forms or half-integral weight forms. If the optional parameter `Exact` is set to `true`, or if a q-expansion basis has already been computed for M, then the result is best-possible, ie the *smallest* integer b such that $f + O(q^b)$ determines any modular form f in M. Otherwise it is a "Sturm bound" similar to (although in some cases sharper than) the bounds given in section 9.4 of [Ste07].

Note: In some much older versions of MAGMA the default was `Exact := true`.

`RModule(M)`
`RSpace(M)`
`VectorSpace(M)`

`Ring` RNG *Default :*

An abstract free module isomorphic to the given space of modular forms M, over the same base ring (unless `Ring` is specified). The second returned object is a map from the abstract module to/from M.

This function is needed when one wants to use linear algebra functions on M (since in Magma, a space of modular forms is not a subtype of vector space).

Example H132E6

```
> M := ModularForms(Gamma1(16),3); M;
Space of modular forms on Gamma_1(16) of weight 3 and dimension 23
over Integer Ring.
> Dimension(CuspidalSubspace(M));
9
> SetPrecision(M,19);
> Basis(NewSubspace(CuspidalSubspace(M)))[1];
q - 76*q^8 + 39*q^9 + 132*q^10 - 44*q^11 + 84*q^12 - 144*q^13 -
232*q^14 + 120*q^15 + 160*q^16 + 158*q^17 - 76*q^18 + O(q^19)
```

We can print the whole basis to less precision:

```
> SetPrecision(M,10);
> Basis(NewSubspace(CuspidalSubspace(M)));
[
    q - 76*q^8 + 39*q^9 + O(q^10),
    q^2 + q^7 - 58*q^8 + 30*q^9 + O(q^10),
    q^3 + 2*q^7 - 42*q^8 + 18*q^9 + O(q^10),
    q^4 + q^7 - 26*q^8 + 13*q^9 + O(q^10),
    q^5 + 2*q^7 - 18*q^8 + 5*q^9 + O(q^10),
    q^6 + 2*q^7 - 12*q^8 + 3*q^9 + O(q^10),
    3*q^7 - 8*q^8 + O(q^10)
]
```

Note the coefficient 3 of q^7, which emphasizes that this is not the reduced echelon form over a field, but the image of a reduced form over the integers:

```
> MQ := BaseExtend(M,RationalField());
> Basis(NewSubspace(CuspidalSubspace(MQ)))[7];
3*q^7 - 8*q^8 + O(q^10)
```

132.4 q-Expansions

The following intrinsics give the q-expansion of a modular form (about the cusp ∞).

Note that q-expansions are printed by default only to precision $O(q^12)$. This may be adjusted using `SetPrecision` (see below), which should be used to control *printing only*; to control the amount of precision computed *internally*, instead use `qExpansion` or `qExpansionBasis` and specify the desired precision.

`qExpansion(f)`

`qExpansion(f, prec)`

`PowerSeries(f)`

`PowerSeries(f, prec)`

The q-expansion (at the cusp ∞) of the modular form (or half-integral weight form) f to absolute precision `prec`. This is an element of the power series ring over the base ring of the parent of f.

`Coefficient(f, n)`

The nth coefficient of the q-expansion of the modular form f.

`Precision(M)`

The default printing precision for elements of the space M of modular forms. This is the precision that is used when printing elements of M if the user does not specifically make a choice. The hard-coded default value is 12.

`SetPrecision(M, prec)`

Set the default printing precision for elements of the space M of modular forms (the hard-coded default value is 12).

Example H132E7

In this example, we compute the q-expansion of a modular form $f \in M_3(\Gamma_1(11))$ in several ways.

```
> M := ModularForms(Gamma1(11),3); M;
Space of modular forms on Gamma_1(11) of weight 3 and dimension 15
over Integer Ring.
> f := M.1;
> f;
1 + O(q^8)
> qExpansion(f);
1 + O(q^8)
> Coefficient(f,16);  // f is a modular form, so has infinite precision
-5457936
> qExpansion(f,17);
1 + 763774*q^15 - 5457936*q^16 + O(q^17)
> PowerSeries(f,20);   // same as qExpansion(f,20)
1 + 763774*q^15 - 5457936*q^16 + 14709156*q^17 - 12391258*q^18 -
```

```
    21614340*q^19 + O(q^20)
```

The "big-oh" notation is supported via addition of a modular form and a power series.

```
> M<q> := Parent(f);
> Parent(q);
Power series ring in q over Integer Ring
> f + O(q^17);
1 + 763774*q^15 - 5457936*q^16 + O(q^17)
> 5*q - O(q^17) + f;
1 + 5*q + 763774*q^15 - 5457936*q^16 + O(q^17)
> 5*q + f;
1 + 5*q + O(q^8)
```

Default printing precision can be set using the command `SetPrecision`.

```
> SetPrecision(M,16);
> f;
1 + 763774*q^15 + O(q^16)
```

Example H132E8

The `PrecisionBound` intrinsic is related to Weierstrass points on modular curves. Let N be a positive integer such that $S = S_2(\Gamma_0(N))$ has dimension at least 2. Then the point ∞ is a Weierstrass point on $X_0(N)$ if and only if `PrecisionBound(S : Exact := true)-1 ne Dimension(S)`.

```
> function InftyIsWP(N)
>    S := CuspidalSubspace(ModularForms(Gamma0(N),2));
>    assert Dimension(S) ge 2;
>    return (PrecisionBound(S : Exact := true)-1) ne Dimension(S);
> end function;
> [<N,InftyIsWP(N)> : N in [97..100]];
[ <97, false>, <98, true>, <99, false>, <100, true> ]
```

It is an open problem to give a simple characterization of the integers N such that ∞ is a Weierstrass point on $X_0(N)$, though Atkin and others have made significant progress on this problem (see, e.g., 1967 Annals paper [Atk67]). I verified that if $N < 3223$ is square free, then ∞ is not a Weierstrass point on $X_0(N)$, which suggests a nice conjecture.

132.5 Arithmetic

`f + g`

The sum of the modular forms f and g.

`f + g`

The sum of the modular form f and the power series g. The q-expansion of f must be coercible into the parent of g. The sum $g+f$ is also defined, as are the differences $f-g$ and $g-f$.

`f - g`

The difference of the modular forms f and g.

`a * f`

The product of the scalar a and the modular form f.

`f / a`

The product of the scalar $1/a$ and the modular form f.

`f ^ n`

The power f^n of the modular form f, where $n \geq 1$ is an integer.

`f * g`

The product of the modular forms f and g. The only condition is that the base fields of f and g be the same. The weight of `f*g` is the sum of the weights of f and g.

Example H132E9

```
> M2 := ModularForms(Gamma0(11), 2);
> f := M2.1;
> g := M2.2;
> f;
1 + 12*q^2 + 12*q^3 + 12*q^4 + 12*q^5 + 24*q^6 + 24*q^7 + O(q^8)
> g;
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
> f+g;
1 + q + 10*q^2 + 11*q^3 + 14*q^4 + 13*q^5 + 26*q^6 + 22*q^7 + O(q^8)
> 2*f;
2 + 24*q^2 + 24*q^3 + 24*q^4 + 24*q^5 + 48*q^6 + 48*q^7 + O(q^8)
> MQ,phi := BaseExtend(M2, RationalField());
> phi(2*f)/2;
1 + 12*q^2 + 12*q^3 + 12*q^4 + 12*q^5 + 24*q^6 + 24*q^7 + O(q^8)
> f^2;
1 + 24*q^2 + 24*q^3 + 168*q^4 + 312*q^5 + 480*q^6 + 624*q^7 + O(q^8)
> Parent($1);
Space of modular forms on Gamma_0(11) of weight 4 and dimension 4 over
```

```
Integer Ring.
> M3 := ModularForms([DirichletGroup(11).1], 3); M3;
Space of modular forms on Gamma_1(11) with character all conjugates of
[$.1], weight 3, and dimension 3 over Integer Ring.
> M3.1*f;
1 + 12*q^2 + 2*q^3 + 6*q^4 - 126*q^5 - 168*q^6 - 384*q^7 + O(q^8)
> Parent($1);
Space of modular forms on Gamma_1(11) of weight 5 and dimension 25
over Integer Ring.
```

132.6 Predicates

`IsAmbientSpace(M)`

Returns `true` if and only if M is an ambient space. Ambient spaces are those space constructed in Section 132.2.1.

`IsCuspidal(M)`

Returns `true` if M is contained in the cuspidal subspace of the ambient space.

`IsEisenstein(M)`

Returns `true` if M is contained in the Eisenstein subspace of the ambient space.

`IsEisensteinSeries(f)`

Returns `true` if f is an Eisenstein newform or was computed using the intrinsic `EisensteinSeries`. (See Section 132.10.)

`IsGamma0(M)`

Returns `true` if M is a space of modular forms for $\Gamma_0(N)$.

`IsGamma1(M)`

Returns `true` if M was created explicitly as a space of modular forms for $\Gamma_1(N)$, or if the `AmbientSpace` of M is such a space. (Note that `IsGamma1` will return `false` for any space `ModularForms(chars,k)`, even if `chars` consists of all mod N Dirichlet characters.)

`IsNew(M)`

Returns `true` if M is contained in the new subspace of its `AmbientSpace`.

`IsNewform(f)`

Returns `true` if f was created using `Newforms`. (Sometimes `true` in other cases in which f is obviously a newform. In number theory, "newform" means "normalized eigenform that lies in the new subspace".)

`IsRingOfAllModularForms(M)`

Returns `true` if and only if M is the ring of all modular forms over a given ring.

Example H132E10

We illustrate each of the above predicates with some simple computations in $M_3(\Gamma_1(11))$.

```
> M := ModularForms(Gamma1(11),3);
> f := Newform(M,1);
> IsAmbientSpace(M);
true
> IsAmbientSpace(CuspidalSubspace(M));
false
> IsCuspidal(M);
false
> IsCuspidal(CuspidalSubspace(M));
true
> IsEisenstein(CuspidalSubspace(M));
false
> IsEisenstein(EisensteinSubspace(M));
true
> IsGamma1(M);
true
> IsNew(M);
true
> IsNewform(M.1);
false
> IsNewform(f);
true
> IsRingOfAllModularForms(M);
false
> Level(f);
11
> Level(M);
11
> Weight(f);
3
> Weight(M);
3
> Weight(M.1);
3
```

132.7 Properties

`AmbientSpace(M)`

The full space of modular forms, in which the given space had been created as a subspace.

`BaseRing(M)`

`CoefficientRing(M)`

The ring over which the given space of modular forms was defined.

`Degree(f)`

The number of Galois-conjugates of the modular form f over the prime subfield of (the fraction field of) the base ring of f.

`Dimension(M)`

The dimension of the space M of modular forms or half-integral weight forms.

For spaces defined using the `ModularForms` constructors, the procedure used to obtain the dimension is to count the relevant Eisenstein series, and apply a formula giving the dimension of the relevant space of cusp forms.

`DimensionByFormula(M)`

The dimension of the given space of modular forms or half-integral weight forms (which must be either a full space or the cuspidal subspace of a full space), as given by the formulas in the paper by Cohen and Oesterle (in 'Modular Forms in One Variable, VI', Lecture Notes in Math. 627).

`DimensionByFormula(N, k)`

`DimensionByFormula(chi, k)`

`DimensionByFormula(N, chi, k)`

`Cuspidal` BoolElt *Default :* `false`

The dimension of the full space of the modular forms or half-integral weight forms with level N, character chi (taken to be trivial if not specified) and weight k, as given by the formulas in the paper by Cohen and Oesterle (in 'Modular Forms in One Variable, VI', Lecture Notes in Math. 627).

If `Cuspidal` is set to `true`, then the dimension of the space of cusp forms is returned.

`DirichletCharacters(M)`

A sequence containing exactly one representative from each Galois-conjugacy class of Dirichlet characters associated to the space of modular forms M.

`DirichletCharacter(f)`

Suppose f is a newform, created using the `Newform` command. This returns a Dirichlet character that is, up to Galois conjugacy, the Nebentypus character of f.

`Eltseq(f)`

The sequence $[a_1, \ldots, a_n]$ such that $f = a_1 g_1 + \cdots + a_n g_n$, where $g_1, \ldots, g_n$ is the basis of the parent of the modular form f.

`Level(f)`

The level of the modular form f.

`Level(M)`

The level of the space of modular forms M.

`Weight(f)`

The weight of the modular form f, if it is defined.

`Weight(M)`

The weight of the space M of modular forms.

`WeightOneHalfData(H)`

A list of tuples describing a basis of the given space of forms of weight 1/2. Each tuple is a pair $< f, t >$, where t is an integer and f is a Dirichlet character. The tuple $< f, t >$ designates the sum over all integers n of $f(n)q^{(tn^2)}$.

Example H132E11

We illustrate each of the above properties with some simple computations in $M_3(\Gamma_1(11))$.

```
> M := ModularForms(Gamma1(11),3);
> Degree(M.1);
1
> f := Newform(M,1);
> Degree(f);
4
> Dimension(M);
15
> DirichletCharacters(M);
[
    1,
    $.1,
    $.1^2,
    $.1^5
]
> Level(f);
11
> Level(M);
```

```
11
> Weight(f);
3
> Weight(M);
3
> Weight(M.1);
3
```

132.8 Subspaces

The following functions compute the cuspidal, Eisenstein, and new subspaces.

`ZeroSubspace(M)`

The trivial subspace of the space of modular forms M.

`CuspidalSubspace(M)`

The subspace of forms f in M such that the constant term of the Fourier expansion of f at every cusp is 0.

`EisensteinSubspace(M)`

The Eisenstein subspace of the space of modular forms M.

`EisensteinProjection(f)`

`CuspidalProjection(f)`

The projection of a given modular form to the `EisensteinSubspace` or to the `CuspidalSubspace`. The sum of the two projections equals the original form (after coercion).

The base ring of the given form must contain the rationals.

`NewSubspace(M)`

The new subspace of the space of modular forms M.

`DihedralSubspace(M)`

For a space M of weight 1 forms, this returns the subspace spanned by the cusp forms attached to dihedral Galois representations.

Example H132E12

We compute a basis of q-expansions for each of the above subspace of $M_2(\Gamma_0(33))$.

```
> M := ModularForms(Gamma0(33),2); M;
Space of modular forms on Gamma_0(33) of weight 2 and dimension 6 over
Integer Ring.
> Basis(M);
[
    1 + O(q^8),
    q - q^5 + 2*q^7 + O(q^8),
    q^2 + 2*q^7 + O(q^8),
    q^3 + O(q^8),
    q^4 + q^5 + O(q^8),
    q^6 + O(q^8)
]
> Basis(CuspidalSubspace(M));
[
    q - q^5 - 2*q^6 + 2*q^7 + O(q^8),
    q^2 - q^4 - q^5 - q^6 + 2*q^7 + O(q^8),
    q^3 - 2*q^6 + O(q^8)
]
> Basis(EisensteinSubspace(M));
[
    1 + O(q^8),
    q + 3*q^2 + 7*q^4 + 6*q^5 + 8*q^7 + O(q^8),
    q^3 + 3*q^6 + O(q^8)
]
> Basis(NewSubspace(M));
[
    q + q^2 - q^3 - q^4 - 2*q^5 - q^6 + 4*q^7 + O(q^8)
]
> Basis(NewSubspace(EisensteinSubspace(M)));
[]
> Basis(NewSubspace(CuspidalSubspace(M)));
[
    q + q^2 - q^3 - q^4 - 2*q^5 - q^6 + 4*q^7 + O(q^8)
]
> ZeroSubspace(M);
Space of modular forms on Gamma_0(33) of weight 2 and dimension 0 over
Integer Ring.
> MQ := BaseChange(M, Rationals()); SetPrecision(MQ, 20);
> b := Basis(MQ); b[5];
q^4 + q^5 + 2*q^8 - q^9 + 2*q^10 + 2*q^11 - q^12 + 2*q^13 +
 2*q^14 - q^15 + 3*q^16 + 2*q^17 - 2*q^18 + 2*q^19 + O(q^20)
> CuspidalProjection(b[5]);
-1/10*q - 3/10*q^2 + 1/10*q^3 + 3/10*q^4 + 2/5*q^5 + 3/10*q^6 - 4/5*q^7
+ 1/2*q^8 - 3/10*q^9 + 1/5*q^10 - 1/10*q^11 - 3/10*q^12 + 3/5*q^13 -
2/5*q^14 - 2/5*q^15 - 1/10*q^16 + 1/5*q^17 + 1/10*q^18 + O(q^20)
```

```
> EisensteinProjection(b[5]);
1/10*q + 3/10*q^2 - 1/10*q^3 + 7/10*q^4 + 3/5*q^5 - 3/10*q^6 + 4/5*q^7
+ 3/2*q^8 - 7/10*q^9 + 9/5*q^10 + 21/10*q^11 - 7/10*q^12 + 7/5*q^13 +
12/5*q^14 - 3/5*q^15 + 31/10*q^16 + 9/5*q^17 - 21/10*q^18 + 2*q^19 +
O(q^20)
> MQ! $1 + MQ! $2;  // Add the previous two answers, inside MQ
q^4 + q^5 + 2*q^8 - q^9 + 2*q^10 + 2*q^11 - q^12 + 2*q^13 +
 2*q^14 - q^15 + 3*q^16 + 2*q^17 - 2*q^18 + 2*q^19 + O(q^20)
```

The two projections sum to the original form.

132.9 Operators

Each space M of modular forms comes equipped with a commuting family $T_1, T_2, T_3, \ldots$ of linear operators acting on it called the *Hecke operators*. Unfortunately, at present, the computation of Hecke and other operators on spaces of modular forms with nontrivial character has not yet been implemented, though computation of characteristic polynomials of Hecke operators is supported.

`HeckeOperator(M, n)`

The matrix representing the nth Hecke operator T_n with respect to `Basis(M)`. (Currently M must be a space of modular forms with trivial character and integral weight ≥ 2.)

`HeckeOperator(n,f)`

The image under the Hecke operator T_n of the given modular form.

`HeckePolynomial(M, n` : *parameters*`)`

`Proof` BoolElt *Default :* `true`

The characteristic polynomial of the nth Hecke operator T_n. In some situations this is more efficient than `CharacteristicPolynomial(HeckeOperator(M,n))` or any of its variants. Note that M can be an arbitrary space of modular forms.

`AtkinLehnerOperator(M, q)`

The matrix representing the qth Atkin-Lehner involution W_q on M with respect to `Basis(M)`. (Currently M must be a cuspidal space of modular forms with trivial character and integral weight ≥ 2.)

`AtkinLehnerOperator(q,f)`

The image under the involution w_q of the given modular form.

Example H132E13

First we compute a characteristic polynomial on $S_2(\Gamma_1(13))$ over both $\mathbf{Z}$ and the finite field $\mathbf{F}_2$.

```
> R<x> := PolynomialRing(Integers());
> S := CuspForms(Gamma1(13),2);
> HeckePolynomial(S, 2);
x^2 + 3*x + 3
> S2 := BaseExtend(S, GF(2));
> R<y> := PolynomialRing(GF(2));
> Factorization(HeckePolynomial(S2,2));
[
    <y^2 + y + 1, 1>
]
```

Next we compute a Hecke operator on $M_4(\Gamma_0(14))$.

```
> M := ModularForms(Gamma0(14),4);
> T := HeckeOperator(M,2);
> T;
[  1   0   0   0   0   0   0 240]
[  0   0   0   0  18  12  50 100]
[  0   1   0   0  -2  18  12 -11]
[  0   0   0   0   1  22  25  46]
[  0   0   1   0  -1 -16 -20 -82]
[  0   0   0   0  -1  -6  -9 -38]
[  0   0   0   1   3   9  15  39]
[  0   0   0   0   0   0   0   8]
> Parent(T);
Full Matrix Algebra of degree 8 over Integer Ring
> Factorization(CharacteristicPolynomial(T));
[
    <x - 8, 2>,
    <x - 2, 1>,
    <x - 1, 2>,
    <x + 2, 1>,
    <x^2 + x + 8, 1>
]
> f := M.1;
> f*T;
1 + 240*q^7 + O(q^8)
> M.1 + 240*M.8;
1 + 240*q^7 + O(q^8)
```

This example demonstrates the Atkin-Lehner involution W_3 on $S_2(\Gamma_0(33))$.

```
> M := ModularForms(33,2);
> S := CuspidalSubspace(M);
> W3 := AtkinLehnerOperator(S, 3);
> W3;
[   1    0    0]
```

```
[ 1/3  1/3 -4/3]
[ 1/3 -2/3 -1/3]
> Factorization(CharacteristicPolynomial(W3));
[
    <x - 1, 2>,
    <x + 1, 1>
]
> f := S.2;
> f*W3;
1/3*q + 1/3*q^2 - 4/3*q^3 - 1/3*q^4 - 2/3*q^5 + 5/3*q^6
     + 4/3*q^7 + O(q^8)
```

The Atkin-Lehner and Hecke operators need not commute:

```
> T3 := HeckeOperator(S, 3);
> T3;
[ 0 -2 -1]
[ 0 -1  1]
[ 1 -2 -1]
> T3*W3 - W3*T3 eq 0;
false
```

132.10 Eisenstein Series

The intrinsics below require that the base ring of M has characteristic 0. To compute mod p eigenforms, use the `Reduction` intrinsic (see Section 132.14).

`EisensteinSeries(M)`

List of the Eisenstein series associated to the modular forms space M. By "associated to" we mean that the Eisenstein series lies in $M \otimes \mathbf{C}$.

`IsEisensteinSeries(f)`

Returns `true` if the modular form f was created using `EisensteinSeries`.

`EisensteinData(f)`

The data $< \chi, \psi, t, \chi', \psi' >$ that defines the Eisenstein series (modular form) f. Here χ is a primitive character of conductor S, ψ is primitive of conductor M, and MSt divides N, where N is the level of f. (The additional characters χ' and ψ' are equal to χ and ψ respectively, except they take values in the big field $\mathbf{Q}(\zeta_{\phi(N)})^*$ instead of $\mathbf{Q}(\zeta_n)^*$, where n is the order of χ or ψ.) The Eisenstein series associated to (χ, ψ, t) has q-expansion

$$c_0 + \sum_{m \geq 1} \left(\sum_{n|m} \psi(n) n^{k-1} \chi(m/n) \right) q^{mt},$$

where $c_0 = 0$ if $S > 1$ and $c_0 = L(1-k, \psi)/2$ if $S = 1$.

Example H132E14

We illustrate the above intrinsics by computing the Eisenstein series in $M_3(\Gamma_1(12))$.

```
> M := ModularForms(Gamma1(12),3); M;
Space of modular forms on Gamma_1(12) of weight 3 and dimension 13
over Integer Ring.
> E := EisensteinSubspace(M); E;
Space of modular forms on Gamma_1(12) of weight 3 and dimension 10
over Integer Ring.
> s := EisensteinSeries(E); s;
[*
-1/9 + q - 3*q^2 + q^3 + 13*q^4 - 24*q^5 - 3*q^6 + 50*q^7 + O(q^8),
-1/9 + q^2 - 3*q^4 + q^6 + O(q^8),
-1/9 + q^4 + O(q^8),
-1/4 + q + q^2 - 8*q^3 + q^4 + 26*q^5 - 8*q^6 - 48*q^7 + O(q^8),
-1/4 + q^3 + q^6 + O(q^8),
q + 3*q^2 + 9*q^3 + 13*q^4 + 24*q^5 + 27*q^6 + 50*q^7 + O(q^8),
q^2 + 3*q^4 + 9*q^6 + O(q^8),
q^4 + O(q^8),
q + 4*q^2 + 8*q^3 + 16*q^4 + 26*q^5 + 32*q^6 + 48*q^7 + O(q^8),
q^3 + 4*q^6 + O(q^8)
*]
> a := EisensteinData(s[1]); a;
<1, $.1, 1, 1, $.2>
> Parent(a[2]);
Group of Dirichlet characters of modulus 3 over Rational Field
> Order(a[2]);
2
> Parent(a[5]);
Group of Dirichlet characters of modulus 12 over Cyclotomic Field of

> Parent(s[1]);
Space of modular forms on Gamma_1(12) of weight 3 and dimension 10
over Rational Field.
> IsEisensteinSeries(s[1]);
true
```

132.11 Weight Half Forms

Modular forms of weight 1/2 are constructed directly as q-expansions following the explicit description given by Serre and Stark (see [SS77]).

`WeightOneHalfData(M)`

For a space M of modular forms of weight 1/2, this returns the basis of the space as described by Serre and Stark. A list of tuples is returned; each tuple contains a character ψ and an integer t, and the corresponding modular form is the theta series defined as the sum over all integers n of $\psi(n)q^{(tn^2)}$.

132.12 Weight One Forms

Modular forms of weight 1 can be defined using the usual constructors. For these spaces, the `Dimension`, the `CuspidalSubspace` and `EisensteinSubspace`, `EisensteinSeries`, a `qExpansionBasis`, and Hecke operators are available, as well as basic functionality such as element arithmetic.

The algorithm used to determine spaces of weight 1 forms is as follows. The Eisenstein series are constructed directly as q-expansions. The cuspidal eigenforms correspond to Galois representations; those corresponding to dihedral Galois representations are obtained explicitly (from characters on ray class groups of quadratic fields). If the dihedral forms span the full space of cusp forms, this is proved by comparing with suitable spaces of integral weight forms; if not, a q-expansion basis for the cuspidal space is obtained using the integral-weight spaces (this is the most time-consuming part of the process).

`DihedralForms(M)`

For a space of weight 1, this returns the cuspidal eigenforms in M corresponding to dihedral Galois representations, broken up according to character. A list of tuples is returned; each tuple contains an element of the `DirichletCharacters` of M, followed by a list of eigenforms.

132.13 Newforms

In this section we describe how to compute both cuspidal and Eisenstein newforms.

The intrinsics below require that the base ring of M has characteristic 0. To compute mod p eigenforms, use the `Reduction` intrinsic (see Section 132.14).

`NumberOfNewformClasses(M : parameters)`

`Proof` BoolElt *Default :* `true`

The number of Galois conjugacy-classes of newforms associate to the modular forms space M, which must have base ring $\mathbf{Z}$ or $\mathbf{Q}$. By "associated to" we mean that the newform lies in $M \otimes \mathbf{C}$.

`Newform(M, i, j : parameters)`

`Proof` BoolElt *Default :* `true`

The jth Galois-conjugate newform in the ith Galois-orbit of newforms in the space of modular forms M, which must have base ring $\mathbf{Z}$ or $\mathbf{Q}$.

`Newform(M, i : parameters)`

`Proof` BoolElt *Default :* `true`

The first Galois-conjugate newform in the ith orbit in the space of modular forms M, which must have base ring $\mathbf{Z}$ or $\mathbf{Q}$.

`Newforms(M : parameters)`

`Proof` BoolElt *Default :* `true`

Sort list of the newforms associated to the space of modular forms M divided up into Galois orbits.

`Newforms(I, M)`

Use this intrinsic to find the newforms associated to the space of modular forms M with prespecified eigenvalues. Here I is a sequence $[\langle p_1, f_1(x)\rangle, ..., \langle p_n, f_n(x)\rangle]$ of pairs. Each pair consists of a prime number that does not divide the level of M and a polynomial. This intrinsic returns the set of newforms $\sum a_n q^n$ in M such that $f_n(a_{p_n}) = 0$. (This intrinsic only works when M is cuspidal and defined over $\mathbf{Q}$ or $\mathbf{Z}$.)

Example H132E15

We compute the newforms in $M_5(\Gamma_1(8))$.

```
> M := ModularForms(Gamma1(8),5); M;
Space of modular forms on Gamma_1(8) of weight 5 and dimension 11 over
Integer Ring.
> NumberOfNewformClasses(M);
4
> Newforms(M);
[* [*
q + 4*q^2 - 14*q^3 + 16*q^4 - 56*q^6 + O(q^8)
*], [*
q + 1/24*(a - 30)*q^2 + 6*q^3 + 1/12*(-a - 162)*q^4 + 1/3*(-a + 6)*q^5
+ 1/4*(a - 30)*q^6 + 1/3*(2*a - 12)*q^7 + O(q^8),
q + 1/24*(b - 30)*q^2 + 6*q^3 + 1/12*(-b - 162)*q^4 + 1/3*(-b + 6)*q^5
+ 1/4*(b - 30)*q^6 + 1/3*(2*b - 12)*q^7 + O(q^8)
*], [*
57/2 + q + q^2 + 82*q^3 + q^4 - 624*q^5 + 82*q^6 - 2400*q^7 + O(q^8)
*], [*
q + 16*q^2 + 82*q^3 + 256*q^4 + 624*q^5 + 1312*q^6 + 2400*q^7 + O(q^8)
*] *]
> Newform(M,1);
```

```
q + 4*q^2 - 14*q^3 + 16*q^4 - 56*q^6 + O(q^8)
> Newform(M,2);
q + 1/24*(a - 30)*q^2 + 6*q^3 + 1/12*(-a - 162)*q^4 + 1/3*(-a + 6)*q^5
+ 1/4*(a - 30)*q^6 + 1/3*(2*a - 12)*q^7 + O(q^8)
> Parent(Newform(M,2));
Space of modular forms on Gamma_1(8) of weight 5 and dimension 2 over
Number Field with defining polynomial x^2 - 12*x + 8676 over the
Rational Field.
> Newform(M,2,2);
q + 1/24*(b - 30)*q^2 + 6*q^3 + 1/12*(-b - 162)*q^4 + 1/3*(-b + 6)*q^5
+ 1/4*(b - 30)*q^6 + 1/3*(2*b - 12)*q^7 + O(q^8)
> IsEisensteinSeries(Newform(M,1));
false
> IsEisensteinSeries(Newform(M,2));
false
> IsEisensteinSeries(Newform(M,3));
true
> IsEisensteinSeries(Newform(M,4));
true
```

The following example demonstrates picking out a newform in $S_2(\Gamma_0(65))$ with prespecified eigenvalues.

```
> S := CuspForms(65,2);
> R<x> := PolynomialRing(IntegerRing());
> I := [<3,x+2>];
> Newforms(I,S);
[* [*
q - q^2 - 2*q^3 - q^4 - q^5 + 2*q^6 - 4*q^7 + O(q^8)
*] *]
> Factorization(HeckePolynomial(S, 2));
[
    <x + 1, 1>,
    <x^2 - 3, 1>,
    <x^2 + 2*x - 1, 1>
]
> I := [<2,x^2-3>];
> Newforms(I,S);
[* [*
q + a*q^2 + (-a + 1)*q^3 + q^4 - q^5 + (a - 3)*q^6 + 2*q^7 + O(q^8),
q + b*q^2 + (-b + 1)*q^3 + q^4 - q^5 + (b - 3)*q^6 + 2*q^7 + O(q^8)
*] *]
```

132.13.1 Labels

It is possible to obtain the galois-conjugacy class of a newform by giving a descriptive label as an argument to `Newforms`. The format of the label is as follows:

`[G0N or G1N][Level]k[Weight][Isogeny Class].`

Some example labels are `"G0N11k2A"`, `"G0N1k12A"`, `"G1N17k2B"`, and `"G1N9k3B"`. If the string `"G0N"` or `"G1N"` is omitted, then the default is `"G0N"`. Thus the following are also valid: `"11k2A"`, `"1k12A"`, `"37k4A"`. If `k[Weight]` is omitted, then the default is weight 2, so the following are valid and all refer to weight 2 modular forms on some $\Gamma_0(N)$: `"11A"`, `"37A"`, `"65B"`. In order, possibilities for the isogeny class are as follows:

`A, B, C, ..., Y, Z, AA, BB, CC, ..., ZZ, AAA, BBB, CCC, ...`.

This is essentially the notation used in [Cre97] for isogeny classes, though sometimes for levels ≤ 450 the ordering differs from that in [Cre97].

Suppose s is a valid label, and let M be the space of modular forms that contains `ModularForm(s)`. Then `ModularForm(s)` is by definition `Newforms(M)[i]` where the isogeny class in the label s is the ith isogeny class. For example `C` corresponds to the 3rd isogeny class and `BB` corresponds to the 28th.

`Newforms(label)`

The Galois-conjugacy class(es) of newforms described by the string *label*. See the introduction for a description of the notation used for the label.

Example H132E16

We give many examples of constructing newforms using labels.

```
> Newforms("11A");
[*
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
*]
>  Newforms("G0N11k2A");
[*
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
*]
>  Newforms("G0N1k12A");
[*
q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 - 16744*q^7 +
O(q^8)
*]
>  Newforms("G1N17k2B");
[*
q + (-a^3 + a^2 - 1)*q^2 + (a^3 - a^2 - a - 1)*q^3 + (2*a^3 - a^2 +
2*a)*q^4 + (-a^3 - a^2)*q^5 + (-a^3 + a^2 - a + 1)*q^6 + (-a^3 + a^2 +
a - 1)*q^7 + O(q^8),
q + (-b^3 + b^2 - 1)*q^2 + (b^3 - b^2 - b - 1)*q^3 + (2*b^3 - b^2 +
2*b)*q^4 + (-b^3 - b^2)*q^5 + (-b^3 + b^2 - b + 1)*q^6 + (-b^3 + b^2 +
b - 1)*q^7 + O(q^8),
q + (-c^3 + c^2 - 1)*q^2 + (c^3 - c^2 - c - 1)*q^3 + (2*c^3 - c^2 +
```

```
2*c)*q^4 + (-c^3 - c^2)*q^5 + (-c^3 + c^2 - c + 1)*q^6 + (-c^3 + c^2 +
c - 1)*q^7 + O(q^8),
q + (-d^3 + d^2 - 1)*q^2 + (d^3 - d^2 - d - 1)*q^3 + (2*d^3 - d^2 +
2*d)*q^4 + (-d^3 - d^2)*q^5 + (-d^3 + d^2 - d + 1)*q^6 + (-d^3 + d^2 +
d - 1)*q^7 + O(q^8)
*]
> Newforms("G1N9k3B");
[*
1/3*(-5*zeta_6 - 2) + q + (4*zeta_6 + 1)*q^2 + q^3 + (20*zeta_6 -
15)*q^4 + (-25*zeta_6 + 26)*q^5 + (4*zeta_6 + 1)*q^6 + (-49*zeta_6 +
1)*q^7 + O(q^8),
1/3*(5*zeta_6 - 7) + q + (-4*zeta_6 + 5)*q^2 + q^3 + (-20*zeta_6 +
5)*q^4 + (25*zeta_6 + 1)*q^5 + (-4*zeta_6 + 5)*q^6 + (49*zeta_6 -
48)*q^7 + O(q^8)
*]
> Newforms("11k2A");
[*
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)

132.14 Reductions and Embeddings

`Reductions(f, p)`

The mod p reductions of the modular forms f, where $p \in \mathbf{Z}$ is a prime number and f is a modular form over a number field (or the rationals or integers). Because of denominators, the list of reductions might be empty. (In some cases when f is defined over a field of large degree, the algorithm that I've implemented is definitely not close to optimal. I know a much better algorithm, but haven't implemented it yet.)

`pAdicEmbeddings(f, p)`

The p-adic embeddings of the modular form f.

`ComplexEmbeddings(f)`

The complex embeddings of the modular form f.

Example H132E17

We compute various reductions and embeddings of a degree 3 newform in $S_2(\Gamma_0(47))$.

```
> M := ModularForms(Gamma0(47),2);
> f := Newform(M,1);
> Degree(f);
4
> f;
q + a*q^2 + (a^3 - a^2 - 6*a + 4)*q^3 + (a^2 - 2)*q^4 + (-4*a^3 +
2*a^2 + 20*a - 10)*q^5 + (-a^2 - a + 1)*q^6 + (3*a^3 - a^2 - 16*a +
7)*q^7 + O(q^8)
> Parent(f);
Space of modular forms on Gamma_0(47) of weight 2 and dimension 4 over
Number Field with defining polynomial x^4 - x^3 - 5*x^2 + 5*x - 1 over
the Rational Field.
> Reductions(f,3);
[* [*
q + 2*q^2 + 2*q^3 + 2*q^4 + q^6 + q^7 + O(q^8)
*], [*
q + $.1^4*q^2 + $.1^25*q^3 + $.1^15*q^4 + $.1^20*q^5 + $.1^3*q^6 +
$.1^3*q^7 + O(q^8),
q + $.1^10*q^2 + $.1^17*q^3 + $.1^5*q^4 + $.1^24*q^5 + $.1*q^6 +
$.1*q^7 + O(q^8),
q + $.1^12*q^2 + $.1^23*q^3 + $.1^19*q^4 + $.1^8*q^5 + $.1^9*q^6 +
```

```
$.1^9*q^7 + O(q^8)
*] *]
```

The reductions are genuine modular forms, so we can compute them to higher precision later.

```
> f3 := Reductions(f,3)[1][1];
> Type(f3);
ModFrmElt
> Parent(f3);
Space of modular forms on Gamma_0(47) of weight 2 and dimension 4 over
Finite field of size 3.
> PowerSeries(f3,15);
q + 2*q^2 + 2*q^3 + 2*q^4 + q^6 + q^7 + q^9 + q^12 + 2*q^14 + O(q^15)
> f3^2;
q^2 + q^3 + 2*q^4 + q^7 + O(q^8)
> pAdicEmbeddings(f,3)[1][1];
q + (1383893738 + O(3^20))*q^2 + (288495368 + O(3^20))*q^3 +
(1448516780 + O(3^20))*q^4 + (291254407*3 + O(3^20))*q^5 + (654373882
+ O(3^20))*q^6 - (443261663 + O(3^20))*q^7 + O(q^8)
```

The p-adic precision can be increased by recreating p-adic field with higher precision.

```
> _ := pAdicField(3 : Precision := 30);
> pAdicEmbeddings(f,3)[1][1];
q + (27072777983102 + O(3^30))*q^2 - (7262683411915 + O(3^30))*q^3 +
(102359491392536 + O(3^30))*q^4 - (26022742991723*3 + O(3^30))*q^5 +
(76458862719010 + O(3^30))*q^6 + (31185356420881 + O(3^30))*q^7 +
O(q^8)
> ComplexEmbeddings(f)[1][1];
q + 0.28384129078391142728240587955711710388*q^2 +
2.23925429984775850028724717074345372615990081162*q^3 -

4.25351411923443363456996356947846775230044737382*q^5 +
0.63559283086221161057191843630479068005905688171 2*q^6 +
2.44657723781885227971790463962077981836158867144*q^7 + O(q^8)
```

132.15 Congruences

`CongruenceGroup(M1, M2, prec)`

A group C that measures all possible congruences (to precision *prec*) between some modular form in M_1 and some modular form in M_2. The group C is defined as follows. Let W_1 be the finite-rank $\mathbf{Z}$-module q-exp$(M_1) \cap \mathbf{Z}[[q]]$ and let W_2 be q-exp$(M_2) \cap \mathbf{Z}[[q]]$. Let V be the saturation of $W_1 + W_2$ in $\mathbf{Z}[[q]]$. Then $C = V/(W_1 + W_2)$.

`CongruenceGroupAnemic(M1, M2, prec)`

Analogous to `CongruenceGroup`, but now considering congruences that hold for all q-expansion coefficients a_n with n coprime to the levels of both $M1$ and $M2$ (rather than for all q-expansion coefficients).

Example H132E18

We verify that the newform corresponding to the first elliptic curve of rank 2 is congruent modulo 5 to some Galois-conjugate newform corresponding to the winding quotient of $J_0(389)$ (there is also a congruence modulo 2 to some conjugate form).

```
> M := ModularForms(Gamma0(389),2);
> f := Newform(M,1);
> Degree(f);
1
> g := Newform(M,5);
> Degree(g);
20
> CongruenceGroup(Parent(f),Parent(g),30);
Abelian Group isomorphic to Z/20
Defined on 1 generator
Relations:
    20*$.1 = 0
```

The congruence can be seen directly by computing the reductions of f and g modulo 5:

```
> fmod5 := Reductions(f,5);
> gmod5 := Reductions(g,5);  // takes a few seconds.
> #gmod5;
7
> #fmod5;
1
> [gbar : gbar in gmod5 | #gbar eq 1];
[ [*
q + 4*q^2 + q^3 + 4*q^4 + q^5 + 4*q^6 + O(q^8)
*], [*
q + 3*q^2 + 3*q^3 + 2*q^4 + 2*q^5 + 4*q^6 + O(q^8)
*] ]
> fmod5[1][1];
q + 3*q^2 + 3*q^3 + 2*q^4 + 2*q^5 + 4*q^6 + O(q^8)
```

132.16 Overconvergent Modular Forms

These routines compute characteristic series of operators on overconvergent modular forms. While these are p-adic modular forms, the result also gives information about classical spaces: it determines the characteristic series up to a congruence (details are given below). The big advantage of this approach is that extremely large weights can be handled (the method works by indirectly computing a small part of the large space).

The algorithm has a running time which is linear in $\log(k)$, where k is the weight. The implementation for level 1 is well optimized.

The algorithm is given in Algorithms 1 and 2 of [Lau11]. Suggestions of David Loeffler and John Voight are used in generating certain spaces of classical modular forms for level $N \geq 2$.

`OverconvergentHeckeSeriesDegreeBound(p, N, k, m)`

This returns a bound on the degree of the characteristic series modulo p^m of the Atkin U_p operator on the space of overconvergent p-adic modular forms of (even) weight k and level $\Gamma_0(N)$. This bound is due to Daqing Wan and depends only on k modulo $p-1$ rather than k itself.

`OverconvergentHeckeSeries(p, N, k, m)`

`WeightBound` RngIntElt *Default :* 6

This returns the characteristic series $P(t)$ modulo p^m of the Atkin U_p operator acting on the space of overconvergent p-adic modular forms of level $\Gamma_0(N)$ and weight k. Here $p \geq 5$ is a prime not dividing N.

When $m \leq k-1$, by Coleman's theorem, $P(t)$ is also the reverse characteristic polynomial modulo p^m of the Atkin U_p operator on the space of classical modular forms of level $\Gamma_0(Np)$ and weight k, In addition, when $m \leq (k-2)/2$, P(t) is the reverse characteristic polynomial modulo p^m of the Hecke T_p operator on the space of classical modular forms of level $\Gamma_0(N)$ and weight k.

The optional parameter `WeightBound` gives an (even integer) bound on the weight of the generators which are chosen for certain spaces of classical modular forms required at one point in the algorithm (for level $N \geq 2$). The default value is 6; however, for most levels the algorithm terminates more quickly with `WeightBound := 4`. For some small levels, the algorithm may fail to terminate with these settings, however it will terminate when `WeightBound` is set to a sufficiently large value. There is some randomization in the algorithm, which may also cause variation in running time. The output is provably correct in all instances where the algorithm terminates.

`OverconvergentHeckeSeries(p, N, kseq, m)`

`WeightBound` RngIntElt *Default :* 6

This returns a sequence containing `OverconvergentHeckeSeries(p, N, k, m)`, as above, for each weight k in the given sequence `kseq`. These weights must be congruent to each other modulo $p-1$. Note: it is more efficient to compute several (congruent) weights together, because much of the computational work is the same.

Example H132E19

```
> _<t> := PolynomialRing(Integers()); // use t for printing
> time OverconvergentHeckeSeries(5,11,10000,5);
625*t^8 + 375*t^7 + 1275*t^6 - 875*t^5 - 661*t^4 + 335*t^3 + 1189*t^2 + 861*t + 1
Time: 0.830
> time OverconvergentHeckeSeries(5,11,10000,5 : WeightBound := 4);
625*t^8 + 375*t^7 + 1275*t^6 - 875*t^5 - 661*t^4 + 335*t^3 + 1189*t^2 + 861*t + 1
Time: 0.400
```

Note that the same result was obtained each time, but the weight bound reduced the computational work involved.

```
> time OverconvergentHeckeSeries(7,3,[1000,1006],5);
[
    7203*t^6 - 4116*t^5 + 6713*t^4 - 700*t^3 - 4675*t^2 - 4426*t + 1,
    2401*t^6 + 8134*t^4 - 3976*t^3 + 5160*t^2 + 5087*t + 1
]
Time: 0.110
> time Pseq := OverconvergentHeckeSeries(7,3,[1000,1006],5: WeightBound := 4);
Time: 0.090
> assert Pseq eq $1; // check that it is the same as the previous result
> OverconvergentHeckeSeriesDegreeBound(7,3,1000,5);
9
> time OverconvergentHeckeSeries(29,1,10000,10);
    134393786323419*t^8 - 174295724342741*t^7 - 174857545225000*t^6
    - 153412311426730*t^5 + 41820892464727*t^4 - 148803482429283*t^3
    - 111232323996568*t^2 + 165679475331974*t + 1
Time: 1.000
```

132.17 Algebraic Relations

`Relations(M, d, prec)`

The relations of degree d satisfied by the q-expansions of in the space M of modular forms. The q-expansions are computed to precision *prec*. If prec is too small, this intrinsic might return relations that are not really satisfied by the modular forms. To be sure of your result, `prec` must be at least as large as `PrecisionBound(M2)`, where M_2 has the same level as M and weight d times the weight of M.

Example H132E20

We compute an equation that defines the canonical embedding of $X_0(34)$.

```
> S := CuspidalSubspace(ModularForms(Gamma0(34)));
> Relations(S, 4, 20);
[
    a^3*c - a^2*b^2 - 3*a^2*c^2 + 2*a*b^3 + 3*a*b^2*c - 3*a*b*c^2 +
        4*a*c^3 - b^4 + 4*b^3*c - 6*b^2*c^2 + 4*b*c^3 - 2*c^4
]
[
    (0  0  1 -1  0 -3  2  3 -3  4 -1  4 -6  4 -2)
]
> // a, b, and c correspond to the cusp forms S.1, S.2 and S.3:
> S.1;
q - 2*q^4 - 2*q^5 + 4*q^7 + O(q^8)
> S.2;
q^2 - q^4 + O(q^8)
> S.3;
q^3 - 2*q^4 - q^5 + q^6 + 4*q^7 + O(q^8)
```

Next we compute the canonical embedding of $X_0(75)$.

```
> S := CuspidalSubspace(ModularForms(Gamma0(75)));
> R := Relations(S, 2, 20); R;
[
    a*c - b^2 - d^2 - 4*e^2,
    a*d - b*c + b*e + d*e - 3*e^2,
    a*e - b*d - c*e
]
> // NOTE: It is much faster to compute in the power
> // series ring than the ring of modular forms!
> a, b, c, d, e := Explode([PowerSeries(f,20) : f in Basis(S)]);
> a*c - b^2 - d^2 - 4*e^2;
O(q^21)
```

The connection between the above computations and models for modular curves is discussed in Steven Galbraith's Oxford Ph.D. thesis.

132.18 Elliptic Curves

Little has been implemented so far.

`ModularForm(E)`

`Newform(E)`

The modular form associated to the elliptic curve E (which must be defined over the rationals).

`Eigenform(E, prec)`

`qEigenform(E, prec)`

The q-expansion of the newform associated to E, to the specified precision.

Note: this is exactly the same as calling `qExpansion(ModularForm(E),prec)`.

`EllipticCurve(f)`

An elliptic curve E with associated modular form f, when f is a weight 2 newform on $\Gamma_0(N)$ with rational Fourier coefficients.

The Cremona database is used to identify the isogeny class. (A routine to compute the curve from scratch is implemented, and can be called with `EllipticCurve(M : Database:=false)` where M is the relevant space of modular symbols; however this is not optimized for large level.)

Example H132E21

```
> M := ModularForms(Gamma0(389),2);
> f := Newform(M,1);
> Degree(f);
1
> E := EllipticCurve(f);
> E;
Elliptic Curve defined by y^2 + y = x^3 + x^2 - 2*x over Rational
Field
> Conductor(E);
389
> time s := PowerSeries(f,200);  // faster because it knows the elliptic curve
Time: 0.509
```

132.19 Modular Symbols

`ModularSymbols(M)`

The sequence of characteristic 0 spaces of modular symbols with given sign associated to the space of modular forms M, when this makes sense.

`ModularSymbols(M, sign)`

The sequence of characteristic 0 spaces of modular symbols with given sign associated to the space of modular forms M, when this makes sense.

Example H132E22

```
> M := ModularForms(Gamma0(389),2);
> ModularSymbols(M,+1);
[
    Full Modular symbols space of level 389, weight 2, and dimension
    33
]
> ModularSymbols(M,-1);
[
    Full Modular symbols space of level 389, weight 2, and dimension
    32
]
> M := ModularForms(Gamma1(13),2);
> ModularSymbols(M);
[
    Full Modular symbols space of level 13, weight 2, and dimension 1,
    Full Modular symbols space of level 13, weight 2, character $.1,
    and dimension 0,
    Full Modular symbols space of level 13, weight 2, character $.1,
    and dimension 4,
    Full Modular symbols space of level 13, weight 2, character $.1,
    and dimension 0,
    Full Modular symbols space of level 13, weight 2, character $.1^2,
    and dimension 2,
    Full Modular symbols space of level 13, weight 2, character $.1,
    and dimension 2
]
> Basis($1)[1];
-1/6*{-7/15, -6/13} + -1/6*{-7/18, -5/13} + -1/6*{-5/16, -4/13} +
-1/6*{-4/17, -3/13} + -1/6*{-3/19, -2/13} + -1/6*{0, oo}
```

133 MODULAR SYMBOLS

Chapter 133
MODULAR SYMBOLS

133.1 Introduction

This chapter, which was written by William Stein (`was@math.harvard.edu`) with the help of feedback from Kevin Buzzard, describes how to compute with modular symbols using MAGMA. Modular symbols provide a presentation for certain homology groups, and as such they can be used to compute an eigenform basis for spaces of cusp forms $S_k(N, \varepsilon)$, where $k \geq 2$ is an integer and ε is an *arbitrary* Dirichlet character. Their generality makes modular symbols a natural tool in applications ranging from verification of modularity of Galois representations to elliptic curve computations.

Our implementation of modular symbols algorithms in MAGMA was deeply influenced by [Cre92, Cre97, Mer94]. The algorithms for computing arithmetic invariants of modular abelian varieties are based on [Ste00]. Those unfamiliar with modular symbols might wish to consult [Ste08] and the references contained therein and peruse [FM99].

133.1.1 Modular Symbols

The *modular group* $\mathrm{SL}_2(\mathbf{Z})$ is the group of 2×2 integer matrices with determinant 1. For each positive integer N let $\Gamma_0(N)$ denote the subgroup of $\mathrm{SL}_2(\mathbf{Z})$ of matrices that are upper triangular modulo N. As explained in the survey paper [DI95], there is an algebraic curve $X_0(N)$ over $\mathbf{Q}$ attached to $\Gamma_0(N)$. The Riemann surface attached to $X_0(N)$ is a compactified quotient of the upper half plane by the action of $\Gamma_0(N)$ via linear fractional transformations. Modular symbols provide an explicit computable presentation for certain "(co-)homology groups" attached to modular curves $X_0(N)$.

Let $\mathbf{P^1}(\mathbf{Q})$ denote the set $\mathbf{Q} \cup \{\infty\}$, and fix a field F. Let $\mathbf{M}$ denote the F-vector space generated by the formal symbols $\{a, b\}$, with $a, b \in \mathbf{P^1}(\mathbf{Q})$, modulo the relations $\{a, b\} + \{b, c\} + \{c, a\} = 0$ for all $a, b, c \in \mathbf{Q}$. (The symbol $\{a, b\}$ can be visualized as the homology class of a geodesic path from a to b in the upper half plane.) Fix a positive integer k. A weight-k symbol is a formal product $X^i Y^{k-2-i}\{a, b\}$, where $X^i Y^{k-2-i} \in F[X, Y]$. Denote by $\mathbf{M_k}$ the formal F-vector space with basis the set of all weight-k modular symbols (thus $\mathbf{M_k} \approx \mathbf{M} \otimes \mathrm{Sym}^{\mathbf{k-2}}(\mathbf{F} \times \mathbf{F})$). The group $\mathrm{GL}_2(\mathbf{Q})$ acts on the left on $\mathbf{M_k}$; the matrix $g = \begin{pmatrix} u & v \\ w & z \end{pmatrix}$ in $\mathrm{GL}_2(\mathbf{Q})$ acts by

$$g(X^i Y^{k-2-i}\{a, b\}) = (zX - vY)^i(-wX + uY)^{k-2-i} \left\{ \frac{ua + v}{wa + z}, \frac{ub + v}{wb + z} \right\}.$$

A *mod N Dirichlet character* ε is a homomorphism

$$\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to F^*.$$

The vector space $\mathbf{M_k}(\mathbf{N}, \varepsilon; \mathbf{F})$ of *modular symbols of weight k, level N and character ε over F* is the quotient of $\mathbf{M_k}$ by the subspace generated by all $x - \varepsilon(u)g(x)$, for x in $\mathbf{M_k}$ and $g = \begin{pmatrix} u & v \\ w & z \end{pmatrix} \in \Gamma_0(N)$. We denote the equivalence class that defines a modular symbol by giving a representative element.

The space of modular symbols is a finite-dimensional vector space, and there is a natural finite presentation for it in terms of Manin symbols.

133.2 Basics

133.2.1 Verbose Output

The verbosity level for modular symbols computations can be set using the command `SetVerbose("ModularSymbols",n)`, where `n` is 0 (silent), 1 (verbose), or 2 (very verbose). (The verbose flag for modular symbols was called `ModularForms` in MAGMA version 2.7.)

133.2.2 Categories

Spaces of modular symbols belong to the category `ModSym`. The category `SetCsp` has exactly one object `Cusps()`, which is the set $\mathbf{P^1}(\mathbf{Q}) = \mathbf{Q} \cup \{\infty\}$ introduced above. The element ∞ of $\mathbf{P^1}(\mathbf{Q})$ is entered using the expression `Cusps()!Infinity()`.

Example H133E1

We compute a basis for the space of modular symbols of weight 2, level 11 and trivial character.

```
> M := ModularSymbols(11,2); M;
Full modular symbols space for Gamma_0(11) of weight 2 and dimension 3
over Rational Field
> Type(M);
ModSym
> Basis(M);
[
    {-1/7, 0},
    {-1/5, 0},
    {oo, 0}
]
> M!<1,[1/5,1]>;
{-1/5, 0}
> // the modular symbols {1/5,1} and {-1/5,0} are equal.
> Type(M!<1,[1/5,1]>);
ModSymElt
```

Using `SetVerbose`, we can see how the computation progresses.

```
> SetVerbose("ModularSymbols",2);
> M := ModularSymbols(11,2);
Computing space of modular symbols of level 11 and weight 2....
I.      Manin symbols list.
```

```
                (0 s)
II.     2-term relations.
                (0.019 s)
III.    3-term relations.
         Computing quotient by 4 relations.
                (0.009 s)
                (total time to create space = 0.029 s)
> SetVerbose("ModularSymbols",0);
```

Modular symbols can be input using `Cusps()`.

```
> M := ModularSymbols(11,2);
> P := Cusps(); P;
Set of all cusps
> Type(P);
SetCsp
> oo := P!Infinity();
> M!<1,[oo,P!0]>;       // note that 0 must be coerced into P.
{oo, 0}
> M!<1,[1/5,1]> + M!<1,[oo,P!0]>;
{-1/5, 0} + {oo, 0}
```

Modular symbols are also defined over finite fields.

```
> M := ModularSymbols(11,2,GF(7)); M;
Full modular symbols space for Gamma_0(11) of weight 2 and dimension 3
over Finite field of size 7
> BaseField(M);
Finite field of size 7
> 7*M!<1,[1/5,1]>;
0
```

133.3 Creation Functions

133.3.1 Ambient Spaces

An ambient space of modular symbols is created by specifying a base ring, character, weight, and optional sign. Note that spaces of modular symbols may be defined directly over any base ring (unlike `ModularForms`, which can only be base extensions of spaces over the integers). The most general signature is `ModularSymbols(eps, k, sign)`, where `eps` is a Dirichlet character (the level is taken to be the modulus of `eps`, and the base ring is taken to be the base ring of `eps`).

For information on Dirichlet characters, see Section 19.8.

Warning: Certain functions, such as `DualVectorSpace`, may fail when given as input a space of modular symbols over a field of positive characteristic, because the Hecke operators T_p, with p prime to the level, need not be semisimple.

`ModularSymbols(N)`

The space of modular symbols of level N, weight 2, and trivial character over the rational numbers.

`ModularSymbols(N, k)`

The space of modular symbols of level N, weight k, and trivial character over the rational numbers.

`ModularSymbols(N, k, F)`

The space of modular symbols of level N, weight k, and trivial character over the field F.

`ModularSymbols(N, k, sign)`

The space of modular symbols of level N, weight k, trivial character, and given *sign* (as an integer) over the rational numbers.

`ModularSymbols(N, k, F, sign)`

The space of modular symbols of level N, weight k, trivial character, and given *sign* (as an integer), over the field F.

`ModularSymbols(eps, k)`

The space of modular symbols of weight k and character ε (as an element of a Dirichlet group). Note that ε determines the level and the base field, so they do not need to be specified.

`ModularSymbols(eps, k, sign)`

The space of modular symbols of weight k and character ε (as an element of a Dirichlet group). The level and base field are specified as part of ε. The third argument "sign" allows for working in certain quotients. The possible values are -1, 0, and $+1$, which correspond to the -1 quotient, full space, and $+1$ quotient, respectively. The $+1$ quotient of M is $M/(*-1)M$, where $*$ is `StarInvolution(M)`.

Example H133E2

We create spaces of modular symbols in several different ways.

```
> M37 := ModularSymbols(37); M37;
Full modular symbols space for Gamma_0(37) of weight 2 and dimension 5
over Rational Field
> Basis(M37);
[
    {-1/29, 0},
    {-1/22, 0},
    {-1/12, 0},
    {-1/18, 0},
    {oo, 0}
```

```
]
```

As M37 is a space of modular symbols, it is not incorrect that its dimension is different than that of the three-dimensional space of modular forms $M_2(\Gamma_0(37))$. We have

$$\dim \mathbf{M_2}(\mathbf{\Gamma_0}(\mathbf{37})) = \mathbf{2} \times (\text{dim cusp forms}) + \mathbf{1} \times (\text{dim Eisenstein series}) = \mathbf{5}.$$

```
> MF := ModularForms(Gamma0(37),2);
> 2*Dimension(CuspidalSubspace(MF)) + Dimension(EisensteinSubspace(MF));
5
```

Next we decompose M37 with respect to the Hecke operators T_2, T_3, and T_5.

```
> D := Decomposition(M37,5); D;
[
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 1
     over Rational Field,
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field
]
```

The first factor corresponds to the standard Eisenstein series, and the second corresponds to an elliptic curve:

```
> E := EllipticCurve(D[2]); E;
Elliptic Curve defined by y^2 + y = x^3 + x^2 - 23*x - 50 over
Rational Field
> Rank(E);
0
```

We now create the space $\mathbf{M_{12}}(\mathbf{1})$ of weight 12 modular symbols of level 1.

```
> M12 := ModularSymbols(1,12); M12;
Full modular symbols space for Gamma_0(1) of weight 12 and dimension 3
over Rational Field
> Basis(M12);
[
    X^10*{0, oo},
    X^8*Y^2*{0, oo},
    X^9*Y*{0, oo}
]

> DimensionCuspFormsGamma0(1,12);
1
> R<z>:=PowerSeriesRing(Rationals());
> Delta(z)+ O(z^7);
z - 24*z^2 + 252*z^3 - 1472*z^4 + 4830*z^5 - 6048*z^6 + O(z^7)
```

As a module, cuspidal modular symbols equal cuspforms with multiplicity two.

```
> M12 := ModularSymbols(1,12);
```

```
> HeckeOperator(CuspidalSubspace(M12),2);
[-24   0]
[  0 -24]
>  qExpansionBasis(CuspidalSubspace(M12),7);
[
    q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 + O(q^7)
]
```

For efficiency purposes, since one is often interested only in q-expansion, it is possible to work in the quotient of the space of modular symbols by all relations $*x = x$ (or $*x = -x$), where $*$ is `StarInvolution(M)`. In either of these quotients (except possibly in characteristic $p > 0$) the cusp forms appear with multiplicity one instead of two.

```
> M12plus := ModularSymbols(1,12,+1);
> Basis(M12plus);
[
    X^10*{0, oo},
    X^8*Y^2*{0, oo}
]
> CuspidalSubspace(M12plus);
Modular symbols space for Gamma_0(1) of weight 12 and dimension 1 over
Rational Field
> qExpansionBasis(CuspidalSubspace(M12),7);
[
    q - 24*q^2 + 252*q^3 - 1472*q^4 + 4830*q^5 - 6048*q^6 + O(q^7)
]
```

The following is an example of how to create Dirichlet characters in MAGMA, and how to create a space of modular symbols with nontrivial character. For more details, see Section 19.8.

```
> G<a,b,c> := DirichletGroup(16*7,CyclotomicField(EulerPhi(16*7)));
> Order(a);
2
> Conductor(a);
4
> Order(b);
4
> Conductor(b);
16
> Order(c);
6
> Conductor(c);
7
> eps := a*b*c;
> M := ModularSymbols(eps,2); M;
Full modular symbols space of level 112, weight 2, character a*b*c,
and dimension 32 over Cyclotomic Field of order 48 and degree 16
> BaseField(M);
Cyclotomic Field of order 48 and degree 16
```

133.3.2 Labels

It is also possible to create many spaces of modular symbols for $\Gamma_0(N)$ by passing a "descriptive label" as an argument to `ModularSymbols`. The most specific label is a string of the form `[Level]k[Weight][IsogenyClass]`, where `[Level]` is the level, `[Weight]` is the weight, `[IsogenyClass]` is a letter code: `A`, `B`, ..., `Z`, `AA`, `BB`, ..., `ZZ`, `AAA`, ..., and `k` is a place holder to separate the level and the weight. If the label is `[Level][IsogenyClass]`, then the weight k is assumed equal to 2. If the label is `[Level]k[Weight]` then the cuspidal subspace of the full ambient space of modular symbols of weight k and level N is returned. The following are valid labels: `11A`, `37B`, `3k12A`, `11k4`. The ordering used on isogenies classes is `lt`; see the documentation for `SortDecomposition`.

Note: There is currently no intrinsic that, given a space of modular symbols, returns its label.

Warning: For 146 of the levels between 56 and 450, our ordering of weight 2 rational newforms disagrees with the ordering used in [Cre97]. Fortunately, it is easy to create a space of modular symbols from one of Cremona's labels using the associated elliptic curve.

```
> E  := EllipticCurve(CremonaDatabase(),"56A");
> M1 := ModularSymbols(E);
```

Observe that Cremona's `"56A"` is different from ours.

```
> M2 := ModularSymbols("56A");
> M2 eq M1;
false
```

`ModularSymbols(s, sign)`

`ModularSymbols(s)`

The space of modular symbols described by a label, the string s, and given *sign*.

Example H133E3

The cusp form $\Delta(q)$ is related to the space of modular symbols whose label is `"1k12A"`.

```
> Del := ModularSymbols("1k12A"); Del;
Modular symbols space for Gamma_0(1) of weight 12 and dimension 2 over
Rational Field
> qEigenform(Del,5);
q - 24*q^2 + 252*q^3 - 1472*q^4 + O(q^5)
```

Next, we create the space corresponding to the first newform on $\Gamma_0(11)$ of weight 4.

```
> M := ModularSymbols("11k4A"); M;
Modular symbols space for Gamma_0(11) of weight 4 and dimension 4 over
Rational Field
> AmbientSpace(M);
Full modular symbols space for Gamma_0(11) of weight 4 and dimension 6
over Rational Field
```

```
> qEigenform(M,5);
q + a*q^2 + (-4*a + 3)*q^3 + (2*a - 6)*q^4 + O(q^5)
> Parent($1);
Power series ring in q over Univariate Quotient Polynomial Algebra in
a over Rational Field with modulus a^2 - 2*a - 2
```

We next create the $+1$ quotient of the cuspidal subspace of weight-4 modular symbols of level 37.

```
> M := ModularSymbols("37k4",+1); M;
Modular symbols space for Gamma_0(37) of weight 4 and dimension 9 over
Rational Field
> AmbientSpace(M);
Full modular symbols space for Gamma_0(37) of weight 4 and dimension
11 over Rational Field
> Factorization(CharacteristicPolynomial(HeckeOperator(M,2)));
[
    <x^4 + 6*x^3 - x^2 - 16*x + 6, 1>,
    <x^5 - 4*x^4 - 21*x^3 + 74*x^2 + 102*x - 296, 1>
]
```

133.3.3 Creation of Elements

Suppose M is a space of weight k modular symbols over a field F. A modular symbol $P(X,Y)\{\alpha,\beta\}$ is input as `M!<P(X,Y),[alpha,beta]>`, where $P(X,Y) \in F[X,Y]$ is homogeneous of degree $k-2$, and $\alpha, \beta \in \mathbf{P^1}(\mathbf{Q})$. Here is an example:

Example H133E4

First create the space $M = \mathbf{M_4}(\mathbf{\Gamma_0}(\mathbf{3}); \mathbf{F_7})$.

```
> F7 := GF(7);
> M := ModularSymbols(3,4,F7);
> R<X,Y> := PolynomialRing(F7,2);
```

Now we input $(X^2 - 2XY)\{0,1\}$.

```
> M!<X^2-2*X*Y,[Cusps()|0,1]>;
6*Y^2*{oo, 0}
```

Note that $(X^2 - 2XY)\{0,1\} = 6Y^2\{\infty, 0\}$ in M.
When $k = 2$, simply enter `M!<1,[alpha,beta]>`.

```
> M := ModularSymbols(11,2);
> M!<1,[Cusps()|0,Infinity()]>;
-1*{oo, 0}
> M![<1,[Cusps()|0,Infinity()]>, <1,[Cusps()|0,1/11]>];
-2*{oo, 0}
```

Any space M of modular symbols is finitely generated. One proof of this uses that every modular symbol is a linear combination of *Manin symbols*. Let $\mathbf{P^1}(\mathbf{Z}/\mathbf{NZ})$ be the set of pairs $(\overline{u},\overline{v}) \in \mathbf{Z}/N\mathbf{Z} \times \mathbf{Z}N\mathbf{Z}$ such that $\mathrm{GCD}(u,v,N) = 1$, where u and v are lifts of $\overline{u}$ and $\overline{v}$ to $\mathbf{Z}$. A Manin symbols $\langle P(X,Y),(\overline{u},\overline{v})\rangle$ is a pair consisting of a homogeneous polynomial $P(X,Y) \in F[X,Y]$ of degree $k-2$ and an element $(\overline{u},\overline{v}) \in \mathbf{P^1}(\mathbf{Z}/\mathbf{NZ})$. The modular symbol associated to $\langle P(X,Y),(\overline{u},\overline{v})\rangle$ is constructed as follows. Choose lifts u,v of $\overline{u},\overline{v}$ such that $\mathrm{GCD}(u,v) = 1$. Then there is a matrix $g = \begin{pmatrix} w & z \\ u & v \end{pmatrix}$ in $\mathrm{SL}_2(\mathbf{Z})$ whose lower two entries are u and v. The modular symbol is then $g(P(X,Y)\{0,\infty\})$. The intrinsic `ConvertFromManinSymbol` computes the modular symbol attached to a Manin symbol. Ever modular symbol can be written as a linear combination of Manin symbols using the intrinsic `ManinSymbol`.

Example H133E5

In this example, we convert between Manin and modular symbols representations of a few elements of a space of modular symbols of weight 4 over $\mathbf{F}_5$.

```
> F5 := GF(5);
> M := ModularSymbols(6,4,F5);
> R<X,Y> := PolynomialRing(F5,2);
> ConvertFromManinSymbol(M,<X^2+Y^2,[1,4]>);
(3*X^2 + 3*X*Y + 2*Y^2)*{-1/2, 0} + (X^2 + 4*X*Y + 4*Y^2)*{-1/3, 0} +
(X^2 + X*Y + 4*Y^2)*{1/3, 1/2}
> ManinSymbol(M.1-3*M.2);
[
    <X^2, (0 1)>,
    <2*X^2, (1 2)>
]
```

Thus the element `M.1-3*M.2` of M corresponds to the sum of Manin symbols $\langle X^2,(0,1)\rangle + 2\langle X^2,(1,2)\rangle$.

`M ! x`

The coercion of x into the space of modular symbols M. Here x can be either a modular symbol that lies in a subspace of M, a 2-tuple that describes a modular symbol, a sequence of such 2-tuples, or anything that can be coerced into `VectorSpace(M)`. If x is a valid sequence of such 2-tuples, then `M!x` is the sum of the coercions into M of the elements of the sequence x.

`ConvertFromManinSymbol(M, x)`

The modular symbol associated to the 2-tuple $x = \langle P(X,Y),[u,v]\rangle$, where $P(X,Y) \in F[X,Y]$ is homogeneous of degree $k-1$, F is the base field of the space of modular symbols M, and $[u,v]$ is a sequence of 2 integers that defines an element of $\mathbf{P^1}(\mathbf{Z}/\mathbf{NZ})$, where N is the level of M.

`ManinSymbol(x)`

An expression for the modular symbol x in terms of Manin symbols, which are represented as 2-tuples $\langle P(X,Y), [u,v] \rangle$.

Example H133E6

```
> M := ModularSymbols(14,2); M;
Full modular symbols space for Gamma_0(14) of weight 2 and dimension 5
over Rational Field
> Basis(M);
[
    {oo, 0},
    {-1/8, 0},
    {-1/10, 0},
    {-1/12, 0},
    {-1/2, -3/7}
]
> M!<1,[1,0]>;
0
> M!<1,[0,1/11]>;
{-1/10, 0} + -1*{-1/12, 0}
> M![<1,[0,1/2]>, <-1,[0,1/7]>];              // sequences are added
{-1/8, 0} + -1*{-1/12, 0} + -1*{-1/2, -3/7}
> M!<1,[0,1/2]> - M!<1,[0,1/7]>;
{-1/8, 0} + -1*{-1/12, 0} + -1*{-1/2, -3/7}
> M!<1,[Cusps()|Infinity(),0]>;               // Infinity() is in Cusps().
{oo, 0}
```

We can also coerce sequences into the underlying vector space of M.

```
> VectorSpace(M);
Full Vector space of degree 5 over Rational Field
Mapping from: Full Vector space of degree 5 over Rational Field to
ModSym: M given by a rule [no inverse]
Mapping from: ModSym: M to Full Vector space of degree 5 over Rational
Field given by a rule [no inverse]
> Eltseq(M.3);
[ 0, 0, 1, 0, 0 ]
> M![ 0, 0, 1, 0, 0 ];
{-1/10, 0}
> M.3;
{-1/10, 0}
```

The "polynomial coefficients" of the modular symbols are homogeneous polynomials in 2 variables of degree $k-2$.

```
> M := ModularSymbols(1,12);
> Basis(M);
[
```

```
    X^10*{0, oo},
    X^8*Y^2*{0, oo},
    X^9*Y*{0, oo}
]
> R<X,Y> := PolynomialRing(Rationals(),2);
> M!<X^9*Y,[Cusps()|0,Infinity()]>;
X^9*Y*{0, oo}
> M!<X^7*Y^3,[Cusps()|0,Infinity()]>;
-25/48*X^9*Y*{0, oo}
> Eltseq(M!<X*Y^9,[1/3,1/2]>);
[ -19171, -58050, -30970 ]
> M![1,2,3];
X^10*{0, oo} + 2*X^8*Y^2*{0, oo} + 3*X^9*Y*{0, oo}
> ManinSymbol(M![1,2,3]);
[
    <X^10, (0 1)>,
    <2*X^8*Y^2, (0 1)>,
    <3*X^9*Y, (0 1)>
]
```

133.4 Bases

`Basis(M)`

Basis for the space of modular symbols M.

`IntegralBasis(M)`

First suppose that the space of modular symbols M equals `AmbientSpace(M)`. Then this intrinsic returns a basis $x_1, \ldots, x_n$ for M such that $\mathbf{Z}x_1 + \cdots + \mathbf{Z}x_n$ is the $\mathbf{Z}$-submodule of M generated by all modular symbols $X^i \cdot Y^{k-2-i}\{\alpha, \beta\}$ with $i = 0, \ldots, k-2$ and $\alpha, \beta \in \mathbf{P^1}(\mathbf{Q})$. If M is not `AmbientSpace(M)`, then this intrinsic returns a $\mathbf{Z}$-basis for $M \cap (\mathbf{Z}x_1 + \cdots + \mathbf{Z}x_n)$, where $x_1, \ldots, x_n$ is an integral basis for `AmbientSpace(M)`. The base field of M must be $\mathbf{Q}$.

Example H133E7

```
> M := ModularSymbols(1,12);
> Basis(M);
[
    X^10*{0, oo},
    X^8*Y^2*{0, oo},
    X^9*Y*{0, oo}
]
> IntegralBasis(M);
[
```

```
    1/48*X^9*Y*{0, oo},
    1/14*X^8*Y^2*{0, oo},
    X^10*{0, oo}
]
```

`IntegralBasis(M)` is a basis for the **Z**-module spanned by the following symbols:

```
> R<X,Y> := PolynomialRing(Rationals(),2);
> [M!<X^i*Y^(10-i),[Cusps()|0,Infinity()]> : i in [0..10]];
[
    -X^10*{0, oo},
    X^9*Y*{0, oo},
    -X^8*Y^2*{0, oo},
    -25/48*X^9*Y*{0, oo},
    9/14*X^8*Y^2*{0, oo},
    5/12*X^9*Y*{0, oo},
    -9/14*X^8*Y^2*{0, oo},
    -25/48*X^9*Y*{0, oo},
    X^8*Y^2*{0, oo},
    X^9*Y*{0, oo},
    X^10*{0, oo}
]
```

We can also compute an integral basis of a subspace.

```
> C := CuspidalSubspace(M);
> IntegralBasis(C);
[
    1/48*X^9*Y*{0, oo},
    1/14*X^8*Y^2*{0, oo}
]
```

In Remark 3 on page 69 of [Mer94], Merel says "it would be interesting to find a basis in terms of Manin symbols" for the **Z**-module of Eisenstein symbols (see Section 133.8 for the definition of `EisensteinSubspace`). Here are the first few examples in the case of level 1:

```
> M := ModularSymbols(1,12);
> E := EisensteinSubspace(M);
> IntegralBasis(E);
[
    691*X^10*{0, oo} + 1620*X^8*Y^2*{0, oo}
]
> ManinSymbol(IntegralBasis(E)[1]);
[
    <691*X^10, (0 1)>,
    <1620*X^8*Y^2, (0 1)>
]
```

To more easily compute several examples, we define a function:

```
> function EisZ(k)
```

```
>    E := EisensteinSubspace(ModularSymbols(1,k));
>    B := IntegralBasis(E);
>    return [ManinSymbol(z) : z in B];
> end function;
> EisZ(12);
[
    [
        <691*X^10, (0 1)>,
        <1620*X^8*Y^2, (0 1)>
    ]
]
> EisZ(16);
[
    [
        <16380*X^12*Y^2, (0 1)>,
        <3617*X^14, (0 1)>
    ]
]
> EisZ(18);
[
    [
        <43867*X^16, (0 1)>,
        <270000*X^14*Y^2, (0 1)>
    ]
]
> EisZ(20);
[
    [
        <174611*X^18, (0 1)>,
        <1349460*X^16*Y^2, (0 1)>
    ]
]
> EisZ(22);
[
    [
        <748125*X^18*Y^2, (0 1)>,
        <77683*X^20, (0 1)>
    ]
]
```

Send me an email if you determine the basis in general. In each example above the coefficient of X^{k-2} is, up to sign, `Numerator(Bernoulli(k)/k)`.

133.5 Associated Vector Space

The functions `VectorSpace`, `DualVectorSpace`, and `Lattice` return the underlying vector space, dual vector space, and lattice associated to a space of modular symbols. A space of modular symbols is represented internally as a subspace of a vector space, and a subspace of the linear dual of the vector space. To carry along the subspace of the linear dual is useful in many computations; one example is efficient computation of Hecke operators. When the base field is $\mathbf{Q}$, the lattice comes from the natural integral structure on modular symbols.

`VectorSpace(M)`

The vector space V underlying the space of modular symbols M, the map $V \to M$, and the map $M \to V$.

`DualVectorSpace(M)`

The subspace of the linear dual of `VectorSpace(AmbientSpace(M))` that is isomorphic to the space of modular symbols M as a module over the Hecke algebra.

`Lattice(M)`

The lattice generated by the integral modular symbols in the vector space representation of the space of modular symbols M. This is the lattice generated by all modular symbols $X^i Y^{k-2-i}\{a, b\}$. The base field of M must be `RationalField()`.

Example H133E8

```
> M := ModularSymbols(DirichletGroup(11).1,3); M;
Full modular symbols space of level 11, weight 3, character $.1, and
dimension 4 over Rational Field
> VectorSpace(M);

133.6 Degeneracy Maps

Consider an ambient space M_1 of modular symbols of level N_1, and suppose M_2 is an ambient space of modular symbols of level a multiple N_2 of N_1 whose weight equals the weight of M_1 and whose character is induced by the character of M_1. Then for each divisor d of N_2/N_1 there are natural maps $\alpha_d : M_1 \to M_2$ and $\beta_d : M_2 \to M_1$ such that $\beta_d \circ \alpha_d$ is multiplication by $d^{k-2} \cdot [\Gamma_0(N_1) : \Gamma_0(N_2)]$, where k is the common weight of M_1 and M_2. On cuspidal parts, the map β_d is dual to the map $f(q) \to f(q^d)$ on modular forms. Use the function `DegeneracyMap` to compute the maps α_d and β_d.

Given a space M of modular symbols and a positive integer N that is a multiple of the level of M, the images of M under the degeneracy maps generate a modular symbols space of level N. The constructor `ModularSymbols(M,N)` computes this space.

Let M be a space of modular symbols of level N, and let N' be a multiple of N. The subspace

$$\sum_{d \mid \frac{N'}{N}} \alpha_d(M) \subset \mathbf{M_k}(\mathbf{N}', \varepsilon)$$

is stable under the Hecke operators. Here is how to create this subspace using MAGMA:

```
> M := ModularSymbols(11,2); M;
Full modular symbols space for Gamma_0(11) of weight 2 and dimension 3
over Rational Field
> M33 := ModularSymbols(M,33); M33;
Modular symbols space for Gamma_0(33) of weight 2 and dimension 6 over
Rational Field
```

`DegeneracyMap(M1, M2, d)`

The degeneracy map $M_1 \to M_2$ of spaces of modular symbols associated to d. Let N_i be the level of M_i for $i = 1, 2$. Suppose that d is a divisor of either the numerator or denominator of the rational number N_1/N_2, written in reduced form. If $N_1 \mid N_2$, then this intrinsic returns $\alpha_d : M_1 \to M_2$, or if $N_2 \mid N_1$, then this intrinsic returns $\beta_d : M_1 \to M_2$. It is an error if neither divisibility holds.

`DegeneracyMatrix(M1, M2, d)`

Given spaces of modular symbols $M1$ and $M2$ and an integer d, return the matrix of `DegeneracyMap(M1,M2,d)` with respect to `Basis(M1)` and `Basis(M2)`. Both `IsAmbient(M1)` and `IsAmbient(M2)` must be true.

`ModularSymbols(M, N')`

The modular symbols space of level N' associated to M. Let N be the level of M. If $N \mid N'$, then this intrinsic returns the modular symbols space

$$\sum_{d \mid \frac{N'}{N}} \alpha_d(M).$$

If $N' \mid N$, then this intrinsic returns the modular symbols space

$$\sum_{d \mid \frac{N}{N'}} \beta_d(M).$$

In this latter case, if `Conductor(DirichletCharacter(M))` does not divide N', then the 0 space is returned.

`M1 !! M2`

The modular symbols subspace of M_1 associated to M_2. Let N_1 be the level of M_1. If `ModularSymbols(M2,N1)` is defined, let M_3 be this modular symbols space, otherwise terminate with an error. If M_3 is contained in M_1, return M_3, otherwise terminate with an error.

Example H133E9

We compute degeneracy maps α_2 and β_2.

```
> M15 := ModularSymbols(15);
> M30 := ModularSymbols(30);
> alp_2 := DegeneracyMap(M15,M30,2);
> alp_2(M15.1);
2*{oo, 0} + -1*{-1/28, 0} + -1*{-1/2, -7/15}
> beta_2 := DegeneracyMap(M30,M15,2);
> beta_2(alp_2(M15.1));
3*{oo, 0}
> M15.1;
{oo, 0}
```

We can consider the space generated by the image of a space of modular symbols of level 11 in spaces of higher level.

```
> X11 := ModularSymbols("11k2A");
> qEigenform(X11,6);
q - 2*q^2 - q^3 + 2*q^4 + q^5 + O(q^6)
```

```
> ModularSymbols(X11,33);
Modular symbols space for Gamma_0(33) of weight 2 and dimension 4 over
Rational Field
> X33 := ModularSymbols(X11,33);
> qExpansionBasis(X33,6);
[
    q - 2*q^2 + 2*q^4 + q^5 + O(q^6),
    q^3 + O(q^6)
]
> Factorization(CharacteristicPolynomial(HeckeOperator(X33,3)));
[
    <x^2 + x + 3, 2>
]
> ModularDegree(X33);
3
```

We can also construct the space generated by the images of `X11` at higher level using the `!!` operator.

```
> M44 := ModularSymbols(44,2);
> A := M44!!X11; A;
Modular symbols space for Gamma_0(44) of weight 2 and dimension 6 over
Rational Field
> X11!!A;       // back to the original space
Modular symbols space for Gamma_0(11) of weight 2 and dimension 2 over
Rational Field
```

133.7 Decomposition

The functions `Decomposition` and `NewformDecomposition` express a space of modular symbols as a direct sum of Hecke-stable subspaces.

In the intrinsics below, the `Proof` parameter affects the internal characteristic polynomial computations. If `Proof` is set to `false` and this causes a characteristic polynomial computation to fail, then the sum of the dimensions of the spaces returned by `Decomposition` will be less than the dimension of `M`. Thus setting `Proof` equal to `false` is usually safe.

`Decomposition(M, bound : parameters)`

`Proof` BoolElt *Default :* `true`

The decomposition of the space of modular symbols M with respect to the Hecke operators T_p with p coprime to the level of M and $p \leq$ `bound`. If `bound` is too small, the constituents of the decomposition are not guaranteed to be "irreducible", in the sense that they can not be decomposed further into kernels and images of Hecke operators T_p with p prime to the level of M. When `Decomposition` is called, the result is cached, so each successive call results in a possibly more refined decomposition.

Important Note: In some cases `NewformDecomposition` is significantly faster than `Decomposition`.

`NewformDecomposition(M : parameters)`

`Proof` BoolElt *Default :* `true`

Unsorted decomposition of the space of modular symbols M into factors corresponding to the Galois conjugacy classes of newforms of level some divisor of the level of M. We require that `IsCuspidal(M)` is `true`.

`AssociatedNewSpace(M)`

The space of modular symbols corresponding to the Galois-conjugacy class of newforms associated to the space of modular symbols M. The level of the newforms is allowed to be a proper divisor of the level of M. The space M must have been created using `NewformDecomposition`.

`SortDecomposition(D)`

Sort the sequence D of spaces of modular symbols with respect to the `lt` comparison operator.

`IsIrreducible(M)`

Returns `true` if and only if `Decomposition(M)` has cardinality 1.

`M1 lt M2`

The ordering on spaces of modular symbols is determined as follows:

(1) This rule applies only if `NewformDecomposition` was used to construct both of M_1 and M_2: If `Level(AssociatedNewSpace(M1))` is not equal to that of $M2$ then the M_i with larger associated level is first.

(2) The smaller dimension is first.

(3) The following applies when the weight is 2 and the character is trivial: Order by W_q eigenvalues, starting with the *smallest* $p \mid N$, with the eigenvalue $+1$ being less than the eigenvalue -1.

(4) Order by abs(trace(a_p)), with p not dividing the level, and with positive trace being smaller in the event that the two absolute values are equal.

Rule (3) is included so that our ordering extends the one used in (most of!) [Cre97].

Example H133E10

First, we compute the decomposition of the space of modular symbols of weight 2 and level 37.

```
> M := ModularSymbols(37,2); M;
Full modular symbols space for Gamma_0(37) of weight 2 and dimension 5
over Rational Field
> D := Decomposition(M,2); D;
[
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 1
     over Rational Field,
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field
]
> IsIrreducible(D[2]);
true
> C := CuspidalSubspace(M); C;
Modular symbols space for Gamma_0(37) of weight 2 and dimension 4 over
Rational Field
> N := NewformDecomposition(C); N;
[
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(37) of weight 2 and dimension 2
     over Rational Field
]
```

Next, we use `NewformDecomposition` to decompose a space having plentiful old subspaces.

```
> M := ModularSymbols(90,2); M;
Full modular symbols space for Gamma_0(90) of weight 2 and dimension
37 over Rational Field
> D := Decomposition(M,11); D;
[
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 11
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 4
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 4
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 8
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 6
     over Rational Field
```

```
]
> C := CuspidalSubspace(M); C;
Modular symbols space for Gamma_0(90) of weight 2 and dimension 22
over Rational Field
> N := NewformDecomposition(C); N;
[
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 4
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 4
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 8
     over Rational Field
]
```

The above decomposition uses all of the Hecke operator; it suggests that the decomposition `D` is not as fine as possible. Indeed, `D[7]` breaks up further:

```
> Decomposition(D[7],11);
[
    Modular symbols space for Gamma_0(90) of weight 2 and dimension 6
    over Rational Field
]
> Decomposition(D[7],19);
[
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 4
     over Rational Field,
     Modular symbols space for Gamma_0(90) of weight 2 and dimension 2
     over Rational Field
]
```

The function `AssociatedNewSpace` allows us to see where each of these subspace comes from. By definition they each arise by taking images under the degeneracy maps from a single Galois-conjugacy class of newforms of *some* level dividing 90.

```
> [Level(AssociatedNewSpace(A)) : A in N];
[ 90, 90, 90, 45, 30, 15 ]
> A := N[4];
> qEigenform(AssociatedNewSpace(A),7);
q + q^2 - q^4 - q^5 + O(q^7)
> qExpansionBasis(A,7);
[
    q - 2*q^4 - q^5 + O(q^7),
    q^2 + q^4 + O(q^7)
```

```
]
```

133.8 Subspaces

The following functions compute the cuspidal, Eisenstein, and new subspaces, along with the complement of a subspace.

`CuspidalSubspace(M)`

The cuspidal subspace of the space of modular symbols M. This is the kernel of `BoundaryMap(M)`.

`IsCuspidal(M)`

Returns `true` if and only if the space of modular symbols M is contained in the cuspidal subspace of the ambient space.

`EisensteinSubspace(M)`

The Eisenstein subspace of the space of modular symbols M. This is the complement in M of the cuspidal subspace of M.

`IsEisenstein(M)`

Returns `true` if and only if the space of modular symbols M is contained in the Eisenstein subspace of the ambient space.

`NewSubspace(M)`

The new subspace of the space of modular symbols M. This is the intersection of `NewSubspace(M,p)` as p varies over all prime divisors of the level of M. Note that M is required to be cuspidal.

`IsNew(M)`

Returns `true` if and only if the space of modular symbols M is contained in the new cuspidal subspace of the ambient space.

`NewSubspace(M, p)`

The p-new subspace of the space of modular symbols M. This is the kernel of the degeneracy map from M to the space of modular symbols of level equal to the level of M divided by p and character the restriction of the character of M. If the character of M does not restrict, then `NewSubspace(M,p)` is equal to M. Note that M is required to be cuspidal.

`Kernel(I, M)`

The kernel of I on the space of modular symbols M. Let T_p denote the pth Hecke operator (see Section 136.14). This is the subspace of M obtained by intersecting the kernels of the operators $f_n(T_{p_n})$, where I is a sequence $[\langle p_1, f_1(x)\rangle, ..., \langle p_n, f_n(x)\rangle]$ of pairs consisting of a prime number and a polynomial. Only primes p_i which do not divide the level of M are used.

`Complement(M)`

The space of modular symbols complementary to the space of modular symbols M in the ambient space of M. Thus the ambient space of M is equal to the direct sum of M and `Complement(M)`.

`BoundaryMap(M)`

A matrix that represents the boundary map from the space of modular symbols M to the vector space whose basis consists of the weight k cusps. (Note: At present there is no intrinsic that lists these cusps.)

Example H133E11

First we compute the cuspidal subspace of the space of modular symbols for $\Gamma_0(11)$.

```
> M := ModularSymbols(11,2); M;
Full modular symbols space for Gamma_0(11) of weight 2 and dimension 3
over Rational Field
> IsCuspidal(M);
false
> C := CuspidalSubspace(M); C;
Modular symbols space for Gamma_0(11) of weight 2 and dimension 2 over
Rational Field
> IsCuspidal(C);
true
```

Next we compute the Eisenstein subspace.

```
> IsEisenstein(C);
false
> E := EisensteinSubspace(M); E;
Modular symbols space for Gamma_0(11) of weight 2 and dimension 1 over
Rational Field
> IsEisenstein(E);
true
> E + C eq M;
true
```

The Eisenstein subspace is the complement of the cuspidal subspace, and conversely.

```
> E eq Complement(C);
true
> C eq Complement(E);
```

```
true
```

Example H133E12

```
> M := ModularSymbols("37B"); M;
Modular symbols space for Gamma_0(37) of weight 2 and dimension 2 over
Rational Field
> BoundaryMap(M);
[0 0]
[0 0]
> A := AmbientSpace(M);
> BoundaryMap(A);
[ 0  0]
[ 0  0]
[ 0  0]
[ 0  0]
[ 1 -1]
```

Observe that the Eisenstein subspace of A is not in the kernel of the boundary map.

```
> Basis(VectorSpace(EisensteinSubspace(A)));
[
    (0 0 0 1 3)
]
```

133.9 Twists

This section is about twists of newforms by Dirichlet characters. A newform is specified by giving a space of modular symbols that contains a single Galois-orbit (over $\mathbf{Q}$ or some extension of $\mathbf{Q}$) of newforms. Spaces of this kind are obtained using `NewformDecomposition`.

To prove that $f_2 = f_1^\chi$ holds for two newforms, the program compares their Hecke eigenvalues up to an appropriate Sturm bound. (For instance, a bound of this kind is given in Lemma 1.4 of [BS02]).

`IsTwist(M1, M2, p)`

Given two spaces `M1` and `M2` of modular symbols that specify newforms f_1 and f_2 as above, and a prime p, this determines whether some Galois conjugate (over $\mathbf{Q}$) of f_2 is the twist of f_1 by a nontrivial Dirichlet character of p-power conductor. If so, a character χ such that $f_2 = f_1^\chi$ is also returned.

`IsMinimalTwist(M, p)`

Given a space `M` of modular symbols that specifies a newform f as above, and a prime p, this determines whether some Galois conjugate (over $\mathbf{Q}$) of f is a twist of some newform of lower level by some Dirichlet character of p-power conductor. If so, it returns `false`, together with the newform of lower level (specified by a space of modular symbols), and the Dirichlet character.

Example H133E13

We exhibit a newform that is a twist of itself, namely the only newform of level 9 and weight 4. The newform is specified by the space of modular symbols on $\Gamma_0(9)$ of weight 4 (with sign 1).

```
> M9 := CuspidalSubspace(ModularSymbols(9, 4, 1));
> newforms := NewformDecomposition(NewSubspace(M9));
> newforms;
[
    Modular symbols space for Gamma_0(9) of weight 4 and dimension 1
    over Rational Field
]
> f := newforms[1];
> Eigenform(f, 20);
q - 8*q^4 + 20*q^7 - 70*q^13 + 64*q^16 + 56*q^19 + O(q^20)
```

Note that here the coefficients for primes congruent to 2 mod 3 are all zero.

```
> bool, chi := IsTwist(f, f, 3);
> bool;
true
> Parent(chi);
Group of Dirichlet characters of modulus 3 over Rational Field
> Conductor(chi), Order(chi);
3 2
```

However, f is not a twist of any newform with lower level:

```
> bool := IsMinimalTwist(f, 3);
> bool;
true
```

133.10 Operators

Each space $\mathbf{M}$ of modular symbols comes equipped with a commuting family $T_1, T_2, T_3, \ldots$ of linear operators acting on it called the Hecke operators.

The Hecke operators are defined recursively, as follows. First, $T_1 = 1$. When $n = p$ is prime,

$$T_p(x) = \left[\begin{pmatrix} p & 0 \\ 0 & 1 \end{pmatrix} + \sum_{r \bmod p} \begin{pmatrix} 1 & r \\ 0 & p \end{pmatrix} \right] x,$$

where the first matrix is omitted if p divides the level N of M. If m and n are coprime, then $T_{mn} = T_m T_n$. If p is a prime, $r \geq 2$ is an integer, ε is the Dirichlet character associated to M, and k is the weight of M, then

$$T_{p^r} = T_p T_{p^{r-1}} - \varepsilon(p) p^{k-1} T_{p^{r-2}}.$$

Example H133E14

In MAGMA, Hecke operators are represented as $n \times n$-matrices, acting from the right, with respect to the basis `Basis(M)`. For example

```
> M := ModularSymbols(12);
> T2 := HeckeOperator(M,2);
> M.1;
{oo, 0}
> T2;
[ 2  0 -1  0  0]
[ 2  0 -1  0  0]
[ 0  0  1 -2 -2]
[ 0 -1  1 -1 -2]
[ 0  1 -1  1  2]
> M.1*T2;
2*{oo, 0} + -1*{-1/10, 0}
```

`HeckeOperator(M, n)`

Compute a matrix representing the nth Hecke operator T_n with respect to `Basis(M)` where M is a space of modular symbols.

`HeckePolynomial(M, n)`

Compute the characteristic polynomial of the Hecke operator T_n with respect to the space of modular symbols M. When n is prime, the Deligne bound on the sizes of Hecke eigenvalues is used, so `HeckePolynomial` is frequently much faster than `CharacteristicPolynomial(HeckeOperator(M,n))`.

`IntegralHeckeOperator(M, n)`

A matrix representing the nth Hecke operator with respect to `Basis(Lattice(M))` where M is a space of modular symbols.

`DualHeckeOperator(M, n)`

Compute a matrix representing the Hecke operator T_n on the dual vector space representation of the space of modular symbols M. This function is much more efficient than `HeckeOperator(M,n)` when the dimension of M is small relative to the dimension of the `AmbientSpace(M)`. Note that `DualHeckeOperator(M,n)` is not guaranteed to be the transpose of `HeckeOperator(M,n)` because `DualHeckeOperator(M,n)` is computed with respect to `Basis(DualVectorSpace(M))`.

`AtkinLehner(M, q)`

A matrix representing the qth Atkin-Lehner involution W_q on the space of modular symbols M, when it is defined. The involution W_q is defined when M has trivial character and even weight. When possible, the Atkin-Lehner map is normalized so that it is an involution; such normalization may not be possible when $k > 2$ and the characteristic of the base field of M divides q.

To each divisor q of N such that $\gcd(q, N/q) = 1$ there is an *Atkin-Lehner involution* W_q on M, which is defined as follows. Using the Euclidean algorithm, choose integers x, y, z, w such that $qxw - (N/q)yz = 1$; let $g = \begin{pmatrix} dx & y \\ Nz & qw \end{pmatrix}$ and define

$$W_q(x) = g(x)/q^{\frac{k-2}{2}}.$$

For example, when $q = N$ we have $g = \begin{pmatrix} 0 & -1 \\ N & 0 \end{pmatrix}$.

`DualAtkinLehner(M, q)`

The action of the Atkin-Lehner involution on the dual representation of the space of modular symbols M, when it is defined.

`StarInvolution(M)`

The conjugation involution $*$ on the space of modular symbols M that sends the modular symbol $X^iY^j\{u, v\}$ to $(-1)^j X^iY^j\{-u, -v\}$.

`DualStarInvolution(M)`

The conjugation involution $*$ on the dual representation of the space of modular symbols M (see the documentation for `StarInvolution`.)

`ThetaOperator(M1, M2)`

Multiplication by $X^pY - XY^p$, which is a possible analogue of the θ-operator. (On mod p modular forms, the θ-operator is the map given by $f \mapsto q\frac{df}{dq}$.) Both M_1 and M_2 must be spaces of modular symbols over a field of positive characteristic p; they must have the same level and character, and the weight of M_2 must equal the weight of M_1 plus $p + 1$.

Example H133E15

```
> M := ModularSymbols(11,4,+1); M;
Full modular symbols space for Gamma_0(11) of weight 4 and dimension 4
over Rational Field
> HeckeOperator(M,2);
[   9    0  2/5 -2/5]
[   0    5  9/5 11/5]
[   0    5  7/5 13/5]
```

```
[   0    0 22/5 23/5]
```

The entries of T_2 are not guaranteed to be integers because `Basis(M)` is just a basis of a $\mathbf{Q}$-vector space. The entries will be integers if we compute T_2 with respect to an integral basis.

```
> IntegralHeckeOperator(M,2);
[ 0  2  0  0]
[ 1  2  0  0]
[-5  6  9  0]
[ 2  0  0  9]
```

The matrix for the Hecke operator on the dual of M is the transpose of T_2. However, the chosen basis for the cuspidal subspace of the dual of M need not satisfy any compatibility with `CuspidalSubspace(M)`.

```
> DualHeckeOperator(M,2);
[   9    0    0    0]
[   0    5    5    0]
[ 2/5  9/5  7/5 22/5]
[-2/5 11/5 13/5 23/5]
> S := CuspidalSubspace(M);
> HeckeOperator(S, 2);
[    5 -13/5]
[    5    -3]
> DualHeckeOperator(S, 2);
[-3/4  1/8]
[-1/2 11/4]
> // NOT the transpose!
```

We can also compute the Atkin-Lehner and the $*$-involution. The $*$-involution is the identity because we are working in the $+1$-quotient, which is the largest quotient of `ModularSymbols(11,4)` where $*$ acts as $+1$.

```
> AtkinLehner(S, 11);
[1 0]
[0 1]
> StarInvolution(S);
[1 0]
[0 1]
```

On the -1 quotient the Atkin-Lehner involution is the same, but $*$ acts as -1:

```
> M := ModularSymbols(11,4,-1); M;
Full modular symbols space for Gamma_0(11) of weight 4 and dimension 2
over Rational Field
> S := CuspidalSubspace(M);
> AtkinLehner(S, 11);
[1 0]
[0 1]
> StarInvolution(S);
[-1  0]
```

```
[ 0 -1]
```

Example H133E16

We compute an example of our analogue of the θ-operator on modular symbols.

```
> N := 11; p := 3;
> k1 := 2; k2 := k1 + (p+1);
> M1 := ModularSymbols(11,k1,GF(p));
> M2 := ModularSymbols(11,k2,GF(p));
> theta  := ThetaOperator(M1,M2); theta;
Mapping from: ModSym: M1 to ModSym: M2 given by a rule [no inverse]
```

Now that we have computed `theta`, we can apply it to one of the modular symbols corresponding to the newform in $S_2(\Gamma_0(11))$.

```
> D := Decomposition(M1,2);
> f := qEigenform(D[2],10); f;
q + q^2 + 2*q^3 + 2*q^4 + q^5 + 2*q^6 + q^7 + q^9 + O(q^10)
> x := D[2].1;
> y := theta(x); y;
(X^4 + X*Y^3)*{-1/7, 0} + (X^4 + X^3*Y + X*Y^3 + Y^4)*{-1/7, 0} + (X^4
+ 2*X^3*Y + 2*X*Y^3 + Y^4)*{-1/5, 0} + Y^4*{oo, 0}
```

Finally, we verify for $n < 10$ that the nth Hecke eigenvalue of $y = \theta(x)$ equals $n \cdot a_n(f)$, where f is as above.

```
> [y*HeckeOperator(M2,n) - n*Coefficient(f,n)*y : n in [1..9]];
[
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    0
]
```

133.11 The Hecke Algebra

`HeckeBound(M)`

A positive integer n such that the Hecke operators $T_1, \ldots, T_n$ generate the Hecke algebra as a $\mathbf{Z}$-module. When the character is trivial, the default bound is $(k/12) \cdot [\mathrm{SL}_2(\mathbf{Z}) : \Gamma_0(N)]$. That this suffices follows from [Stu87], as is explained in [AS02]. When the character of the space of modular symbols M is nontrivial, the default bound is twice the above bound; however, *it is not known that this bound is large enough in all cases in which the character is nontrivial*, so one may wish to increase the bound using `SetHeckeBound`.

`SetHeckeBound(M, n)`

Many computations require a bound n such that $T_1, \ldots, T_n$ generate the Hecke algebra associated to the space of modular symbols M as a $\mathbf{Z}$-module. This command allows you to set the bound that is used internally. Setting it too low can result in functions quickly producing incorrect results.

`HeckeAlgebra(M : Bound)`

The Hecke algebra associated to the space of modular symbols M. This is an algebra `TQ` over $\mathbf{Q}$, such that `Generators(TQ)` is a set that generates the ring $\mathbf{Z}[T_1, T_2, T_3, \ldots]$, as a $\mathbf{Z}$-module. If the optional integer parameter `Bound` is set, then `HeckeAlgebra` only computes the algebra generated by those T_n, with $n \leq$ `Bound`.

`DiscriminantOfHeckeAlgebra(M : Bound)`

The discriminant of the Hecke algebra associated to the space of modular symbols M. If the optional parameter `Bound` is set, then the discriminant of the algebra generated by only those T_n, with $n \leq$ `Bound`, is computed instead.

`HeckeEigenvalueRing(M : parameters)`

`Bound` RngIntElt *Default :* -1

The order generated by the Fourier coefficients of one of the q-expansions of a newform corresponding to the space of modular symbols M, along with a map from the ring containing the coefficients of `qExpansion(A)` to the order. If the optional parameter `Bound` is set, then the order generated only by those a_n, with $n \leq$ `Bound`, is computed.

`HeckeEigenvalueField(M)`

The number field generated by the Fourier coefficients of one of the q-expansions of a newform corresponding to the space of modular symbols M, along with a map from the ring containing the coefficients of `qExpansion(M)` to the number field. We require that M be defined over $\mathbf{Q}$.

Example H133E17

In this example, we compute the discriminant of the Hecke algebra of prime level 389.

```
> M := ModularSymbols(389,2,+1);
> C := CuspidalSubspace(M);
> DiscriminantOfHeckeAlgebra(C);
629670054720061882880174736321392595498204931550235108311040000000
> Factorization($1);
[ <2, 53>, <3, 4>, <5, 6>, <31, 2>, <37, 1>, <389, 1>, <3881, 1>,
<215517113148241, 1>, <477439237737571441, 1> ]
```

The prime 389 is the only prime $p < 10000$ such that p divides the discriminant of the Hecke algebra associated to $S_2(\Gamma_0(p))$. It is an open problem to decide whether or not there are any other such primes. Are there infinitely many?

133.12 The Intersection Pairing

MAGMA can compute the intersection pairing

$$H_1(X_0(N), \mathbf{Q}) \times H_1(X_0(N), \mathbf{Q}) \to \mathbf{Q}$$

on the homology of the modular curve $X_0(N)$. The algorithm that we implemented is essentially the one given in [Mer93]. (Warning: There is a typo in Proposition 4 of [Mer93]; W_i should be replaced by $W_i^{\varepsilon_i}$.)

`IntersectionPairing(x, y)`

The intersection pairing of the homology classes corresponding to the weight-2 cuspidal modular symbols x and y. The symbols x and y must have the same parent, which must have trivial character and not be a $+1$ or -1 quotient.

Example H133E18

In this example, we illustrate several basic properties of the intersection pairing on $H_1(X_0(37), \mathbf{Z})$. First, let `H37` be the space of modular symbols that corresponds to $H_1(X_0(37), \mathbf{Z})$, and compute a basis for `H37`.

```
> M37 := ModularSymbols(37,2);
> H37 := CuspidalSubspace(M37);
> Z := IntegralBasis(H37); Z;
[
    {-1/29, 0},
    {-1/22, 0},
    {-1/12, 0},
    {-1/18, 0}
]
```

Now we compute some intersection numbers.

```
> IntersectionPairing(Z[1],Z[2]);
```

```
-1
> IntersectionPairing(Z[3],Z[4]);
0
```

The intersection pairing is perfect and skew-symmetric, so the matrix that defines it is skew-symmetric and has determinant ± 1 (in fact, it has determinant $+1$).

```
> A := MatrixAlgebra(RationalField(),4);
> I := A![IntersectionPairing(x,y) : x in Z, y in Z]; I;
[ 0  1  0  1]
[-1  0  1  1]
[ 0 -1  0  0]
[-1 -1  0  0]
> I + Transpose(I) eq 0;
true
> Determinant(I);
1
```

The Hecke operators are compatible with the intersection pairing in the sense that $(T_n x, y) = (x, T_n y)$.

```
> T2 := HeckeOperator(M37,2);
> IntersectionPairing(Z[1]*T2,Z[2]);
1
> IntersectionPairing(Z[1],Z[2]*T2);
1
```

It is note the case $(T_n x, T_n y) = (x, y)$ for all n, x, and y.

```
> IntersectionPairing(Z[1]*T2,Z[2]*T2);
-2
```

The existence of the intersection pairing implies that $H_1(X_0(N), \mathbf{Z})$ is isomorphic, as a module over the Hecke algebra, to its linear dual $\mathrm{Hom}(H_1(X_0(N), \mathbf{Z}), \mathbf{Z})$.

133.13 q-Expansions

The following functions should only be called on modular symbols spaces that are cuspidal. For q-expansions of Eisenstein series, use the modular forms functions instead (see the example below).

`Eigenform(M, prec)`

`Eigenform(M)`

`qEigenform(M, prec)`

`qEigenform(M)`

`PowerSeries(M, prec)`

`PowerSeries(M)`

The q-expansion of one of the Galois-conjugate newforms associated to the irreducible cuspidal space M of modular symbols, computed to absolute precision *prec* (which defaults to the highest precision computed in previous calls to this intrinsic, or 8 if none have been computed). The coefficients of the q-expansion lie in a quotient of a polynomial extension of the base field of M. In most cases, it is necessary for M to have been defined using `NewformDecomposition`.

`qExpansionBasis(M, prec : parameters)`

`Al` MonStgElt *Default :* "$Newform$"

The reduced row-echelon basis of q-expansions for the space of modular forms associated to M, where K is the base field of M. The absolute precision of the q-expansions is *prec*.

The optional parameter `Al` can take the values `"Newform"` and `"Universal"`. The default is `"Newform"`, which computes a basis of q-expansions by finding a decomposition of M into subspaces corresponding to newforms, computing their q-expansions, and then taking all of their images under the degeneracy maps. If `Al := "Universal"` then the algorithm of Section 4.3 of [Mer94] is used. This latter algorithm does not require computing a newform decomposition of M, but requires computing the action of many more Hecke operators. Consequently, in practice, our implementation of Merel's algorithm is usually less efficient than our implementation of the newform algorithm.

`qIntegralBasis(M)`

`qIntegralBasis(M, prec)`

`qIntegralBasis(seq, prec)`

`Al` MonStgElt *Default :* "$Newform$"

The reduced integral basis of q-expansions for the space of modular forms associated to the given space M of modular symbols (or the given sequence of spaces). The q-expansions are computed to absolute precision *prec*. The base field of M must be either the rationals or a cyclotomic field.

`SystemOfEigenvalues(M, prec)`

The sequence of Hecke eigenvalues $[a_2, a_3, a_5, a_7, \ldots, a_p]$ attached to the space of modular symbols M, where p is the largest prime less than or equal to *prec*. Let K be the base field of M. Then the a_ℓ either lie in K or an extension of K (which may be constructed either as a number field or as a quotient of $K[x]$). We assume that M corresponds to a single Galois-conjugacy class of newforms.

Example H133E19

First we compute a q-basis and a representative newform for the two-dimensional space $S_2(\Gamma_0(23))$. We work in the $+1$ quotient of modular symbols since, for the purpose of computing q-expansions, nothing is lost and many algorithms are more efficient.

```
> M := CuspidalSubspace(ModularSymbols(23,2, +1));
> qExpansionBasis(M);
[
    q - q^3 - q^4 - 2*q^6 + 2*q^7 + O(q^8),
    q^2 - 2*q^3 - q^4 + 2*q^5 + q^6 + 2*q^7 + O(q^8)
]
> f := qEigenform(M,6); f;
q + a*q^2 + (-2*a - 1)*q^3 + (-a - 1)*q^4 + 2*a*q^5 + O(q^6)
> Parent(f);
Power series ring in q over Univariate Quotient Polynomial Algebra
in a over Rational Field with modulus a^2 + a - 1
> PowerSeries(M);
q + a*q^2 + (-2*a - 1)*q^3 + (-a - 1)*q^4 + 2*a*q^5 + (a - 2)*q^6 +
    (2*a + 2)*q^7 + O(q^8)
> SystemOfEigenvalues(M, 7);
[
    a,
    -2*a - 1,
    2*a,
    2*a + 2
]
```

Next we compare an integral and rational basis of q-expansions for $S_2(\Gamma_0(65))$, computed using modular symbols.

```
> S := CuspidalSubspace(ModularSymbols(65,2,+1));
> qExpansionBasis(S);
[
    q + 1/3*q^6 + 1/3*q^7 + O(q^8),
    q^2 - 1/3*q^6 + 2/3*q^7 + O(q^8),
    q^3 - 4/3*q^6 + 2/3*q^7 + O(q^8),
    q^4 - 1/3*q^6 + 5/3*q^7 + O(q^8),
    q^5 + 5/3*q^6 + 2/3*q^7 + O(q^8)
]
> qIntegralBasis(S);
[
    q + q^5 + 2*q^6 + q^7 + O(q^8),
    q^2 + 2*q^5 + 3*q^6 + 2*q^7 + O(q^8),
    q^3 + 2*q^5 + 2*q^6 + 2*q^7 + O(q^8),
    q^4 + 2*q^5 + 3*q^6 + 3*q^7 + O(q^8),
    3*q^5 + 5*q^6 + 2*q^7 + O(q^8)
```

```
]
```

If you're interested in q-expansions of Eisenstein series, see the chapter on modular forms. For example:

```
> E := EisensteinSubspace(ModularForms(65,2));
> Basis(E);
[
    1 + O(q^8),
    q + 3*q^2 + 4*q^3 + 7*q^4 + 12*q^6 + 8*q^7 + O(q^8),
    q^5 + O(q^8)
]
```

133.14 Special Values of L-functions

Let M be an irreducible space of cuspidal modular symbols defined over $\mathbf{Q}$, irreducible in the sense that M corresponds to a single Galois-conjugacy class of cuspidal newforms. Such an M can be computed using `NewformDecomposition`. Let $f^{(1)}, \ldots, f^{(d)}$ be the $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$-conjugate newforms that correspond to M, and write $f^{(d)} = \sum_{n=1}^{\infty} a_n^{(d)} q^n$. By a theorem of Hecke, the Dirichlet series

$$L(f^{(i)}, s) = \sum_{n=1}^{\infty} \frac{a_n^{(i)}}{n^s}$$

extends (uniquely) to a holomorphic function on the whole complex plane. Of particular interest is the special value

$$L(M, j) = L(f^{(1)}, j) \cdots L(f^{(d)}, j),$$

for any $j \in \{1, 2, \ldots, k-1\}$.

In this section we describe how to approximate the complex numbers $L(M, j)$ in Magma. If you are interested in computing individual special values $L(f^{(i)}, j)$, then you should use the modular forms package instead of the modular symbols package for this.

The variable `prec` below refers to the number of terms of the q-expansion of each $f^{(i)}$ that are used in the computation, and not to the number of decimals of the answer that are correct. Thus, for example, to get a heuristic idea of the quality of an answer, you can increase `prec`, make another call to `LSeries`, and observe the difference between the two answers. If the difference is "small", then the approximation is probably "good".

`LSeries(M, j, prec)`

The special value $L(M, j)$, where j is an integer that lies in the critical strip, so $1 \leq j \leq k-1$ with k the weight of M. Here M is a space of modular symbols with sign 0, and *prec* is a positive integer which specifies the numbers of terms of q-expansions to use in the computation.

`LSeriesLeadingCoefficient(M, j, prec)`

The leading coefficient of Taylor expansion about the critical integer j and order of vanishing of $L(M,s)$ at $s=1$. Thus if the series expansion of $L(M,s)$ about $s=1$ is

$$L(M,s) = a_r(s-1)^r + a_{r+1}(s-1)^{r+1} + a_{r+2}(s-1)^{r+2} + \cdots,$$

then the leading coefficient of $L(M,s)$ is a_r and the order of vanishing is r.

`RealVolume(M, prec)`

The volume of $A_M(\mathbf{R})$, which is defined as follows. Let $S \subset \mathbf{C}[[q]]$ be the space of cusp forms associated to M. Choose a basis $f_1, \ldots, f_d$ for the free $\mathbf{Z}$-module $S \cap \mathbf{Z}[[q]]$; one can prove that $f_1, \ldots, f_d$ is also a basis for S. There is a period map Φ from integral cuspidal modular symbols H to $\mathbf{C}^d$ that sends a modular symbol $x \in H$ to the d-tuple of integrals $(\langle f_1, x\rangle, \ldots, \langle f_d, x\rangle) \in \mathbf{C}^d$. The cokernel of Φ is isomorphic to $A_M(\mathbf{C})$. Moreover, the standard measure on the Euclidean space $\mathbf{C}^d$ induces a measure on $A_M(\mathbf{R})$. It is with respect to this measure that we compute the volume. For more details, see Section 3.12.16 of [Ste00].

`MinusVolume(M, prec)`

The volume of the subgroup of $A_M(\mathbf{C})$ on which complex conjugation acts as -1.

`LRatio(M, j : parameters)`

`Bound` RngIntElt *Default :* -1

The rational number

$$\frac{L(A,j)\cdot(j-1)!}{(2\pi)^{j-1}\cdot\Omega,}$$

where j is a "critical integer", so $1 \le j \le k-1$, and Ω is `RealVolume(M)` when j is odd and `MinusVolume(M)` when j is even. If the optional parameter Bound is set, then `LRatio` is only a divisibility upper bound on the above rational number. If `Sign(M)` is not 0, then `LRatio(M,j)` is only correct up to a power of 2.

`LRatioOddPart(M, j)`

The odd part of the rational number `LRatio(M,j)`. Hopefully, computing `LRatioOddPart(M,j)` takes less time than finding the odd part of `LRatio(M,j)`.

Example H133E20

```
> M := ModularSymbols(11,2);
> C := CuspidalSubspace(M);
> LSeries(C,1,100);
0.25384186085591068433775892 33
> A := ModularSymbols("65B"); A;  // <--> dimension two abelian variety
Modular symbols space of level 65, weight 2, and dimension 4
> LSeries(A,1,100);
0.91225158869818984109351402 11 +  0.E-29*i
```

133.14.1 Winding Elements

Let $\mathbf{M_k(N)}$ be a space of modular symbols over $\mathbf{Q}$. For $i = 1, \ldots, k$, the *ith winding element*

$$\mathbf{e}_i = X^{i-1}Y^{k-2-(i-1)}\{0, \infty\} \in \mathbf{M_k(N)}$$

is of importance for the computation of special values. For any modular form $f \in S_k(N)$ and homogeneous polynomial $P(X, Y)$ of degree $k-2$, let

$$\langle f, P(X,Y)\{0,\infty\}\rangle = -2\pi i \cdot \int_0^{i\infty} f(z)P(z,1)\mathrm{dz}.$$

Fix a newform $f \in S_k(N)$ corresponding to a space M of modular symbols, and let j be a integer in $\{0, 1, \ldots, k-1\}$. The winding element is significant because

$$L(f, j) = \frac{(2\pi)^{j-1}}{i^{j+1}(j-1)!} \cdot \langle f, X^{j-1}Y^{k-2-(j-1)}\{0,\infty\}\rangle.$$

Moreover, the submodule that is generated by the winding element is used in the formula for a canonical rational part of the number $L(M, j)$ (see `LRatio`, above).

`WindingElement(M)`

The winding element $Y^{k-2}\{0, \infty\}$.

`WindingElement(M, i)`

The winding element $X^{i-1}Y^{k-2-(i-1)}\{0, \infty\}$.

`TwistedWindingElement(M, i, eps)`

The element $\sum_{a\in(\mathbf{Z}/m\mathbf{Z})^*} \varepsilon(a)X^{i-1}Y^{k-2-(i-1)}\{0, \frac{a}{m}\}$.

`WindingLattice(M, j :` *parameters*`)`

`Bound` RngIntElt *Default :* -1

The image under `RationalMapping(M)` of the lattice generated by the images of the jth winding element under all Hecke operators T_n. If M is the ambient space, then the image under `RationalMapping(M)` is not taken.

`WindingSubmodule(M, j :` *parameters*`)`

`Bound` RngIntElt *Default :* -1

The image under `RationalMapping(M)` of the vector space generated by all images of `WindingElement(M,j)` under all Hecke operators T_n. If M is the ambient space, then the image under the rational period mapping is not taken.

`TwistedWindingSubmodule(M, j, eps)`

The Hecke submodule of the vector space $\Phi(M)$ generated by the image of the jth ε-twisted modular winding element, where Φ is `RationalMapping(M)`. This module is useful, for example, because in characteristic 0, if M is new of weight 2, has sign $+1$ or -1, and corresponds to a collection $\{f_i\}$ of Galois-conjugate newforms, then the dimension of the twisted winding submodule equals the cardinality of the subset of f_i such that $L(f_i, eps, 1) \neq 0$.

133.15 The Associated Complex Torus

Let M be a space of cuspidal modular symbols, which is the kernel of an ideal in the Hecke algebra. When M has weight 2 there is an abelian variety A_M attached to M; more generally, there is a complex torus $A_M(\mathbf{C})$ attached to M. The associated complex torus $A_M(\mathbf{C})$ is constructed as follows. Let S be the space of modular forms corresponding to M. The integration pairing gives rise to a natural map $M \to \mathrm{Hom}(S, \mathbf{C})$, and the cokernel of this map is $A_M(\mathbf{C})$.

`SubgroupOfTorus(M, x)`

The cyclic subgroup of the complex torus attached to the space of modular symbols M that is generated by the image under the period map of the modular symbol x.

`SubgroupOfTorus(M, s)`

An abelian group that is isomorphic to the finite group generated by the sequence of images $\pi(s[i])$ in the complex torus attached to M, where π is `PeriodMapping(M)`.

Example H133E21

The cuspidal subgroup of $J_0(N)$ is the subgroup generated by the degree 0 divisors on $X_0(N)$ of the form $(\alpha) - (\beta)$, where α and β are cusps. The following examples illustrate how to use the above functions to compute the cuspidal subgroup, as an abstract abelian group.
The modular symbols approach has the advantage that it is essentially no more complicated for N highly composite than for N prime. However, it is only applicable when the corresponding space of modular symbols can be computed in a reasonable amount of time, which at present means that N should have less than 5 decimal digits. There are other methods which may be much more efficient in special cases. For example, when p is prime Andrew Ogg showed that the cuspidal subgroup of $J_0(p)$ is cyclic of order equal to the numerator of $(p-1)/12$. More generally, he gave a simple formula for the order of the cuspidal subgroup when $N = pq$ is the product of two primes. See also papers of Ligozat.

```
> M := ModularSymbols(20); M;
Full Modular symbols space of level 20, weight 2, and dimension 7
> e := M ! <1, [Cusps()|0,Infinity()] >;   // the path from 0 to infinity
> e;
-1*{oo, 0}
> J0of20 := CuspidalSubspace(M);
```

```
> A := SubgroupOfTorus(J0of20, e); A;
Abelian Group isomorphic to Z/6
Defined on 1 generator
Relations:
    6*A.1 = 0
> // Next, the subgroup generated by all cusps
> A := SubgroupOfTorus(J0of20, IntegralBasis(M));  A;
Abelian Group isomorphic to Z/6
Defined on 1 generator
Relations:
    6*A.1 = 0
> // Let's do another example.
> M := ModularSymbols(100);
> J0of100 := CuspidalSubspace(M);
> A := SubgroupOfTorus(J0of100, IntegralBasis(M));  A;
Abelian Group isomorphic to Z/6 + Z/30 + Z/30 + Z/30 + Z/30
Defined on 5 generators
Relations:
    6*A.1 = 0
    30*A.2 = 0
    30*A.3 = 0
    30*A.4 = 0
    30*A.5 = 0
> M := ModularSymbols(77);
> J0of77 := CuspidalSubspace(M);
> A := SubgroupOfTorus(J0of77, IntegralBasis(M)); A;

> Numerator((97-1)/12);
8
```

Example H133E22

The following code creates a file that contains a table which lists, for each integer N in some range, the abstract group structure of the subgroup of $J_0(N) = \mathrm{Jac}(X_0(N))$ generated by the cusps $(\alpha) - (\infty)$, with $\alpha \in \mathbf{Q} \cup \{\infty\}$.

```
> function CuspidalSubgroup(N)
>    M := ModularSymbols(N);
```

```
>    J := CuspidalSubspace(M);
>    G := SubgroupOfTorus(J,IntegralBasis(M));
>    return G;
> end function;
> // Test the function
> CuspidalSubgroup(65);
Abelian Group isomorphic to Z/2 + Z/84
Defined on 2 generators
Relations:
    2*$.1 = 0
    84*$.2 = 0
> procedure CuspidalTable(start, stop)
>    fname := Sprintf("cuspidal_subgroup_%o-%o.m", start, stop);
>    file  := Open(fname,"w");
>       for N in [start..stop] do
>       G := Invariants(CuspidalSubgroup(N));
>       fprintf file, "C[%o] := \t%o;\n\n", N, G;
>       printf "C[%o] := \t%o;\n\n", N, G;
>       Flush(file);
>    end for;
> end procedure;
```

`ModularKernel(M)`

The kernel of the modular isogeny. Let T be the complex torus attached to the space of modular symbols M. Then the modular isogeny is the natural map from the dual of T into T induced by autoduality of `CuspidalSubspace(AmbientSpace(M))`.

`CongruenceGroup(M` : *parameters*`)`

`Bound` RngIntElt *Default :* -1

The congruence group of the space of cusp forms corresponding to the space of cuspidal modular symbols M. Let $S = S_k(\Gamma_0(N), \mathbf{Z})$, let V be the sub $\mathbf{Z}$-module corresponding to M, and W be its orthogonal complement. Then the congruence group is $S/(V + W)$. This group encodes information about congruences between forms in V and forms in the complement of V.

The optional parameter `Bound` is a positive integer b such that the q-expansions of cusp forms are computed to absolute precision b. If the bound is too small, then `CongruenceGroup` will give only an upper bound on the correct answer. The default is `HeckeBound(M) + 1`, which gives a provably correct answer.

`IntersectionGroup(M1, M2)`

An abelian group G that encodes information about the intersection of the complex tori corresponding to the spaces of modular symbols M_1 and M_2. We require that M_1 and M_2 lie in a common ambient space. When the `IntersectionGroup(M1,M2)` is finite, it is isomorphic to $A_{M_1}(\mathbf{C}) \cap A_{M_2}(\mathbf{C})$.

`IntersectionGroup(S)`

An abelian group G that encodes information about the intersection of the collection of complex tori corresponding to the sequence S of spaces of modular symbols.

Example H133E23

In this example, we investigate a 2-dimensional abelian variety B, which is a quotient of $J_0(43)$. The purpose of this example is to show how numerical computation with modular symbols suggests interesting arithmetic questions about familiar abelian varieties. In the following example, we find that the conjecture of Birch and Swinnerton-Dyer (plus the Manin $c = 1$ conjecture) implies that the first nontrivial Shafarevich-Tate group of an (optimal) modular abelian variety has order *two*. Thus the surprising existence of an abelian varieties with non-square order could have been (but was not) hinted at long ago by somebody playing around with a modular symbols package (in fact, it was discovered by B. Poonen and M. Stoll [PS99] while they were designing and implementing algorithms for computing with Jacobians of genus-two curves).

```
> M43 := ModularSymbols(43,2);     // Level 43, weight 2.
> H1  := CuspidalSubspace(M43);    // H_1(X_0(43),Q)
> D   := NewformDecomposition(H1); // factors corresponding to newforms
> A,B := Explode(D);
> A;     // The homology of the elliptic curve "43A"
Modular symbols space of level 43, weight 2, and dimension 2
> B;     // The homology of the 2-dimensional abelian variety "43B"
Modular symbols space of level 43, weight 2, and dimension 4
> LRatio(B,1);        // L(B,1)/Omega_B
2/7
```

The Birch and Swinnerton-Dyer conjecture predicts that the Shafarevich-Tate group of B has order as given by the formula for `ShaAn` in the code below. To compute this value, it remains to compute $\#B(\mathbf{Q})$ and the Tamagawa number c_{43}.

```
> T := TorsionBound(B,11);  T; // #B(Q) divides this number
7
> // Compute the subgroup of B(Q) generated by (0)-(oo).
> C := SubgroupOfTorus(B,WindingElement(M43));  C;
Abelian Group isomorphic to Z/7
Defined on 1 generator
Relations:
    7*C.1 = 0
> TamagawaNumber(B,43);
7
> ShaAn := LRatio(B,1)*TorsionBound(B,11)^2/TamagawaNumber(B,43);
```

`ShaAn` is the Birch and Swinnerton-Dyer conjectural order of the Shafarevich-Tate group of B, under the assumption that the Manin constant of B is 1.

```
> ShaAn;
2
```

One of the Galois conjugate newforms associated to B is given below.

```
> qEigenform(B,12);
```

```
q + a*q^2 - a*q^3 + (-a + 2)*q^5 - 2*q^6 + (a - 2)*q^7 - 2*a*q^8 - q^9
    + (2*a - 2)*q^10 + (2*a - 1)*q^11 + O(q^12)
> BaseRing(Parent(qEigenform(B,12)));
Univariate Quotient Polynomial Algebra in a over Rational Field
with modulus a^2 - 2
> qIntegralBasis(B,12);
[
    q + 2*q^5 - 2*q^6 - 2*q^7 - q^9 - 2*q^10 - q^11 + O(q^12),
    q^2 - q^3 - q^5 + q^7 - 2*q^8 + 2*q^10 + 2*q^11 + O(q^12)
]
```

By integrating homology against the differentials corresponding to the two modular forms above, we obtain a lattice that defines the complex torus $A_B(\mathbf{C})$:

```
> Periods(B,97);
[
    (-0.22594995830676421187395192 -
        1.76664467629959953227333314 0*i
        0.52502811591322194337294916 48 +
        0.80660185770293072302831423 71*i),
    (0.59815631622412229864757672 20 -
        1.92008563861211949327648563 2*i
        0.82410627422619603486491720 82 -
        0.15344096225717705687483549 95*i),
    (-0.82410627453088651052152864 45 -
        0.15344096231251996100315249 20*i
        -0.29907815831297409149196804 34 -
        0.96004281996010777990314973 67*i),
    (-0.59815631622412229864757672 20 -
        1.92008563861211949327648563 2*i
        -0.82410627422619603486491720 83 -
        0.15344096225717705687483549 95*i)
]
```

Finally, it is tempting to ask whether or not the (conjectural) two-torsion element of the Shafarevich-Tate group of B suggested above is "visible" in the sense that it is "explained by a jump in the rank of the Mordell-Weil group of A" (see [CM00]). The following computation suggests, but does not prove, that this is the case.

```
> G := MordellWeilGroup(EllipticCurve(A)); G;
Abelian Group isomorphic to Z
Defined on 1 generator (free)
> IntersectionGroup(A,B);
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0
```

133.15.1 The Period Map

Let M be a space of modular symbols the corresponds to a Galois-conjugacy class of newforms. The *period map* attached to M is a linear map

$$\text{AmbientSpace(M)} \to \mathbf{C}^d,$$

where d is the dimension of the space of modular forms associated to M. The cokernel of the period map is a complex torus $A_M(\mathbf{C})$. The terminology "period mapping" comes from the fact that there are (often?) mereomorphic functions on $\mathbf{C}^d$ whose periods are the image of the integral cuspidal modular symbols under the period mapping.

In the functions below, M must not be a $+1$ or -1 quotient and must be cuspidal.

`PeriodMapping(M, prec)`

The period mapping attached to the space of modular symbols M, computed using `prec` terms of the q-expansions of modular forms associated to M.

`Periods(M, prec)`

The complex period lattice associated to the space of modular symbols M, computed using `prec` terms of the q-expansions of modular forms associated to M.

`ClassicalPeriod(M, j, prec)`

The value

$$r_j(f) = \int_0^{i\infty} f(z) z^j dz.$$

133.15.2 Projection Mappings

Let M be a space of modular symbols over a field K. For many purposes it is useful to have a surjective map

$$\pi : \text{AmbientSpace(M)} \to V,$$

where V is a vector space over K and $\ker(\pi)$ is the same as the kernel of the period mapping.

`RationalMapping(M)`

A surjective linear map from the ambient space of the space of modular symbols M to a vector space, such that the kernel of this map is the same as the kernel of the period mapping.

`IntegralMapping(M)`

A surjective linear map from the ambient space of the space of modular symbols M to a vector space, such that the kernel of this map is the same as the kernel of the period mapping. This map is chosen in such a way that the image of

`IntegralBasis(CuspidalSubspace(AmbientSpace(M)))`

is the standard $\mathbf{Z}$-lattice. (Note that M must be defined over $\mathbf{Q}$.)

Example H133E24

```
> M := ModularSymbols(33); M;
Full Modular symbols space of level 33, weight 2, and dimension 9
> S := CuspidalSubspace(M);
> N := NewSubspace(S);
> phi := RationalMapping(N);
> [phi(x) : x in IntegralBasis(S)];
[
    ( -2 4/3),
    ( -4 2/3),
    ( -2 2/3),
    (-2  0),
    (  -2 -2/3),
    (-4  0)
]
```

Notice that the image of the basis `IntegralBasis(S)` for $H_1(X_0(33), \mathbf{Z})$ is not $\mathbf{Z} \times \mathbf{Z}$. However, `IntegralMapping(N)` is normalized so that the image is $\mathbf{Z} \times \mathbf{Z}$:

```
> int := IntegralMapping(N);
> [int(S.i) : i in [1..Dimension(S)]];
[
    ( 2 -1),
    ( 1 -2),
    ( 1 -1),
    ( 0 -2),
    ( 0 -1),
    (-1 -1)
]
```

Consider a quotient A_f of $J_0(N)$ attached to a newform $f \in S_2(\Gamma_0(N))$. Using `IntegralMapping` and the Abel-Jacobi theorem, we can see the image in $A_f(\mathbf{Q})$ of the point $(0) - (\infty) \in J_0(N)(\mathbf{Q})$. In the level 97 example below, this image has order 8, which is the numerator of $(97-1)/12$.

```
> Af := ModularSymbols("97B"); Af;
Modular symbols space of level 97, weight 2, and dimension 8
> int := IntegralMapping(Af);
> // Let x be the modular symbol {0,oo}
> x := AmbientSpace(Af)!<1,[Cusps()|0,Infinity()]>;
> int(x);
(-5/8  1/4 -1/4    0    0  1/4  3/8  1/4)
> Numerator((97-1)/12);
8
```

133.16 Modular Abelian Varieties

Let M be a space of weight 2 cuspidal modular symbols with trivial character that corresponds to a Galois-conjugacy class of newforms, and let $A_M(\mathbf{C})$ be the cokernel of the period map. G. Shimura proved that $A_M(\mathbf{C})$ is the set of complex points of an abelian variety A_M defined over $\mathbf{Q}$. Let N be the level of M and let $J_0(N)$ be the Jacobian of the modular curve $X_0(N)$. Shimura constructed A_M as a quotient of $J_0(N)$ by an abelian subvariety. More precisely, if I is the annihilator of M in the Hecke algebra, then $A_M = J_0(N)/IJ_0(N)$.

When A_M has dimension 1 it is an elliptic curve, and the theory of computing with A_M is well developed, though many interesting problems remain. In the contrary case, when A_M has dimension greater than 1, the theory of computation with A_M is still in its infancy. Fortunately, it is possible to compute a number of interesting quantities about A_M using algorithms that rely on our extensive knowledge of $J_0(N)$.

MAGMA contains functions for computing the modular degree, congruence modulus, upper and lower bounds on the order of the torsion subgroup, and the order of the component group of the closed fiber of the Néron model of A_M at primes that exactly divide the level of M.

133.16.1 Modular Degree and Torsion

`ModularDegree(M)`

The modular degree of the space of modular symbols M, which is defined as follows. Let M be a space of modular symbols of weight 2 and trivial character. The modular degree of M is the square root of `#ModularKernel(M)`. When M corresponds to an elliptic curve $E = A_M$, then the modular degree of M is the degree of induced map $X_0(N) \to E$.

`CongruenceModulus(M : parameters)`

`Bound` RNGINTELT *Default :* -1

The congruence number r of the space of modular symbols M. This is the index in $S_k(\Gamma_0(N), \mathbf{Z})$ of the sum $L + W$ of the lattice W of cusp forms L corresponding to M and the lattice of cusp forms corresponding to the complement of L in S.

`TorsionBound(M, maxp)`

The following upper bound on the order of the torsion subgroup of the abelian variety A attached to the space of modular symbols M:

$$\gcd\{\#A(\mathbf{F}_p) : 3 \leq p \leq \text{maxp},\ \ p \not| N\},$$

where N is the level of M. This bound is an isogeny invariant, so it is also a bound on the order of the torsion subgroup of the dual abelian variety $A^\vee$ of A.

To compute a lower bound, use `#SubgroupOfTorus(M,WindingElement(M))`.

Example H133E25

We compute the first example of an optimal elliptic curve over $\mathbf{Q}$ such that the congruence modulus does not equal the modular degree. (See [FM99] for further discussion of this problem. We warn the reader that the divisibility $r \mid \deg(\phi) \mid rN^i$ cited there is incorrect, as our `54B` example shows.)

```
> E := ModularSymbols("54B");
> ModularDegree(E);
2
> CongruenceModulus(E);
6
```

We next verify directly that the congruence modulus is divisible by 3.

```
> A := ModularSymbols("27A"); A;   // 27=54/2.
Modular symbols space of level 27, weight 2, and dimension 2
> A54 := ModularSymbols(A,54); A54;  // all images of A at level 54.
Modular symbols space of level 54, weight 2, and dimension 4
> qE := qIntegralBasis(E,17);
> qA54 := qIntegralBasis(A54,17);
> &+qA54 - &+qE;
-3*q^4 + 3*q^5 - 3*q^8 + 3*q^10 - 3*q^11 + 9*q^13 + 3*q^16 + O(q^17)
> IntersectionGroup(E,A54);   // however, the intersection is trivial.
Abelian Group of order 1
```

Ken Ribet proved that if E is an optimal elliptic curve quotient of $J_0(N)$, with N prime, and if f_E is the corresponding newform, then the congruence modulus of f_E equals the modular degree of E. The author is aware of no counterexamples to the following more general statement: "If E is an optimal elliptic curve of square-free conductor, then the congruence modulus of the newform f_E attached to E equals the modular degree of E." An analogous statement for abelian varieties is false, even at prime level. The first counterexample is `ModularSymbols("431F")`, which corresponds to an abelian variety of dimension 24. In this case, the modular degree is $2^{11} \cdot 6947$, whereas the congruence modulus is $2^{10} \cdot 6947$.
The following code makes a table of congruence moduli and modular degrees for the elliptic curves of conductor near 54. Notice the counterexample at level 54.

```
> for N in [53..55] do
>    C := CuspidalSubspace(ModularSymbols(N,2));
>    newforms := NewSubspace(C);
>    D := EllipticFactors(newforms,19);
>    for E in D do
>       printf "%o:\t%o,\t%o\n", N, ModularDegree(E), CongruenceModulus(E);
>    end for;
> end for;
53:     2,      2
54:     2,      6
54:     6,      6
55:     2,      2
```

`ModularKernel` makes sense even for spaces of modular symbols of weight greater than 2. As in the case of weight 2, this number gives information about congruences between modular forms.

The following example illustrates how `ModularKernel` suggest a congruence between a form of level 10 and weight 4 with a form of level 5.

```
> M := ModularSymbols(10,4);
> S := CuspidalSubspace(M);
> D := NewformDecomposition(S); D;
[
    Modular symbols space of level 10, weight 4, and dimension 2,
    Modular symbols space of level 10, weight 4, and dimension 4
]
> #ModularKernel(D[1]);
10
> f := qEigenform(D[1],8);
> g := qEigenform(D[2],8);
> g2 := Evaluate(g,Parent(g).1^2);
> f-(g+6*g2);   // a congruence modulo 10!
-10*q^3 + 20*q^4 + 10*q^5 - 20*q^6 - 10*q^7 + O(q^8)
```

133.16.2 Tamagawa Numbers and Orders of Component Groups

We provide several functions for computing the orders of component groups of optimal quotients of $J_0(N)$ at primes p that exactly divide N. Our algorithm involves Grothendieck's monodromy pairing on the character group of the toric part of the closed fiber at p of the Néron model of $J_0(N)$; the theory behind this algorithm is described in [Ste01] (or [Ste00]); see [KS00] for a computationally-oriented introduction to the algorithm. When N is prime, we use the Mestre and Oesterlé method to construct the character group of the torus, as described in [Mes86]. In general, the ideal theory of quaternion algebras is used.

Note: In the appendix to [Maz77], Mazur and Rapaport give an explicit formula for the order of the component group of $J_0(N)$ at primes $p \geq 5$ that exactly divide N. Their formula is not currently used by the `ComponentGroupOrder` function.

The `RealTamagawaNumber` function computes the order of the "component group at infinity".

`ComponentGroupOrder(M, p)`

The order of the component group at p. This is the order of the group of $\overline{\mathbf{F}}_p$-points of the component group of the reduction modulo p of the Néron model of the abelian variety attached to the space of modular symbols M. At present, it is necessary that p exactly divides the level. If `Sign(M)` is not equal to 0, then only the odd part of the order is returned.

`TamagawaNumber(M, p)`

The order of the group of $\mathbf{F}_p$-rational points of the component group of the space of modular symbols M. We require M to be associated to a single Galois-conjugacy class of newforms.

`RealTamagawaNumber(M)`

The number of connected components of $A_M(\mathbf{R})$.

`MinusTamagawaNumber(M)`

The number of connected components of the subgroup $A_M(\mathbf{C})^-$ of $A_M(\mathbf{C})$ on which complex conjugation acts as -1

Example H133E26

We compute the orders of the component groups of some abelian varieties.

```
> X11 := ModularSymbols("11A");     // corresponds to X_0(11).
> ComponentGroupOrder(X11,11);
5
> TamagawaNumber(X11,11);
5
> RealTamagawaNumber(X11);
1
> MinusTamagawaNumber(X11);
1
> J37 := ModularSymbols("37"); J37;
Modular symbols space of level 37, weight 2, and dimension 4
> ComponentGroupOrder(J37,37);
3
> A, B := Explode(NewformDecomposition(J37));
> ComponentGroupOrder(A,37);
3
> ComponentGroupOrder(B,37);
1
```

We can also compute component groups of optimal quotients whose dimension is greater than 1. The abelian varieties `B` and `C` below correspond to the Jacobians labeled $65B$ and $65A$ in [FLS$^+$01], respectively.

```
> J65 := ModularSymbols("65");
> A,B,C := Explode(SortDecomposition(NewformDecomposition(J65)));
> B;
Modular symbols space of level 65, weight 2, and dimension 4
> C;
Modular symbols space of level 65, weight 2, and dimension 4
> ComponentGroupOrder(B,5);      // not the Tamagawa number
3
> ComponentGroupOrder(B,13);
3
> ComponentGroupOrder(C,5);
7
> ComponentGroupOrder(C,13);
1
```

```
> HeckeEigenvalueField(C);
Number Field with defining polynomial x^2 + 2*x - 1 over the
Rational Field
Mapping from: Univariate Quotient Polynomial Algebra in a over
Rational Field
with modulus a^2 + 2*a - 1 to Number Field with defining
polynomial x^2 + 2*x - 1 over the Rational Field given by a rule
[no inverse]
> ComponentGroupOrder(J65,5);
42
```

When the Atkin-Lehner involution W_p acts as $+1$ on a modular abelian variety A, the order of the component group can be larger than the Tamagawa number $c_p = [A(\mathbf{Q}_p) : A_0(\mathbf{Q}_p)]$ that appears in the conjecture of Birch and Swinnerton-Dyer.

```
> AtkinLehner(B,5);
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
> ComponentGroupOrder(B,5);
3
> TamagawaNumber(B,5);
1
```

The real and minus Tamagawa numbers are defined for spaces of modular symbols of any weight over the rationals.

```
> Del := ModularSymbols("1k12A");
> Del;
Modular symbols space of level 1, weight 12, and dimension 2
```

Next we see that the period lattice associated to Δ is rectangular.

```
> RealTamagawaNumber(Del);
2
> MinusTamagawaNumber(Del);
2
> Periods(Del,40);
[
    (-0.00048533816492995160492413044 29*i),
    (0.00114073744958307 9336044545337)
]
```

133.17 Elliptic Curves

Let E be an elliptic curve. By the modularity theorem, which was recently proved by Breuil, Conrad, Diamond, Taylor, and Wiles there is a two-dimensional space M of modular symbols attached to E. Let N be the conductor of E; then M is obtained from `ModularSymbols(N,2)` by intersecting the kernels of $T_p - a_p(E)$ for sufficiently many p.

Warning: The computation of M can already be very resource intensive for elliptic curves for which `Conductor(E)` is on the order of 5000. For example, the seemingly harmless expression `ModularSymbols(EllipticCurve([0,6]))` would bring my computer to its knees.

`ModularSymbols(E)`

`ModularSymbols(E, sign)`

The space M of modular symbols associated to the elliptic curve E.

`EllipticCurve(M)`

`Database`	BoolElt	*Default :* `true`

An elliptic curve over the rational numbers that lies in the isogeny class of elliptic curves associated to M.

By default, the Cremona database is used. To compute the curve from scratch, set the optional parameter `Database` to `false`. (Note however that this is not optimized for large level.)

`pAdicLSeries(E, p)`

`CoefficientPrecision`	RngIntElt	*Default :* 3
`SeriesPrecision`	RngIntElt	*Default :* 5
`QuadraticTwist`	RngIntElt	*Default :* 1
`ProperScaling`	BoolElt	*Default :* `true`

Given an elliptic curve over the rationals and a prime of multiplicative or good ordinary reduction, compute the p-adic L-series. For technical reasons involving caching, the curve is required to be given by a (global) minimal model.

This computation can be rather time-consuming for large conductors and/or primes. The algorithm needs to compute the modular symbols (taking N^3 time or so), and typically needs to evaluate $2(p-1)p^n$ of them, where n is the desired coefficient precision. Also, the desired coefficient precision does not always apply to every term in the series.

The `QuadraticTwist` vararg computes the p-adic L-series for a twist by a fundamental discriminant D. This requires $|D|$ as many modular symbols to be computed, but in most cases is much faster than computing the modular symbols for the twisted curve. The twisting discriminant is required to be coprime to the conductor of the curve.

The `ProperScaling` vararg indicates whether to ensure that the scaling of the p-adic L-series is correct. For many applications, only the valuation of the coefficients

is needed. The computation of the proper scaling induces a bit of extra overhead, but is still typically faster than computing the modular symbols for examples of interest.

Example H133E27

We use the elliptic curve functions to numerically compute the Birch and Swinnerton-Dyer conjectural order of the Shafarevich-Tate group of the elliptic curve **389A**, which is the curve of rank 2 with smallest conductor. The Birch and Swinnerton-Dyer conjecture asserts that

$$\frac{L^{(r)}(E,1)}{r!} = \frac{\prod c_p \cdot \mathrm{Sha} \cdot \mathrm{Reg}}{|E(\mathbf{Q})_{\mathrm{tor}}|^2},$$

where r is the order of vanishing of $L(E,s)$ at $s=1$.

```
> E := EllipticCurve(CremonaDatabase(),"389A");
> M := ModularSymbols(E);
> M;
Modular symbols space of level 389, weight 2, and dimension 2
> LRatio(M,1);
0
```

Next we compute the analytic rank and the leading coefficient of the L-series at $s=1$. (If your computer is very slow, use a number smaller than 300 below.)

```
> L1, r := LSeriesLeadingCoefficient(M,1,300);
> L1;
0.75931650029224679065762600 31
> r;        // The analytic rank is 2.
2
```

Finally we check that the rank conjecture is true in this case, and compute the conjectural order of the Shafarevich-Tate group.

```
> Rank(E);  // The algebraic rank is 2.
2
> Omega := Periods(M,300)[2][1] * 2; Omega;
4.980435433609741580582713757
> Reg := Regulator(E); Reg;
0.1524601779431437875
> #TorsionSubgroup(E);
1
> TamagawaNumber(E,389);
1
> TamagawaNumber(M,389);        // entirely different algorithm
1
> Sha := L1/(Omega*Reg); Sha;
0.9999979295234896211
> f := pAdicLSeries(E,3); _<T> := Parent(f); f;
O(3^11) + O(3^3)*T - (1 + O(3^3))*T^2 + (2 + O(3^2))*T^3
 - (2 + O(3^2))*T^4 + (1 + O(3^2))*T^5 + O(T^6)
```

133.18 Dimension Formulas

`DimensionCuspFormsGamma0(N, k)`

The dimension of the space $S_k(\Gamma_0(N))$ of weight k cusp forms for $\Gamma_0(N)$.

`DimensionNewCuspFormsGamma0(N, k)`

The dimension of the new subspace of the space $S_k(\Gamma_0(N))$ of weight k cusp forms for $\Gamma_0(N)$.

`DimensionCuspFormsGamma1(N, k)`

The dimension of the space $S_k(\Gamma_1(N))$ of weight k cusp forms for $\Gamma_1(N)$.

`DimensionNewCuspFormsGamma1(N, k)`

The dimension of the new subspace of the space $S_k(\Gamma_1(N))$ of weight k cusp forms for $\Gamma_1(N)$.

`DimensionCuspForms(eps, k)`

The dimension of the space $S_k(\Gamma_1(N))(\varepsilon)$ of cusp forms of weight k and Dirichlet character `eps`. The level N is the modulus of `eps`. The dimension is computed using the formula of Cohen and Oesterlè (see [CO77]).

Example H133E28

```
> DimensionCuspFormsGamma0(11,2);
1
> DimensionCuspFormsGamma0(1,12);
1
> DimensionCuspFormsGamma0(5077,2);
422
> DimensionCuspFormsGamma1(5077,2);
1071460
> G := DirichletGroup(5*7);
> eps := G.1*G.2;
> IsOdd(eps);
true

134 BRANDT MODULES

Chapter 134
BRANDT MODULES

134.1 Introduction

Brandt modules provide a representation in terms of quaternion ideals of certain cohomology subgroups associated to Shimura curves $X_0^D(N)$ which generalize the classical modular curves $X_0(N)$. The Brandt module datatype is that of a Hecke module – a free module of finite rank with the action of a ring of Hecke operators – which is equipped with a canonical basis (identified with left quaternion ideal classes) and an inner product which is adjoint with respect to the Hecke operators. The machinery of modular symbols, Brandt modules, and, in a future release, a module of singular elliptic curves, form the computational machinery underlying modular forms in MAGMA.

Brandt modules were implemented by David Kohel, motivated by the article of Mestre and Oesterlé [Mes86] on the method of graphs for supersingular elliptic curves, the article of Pizer [Piz80] on computing spaces of modular forms using quaternion arithmetic, and grew out of research in the author's thesis [Koh96] on endomorphism ring structure of elliptic curves over finite fields. The Brandt module machinery is described in the article [Koh01] and has been used, together with modular symbols, in the computation of component groups of quotients of the Jacobians $J_0(N)$ of classical modular curves [KS00].

134.2 Brandt Module Creation

We first describe the various constructors for Brandt modules and their elements.

`BrandtModule(D)`

`BrandtModule(D, m)`

`ComputeGrams` BOOLELT *Default :* `true`

Given a product D of an odd number of primes, and a integer m which has valuation at most one at each prime divisor p of D, return a Brandt module of level (D, m) over the integers. If not specified, then the conductor m is taken to be 1.

The parameter `ComputeGrams` can be set to `false` in order to not compute the $h \times h$ array, where h is the left class number of level (D, m), of reduced Gram matrices of the quaternion ideal norm forms. Instead the basis of quaternion ideals is stored and the collection of degree p ideal homomorphisms is then computed in order to find the Hecke operator T_p for each prime p.

For very large levels, setting `ComputeGrams` to `false` is more space efficient. For moderate sized levels for which one wants to compute many Hecke operators, it is preferable to compute the Gram matrices and determine the Hecke operators using theta series.

`BrandtModule(A)`

`BrandtModule(A, R)`

`ComputeGrams` BoolElt *Default :* `true`

Given a definite order A in a quaternion algebra over $\mathbf{Q}$, returns the Brandt module on the left ideals classes for A, as a module over R. If not specified, the ring R is taken to be the integers. The parameter `ComputeGrams` is as previously described.

`BaseExtend(M, R)`

Forms the Brandt module with coefficient ring base extended to R.

`BrandtModule(M, N)`

This constructor is an alternative to `BrandtModule(D, N)` above, and *uses a different algorithm* which is preferable in the case where N is not very small.

It constructs the Brandt module attached to an Eichler order of level N inside the maximal order M. The algorithm avoids explicitly working with the Eichler order.

Example H134E1

In the following example we create the Brandt module of level 101 over the field of 7 elements and decompose it into its invariant subspaces.

```
> A := QuaternionOrder(101);
> FF := FiniteField(7);
> M := BrandtModule(A,FF);
> Decomposition(M,13);
[
    Brandt module of level (101,1), dimension 1, and degree 9 over Finite
    field of size 7,
    Brandt module of level (101,1), dimension 1, and degree 9 over Finite
    field of size 7,
    Brandt module of level (101,1), dimension 1, and degree 9 over Finite
    field of size 7,
    Brandt module of level (101,1), dimension 6, and degree 9 over Finite
    field of size 7
]
```

We note that Brandt modules of non-prime discriminant can be useful for studying isogeny factors of modular curves, since it is possible to describe exactly the piece of cohomology of interest, without first computing a much larger space. In this example we see that the space of weight 2 cusp forms for $\Gamma_0(1491)$, where $1491 = 3 \cdot 7 \cdot 71$, is of dimension 189 (plus an Eisenstein space of dimension 7), while the newspace has dimension 71. The Jacobian of the Shimura curve $X_0^{1491}(1)$ is isogenous to the new factor of $J_0(1491)$, so that we can study the newspace directly via the Brandt module.

```
> DimensionCuspFormsGamma0(3*7*71,2);
189
> DimensionNewCuspFormsGamma0(3*7*71,2);
```

```
71
> BrandtModuleDimension(3*7*71,1);
72
> M := BrandtModule(3*7*71 : ComputeGrams := false);
> S := CuspidalSubspace(M);
> Dimension(S);
71
> [ Dimension(N) : N in Decomposition(S,13 : Sort := true) ];
[ 6, 6, 6, 6, 11, 12, 12, 12 ]
```

In this example by setting `ComputeGrams` equal to `false` we obtain the Brandt module much faster, but the decomposition is much more expensive. For most applications the default computation of Gram matrices is preferable.

134.2.1 Creation of Elements

`M ! x`

Given a sequence or module element x compatible with the Brandt module M, forms the corresponding element in M.

`M . i`

For a Brandt module M and integer i, returns the i-th basis element.

134.2.2 Operations on Elements

Brandt module elements support standard operations.

`a * x`
`x * a`

The scalar multiplication of a Brandt module element x by an element a in the base ring.

`x * T`

Given a Brandt module element x and an element T of the algebra of Hecke operators of degree compatible with the parent of x or of its ambient module, returns the image of x under T.

`x + y`

Returns the sum of two Brandt module elements.

`x - y`

Returns the difference of two Brandt module elements.

`x eq y`

Returns `true` if x and y are equal elements of the same Brandt module.

`Eltseq(x)`

Returns the sequence of coefficients of the Brandt module element x.

`InnerProduct(x, y)`

Returns the inner product of the Brandt module elements x and y with respect to the canonical pairing on their common parent.

`Norm(x)`

Returns the inner product of the Brandt module element x with itself.

134.2.3 Categories and Parent

Brandt modules belong to the category `ModBrdt`, with elements of type `ModBrdtElt`, involved in the type checking of arguments in MAGMA programming. The `Parent` of an element is the space to which it belongs.

`Category(M)` `Type(M)`
`Category(x)` `Type(x)`

The category, `ModBrdt` or `ModBrdtElt`, of the Brandt module M or of the Brandt module element x.

`Parent(x)`

The parent module M of a Brandt module element x.

`x in M`

Returns `true` if M is the parent of x.

134.2.4 Elementary Invariants

Here we describe the elementary invariants of the Brandt module, defined with respect to a definite quaternion order A in a quaternion algebra $\mathbf{H}$ over $\mathbf{Q}$. The *level* of M is defined to be the reduced discriminant of A, the *discriminant* is defined to be the discriminant of the algebra $\mathbf{H}$, and the *conductor* to be the index of A in any maximal order of $\mathbf{H}$ which contains it. We note that the discriminant of M is just the product of the ramified primes of $\mathbf{H}$, and the product of the conductor and discriminant of M is the reduced discriminant of A.

`Level(M)`

Returns the level of the Brandt module, which is the product of the discriminant and the conductor, and equal to the reduced discriminant of its defining quaternion order.

`Discriminant(M)`

Returns the discriminant of the quaternion algebra **H** with respect to which the Brandt module M is defined (equal to the product of the primes which ramify in **H**).

`Conductor(M)`

Returns the conductor or index of the defining quaternion order of the Brandt module M in a maximal order of its quaternion algebra.

`BaseRing(M)`

The ring over which the Brandt module M is defined.

`Basis(M)`

Returns the basis of the Brandt module M.

134.2.5 Associated Structures

The following give structures associated to Brandt modules. In particular we note the definition of the `AmbientModule`, which is the full module containing a given Brandt module whose basis corresponds to the left quaternion ideals. Elements of every submodule of the ambient module are displayed with respect to the basis of the ambient module.

`AmbientModule(M)`

The full module of level (D, m) containing a given module of this level.

`IsAmbient(M)`

Returns `true` if and only if the Brandt module M is its own ambient module.

`Dimension(M)`
`Rank(M)`

Returns the rank of the Brandt module M over its base ring.

`Degree(M)`

Returns the degree of the Brandt module M, defined to be the dimension of its ambient module.

`GramMatrix(M)`

The matrix $(\langle u_i, u_j \rangle)$ defined with respect to the basis $\{u_i\}$ of the Brandt module M.

`InnerProductMatrix(M)`

Returns the Gram matrix of the ambient module of the Brandt module M.

Example H134E2

The following example demonstrates the use of `AmbientModule` to get back to the original Brandt module.

```
> M := BrandtModule(3,17);
> S := CuspidalSubspace(M);
> M eq AmbientModule(M);
true
```

`Ideals(M)`

This constructs the quaternionic ideals which correspond to the basis of the Brandt module M. It is only implemented when M was constructed using `BrandtModule(M, N)` – the case where the new algorithm is used, which avoids constructing these ideals explicitly.

134.2.6 Verbose Output

The verbose level for Brandt modules is set with the command `SetVerbose("Brandt",n)`. Since the construction of a Brandt module requires intensive quaternion algebra machinery for ideal enumeration, the `Quaternion` verbose flag is also relevant. In both cases, the value of n can be 0 (silent), 1 (verbose), or 2 (very verbose).

Example H134E3

In the following example we show the verbose output from the quaternion ideal enumeration in the creation of the Brandt module of level $(37, 1)$.

```
> SetVerbose("Quaternion",2);
> BrandtModule(37);
Ideal number 1, right order module
Full RSpace of degree 4 over Integer Ring
Inner Product Matrix:
[ 2  0  1  1]
[ 0  4 -1  2]
[ 1 -1 10  0]
[ 1  2  0 20]
Frontier at 2-depth 1 has 3 elements.
Number of ideals = 1
Ideal number 2, new right order module
Full RSpace of degree 4 over Integer Ring
Inner Product Matrix:
[ 2 -1  0  1]
[-1  8 -1 -4]
[ 0 -1 10 -2]
[ 1 -4 -2 12]
Ideal number 3, new right order module
Full RSpace of degree 4 over Integer Ring
```

```
Inner Product Matrix:
[ 2  1  0 -1]
[ 1  8  1  3]
[ 0  1 10 -2]
[-1  3 -2 12]
Frontier at 2-depth 2 has 4 elements.
Number of ideals = 3
Brandt module of level (37,1), dimension 3, and degree 3 over Integer Ring
```

134.3 Subspaces and Decomposition

`EisensteinSubspace(M)`

Returns the Eisenstein subspace of the Brandt module M. When the level of M is square-free this will be the submodule generated by a vector of the form $(w/w_1, \ldots, w/w_n)$, if it exists in M, where w_i is the number of automorphisms of the i-th basis ideal and $w = \mathrm{LCM}(\{w_i\})$.

`CuspidalSubspace(M)`

Returns the cuspidal subspace, defined to be the orthogonal complement of the Eisenstein subspace of the Brandt module M. If the discriminant of M is coprime to the conductor, then the cuspidal subspace consists of the vectors in M of the form $(a_1, \ldots, a_n)$, where $\sum_i a_i = 0$.

`OrthogonalComplement(M)`

The Brandt module orthogonal to the given module M in the ambient module of M.

`M meet N`

Returns the intersection of the Brandt modules M and N.

`Decomposition(M, B)`

`Sort` BoolElt *Default :* `true`

Returns a decomposition of the Brandt module with respect to the Atkin–Lehner operators and Hecke operators up to the bound B. The parameter `Sort` can be set to `true` to return a sequence sorted under the operator `lt` as defined below.

`SortDecomposition(D)`

Sort the sequence D of spaces of Brandt modules with respect to the `lt` comparison operator.

Example H134E4

```
> M := BrandtModule(2*3*17);
> Decomp := Decomposition(M,11 : Sort := true);
> Decomp;
[
    Brandt module of level (102,1), dimension 1, and degree 4 over Integer Ring,
    Brandt module of level (102,1), dimension 1, and degree 4 over Integer Ring,
    Brandt module of level (102,1), dimension 1, and degree 4 over Integer Ring,
    Brandt module of level (102,1), dimension 1, and degree 4 over Integer Ring
]
> [ IsEisenstein(N) : N in Decomp ];
[ true, false, false, false ]
```

134.3.1 Boolean Tests on Subspaces

`IsEisenstein(M)`

Returns `true` if and only if the Brandt module M is contained in the Eisenstein subspace of the ambient module.

`IsCuspidal(M)`

Returns `true` if and only if the Brandt module M is contained in the cuspidal subspace of the ambient module.

`IsIndecomposable(M, B)`

Returns `true` if an only if the Brandt module M does not decompose into complementary Hecke-invariant submodules under the Atkin-Lehner operators, nor under the Hecke operators T_n, for $n \leq B$.

`M1 subset M2`

Returns `true` if and only if $M1$ is contained in the module $M2$.

`M1 lt M2`

`Bound` RngIntElt *Default :* 101

Given two indecomposable subspaces, M_1 and M_2, returns `true` if and only if $M_1 < M_2$ under the following ordering:

(1) Order by dimension, with smaller dimension being less.

(2) An Eisenstein subspace is less than a cuspidal subspace of the same dimension.

(3) Order by Atkin–Lehner eigenvalues, starting with *smallest* prime dividing the level and with '+' being less than '–'.

(4) Order by $|\operatorname{Tr}(T_{p^i}(M_j))|$, p not dividing the level, and $1 \leq i \leq g$, where g is `Dimension`(M_1), with the positive one being smaller in the event of equality.

Condition (4) differs from the similar one for modular symbols, but permits the comparison of arbitrary Brandt modules. The algorithm returns `false` if all primes up to value of the parameter `Bound` fail to differentiate the arguments.

`M1 gt M2`

`Bound` RngIntElt *Default :* 101

Returns the complement of `lt` for Brandt modules $M1$ and $M2$.

Example H134E5

```
> M := BrandtModule(7,7);
> E := EisensteinSubspace(M);
> Basis(E);
[
    (1 1 0 0),
    (0 0 1 1)
]
> S := CuspidalSubspace(M);
> Basis(S);
[
    ( 1 -1  0  0),
    ( 0  0  1 -1)
]
> PS<q> := LaurentSeriesRing(RationalField());
> qExpansionBasis(S,100);
[
    q + q^2 - q^4 - 3*q^8 - 3*q^9 + 4*q^11 - q^16 - 3*q^18 + 4*q^22 + 8*q^23
        - 5*q^25 + 2*q^29 + 5*q^32 + 3*q^36 - 6*q^37 - 12*q^43 - 4*q^44 +
        8*q^46 - 5*q^50 - 10*q^53 + 2*q^58 + 7*q^64 + 4*q^67 + 16*q^71 +
        9*q^72 - 6*q^74 + 8*q^79 + 9*q^81 - 12*q^86 - 12*q^88 - 8*q^92 -
        12*q^99 + 5*q^100 + O(q^101)
]
```

134.4 Hecke Operators

A Brandt module M is equipped with a family of linear Hecke operators which act on it. These are returned as matrices, which act on the right with respect to the basis `Basis(M)`, but the Hecke operators of the ambient module may also be applied to elements of submodules. The system of Hecke operators are computed by default using the theta series which define the classical Brandt matrices. If a module is created with the `ComputeGram` parameter set to false, the Hecke operators are determined by means of enumeration of ideals in a p-neighbouring operation analogous to the method of graphs approach of Mestre and Oesterlé [Mes86].

`HeckeOperator(M, n)`

Compute a matrix representing the nth Hecke operator T_n with respect to `Basis(M)` for the Brandt module M.

`AtkinLehnerOperator(M, p)`

Computes the Atkin–Lehner operator on the Brandt module M, where p is a prime dividing the discriminant of M.

134.5 q-Expansions

We can associate a theta series to any pair of elements of a Brandt module, which give embeddings (with respect to any fixed module element) of the Brandt module in a space of weight 2 modular forms.

`ThetaSeries(x, y, prec)`

Returns the theta series associated to the pair (x, y) of elements of a Brandt module, as an element of a power series ring.

`qExpansionBasis(M, prec)`

A sequence of power series elements, to precision *prec*, spanning the image of the theta functions associated to pairs in the Brandt module M.

134.6 Dimensions of Spaces

`BrandtModuleDimension(D, N)`

The dimension of the Brandt module of level (D, N), computed by means of standard formulas.

Example H134E6

In the following example we demonstrate the computation of the dimensions of the Brandt modules for the sequence of Eichler orders of index 3^i in a maximal order in the quaternion algebra of discriminant $2 \cdot 3 \cdot 7$.

```
> D := 2*5*7;
> for i in [0..10] do
>     BrandtModuleDimension(D,3^i);
> end for;
2
8
24
72
216
648
1944
5832
17496
52488
157464
```

134.7 Brandt Modules Over $F_q[t]$

This section concerns the case of quaternion orders whose base ring is $F_q[t]$. The definitions and constructions are similar to the case of quaternion orders over the integers. The implementation follows the new implementation over the integers (avoiding working explicitly in terms of ideals in Eichler orders), and makes use of techniques for quadratic forms over $F_q[t]$ (developed by Markus Kirschmer).

The following intrinsics are provided. Where no description is given, the arguments and return values are similar to the corresponding intrinsics over the integers.

```
BrandtModuleDimension(D, N)
```

```
BrandtModuleDimensionOfNewSubspace(D, N)
```

```
BrandtModule(M, N)
```

This constructs the Brandt module attached to an Eichler order of level N in the maximal order M.

```
QuaternionOrder(M)
```

```
Level(M)
```

```
Discriminant(M)
```

```
Conductor(M)
```

```
Ideals(M)
```

```
InnerProductMatrix(M)
```

```
HeckeOperator(M, n)
```

```
HeckeEigenvectors(M)
```

This returns the common eigenvectors for the Hecke operators on the Brandt module M, as elements of M.

```
HeckeEigenvalue(f, p)
```

For a Hecke eigenform f in a Brandt module, this returns the eigenvalue for the Hecke operator at the prime p.

135 SUPERSINGULAR DIVISORS ON MODULAR CURVES

Chapter 135
SUPERSINGULAR DIVISORS ON MODULAR CURVES

135.1 Introduction

This chapter is about how to use MAGMA to compute with the Hecke module $D(N,p)$ of divisors on the supersingular points on $X_0(N)$ in characteristic p.

Let p be a prime. A divisor on the supersingular points of $X_0(1)$ in characteristic p is a finite formal linear combination of supersingular j-invariants $j \in \mathbf{F}_{p^2}$. More generally, suppose N is an integer that is not divisible by p. The module $D(N,p)$ of divisors on the supersingular points of $X_0(N)$ in characteristic p is the free abelian group generated by isomorphism classes of pairs (E,C) where E is a supersingular elliptic curve over $\mathbf{F}_{p^2}$ and C is a cyclic subgroup of E of order N. (We call such a pair (E,C) an elliptic curve enhanced with level N structure.) The abelian group $D(N,p)$ of divisors is equipped in a natural way with an action of Hecke operators T_n.

The module of supersingular points is a special case of the Brandt module construction (see Chapter 134) because of the following equivalence between objects:

- pairs (E,C) as above,
- isomorphism classes of left ideals of an Eichler order of level N in the quaternion algebra over $\mathbf{Q}$ ramified at, and p and ∞,
- supersingular points on $X_0(N)/\mathbf{F}_p$ over $\overline{\mathbf{F}}_p$.

The supersingular points of $X_0(N)/\mathbf{F}_p$ correspond to singularities of the special fiber of a minimal model of $X_0(Np)$ at p. This special fiber, $X_0(Np)/\mathbf{F}_p$, is isomorphic to two copies of $X_0(N)/\mathbf{F}_p$ joined at the supersingular points as simple double points. The structure of the multiplicative part of the Jacobian $J_0(Np)$ at p is captured by the behavior of the supersingular points of $X_0(N)/\mathbf{F}_p$ (see Grothendieck [Gro72] and Deligne-Rapoport [DR73]). The system of Hecke operators on the supersingular divisor group gives a representation of the p-new subspace of modular forms of level Np. We therefore refer to the *level* of the supersingular module as Np, and use the term *auxiliary level* to refer to N.

There are many reasons why one might be interested in computing with $D(N,p)$. Foremost, $D(N,p)$ is isomorphic as a module over the Hecke algebra to a subspace of the modular forms for $\Gamma_0(N)$ of weight 2 and level Np (more precisely, $D(N,p)\otimes\mathbf{C}$ is isomorphic to the p-new subspace of $M_2(\Gamma_0(Np))$). If $N = 1,2,3,5,7,13$, then MAGMA computes $D(N,p)$ using the highly-efficient method of graphs, which for small q quickly produce very sparse matrices that represent Hecke operators T_q. There are also formulas of Gross, Kudla, Merel, and others that involve the explicit representation of an eigenform in terms of a

basis of supersingular j-invariants, and Stein has a formula, which involves $D(N,p)$, for orders of component groups of modular abelian varieties (see the `ComponentGroupOrder` command in the modular symbols package).

MAGMA computes the module of supersingular divisors using either the method of graphs of Mestre–Oesterlé when $N = 1, 2, 3, 5, 7, 13$ or Brandt modules in general. When it is applicable, the method of graphs is much faster (in MAGMA) than Brandt modules, but the Brandt modules method works in general.

The modular curve approach computes correspondences on the modular curves $X_0(N)$ by means of pre-computed models for the system of covering maps $X_0(N\ell) \to X_0(N)$. Such correspondences give rise to the Hecke operators T_ℓ as the adjacency matrices of the graphs of ℓ-isogenies of the basis of $D(N,p)$. For the alternative approach through Brandt modules, the reader should consult Chapter 134 and the articles of Pizer [Piz80] and Kohel [Koh01].

This package still has some unnecessary limitations. When using Brandt modules to compute the module of supersingular divisor in MAGMA, no facility is currently provided for describing the divisors in terms of supersingular elliptic curves. Also, it is currently only possible to work with the module of supersingular divisors over the integers.

135.1.1 Categories

Modules of supersingular points belong to the category `ModSS`, and the elements of these modules belong to `ModSSElt`.

135.1.2 Verbose Output

To set the verbosity level use the command `SetVerbose("SupersingularModule",n)`, where `n` is 0 (silent), 1 (verbose), or 2 (very verbose).

135.2 Creation Functions

135.2.1 Ambient Spaces

An ambient supersingular divisors module is specified by giving an integer N (the level) and a prime p (the characteristic).

`SupersingularModule(p,N : parameters)`

`Brandt` BOOLELT *Default :* `false`

The module M of supersingular points on $X_0(N)$ over $\overline{\mathbf{F}}_p$. Equivalently, this is the free abelian group on the supersingular elliptic curves in characteristic p enhanced with level N structure. We require that N and p are coprime.

`SupersingularModule(p)`

The Hecke module M of divisors of degree 0 on the supersingular points on $X_0(1)$ over $\overline{\mathbf{F}}_p$. Equivalently, this is the free abelian group on the supersingular j-invariants in characteristic p.

Example H135E1

```
> SupersingularModule(11);
Supersingular module associated to X_0(1)/GF(11) of dimension 2
> SupersingularModule(11,3);
Supersingular module associated to X_0(3)/GF(11) of dimension 4
> SupersingularModule(3,11);
Supersingular module associated to X_0(11)/GF(3) of dimension 2
```

The optional parameter `Brandt` forces computation of the supersingular module using quaternion arithmetic, even if this will be slower. (It's not clear why anyone would want to do use this parameter except to compute the same thing using two different algorithms.)

```
> SupersingularModule(97);
Supersingular module associated to X_0(1)/GF(97) of dimension 8
> SupersingularModule(97 : Brandt := true);
Supersingular module associated to X_0(1)/GF(97) of dimension 8
```

135.2.2 Elements

`M . i`

The ith basis element of the module M.

`M ! x`

The coercion of x into the module M.

Example H135E2

First we create the supersingular module attached to $p = 11$, $N = 3$. This is the free abelian group generated by the supersingular points on $X_0(3)$ in characteristic 11, equipped with the structure of module over the Hecke algebra.

```
> X := SupersingularModule(11,3);
> P := X.1;
> P;
(5, 5)
> Eltseq(P);
[ 1, 0, 0, 0 ]
> X![ 1, 0, 0, 0 ];
(5, 5)
```

Note that the module associated to $p = 3$, $N = 11$ is computed using Brandt matrices (since $X_0(11)$ has positive genus), so elements are printed in a less informative way.

```
> Z := SupersingularModule(3,11); Z;
Supersingular module associated to X_0(11)/GF(3) of dimension 2
> P := Z.1;
> P;
```

```
[E1]
> Eltseq(P);
[ 1, 0 ]
> Z![1,0];
[E1]
```

135.2.3 Subspaces

`CuspidalSubspace(M)`

The cuspidal submodule X of M. Thus X is the submodule of divisors of degree 0 on the supersingular points. It is "cuspidal" in the sense that $X \otimes \mathbf{Q}$ is isomorphic as a Hecke module to the space $S_2(\Gamma_0(Np); \mathbf{Q})^{p\text{-new}}$ of p-new cuspforms with Fourier coefficients in $\mathbf{Q}$. Explicitly, the cuspidal subspace is the subspace of elements such that the sum of the coefficients is 0 (i.e., the subspace of divisors of degree 0).

`EisensteinSubspace(M)`

The Eisenstein submodule of M, i.e., the orthogonal complement of the cuspidal subspace of M with respect to the monodromy pairing.

`OrthogonalComplement(M)`

The orthogonal complement of the module M in the ambient space with respect to the monodromy pairing.

`Kernel(I, M)`

The kernel of I on the module M. This is the subspace of M obtained by intersecting the kernels of the operators $f_n(T_{p_n})$, where I is a sequence $[\langle p_1, f_1(x)\rangle, ..., \langle p_n, f_n(x)\rangle]$ of pairs consisting of a prime number and a polynomial.

`Decomposition(M, n)`

Decomposition of the module M with respect to the Hecke operators $T_1, T_2, \ldots, T_n$.

Example H135E3

We compute bases for the cuspidal and eisenstein subspaces when $p = 11$ and $N = 1$.

```
> M := SupersingularModule(11); Basis(M);
[
    (1, 1),
    (0, 0)
]
> S := CuspidalSubspace(M);
> E := EisensteinSubspace(M);
> Basis(S);
[
    (1, 1) - (0, 0)
```

```
]
> Basis(E);
[
    3*(1, 1) + 2*(0, 0)
]
```

Next we compute the orthogonal complement of each subspace.

```
> Basis(OrthogonalComplement(E));
[
    (1, 1) - (0, 0)
]
> Basis(OrthogonalComplement(S));
[
    3*(1, 1) + 2*(0, 0)
]
> S eq OrthogonalComplement(E);
true
```

Note that the Hecke operator T_2 acts as -2 on the cuspidal subspace. Using the `Kernel` command, we compute the subspace of M on which T_2 acts as -2, and recover the cuspidal subspace.

```
> R<x> := PolynomialRing(Integers());
> I := [<2, x + 2>];
> K := Kernel(I,M);
> Basis(K);
[
    (1, 1) - (0, 0)
]
```

We can also compute the decomposition of M into submodules for the action of the first few Hecke operators (typically a few Hecke operators are enough to give a complete decomposition with respect to all Hecke operators).

```
> Decomposition(M,5);
[
    Supersingular module associated to X_0(1)/GF(11) of dimension 1,
    Supersingular module associated to X_0(1)/GF(11) of dimension 1
]
```

135.3 Basis

`Basis(M)`

A basis for M as a $\mathbf{Z}$-module.

135.4 Properties

`AuxiliaryLevel(M)`

The level of the module M, where the auxiliary level of `SupersingularModule(N,p)` is, by definition, N.

`BaseRing(M)`

The base ring of the module M. (Currently this is always $\mathbf{Z}$.)

`Degree(P)`

The sum of the coefficients of the module element P, where P is written with respect the basis of the ambient space of the parent of M.

`Dimension(M)`

The dimension of the module M.

`Eltseq(P)`

A sequence of integers that defines the module element P.

`Level(M)`

The level of the module M, where the level of `SupersingularModule(N,p)` is, by definition, Np.

`ModularEquation(M)`

The equation of $X_0(N)$ that we use when using the Mestre method to compute with the module M of supersingular points.

`Prime(M)`

The prime of the module M, where the prime of `SupersingularModule(N,p)` is, by definition, p.

Example H135E4

```
> M := SupersingularModule(3,11);
> AuxiliaryLevel(M);
11
> BaseRing(M);
Integer Ring
> Degree(M.1+7*M.2);
8
> Dimension(M);
2
> Eltseq(M.1+7*M.2);
[ 1, 7 ]
> Level(M);
```

```
33
> Prime(M);
3
> M := SupersingularModule(11,3); M;
Supersingular module associated to X_0(3)/GF(11) of dimension 4
> ModularEquation(M);
x*y + 8
```

135.5 Associated Spaces

`BrandtModule(M)`

The Brandt module associated to the supersingular module M.

`ModularSymbols(M : parameters)`

`Proof` BoolElt *Default :* `true`

The space of modular symbols corresponding to the supersingular module M.

`ModularSymbols(M, sign : parameters)`

`Proof` BoolElt *Default :* `true`

The $+1$ or -1 quotient of the space of modular symbols corresponding to the supersingular module M.

`RSpace(M)`

The $\mathbf{Z}$-module V underlying the supersingular module M along with an invertible map $V \to M$.

Example H135E5

We compute the Brandt module and modular symbols spaces associated to the supersingular module for $p = 3$, $N = 11$, and verify that T_2 has the same characteristic polynomial on each.

```
> M := SupersingularModule(3,11);
> B := BrandtModule(M); B;
Brandt module of level (3,11), dimension 2, and degree 2 over
Integer Ring
> MS := ModularSymbols(M); MS;
Modular symbols space for Gamma_0(33) of weight 2 and dimension 4
over Rational Field
> Factorization(CharacteristicPolynomial(HeckeOperator(B, 2)));
[
    <$.1 - 3, 1>,
    <$.1 - 1, 1>
]
> Factorization(CharacteristicPolynomial(HeckeOperator(MS, 2)));
```

```
[
    <$.1 - 3, 2>,
    <$.1 - 1, 2>
]
```

There is an associated Brandt module even if the underlying computations on M are done using the Mestre-Oesterle graph method.

```
> M := SupersingularModule(11);
> UsesMestre(M);
true
> B := BrandtModule(M); B;   // takes a while
Brandt module of level (11,1), dimension 2, and degree 2 over
Integer Ring
```

135.6 Predicates

`IsAmbientSpace(M)`

Returns `true` if the supersingular module M is the full module of supersingular points and not a submodule.

`M1 eq M2`

Returns `true` if the supersingular module M_1 equals M_2.

`P eq Q`

Returns `true` if the module element P equals Q.

`M1 subset M2`

Returns `true` if the supersingular module M_1 is a subset of M_2.

`UsesBrandt(M)`

Returns `true` if the underlying computations on the supersingular module M are done using Brandt modules.

`UsesMestre(M)`

Returns `true` if the underlying computations on the supersingular module M are done using the Mestre-Oesterle method of graphs.

Example H135E6

In this example we illustrate each of the above predicates.

```
> M := SupersingularModule(11);
> S := CuspidalSubspace(M);
> IsAmbientSpace(S);
false
> IsAmbientSpace(M);
true
> S eq M;
false
> S eq S;
true
> S.1 eq S.1;
true
> S.1 eq M.1 - M.2;
true
> S.1 eq M.1;
false
> S subset M;
true
> UsesBrandt(S);
false
> UsesMestre(S);
true
> M := SupersingularModule(11 : Brandt := true);
> UsesBrandt(M);
true
> UsesMestre(M);
false
```

135.7 Arithmetic

The standard arithmetic operations + and − and left scalar multiplication are defined for elements of supersingular modules. Also one can add and intersect two submodules of an ambient supersingular module.

`P + Q` `P - Q` `a * P`

`M1 + M2`

The submodule generated by all sums of elements in the supersingular modules M_1 and M_2.

`M1 meet M2`

The intersection of the supersingular modules M_1 and M_2.

Example H135E7

First we illustrate some arithmetic on elements.

```
> M := SupersingularModule(11);
> P := M.1; P;
(1, 1)
> Q := M.2; Q;
(0, 0)
> P + Q;
(1, 1) + (0, 0)
> P - Q;
(1, 1) - (0, 0)
> 3*P;
3*(1, 1)
```

Next we illustrate some arithmetic on submodules.

```
> E := EisensteinSubspace(M);
> S := CuspidalSubspace(M);
> V := E + S;
> V;
Supersingular module associated to X_0(1)/GF(11) of dimension 2
> Basis(V);
[
    (1, 1) + 4*(0, 0),
    5*(0, 0)
]
```

The index of $E + S$ in M is of interest since it is related to congruences between Eisenstein series and cusp forms. Upon converting each of E and S to an `RSpace`, we find that the index is 5.

```
> RSpace(M)/RSpace(V);
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 5 ]
```

The intersection of E and S is the zero module.

```
> W := E meet S; W;
Supersingular module associated to X_0(1)/GF(11) of dimension 0
> Basis(W);
[]
```

135.8 Operators

`HeckeOperator(M, n)`

Compute a matrix representing the nth Hecke operator T_n with respect to `Basis(M)` for the supersingular module M.

`AtkinLehnerOperator(M, q)`

A matrix representing the Atkin-Lehner involution W_q on the supersingular module M. The number q must equal either `Prime(M)` or `AuxiliaryLevel(M)`.

Example H135E8

In this example we observe that T_2 and W_3 have the same characteristic polynomial on $S_2(\Gamma_0(33))$ as on the cuspidal subspace of the supersingular module with $p = 11$, $N = 3$.

```
> SS := CuspidalSubspace(SupersingularModule(11, 3));
> MF := CuspForms(33, 2);
> Factorization(CharacteristicPolynomial(HeckeOperator(SS, 2)));
[
    <$.1 - 1, 1>,
    <$.1 + 2, 2>
]
> Factorization(CharacteristicPolynomial(HeckeOperator(MF, 2)));
[
    <$.1 - 1, 1>,
    <$.1 + 2, 2>
]
> Factorization(CharacteristicPolynomial(AtkinLehnerOperator(SS, 3)));
[
    <$.1 - 1, 1>,
    <$.1 + 1, 2>
]
> Factorization(CharacteristicPolynomial(AtkinLehnerOperator(MF, 3)));
[
    <$.1 - 1, 2>,
    <$.1 + 1, 1>
]
```

The supersingular module with $p = 3$ and $N = 11$ is isomorphic as a module to the subspace of 3-new cuspforms in $S_2(\Gamma_0(33))$.

```
> SS := CuspidalSubspace(SupersingularModule(3, 11));
> MF := NewSubspace(CuspForms(33,2), 3);
> HeckeOperator(SS, 17);
[-2]
> HeckeOperator(MF, 17);
[-2]
> AtkinLehnerOperator(SS, 11);
[-1]
```

```
> AtkinLehnerOperator(MF, 11);
[-1]
```

135.9 The Monodromy Pairing

The monodromy pairing is a nondegenerate Hecke equivariant integer valued pairing on the module of supersingular points. (Note that it is not perfect, in general.) This pairing is simple to describe in terms of the basis for the supersingular module given by the enhanced supersingular elliptic curves. If E and F are two supersingular elliptic curve in characteristic p equipped with level N structure, then E and F pair to 0 unless $E \cong F$, in which case they pair to half the number of automorphisms of E.

`MonodromyPairing(P, Q)`

The monodromy pairing of elements P and Q of a supersingular module.

`MonodromyWeights(M)`

The diagonal entries that define the monodromy pairing on the ambient space.

Example H135E9

We compute the Brandt module and modular symbols spaces associated to the supersingular module for $p = 3$, $N = 11$, and verify that T_2 acts in a compatible way on them.

```
> M := SupersingularModule(11);
> MonodromyWeights(M);
[ 2, 3 ]
> P := Basis(CuspidalSubspace(M))[1]; P;
(1, 1) - (0, 0)
> Q := Basis(EisensteinSubspace(M))[1]; Q;
3*(1, 1) + 2*(0, 0)
> Basis(M);
[
    (1, 1),
    (0, 0)
]
> MonodromyPairing(P,Q);
0
> MonodromyPairing(P,P);
5
```

136 MODULAR ABELIAN VARIETIES

Chapter 136
MODULAR ABELIAN VARIETIES

136.1 Introduction

This chapter is the reference for the modular abelian varieties package in MAGMA. A *modular abelian variety* is an abelian variety that is a quotient of the modular Jacobian $J_1(N)$, for some integer N. This package provides extensive functionality for computing with such abelian varieties, including functions for enumerating and decomposing modular abelian varieties, isomorphism testing, computing exact endomorphism and homomorphism rings, doing arithmetic with finite subgroups and computing information about torsion subgroups, special values of L-functions and Tamagawa numbers.

Essentially none of the algorithms in this package use explicit defining equations for varieties, and as such work in a great degree of generality. For example, many even make sense for Grothendieck motives attached to modular forms, and we have included the corresponding functionality, when it makes sense.

MAGMA V2.11 was the first release of the modular abelian varieties package. The major drawback of the current version is that complete decomposition into simples is only implemented over the rational numbers. Thus the interesting behavior over number fields, involving extra inner twists, which leads to $\mathbf{Q}$-curves and associated questions, is not available (much of it is implemented, but there are some fundamental theoretical obstructions to overcome).

Our philosophy for representing modular abelian varieties is perhaps different than what you might expect, so we describe how we view an abelian subvariety A over $\mathbf{Q}$ contained in the modular Jacobian $J_0(N)$. By the Abel-Jacobi theorem we may view $J_0(N)$ over the complex numbers as a complex vector space V modulo the lattice $H_1(J_0(N), \mathbf{Z}) = H_1(X_0(N), \mathbf{Z})$. An abelian subvariety $A \subset J_0(N)$ and the map $i : A \to J_0(N)$ is completely determined by giving the image of $H_1(A, \mathbf{Q})$ in the vector space $H_1(X_0(N), \mathbf{Q})$. At this point, it might appear that we have to compute lots of floating point numbers and approximate lattices in the complex numbers, but this is not the case. Instead, we use modular symbols to compute $H_1(X_0(N), \mathbf{Z})$ as an abstract abelian group, and use everything we can from the extensive theory of modular forms to compute things about the abelian varieties determined by subgroups of $H_1(X_0(N), \mathbf{Z})$ and other related abelian varieties. Note that even though we work with homology, which is associated to complex tori, the abelian variety A over $\mathbf{Q}$ is still determined by our defining data (a certain subgroup of $H_1(X_0(N), \mathbf{Z})$), and our algorithms can often take advantage of this.

136.1.1 Categories

Modular abelian varieties belong to the category `ModAbVar`, and the elements of modular abelian varieties belong to `ModAbVarElt`. The category `MapModAbVar` consists of homomorphisms between modular abelian varieties (sometimes only up to isogeny, i.e., with a denominator). Spaces of homomorphisms between modular abelian varieties form the category `HomModAbVar`. Finitely generated subgroups of modular abelian varieties form the category `ModAbVarSubGrp`. Homology of a modular abelian variety is in the category `ModAbVarHomol`. The L-series of modular abelian varieties are in `ModAbVarLSer`.

Example H136E1

We create an object of each category.

```
> A := JZero(11);
> Type(A);
ModAbVar
> Type(A!0);
ModAbVarElt
> Type(nIsogeny(A,2));
MapModAbVar
> Type(nTorsionSubgroup(A,2));
ModAbVarSubGrp
> Type(End(A));
HomModAbVar
> Type(Homology(A));
ModAbVarHomol
> Type(LSeries(A));
ModAbVarLSer
```

136.1.2 Verbose Output

The verbosity level is set using the command `SetVerbose("ModAbVar",n)`, where `n` is 0 (silent), 1 (verbose), or 2 (very verbose). The default verbose level is 0.

Two additional verbose levels are included in this package. Level 3 is exactly like level 1, except instead of displaying to the screen, verbose output is appended to the file `ModAbVar-verbose.log` in the directory that MAGMA was run from. Verbose level 4 is exactly like level 2, except verbose output is appended to `ModAbVar-verbose.log`. On a UNIX-like system, use the shell command `tail -f ModAbVar-verbose.log` to watch the verbose log in another terminal.

Example H136E2

Using `SetVerbose`, we get some information about what is happening during computations.

```
> SetVerbose("ModAbVar",1);   // some verbose output
> SetVerbose("ModAbVar",2);   // tons of verbose output
> SetVerbose("ModAbVar",3);   // some verbose output to ModAbVar-verbose.log
> SetVerbose("ModAbVar",4);   // tons of verbose output to ModAbVar-verbose.log
```

136.2 Creation and Basic Functions

The functions described below create modular abelian varieties, combine them together in various ways, and obtain simple information about them.

Modular abelian varieties are much less restricted than spaces of modular symbols as one can take arbitrary finite direct sums.

136.2.1 Creating the Modular Jacobian $J_0(N)$

The `JZero` command will create the Jacobian $J_0(N)$ of the modular curve $X_0(N)$ (which parameterizes isomorphism classes of pairs of elliptic curves and cyclic subgroups of order N). Higher weight motivic analogues of this Jacobian can be created. Computations can be carried out in the $+1$ or -1 quotient of homology for efficiency, though certain results will be off by factors of 2.

`JZero(N : parameters)`

`JZero(N, k : parameters)`

`Sign` RngIntElt *Default :* 0

Create the modular abelian variety $J_0(N)$ of level N and weight 2 or weight $k \geq 2$, i.e., the Jacobian of the modular curve $X_0(N)$. The parameter `Sign` determines whether computations will be carried out in the $+1$ or -1 quotient of homology.

Example H136E3

```
> JZero(23);
Modular abelian variety JZero(23) of dimension 2 and level 23 over Q
> JZero(23 : Sign := +1);
Modular abelian variety JZero(23) of dimension 2 and level 23 over Q
with sign 1
> JZero(23,4);
Modular motive JZero(23,4) of dimension 5 and level 23 over Q
> JZero(23,4 : Sign := -1);
Modular motive JZero(23,4) of dimension 5 and level 23 over Q with
sign -1
> JZero(389,2 : Sign := +1);
Modular abelian variety JZero(389) of dimension 32 and level 389
over Q with sign 1
```

136.2.2 Creating the Modular Jacobians $J_1(N)$ and $J_H(N)$

The `JOne` command creates the Jacobian of the modular curve $X_1(N)$ (which parameterizes isomorphism classes of pairs of elliptic curves and cyclic subgroups of order N). The command `Js` creates an abelian variety isogenous to $J_1(N)$; more precisely it is the product of abelian varieties $J_\varepsilon(N)$, where $J_\varepsilon(N)$ is the abelian variety attached to all modular forms whose character is a Galois conjugate of ε. Creating $J_s(N)$ is much faster than creating $J_1(N)$, since less time is spent finding the integral structure on homology.

The `JH` command creates the Jacobian $J_H(N)$ of the curve $X_H(N)$, which is the quotient of $X_1(N)$ by the subgroup H of the integers modulo N.

`JOne(N : parameters)`

`JOne(N, k : parameters)`

`Sign` RngIntElt *Default :* 0

Create the modular abelian variety $J_1(N)$ of level N and weight k, if given, or 2, i.e., the Jacobian of the modular curve $X_1(N)$. Note that creating and finding the integral structure on $J_s(N)$, which is isogenous to $J_1(N)$, is much faster. Computing with $J_1(N)$ may be expensive.

`Js(N : parameters)`

`Js(N, k : parameters)`

`Sign` RngIntElt *Default :* 0

A modular abelian variety that is $\mathbf{Q}$-isogenous to the weight k (or 2) version of $J_1(N)$. More precisely, the direct sum of the modular abelian varieties attached to modular symbols spaces with Nebentypus.

`JH(N, d : parameters)`

`JH(N, k, d : parameters)`

`Sign` RngIntElt *Default :* 0

Suppose H is some (cyclic) subgroup of $G = (\mathbf{Z}/N\mathbf{Z})^*$ such that G/H has order d. Create the modular abelian variety $J_H(N)$ of level N and weight k (or 2 if k not given), where $J_H(N)$ is *isogenous* to the Jacobian of the modular curve $X_H(N)$ associated to the subgroup of $\mathrm{SL}_2(\mathbf{Z})$ of matrices $[a, b; c, d]$ with c divisible by N and a in H modulo N. It is the product of modular symbols varieties $J(\epsilon)$ for all Dirichlet characters ϵ that are trivial on H.

The parameter `Sign` determines whether computations will be carried out in the $+1$ or -1 quotient of homology.

`JH(N, gens : parameters)`

`JH(N, k, gens : parameters)`

`Sign` RngIntElt *Default :* 0

Let H be the subgroup of $(\mathbf{Z}/N\mathbf{Z})^*$ generated by the sequence of integers, *gens*. Create the modular abelian variety $J_H(N)$ of level N and weight k (or 2 if k not given), where $J_H(N)$ is isogenous to the Jacobian of the modular curve $X_H(N)$ associated to the subgroup of $\mathrm{SL}_2(\mathbf{Z})$ of matrices $[a, b; c, d]$ with c divisible by N and a in H modulo N. It is the product of modular symbols variety $J(\epsilon)$ for all Dirichlet characters ϵ that are trivial on H.

The parameter `Sign` determines whether computations will be carried out in the $+1$ or -1 quotient of homology.

Example H136E4

```
> JOne(13);
Modular abelian variety JOne(13) of dimension 2 and level 13 over Q
> JOne(13,4);
Modular motive JOne(13,4) of dimension 15 and level 13 over Q
> JOne(13,4 : Sign := 1);
Modular motive JOne(13,4) of dimension 15 and level 13 over Q
> JH(13,6);
Modular abelian variety J_H(13) of dimension 2 and level 13 over Q
> JH(13,3);
Modular abelian variety J_H(13) of dimension 0 and level 13 over Q
> JH(13,[-1]);
Modular abelian variety J_H(13) of dimension 2 and level 13 over Q
> JOne(17);
Modular abelian variety JOne(17) of dimension 5 and level 17 over Q
> Js(17);
Modular abelian variety Js(17) of dimension 5 and level 17 over Q
> IsIsogenous(JOne(17),Js(17));
true
> Degree(NaturalMap(JOne(17),Js(17)));
16
> JH(17,2);
Modular abelian variety J_H(17) of dimension 1 and level 17 over Q
> JH(17,4);
Modular abelian variety J_H(17) of dimension 1 and level 17 over Q
> JH(17,8);
Modular abelian variety J_H(17) of dimension 5 and level 17 over Q
```

136.2.3 Abelian Varieties Attached to Modular Forms

The following commands create abelian varieties attached to spaces of modular forms, sequences of spaces of forms, newforms, and characters. If an input space of modular forms is not cuspidal, MAGMA automatically replaces it with its cuspidal subspace.

`ModularAbelianVariety(M : parameters)`

`Sign` RNGINTELT *Default :* 0

The abelian variety attached to the modular forms space M.

`ModularAbelianVariety(X : parameters)`

`Sign` RNGINTELT *Default :* 0

The abelian variety attached to the sequence X of modular forms spaces. This is the direct sum of the spaces attached to each element of the sequence.

`ModularAbelianVariety(eps : parameters)`

`ModularAbelianVariety(eps, k : parameters)`

`Sign` RNGINTELT *Default :* 0

The abelian variety associated to the dirichlet character ϵ. This corresponds to the space of modular forms of weight k and character any Galois conjugate of ϵ. We include all Galois conjugates in order to obtain an abelian variety that is defined over $\mathbf{Q}$.

`ModularAbelianVariety(f)`

The abelian variety attached to the newform f.

`Newform(A)`

A newform f such that the modular abelian variety A is isogenous to the newform abelian variety A_f. An error occurs if A is not attached to a newform.

Example H136E5

We first create the modular abelian variety attached to the spaces $S_2(\Gamma_0(11))$ and $S_2(\Gamma_1(13))$. This is the direct sum of $J_0(11)$ with $J_1(13)$.

```
> X := [ModularForms(11,2), ModularForms(Gamma1(13),2)];
> A := ModularAbelianVariety(X); A;
Modular abelian variety of dimension 3 and level 11*13 over Q
> IsIsomorphic(A, JZero(11)*JOne(13));
true Homomorphism N(1) from modular abelian variety of dimension
3 to JZero(11) x JOne(13) (not printing 6x6 matrix)
```

Next we create the modular abelian variety A attached to $S_2(\Gamma_1(17))$ along with $J_1(17)$ and $J_s(17)$. We then note that A is isomorphic to $J_1(17)$, but there is no reason that A should be isomorphic to $J_s(17)$ (they are probably only isogenous). This example illustrates the fact that the abelian variety computed by MAGMA attached to $S_2(\Gamma_1(17))$ is $J_1(17)$ rather than $J_s(17)$.

(Recall that $J_s(N)$ is a product of copies of abelian varieties corresponding to conjugacy classes of characters.)

```
> A := ModularAbelianVariety(ModularForms(Gamma1(17),2)); A;
Modular abelian variety of dimension 5 and level 17 over Q
> B := JOne(17); B;
Modular abelian variety JOne(17) of dimension 5 and level 17 over Q
> C := Js(17); C;
Modular abelian variety Js(17) of dimension 5 and level 17 over Q
> IsIsomorphic(A,B);
true Homomorphism from modular abelian variety of dimension 5 to
JOne(17) (not printing 10x10 matrix)
> Degree(NaturalMap(A,C));
16
```

Example H136E6

If ε is a Dirichlet character and $k \geq 2$ is an integer, let S be the space of modular forms with weight k and character a Galois conjugate of ε. The command `ModularAbelianVariety(eps,k)` computes the modular abelian variety attached to S.

```
> G<eps> := DirichletGroup(13,CyclotomicField(12));
> Order(eps^2);
6
> ModularAbelianVariety(eps^2);
Modular abelian variety of dimension 2 and level 13 over Q
> ModularAbelianVariety(eps,3);
Modular motive of dimension 4 and level 13 over Q
```

Next we compute the modular abelian variety attached to a newform in $S_2(\Gamma_1(25))$.

```
> S := CuspForms(Gamma1(25),2);
> N := Newforms(S);
> #N;
2
> f := N[1][1];
> PowerSeries(f,4);
q + a*q^2 + 1/1355*(941*a^7 + 4820*a^6 + 11150*a^5 + 11522*a^4 +
    3582*a^3 + 10041*a^2 + 24432*a - 5718)*q^3 + O(q^4)
> A_f := ModularAbelianVariety(f);
> A_f;
Modular abelian variety Af of dimension 8 and level 5^2 over Q
```

The abelian variety A_f also determines the newform:

```
> PowerSeries(Newform(A_f),4);
q + a*q^2 + 1/1355*(941*a^7 + 4820*a^6 + 11150*a^5 + 11522*a^4 +
    3582*a^3 + 10041*a^2 + 24432*a - 5718)*q^3 + O(q^4)
```

Example H136E7

The `Newform` command works even if A wasn't explicitly created using a newform.

```
> A := Decomposition(JZero(37))[1];
> Newform(A);
q - 2*q^2 - 3*q^3 + 2*q^4 - 2*q^5 + 6*q^6 - q^7 + O(q^8)
```

136.2.4 Abelian Varieties Attached to Modular Symbols

The commands below associate modular abelian varieties to spaces of modular symbols and to sequences of spaces of modular symbols. Conversely, they associate spaces of modular symbols to modular abelian varieties. If an input space of modular symbols is not cuspidal, it is replaced by its cuspidal subspace.

`ModularAbelianVariety(M)`

The abelian variety attached to the modular symbols space M.

`ModularAbelianVariety(X)`

The abelian variety attached to the sequence X of modular symbols spaces.

`ModularSymbols(A)`

A sequence of spaces of modular symbols associated to the abelian variety A.

Example H136E8

We create modular abelian varieties attached to several spaces of modular symbols.

```
> M := ModularSymbols(37,2);
> ModularAbelianVariety(M);
Modular abelian variety of dimension 2 and level 37 over Q
> M := ModularSymbols(Gamma1(17));
> ModularAbelianVariety(M);
Modular abelian variety of dimension 5 and level 17 over Q
```

Note that the sign of the space of modular symbols determines the sign of the corresponding abelian variety.

```
> M := ModularSymbols(Gamma1(17),2,+1);
> A := ModularAbelianVariety(M); A;
Modular abelian variety of dimension 5 and level 17 over Q with sign 1
```

We can also create an abelian variety attached to any sequence of modular symbols spaces.

```
> ModularAbelianVariety([ModularSymbols(11), ModularSymbols(Gamma1(13))]);
```

```
Modular abelian variety of dimension 3 and level 11*13 over Q
```

Conversely, there is a sequence of modular symbols spaces associated to any abelian variety defined over $\mathbf{Q}$. These need not be the same as the spaces used to define the modular abelian variety; instead they are what is used internally in computations on that abelian variety.

```
> ModularSymbols(JOne(13));
[
    Modular symbols space of level 13, weight 2, character $.1,
    and dimension 2 over Cyclotomic Field of order 6 and degree 2
]
> ModularSymbols(JZero(37));
[
    Modular symbols space for Gamma_0(37) of weight 2 and
    dimension 4 over Rational Field
]
> A := JOne(17);
> ModularSymbols(A);
[
    Modular symbols space for Gamma_0(17) of weight 2 and
    dimension 2 over Rational Field,
    Modular symbols space of level 17, weight 2, character $.1,
    and dimension 2 over Cyclotomic Field of order 8 and degree 4
]
```

136.2.5 Creation of Abelian Subvarieties

Suppose A is an abelian variety and V is a vector subspace of the rational homology $H_1(A, \mathbf{Q})$. Then it can be determined whether or not V is the rational homology of an abelian subvariety of A, and if so that abelian subvariety can be computed.

The other commands below are used to create the zero-dimensional abelian variety.

`DefinesAbelianSubvariety(A, V)`

Return `true` if and only if the subspace V of rational homology defines an abelian subvariety of the variety A. If so, also returns the abelian subvariety.

This intrinsic relies on knowing a complete decomposition of A as a product of simple abelian varieties (so it is currently restricted to abelian varieties for which such a decomposition can be computed in Magma, e.g., modular abelian varieties over $\mathbf{Q}$).

`ZeroModularAbelianVariety()`

The zero-dimensional abelian variety.

`ZeroModularAbelianVariety(k)`

The zero-dimensional abelian variety of weight k.

`ZeroSubvariety(A)`

Returns the zero subvariety of the abelian variety A.

Example H136E9

We define two subspaces of the rational homology of $J_0(33)$; one defines an abelian subvariety and the other does not.

```
> A := JZero(33);
> w3 := AtkinLehnerOperator(A,3);
> W := Kernel(Matrix(w3)+1);
> DefinesAbelianSubvariety(A,W);
true Modular abelian variety of dimension 1 and level 3*11 over Q
> V := RationalHomology(A);
> DefinesAbelianSubvariety(A,W + sub<V|[V.1]>);
false
```

We create several zero-dimensional abelian varieties.

```
> ZeroModularAbelianVariety();
Modular abelian variety ZERO of dimension 0 and level 1 over Q
> ZeroModularAbelianVariety(2);
Modular abelian variety ZERO of dimension 0 and level 1 over Q
> ZeroSubvariety(JZero(11));
Modular abelian variety ZERO of dimension 0 and level 11 over Q
```

136.2.6 Creation Using a Label

As a useful shorthand, it is sometimes possible to create modular abelian varieties by giving a short string. If the string contains a single integer N, e.g., 37, then the corresponding abelian variety is $J_0(N)$. If it is of the form `"<level>k<weight>"`, then it is the possibly motivic $J_0(N)$ of weight k. If it is of the form `"<level>k<weight><isogeny code>"`, where `<isogeny code>` is one of `"A"`, `"B"`, ... `"Z"`, `"AA"`, `"BB"`, ... `"ZZ"`, `"AAA"`, `"BBB"`, ... then the corresponding abelian variety is `JZero(N,k)(iso)`, where iso is a positive integer, and `"A"` corresponds to iso=1, `"Z"` to iso=26, `"AA"` to iso=27, `"ZZ"` to iso=52, `"AAA"` to iso=53, etc.

This labeling convention is the same as the one used for modular symbols, and extends the one used for Cremona's database of elliptic curves, except that Cremona's database contains some random scrambling for levels between 56 and 450. If the weight part of the label is omitted, the weight is assumed to be 2. To get the optimal quotient of $J_0(N)$ with Cremona label s, set the optional parameter `Cremona` equal to true.

`ModularAbelianVariety(s : parameters)`

`Sign`	RngIntElt	*Default :* 0
`Cremona`	BoolElt	*Default :* `false`

The abelian variety defined by the string s. The parameter `Sign` determines whether computations will be carried out in the $+1$ or -1 quotient of homology. If the parameter `Cremona` is set to `true`, the optimal quotient of $J_0(N)$ with Cremona label s will be returned.

Example H136E10

```
> ModularAbelianVariety("37");
Modular abelian variety 37 of dimension 2 and level 37 over Q
> ModularAbelianVariety("37A");
Modular abelian variety 37A of dimension 1 and level 37 over Q
> ModularAbelianVariety("11k4A");
Modular motive 11k4A of dimension 2 and level 11 over Q
> ModularAbelianVariety("65C");
Modular abelian variety 65C of dimension 2 and level 5*13 over Q
> ModularDegree(ModularAbelianVariety("56A"));
4
> ModularDegree(ModularAbelianVariety("56A" : Cremona := true));
2
```

136.2.7 Invariants

Commands are available which can retrieve the base ring, dimension, character of the defining modular form, a field of definition, the level, the sign, the weights, and a short name of a modular abelian variety.

`BaseRing(A)`

The ring that the modular abelian variety A is defined over.

`Dimension(A)`

The dimension of the modular abelian variety A.

`DirichletCharacter(A)`

If the modular abelian variety $A = A_f$ is attached to a newform, returns the Nebentypus character of f. Since f is only well-defined up to $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ conjugacy, the character is also only well-defined up to $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ conjugacy.

For information on Dirichlet characters, see 19.8.

`DirichletCharacters(A)`

List of all Dirichlet characters of spaces of modular symbols associated with the modular symbols abelian variety which parameterizes A.

`FieldOfDefinition(A)`

The best known field of definition of the modular abelian variety A.

`Level(A)`

An integer N such that the modular abelian variety A is a quotient of a power of $J_1(N)$. Note that N need not be minimal. It is determined by how A is explicitly represented as a quotient of modular Jacobians.

`Sign(A)`

The sign of the modular abelian variety A, which is either 0, -1, or $+1$. If the sign is $+1$ or -1, then only the corresponding complex-conjugation eigenspace of the homology of A is computed, so various computations will be off by a factor of 2.

`Weights(A)`

The set of weights of the modular abelian variety A. The weight need not be unique since direct sums of modular symbols spaces of different weights are allowed.

Example H136E11

We illustrate all the commands for $J_0(23)$.

```
> A := JZero(23);
> BaseRing(A);
Rational Field
> Dimension(A);
2
> DirichletCharacter(A);
1
> FieldOfDefinition(A);
Rational Field
> Level(A);
23
> Sign(A);
0
> Weights(A);
{ 2 }
```

Example H136E12

This is an example of a nontrivial Dirichlet character.

```
> eps := DirichletCharacter(JOne(23)(2)); eps;
$.1^2
> Order(eps);
11
```

Example H136E13

We illustrate the `Weights` command in several cases.

```
> Weights(JZero(11));
{ 2 }
> Weights(JZero(11,4));
{ 4 }
> Weights(JOne(13,3));
{ 3 }
> Weights(DirectSum(JZero(11),JOne(13,3)));
{ 2, 3 }
> Weights(DirectSum(JZero(11),JZero(13,3)));
{ 2 }
```

Example H136E14

We display a few fields of definition.

```
> FieldOfDefinition(JOne(13));
Rational Field
> FieldOfDefinition(BaseExtend(JZero(11),QuadraticField(7)));
Rational Field
> FieldOfDefinition(ChangeRing(JZero(11),GF(7)));
Finite field of size 7
```

Example H136E15

In the following example we quotient $J_0(11)$ out by a 5-torsion point. The resulting abelian variety might not be defined over $\mathbf{Q}$, and the `FieldOfDefinition` command currently plays it safe and returns $\overline{\mathbf{Q}}$.

```
> A := JZero(11);
> G := nTorsionSubgroup(A,5);
> H := Subgroup([G.1]);
> H;
Finitely generated subgroup of abelian variety with invariants [ 5 ]
> FieldOfDefinition(A/H);
Algebraically closed field with no variables
```

136.2.8 Conductor

Let A be a modular abelian variety over $\mathbf{Q}$. The conductor command computes the conductor of A by factoring A into newform abelian varieties A_f whose conductor is N^d, where N is the level of f and d is the dimension of A_f.

`Conductor(A)`

The conductor of the abelian variety A. We require that A is defined over $\mathbf{Q}$. When $A = A_f$ is attached to a newform of level N, then the conductor of A is N^d, where d is the dimension of A.

Example H136E16

```
> Factorization(Conductor(JZero(33)));
[ <3, 1>, <11, 3> ]
> Factorization(Conductor(JZero(11)^5));
[ <11, 5> ]
> Factorization(Conductor(OldSubvariety(JZero(46))));
[ <23, 4> ]
> Factorization(Conductor(JOne(25)));
[ <5, 24> ]
```

136.2.9 Number of Points

Given an abelian variety A over a field K a divisor and a multiple of $\#A(K)$ can be computed. When finite, the multiple of the number of rational points is computed using reduction mod primes up to 100. Currently the lower bound is nontrivial only when A is a quotient of $J_0(N)$.

`NumberOfRationalPoints(A)`

A divisor and a multiple of the cardinality of $A(K)$, where A is a modular abelian variety defined over a field K. If K is an abelian number field, then we assume the Birch and Swinnerton-Dyer conjecture.

`#A`

The cardinality of $A(K)$ where A is a modular abelian variety defined over the field K if an exact value for this cardinality is known.

Example H136E17

```
> #JZero(11);
5
> #JZero(23);
11
> NumberOfRationalPoints(JZero(37));
Infinity Infinity
> NumberOfRationalPoints(JOne(13));
1 19
> NumberOfRationalPoints(JOne(23));
1 408991
> Factorization(408991);
[ <11, 1>, <37181, 1> ]
> NumberOfRationalPoints(ModularAbelianVariety("43B"));
7 7
```

136.2.10 Inner Twists and Complex Multiplication

If f is a newform then an *inner twist* of f is a Dirichlet character χ such that the twist of f by χ equals a Galois conjugate of f, at least at Fourier coefficients whose subscript is coprime to some fixed integer. A *CM twist* is a nontrivial character χ such that f twisted by χ equals f, at least at Fourier coefficients whose subscript is coprime to some fixed integer. The commands below find the CM and inner twists of the newform corresponding to a newform abelian variety.

The optional parameter `Proof` to each command is by default `false`. If `true`, it uses a huge number of terms of q-expansions. If `false`, it uses far less (and is hence very quick), and in practice this should be fine. The computation of inner and CM twists is not provably correct, even if the `Proof := true` option is set. It's very likely to be correct when `Proof := true`, but not provably correct. (More precisely, MAGMA only checks that each twist is a twist to precision 10^{-5}, but does not prove that this precision is sufficient.)

`CMTwists(A : parameters)`

`Proof` BOOLELT *Default :* `false`

A sequence of the CM inner twist characters of the newform abelian variety $A = A_f$ that are defined over the base ring of A. To gain all CM twists, base extend to `AlgebraicClosure(RationalField())` first.

`InnerTwists(A : parameters)`

`Proof` BOOLELT *Default :* `false`

A sequence of the inner twist characters of the newform abelian variety $A = A_f$ that are defined over the base ring of A. To gain all inner twists, first base extend to `AlgebraicClosure(RationalField())`.

Example H136E18

We compute the inner twists for $J_1(13)$.

```
> A := JOne(13); A;
Modular abelian variety JOne(13) of dimension 2 and level 13 over Q
> CMTwists(A);
[]
> A2 := BaseExtend(A,AlgebraicClosure(RationalField()));
> CMTwists(A2);
[]
> InnerTwists(A2);
[
    1,
    $.1^5
]
> Parent($1[2]);
Group of Dirichlet characters of modulus 13 over Cyclotomic Field
of order 6 and degree 2
```

We compute the inner twists for the second newform factor of $J_1(23)$.

```
> A := Decomposition(JOne(23))[2]; A;
Modular abelian variety image(23A[2]) of dimension 10, level 23
and conductor 23^10 over Q
> InnerTwists(BaseExtend(A,AlgebraicClosure(RationalField())));
[
    1,
    $.1^20
]
```

The CM elliptic curve $J_0(32)$ has a nontrivial CM inner twist.

```
> A := JZero(32);
> InnerTwists(BaseExtend(A,AlgebraicClosure(RationalField())));
[
    1,
    $.1
]
> CMTwists(BaseExtend(A,AlgebraicClosure(RationalField())));
[
    $.1
]
```

Quotients of $J_0(N)$ can also have nontrivial inner twists, which are not CM twists.

```
> J := JZero(81);
> A := Decomposition(J)[1];
> InnerTwists(BaseExtend(A,AlgebraicClosure(RationalField())));
[
    1,
```

```
    $.1
]
> CMTwists(BaseExtend(A,AlgebraicClosure(RationalField())));
[]
> Newform(A);
q + a*q^2 + q^4 - a*q^5 + 2*q^7 + O(q^8)
```

Example H136E19

The following is an example of a 4-dimensional abelian variety $A = A_f$ in $J_0(512)$ that has four inner twists, none of which are CM twists. One can use this fact to prove that if a_p is a prime-indexed Fourier coefficient of f, then $a_p^2 \in \mathbf{Z}$. Thus no single a_p generates the degree 4 field generated by all a_n.

```
> J := JZero(512, 2, +1);
> A := Decomposition(J)[7]; A;
Modular abelian variety 512G of dimension 4, level 2^9 and
conductor 2^36 over Q with sign 1
> f := Newform(A); f;
q + 1/12*(a^3 - 30*a)*q^3 + 1/12*(-a^3 + 42*a)*q^5 +
     1/6*(-a^2 + 18)*q^7 + O(q^8)
> Coefficient(f,3)^2;
6
> Coefficient(f,5)^2;
12
> Coefficient(f,7)^2;
8
> Abar := BaseExtend(JZero(512,2,+1)(7),AlgebraicClosure(RationalField()));
> InnerTwists(Abar);
[
    1,
    $.1,
    $.2,
    $.1*$.2
]
> CMTwists(Abar);
[]
```

136.2.11 Predicates

Most of the predicates below work in full generality. The ones whose domain of applicability is somewhat limited are `IsIsomorphic`, `IsQuaternionic`, and `IsSelfDual`. In theory, it is possible to determine isomorphism for more general classes of modular abelian varieties, but this has not yet been implemented.

`CanDetermineIsomorphism(A, B)`

Return `true` if we can determine whether or not the modular abelian varieties A and B are isomorphic. If we can determine isomorphism, also returns `true` if A and B are isomorphic and an explicit isomorphism, or `false` if they are not isomorphic. If we can not determine isomorphism, also returns the reason why we cannot as a string. If A and B are simple and defined over $\mathbf{Q}$, then there is an algorithm to determine whether or not A and B are isomorphic; it has been implemented in most (but not all) cases in MAGMA. If one of A or B has simple factors of multiplicity one, then in principal it is possible, but the algorithm has not been programmed.

`HasMultiplicityOne(A)`

Return `true` if the simple factors of the modular abelian variety A appear with multiplicity one.

`IsAbelianVariety(A)`

Return `true` if A is an abelian variety, i.e., defined over a ring of characteristic 0 in which the conductor is invertible, or a finite field whose characteristic does not divide the conductor of A. For example, if A has positive dimension and is defined over $\mathbf{Z}$, then Raynaud's theorem implies that A is not an abelian variety.

`IsAttachedToModularSymbols(A)`

Return `true` if the underlying homology of the modular abelian variety A is being computed using a space of modular symbols. For example, this will be true for $J_0(N)$ and for newform abelian varieties.

`IsAttachedToNewform(A)`

Return `true` if the modular abelian variety A is isogenous to a newform abelian variety A_f. This intrinsic also returns the abelian variety A_f and an explicit isogeny from A_f to A.

`IsIsogenous(A, B)`

Return `true` if the modular abelian varieties A and B are isogenous. If this can *not* be determined, an error occurs. It is always possible to determine whether or not A and B are isogenous when both are defined over $\mathbf{Q}$.

`IsIsomorphic(A, B)`

Return `true` if the modular abelian varieties A and B are isomorphic. If so, also returns an explicit isomorphism. This command will work if A and B are defined over $\mathbf{Q}$ and the simple factors occur with multiplicity one, and may work otherwise, but an error may occur in the general case. Use the command `CanDetermineIsomorphism` to avoid getting an error.

`IsOnlyMotivic(A)`

Return `true` if any of the modular forms attached to the modular abelian variety A have weight bigger than 2.

`IsQuaternionic(A)`

Return `true` if and only if some simple factor of the modular abelian variety A over the base ring has quaternionic multiplication.

`IsSelfDual(A)`

Return `true` if the modular abelian variety A is known to be isomorphic to its dual. An error occurs if MAGMA is unable to decide.

`IsSimple(A)`

Return `true` if and only if the modular abelian variety A has no proper abelian subvarieties over `BaseRing(A)`.

Example H136E20

We test whether a few objects are actually abelian varieties.

```
> A := JZero(11);
> A11 := ChangeRing(A,GF(11));
> IsAbelianVariety(A11);
false
> AZ := ChangeRing(A,Integers());
> IsAbelianVariety(AZ);
false
> A3 := ChangeRing(A,pAdicRing(3));
> IsAbelianVariety(A3);
true
```

Example H136E21

A modular motive is sometimes also an abelian variety, but only over the complex numbers.

```
> A := JZero(11,4); A;
Modular motive JZero(11,4) of dimension 2 and level 11 over Q
> IsAbelianVariety(A);
false
> IsOnlyMotivic(A);
true
> IsAbelianVariety(BaseExtend(A,ComplexField()));
true
```

Example H136E22

Abelian varieties $J_0(N)$ and $J_s(N)$ are attached to modular symbols, as are newform abelian varieties.

```
> J := JZero(37);
> IsAttachedToModularSymbols(J);
true
> A := Decomposition(J)[1];
> IsAttachedToModularSymbols(A);
false
> t, Af := IsAttachedToNewform(A);
> IsAttachedToModularSymbols(Af);
true
> IsIsomorphic(A,Af);
true Homomorphism from 37A to 37A given on integral homology by:
[1 0]
[0 1]
> IsAttachedToModularSymbols(Js(17));
true
> IsAttachedToModularSymbols(JOne(17));
false
```

Example H136E23

We test isogeny between a few abelian varieties.

```
> IsIsogenous(JZero(11),JOne(11));
true
> IsIsogenous(JZero(11)*JZero(11),JZero(22));
true
> IsIsogenous(JZero(11)*JZero(11),JZero(33));
false
> IsIsogenous(JZero(11),JZero(14));
false
> IsIsogenous(JZero(11)^2,JZero(22));
```

```
true
> A := JZero(37)(2); B := JOne(13);
> IsIsogenous(A*B*A, A*A*B);
true
> A := JZero(43);
> G := RationalCuspidalSubgroup(A);
> IsIsogenous(A,A/G);
true
```

Next we test isomorphism between some abelian varieties.

```
> A := JZero(43);
> G := RationalCuspidalSubgroup(A);
> B := A/G;
> CanDetermineIsomorphism(A,B);
true false
> IsIsomorphic(A,B);
false
> IsIsomorphic(JZero(11),JOne(11));
false
> IsIsomorphic(JZero(13),JOne(13));
false
> IsIsomorphic(Js(13),JOne(13));
true Homomorphism from Js(13) to JOne(13) given on integral
homology by:
[ 0  0 -1  0]
[ 0  0  0 -1]
[ 1  0 -1  0]
[ 0  1  0 -1]
> CanDetermineIsomorphism(Js(17),JOne(17));
false All tests failed to decide whether A and B are isomorphic.
```

Example H136E24

We test whether certain Jacobians have simple factors with multiplicity one.

```
> HasMultiplicityOne(JZero(43));
true
> HasMultiplicityOne(JZero(33));
false
> Decomposition(JZero(33));
[
    Modular abelian variety 33A of dimension 1, level 3*11 and
    conductor 3*11 over Q,
    Modular abelian variety N(11,33,1)(11A) of dimension 1, level
    3*11 and conductor 11 over Q,
    Modular abelian variety N(11,33,3)(11A) of dimension 1, level
    3*11 and conductor 11 over Q
```

```
]
```

Example H136E25

We give an example of a non-quaternionic surface.

```
> IsQuaternionic(JOne(13));
false
```

Example H136E26

Jacobians are self dual, and there is a surface of level 43 that is self dual and a surface of level 69 that is not.

```
> IsSelfDual(JOne(13));
true
> IsSelfDual(JZero(69)(2));
false
```

The surface A below is isomorphic to its dual. The natural polarization has kernel that is the kernel of multiplication by 2.

```
> A  := JZero(43)(2);
> A;
Modular abelian variety 43B of dimension 2, level 43 and
conductor 43^2 over Q
> IsSelfDual(A);
true
> phi := ModularPolarization(A);
> Invariants(Kernel(phi));
[ 2, 2, 2, 2 ]
```

Example H136E27

We test a few abelian varieties for simplicity.

```
> IsSimple(JOne(25));
false
> IsSimple(JOne(13));
true
> IsSimple(JZero(11)^10);
false
> IsSimple(NewSubvariety(JZero(100)));
true
```

136.2.12 Equality and Inclusion Testing

These functions test whether two abelian varieties are exactly equal or if one is a subset of another.

`A eq B`

Return `true` if the modular abelian varieties A and B are equal.

`A subset B`

Return `true` if the modular abelian variety A is a subset of the modular abelian variety B.

Example H136E28

This example illustrates that taking the direct product of abelian varieties is not commutative, as measured by equality (though it is as measured by isomorphism).

```
> A := JZero(11);
> B := JZero(14);
> A*B eq A*B;
true
> A*B eq B*A;
false
> IsIsomorphic(A*B, B*A);
true Homomorphism N(1) from JZero(11) x JZero(14) to JZero(14) x JZero(11)
given on integral homology by:
[0 0 1 0]
[0 0 0 1]
[1 0 0 0]
[0 1 0 0]
```

Example H136E29

The first inclusion below is as expected, but the second non-inclusion might be surprising. We do not consider $J_0(11)$ as a subset of $J_0(22)$, even though there is an injective map from one to the other, since to be a subset is much stronger than just the existence of an inclusion map.

```
> JZero(37) subset JZero(37);
true
> JZero(11) subset JZero(22);
false
> IsInjective(NaturalMap(JZero(11),JZero(22)));
true
```

136.2.13 Modular Embedding and Parameterization

Every modular abelian variety A is equipped with a modular parameterization and a modular embedding. The modular parameterization is a surjective homomorphism from a modular symbols abelian variety, such as $J_0(N)$. The modular embedding is a homomorphism to a modular symbols abelian variety, which is only guaranteed to be *injective in the category of abelian varieties up to isogeny*, i.e., to have finite kernel as a morphism of abelian varieties. The structure of these two homomorphisms is extremely important as they completely define A.

`CommonModularStructure(X)`

This intrinsic finds modular abelian varieties J_e and J_p associated to modular symbols and returns a list of finite-kernel maps from the abelian varieties in the sequence X to J_e and a list of modular parameterizations from J_p to the abelian varieties in X.

`ModularEmbedding(A)`

A morphism with finite kernel from the modular abelian variety A to a modular abelian variety attached to modular symbols. This is only guaranteed to be an embedding in the category of abelian varieties up to isogeny.

`ModularParameterization(A)`

A surjective morphism to the modular abelian variety A from an abelian variety attached to modular symbols.

Example H136E30

```
> X := [JZero(11),ModularAbelianVariety("37B")];
> CommonModularStructure(X);
[*
Homomorphism from JZero(11) to JZero(11) x JZero(37) given on integral
homology by:
[1 0 0 0 0 0]
[0 1 0 0 0 0],
Homomorphism from 37B to JZero(11) x JZero(37) given on integral
homology by:
[0 0 1 1 1 0]
[0 0 0 0 0 1]
*] [*
Homomorphism from JZero(11) x JZero(37) to JZero(11) (not printing 6x2
matrix),
Homomorphism from JZero(11) x JZero(37) to 37B (not printing 6x2
matrix)
*]
```

Example H136E31

This example illustrates that the modular "embedding" need only be an embedding in the category of abelian varieties up to isogeny.

```
> A := JZero(37)(1);
> x := A![1/2,1];
> B := A/Subgroup([x]);
> e := ModularEmbedding(B);
> e;
Homomorphism from modular abelian variety of dimension 1 to
JZero(37)_Qbar given on integral homology by:
[ 1 -1  1  0]
[ 2 -2 -2  2]
> IsInjective(e);
false
```

Moreover, the modular parameterization is surjective, but it need be optimal (have connected kernel).

```
> pi := ModularParameterization(B);
> IsSurjective(pi);
true
> ComponentGroupOfKernel(pi);
Finitely generated subgroup of abelian variety with invariants [ 2 ]
> IsOptimal(pi);
false
```

136.2.14 Coercion

Coercion can be used to create points on modular abelian varieties from vectors on a basis of integral homology, from other elements of modular abelian varieties, or from modular symbols. See the examples below, especially the last one, to understand some of the subtleties of coercion that arise because we view an abelian variety as a vector space modulo a lattice, and that lattice can be embedded in any way in $\mathbf{Q}^n$.

`A ! x`

Coerce x into the modular abelian variety A. The argument x can be an element of a modular abelian variety, the integer 0, a sequence like that obtained by from `Eltseq` of element of A (i.e., a linear combination of *integral* homology), a vector on the basis for *rational* homology, or a tuple of the form $\langle P(X,Y), [u,v]\rangle$ defining a modular symbol.

Example H136E32

If you coerce a *sequence* of rationals or reals into an abelian variety A, then MAGMA computes the corresponding linear combination of a basis of integral homology and returns the point it defines. The sequence must have length the rank of the integral homology.

```
> JZero(11)![1/2,1/5];
Element of abelian variety defined by [1/2 1/5] modulo homology
```

If you coerce exactly two cusps (or extended reals) into A, then MAGMA computes the point corresponding to that modular symbol.

```
> JZero(11)![Cusps()|1/2,1/5];
0
> JZero(11)![Sqrt(2),0];
Element of abelian variety defined by
[1.41421356237309504880168872419 8] modulo homology
> JZero(11)![Cusps()|0,Infinity()];     // cusps
Element of abelian variety defined by [0 1/5] modulo homology
> JZero(11)![0,Infinity()];             // extended reals
Element of abelian variety defined by [0 1/5] modulo homology
```

Coercion of modular symbols also works for higher weight.

```
> JZero(11,4)![0,Infinity()];
Element of abelian variety defined by [-4/61 5/61 1/61 -1/61]
modulo homology
> R<x,y> := PolynomialRing(RationalField(),2);
> JZero(11,4)!<x^2,[0,Infinity()]>;
Element of abelian variety defined by [-4/61 5/61 1/61 -1/61]
modulo homology
> JZero(11,4)!<y^2,[0,Infinity()]>;
Element of abelian variety defined by [44/61 -55/61 -11/61 11/61]
modulo homology
```

You can also coerce elements from abelian subvarieties into an ambient abelian variety.

```
> J := JZero(37); A := Decomposition(J)[1];
> x := A![1/5,0];
> Parent(x);
Modular abelian variety 37A of dimension 1, level 37 and
conductor 37 over Q
> x in J;
false
> y := J!x; y;
Element of abelian variety defined by [1/5 -1/5 1/5 0] modulo
homology
> y in J;
true
> Parent(y);
```

```
Modular abelian variety JZero(37) of dimension 2 and level 37 over Q
```

Coercion also provides an easy way to create the 0 element.

```
> JZero(37)!0;
0
```

Example H136E33

The following example illustrates the subtlety of coercion when the element being coerced in is a vector instead of a sequence. We create the quotient of $J_0(11)$ by a cyclic subgroup of order 10. The lattice that defines $J_0(11)$ is $\mathbf{Z} \times \mathbf{Z}$, but the lattice that defines this quotient is $(1/10)\mathbf{Z} \times \mathbf{Z}$. Thus the natural quotient map on vector spaces is defined by the identity matrix. On the other hand, the matrix of the quotient with respect to a basis for integral homology has determinant 10.

```
> A := JZero(11);
> x := A![1/10,0]; x;
Element of abelian variety defined by [1/10 0] modulo homology
> Order(x);
10
> B,pi := A/Subgroup([x]);
> B;
Modular abelian variety of dimension 1 and level 11 over Qbar
> pi;
Homomorphism from JZero(11)_Qbar to modular abelian variety of
dimension 1 given on integral homology by:
[10  0]
[ 0  1]
> Matrix(pi);
[1 0]
[0 1]
> IntegralMatrix(pi);
[10  0]
[ 0  1]
> base := Basis(IntegralHomology(B)); base;
[
    (1/10    0),
    (0 1)
]
```

If we coerce in the sequence [1/10,0] we get the point in B that is represented by 1/10th of the first generator for homology. If we coerce in the vector $(1/10, 0)$, we instead get the element of B represented by that element of the rational homology, which is 0, since the lattice that defines B is embedded in such a way that it contains $(1/10, 0)$.

```
> y := B![1/10,0]; y;
Element of abelian variety defined by [1/10 0] modulo homology
> Order(y);
10
```

```
> z := B!base[1]; z;
0
```

136.2.15 Modular Symbols to Homology

Modular symbols determine elements of the rational homology of $J_0(N)$, $J_1(N)$, etc., and hence of arbitrary modular abelian varieties, by using the modular parameterization. The commands below convert from modular symbols, which are represented in various ways, to vectors on the basis for rational or integral homology.

`ModularSymbolToIntegralHomology(A, x)`

The element of integral homology of the abelian variety A, naturally associated to the (formal) modular symbol $x = P(X,Y)\{\alpha,\beta\}$, where α, β are in $P^1(\mathbf{Q})$ and P is a homogeneous polynomial of degree 2. The returned vector is written with respect to the basis of integral homology. The argument x may be given as a sequence $[\alpha,\beta]$ or as a tuple $\langle P(X,Y),[\alpha,\beta]\rangle$ where α and β are in `Cusps()`.

`ModularSymbolToRationalHomology(A, x)`

The element of rational homology of the abelian variety A naturally associated to the (formal) modular symbol $x = P(X,Y)\{\alpha,\beta\}$, where α, β are in $P^1(\mathbf{Q})$ and P is a homogeneous polynomial of degree 2. The returned vector is written with respect to the basis of rational homology. The argument x may be given as a modular symbol, a sequence $[\alpha,\beta]$ or as a tuple $\langle P(X,Y),[\alpha,\beta]\rangle$ where α and β are in `Cusps()`.

Example H136E34

```
> A := JZero(11);
> x := ModularSymbolToIntegralHomology(A,[0,Infinity()]); x;
(  0 1/5)
> z := A!x; z;
Element of abelian variety defined by [0 1/5] modulo homology
> Order(z);
5
> A := JZero(47);
> x := ModularSymbolToIntegralHomology(A,[0,Infinity()]); x;
(-1/23  3/23 -4/23  4/23 -3/23  1/23  2/23  8/23)
> z := A!x;
> Order(z);
23
```

Example H136E35

```
> J := JZero(11,4);
> IntegralHomology(J);
Lattice of rank 4 and degree 4
Basis:
( 3  1 -1 -1)
( 1 -1 -3  1)
( 2 -2  2  2)
( 2 -2  2 -2)
Basis Denominator: 8
> ModularSymbolToIntegralHomology(J,[0,Infinity()]);
(-4/61  5/61  1/61 -1/61)
```

Notice that for weight greater than 2 the homogeneous polynomial part of the modular symbol may be omitted. If so, it defaults to x^{k-2}.

```
> R<x,y> := PolynomialRing(RationalField(),2);
> ModularSymbolToIntegralHomology(J,<x^2,[0,Infinity()]>);
(-4/61  5/61  1/61 -1/61)
> ModularSymbolToIntegralHomology(J,<y^2,[0,Infinity()]>);
( 44/61 -55/61 -11/61  11/61)
```

The result of coercion to rational homology is different because it is written in terms of the basis for rational homology instead of the basis for integral homology, and in this example the two basis differ.

```
> ModularSymbolToRationalHomology(J,[0,Infinity()]);
( -7/488  -9/488 -11/488  13/488)
```

Coercion is also a way to define torsion points on abelian varieties.

```
> JZero(37)![1/5,0,0,0];
Element of abelian variety defined by [1/5 0 0 0] modulo homology
```

136.2.16 Embeddings

The `Embeddings` command contains a list of embeddings (up to isogeny) from A to other abelian varieties. The `AssertEmbedding` command allows you to add an embedding to the beginning of the list. The embeddings are used for computing intersections, sums, etc., with the embedding at the front of the list having highest priority.

`Embeddings(A)`

A list of morphisms from the modular abelian variety A into abelian varieties, which are used in making sense of intersections, sums, etc. The embeddings at the beginning of the list take precedence over those that occur later. Note that these maps might not really be injective; e.g., the modular embedding, which need only be injective on homology, is at the end of this list.

`AssertEmbedding(~A, phi)`

Place the homomorphism ϕ of abelian varieties at the beginning of `Embeddings(A)` where A is a modular abelian variety. The morphism ϕ must have finite kernel.

Example H136E36

Every modular abelian variety comes equipped with at least one embedding, the "modular embedding".

```
> Embeddings(JZero(11));
[*
Homomorphism from JZero(11) to JZero(11) given on integral homology by:
[1 0]
[0 1]
*]
> A := JZero(37)(1);
> Embeddings(A);
[*
Homomorphism from 37A to JZero(37) given on integral homology by:
[ 1 -1  1  0]
[ 1 -1 -1  1]
*]
```

We add another embedding to the list of embeddings for A.

```
> phi := NaturalMap(A,JZero(37*2));
> AssertEmbedding(~A,phi);
> Embeddings(A);
[*
Homomorphism N(1) from 37A to JZero(74) given on integral homology
by:
[-1  1 -1  0  2 -1  1  0 -2  1 -2  2 -1  2 -1  1]
[-1  0  0  0  2 -1  1 -2  0  0 -1  1 -1  2  1 -1],
Homomorphism from 37A to JZero(37) given on integral homology by:
[ 1 -1  1  0]
[ 1 -1 -1  1]
*]
```

The following intersection would not make sense if we hadn't chosen an embedding of A into $J_0(74)$.

```
> B := Codomain(phi)(1); B;
Modular abelian variety 74A of dimension 2, level 2*37 and
conductor 2^2*37^2 over Q
> #(A meet B);
1
```

136.2.17 Base Change

The `BaseExtend` and `ChangeRing` commands allow you to change the base ring of a modular abelian variety. The `BaseExtend` command is the same `ChangeRing`, but is more restrictive. For example, if A is over $\mathbf{Q}$ then `BaseExtend(A,GF(2))` is not allowed, but `ChangeRing(A,GF(2))` is.

Abelian varieties can have their base ring set to a finite field, but there is very little that is implemented for abelian varieties over finite fields. Computing the number of points is implemented, but creation of actual points or homomorphisms is not.

`CanChangeRing(A, R)`

Return `true` if it is possible to change the base ring of the modular abelian variety A to the ring R, and the modular abelian variety over R when possible.

`ChangeRing(A, R)`

Return the modular abelian variety obtained from the modular abelian variety A having base ring R.

`BaseExtend(A, R)`

Extend the base ring of the modular abelian variety A to the ring R, if possible. This is a more restrictive version of `ChangeRing`.

Example H136E37

We consider $J_1(13)$ over many fields and rings.

```
> A := JOne(13);
> BaseExtend(A,CyclotomicField(7));
Modular abelian variety JOne(13) of dimension 2 and level 13 over
Q(zeta_7)
> BaseExtend(A,AlgebraicClosure(RationalField()));
Modular abelian variety JOne(13)_Qbar of dimension 2 and level 13
over Qbar
> BaseExtend(A,RealField());
Modular abelian variety JOne(13)_R of dimension 2 and level 13 over R
> BaseExtend(A,ComplexField());
Modular abelian variety JOne(13)_C of dimension 2 and level 13 over C
> ChangeRing(A,GF(3));
Modular abelian variety JOne(13)_GF(3) of dimension 2 and level 13
over GF(3)
> #ChangeRing(A,GF(3));
19 19
> B := ChangeRing(A,GF(13)); B;
Modular abelian variety JOne(13)_GF(13) of dimension 2 and level 13
over GF(13)
> IsAbelianVariety(B);
false
> ChangeRing(A,Integers());
```

```
Modular abelian variety JOne(13)_Z of dimension 2 and level 13 over
Z
> ChangeRing(A,PolynomialRing(RationalField(),10));
Modular abelian variety JOne(13) of dimension 2 and level 13 over
Polynomial ring of rank 10 over Rational Field
Lexicographical Order
Variables: $.1, $.2, $.3, $.4, $.5, $.6, $.7, $.8, $.9, $.10
```

136.2.18 Additional Examples

Example H136E38

The simplest abelian variety is an abelian variety of dimension 0, i.e., a point.

```
> A := ZeroModularAbelianVariety(); A;
Modular abelian variety ZERO of dimension 0 and level 1 over Q
```

We create the Jacobian $J_0(22)$ of the modular curve $X_0(22)$ as follows:

```
> J := JZero(22); J;
Modular abelian variety JZero(22) of dimension 2 and level 2*11 over Q
```

Notice that A is a subset of $J_0(22)$.

```
> A subset J;
true
```

We can also create the higher weight analogues $J_0(N, k)$ of $J_0(N)$, which are motives defined over $\mathbf{Q}$. Many computations that make sense for $J_0(N)$ also make sense for these higher weight analogues.

```
> J4 := JZero(22,4); J4;
Modular motive JZero(22,4) of dimension 7 and level 2*11 over Q
> IsOnlyMotivic(J4);
true
```

One can also create $J_1(N)$:

```
> JOne(22);
Modular abelian variety JOne(22) of dimension 6 and level 2*11 over Q
```

For efficiency purposes, it is often much quicker to do computations working only with the $+1$ quotient of $H_1(J_0(N), \mathbf{Z})$, or using only the -1 quotient. These computations will be off by powers of 2, or subgroups will be halved and off by a power of 2. Nonetheless, if you know what you are doing, such computations can be very useful. Create $J_0(N)$, but working only with the $+1$ quotient of homology as follows:

```
> Jplus := JZero(22,2,+1); Jplus;
Modular abelian variety JZero(22) of dimension 2 and level 2*11 over Q
with sign 1
> Sign(Jplus);
1
```

```
> Sign(JZero(22));
0
```

Notice that the sign is printed out when it is 1 or -1. Also, sign 0 is shorthand for "no sign", i.e., working with the full homology.

Example H136E39

Let $\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to \mathbf{Q}(\zeta_n)^*$ be Dirichlet character. The command `ModularAbelianVariety(eps)` creates the modular abelian variety *over* $\mathbf{Q}$ corresponding to the cusp forms with Dirichlet character any Galois conjugate of ε.

```
> G<eps> := DirichletGroup(22,CyclotomicField(EulerPhi(22)));
> Order(eps);
10
> Conductor(eps);
11
> A := ModularAbelianVariety(eps); A;
Modular abelian variety of dimension 0 and level 2*11 over Q
> A := ModularAbelianVariety(eps^2); A;
Modular abelian variety of dimension 4 and level 2*11 over Q
```

Example H136E40

Let H be a subgroup of $G = (\mathbf{Z}/N\mathbf{Z})^*$. The group $(\mathbf{Z}/N\mathbf{Z})^*$ acts by diamond bracket operators as a group of automorphisms on $X_1(N)$, and the modular curve $X_H(N)$ is the quotient of $X_1(N)$ by the action of H. Thus if $H = 1$, then $X_H(N) = X_1(N)$, and if $H = G$, then $X_H(N) = X_0(N)$. The command `JH(N,d)` creates an abelian variety *isogenous to* the Jacobian of $X_H(N)$, where d is the index of H in G (thus $d = 1$ corresponds to $J_0(N)$). A weight k and sign (either 0 or ± 1) can be provided. More precisely, `JH(N,d)` is the product of $J(\varepsilon)$, where ε varies over Dirichlet characters such that $\varepsilon(H) = \{1\}$.

```
> JH(22,1);
Modular abelian variety JZero(22) of dimension 2 and level 2*11 over Q
> JH(22,10);
Modular abelian variety Js(22) of dimension 6 and level 2*11 over Q
> JH(22,2);
Modular abelian variety J_H(22) of dimension 2 and level 2*11 over Q
```

As a shortcut, the command `Js(N)` creates a modular abelian variety that is isogenous to $J_1(N)$. Thus `Js(N)` is the same as `JH(N,d)`, where d is the order of $(\mathbf{Z}/N\mathbf{Z})^*$.

```
> Js(22);
Modular abelian variety Js(22) of dimension 6 and level 2*11 over Q
> JH(22,10) eq Js(22);
true
```

Example H136E41

We can also create modular abelian varieties attached to spaces of modular forms and spaces of modular symbols:

```
> ModularAbelianVariety(ModularForms(22));
Modular abelian variety of dimension 2 and level 2*11 over Q
> ModularAbelianVariety(ModularSymbols(22));
Modular abelian variety of dimension 2 and level 2*11 over Q
```

Example H136E42

Here is another example, in which the space of modular forms is on $\Gamma_1(25)$.

```
> M := ModularForms(Gamma1(25)); M;
Space of modular forms on Gamma_1(25) of weight 2 and dimension
39 over Integer Ring.
> S := CuspidalSubspace(M); S;
Space of modular forms on Gamma_1(25) of weight 2 and dimension
12 over Integer Ring.
> A := ModularAbelianVariety(S); A;
Modular abelian variety of dimension 12 and level 5^2 over Q
```

Example H136E43

We can also construct abelian varieties attached to newforms.

```
> S := CuspForms(43);
> N := Newforms(S); N;
[* [*
q - 2*q^2 - 2*q^3 + 2*q^4 - 4*q^5 + 4*q^6 + O(q^8)
*], [*
q + a*q^2 - a*q^3 + (-a + 2)*q^5 - 2*q^6 + (a - 2)*q^7 + O(q^8),
q + b*q^2 - b*q^3 + (-b + 2)*q^5 - 2*q^6 + (b - 2)*q^7 + O(q^8)
*] *]
> f := N[2][1]; f;
q + a*q^2 - a*q^3 + (-a + 2)*q^5 - 2*q^6 + (a - 2)*q^7 + O(q^8)
> A := ModularAbelianVariety(f); A;
Modular abelian variety Af of dimension 2 and level 43 over Q
> Newform(A);
q + a*q^2 - a*q^3 + (-a + 2)*q^5 - 2*q^6 + (a - 2)*q^7 + O(q^8)
```

When possible, we can also obtain a newform that gives rise to an abelian variety.

```
> J := JZero(43);
> D := Decomposition(J); D;
[
    Modular abelian variety 43A of dimension 1, level 43 and
    conductor 43 over Q,
    Modular abelian variety 43B of dimension 2, level 43 and
```

```
    conductor 43^2 over Q
]
> Newform(D[2]);
q + a*q^2 - a*q^3 + (-a + 2)*q^5 - 2*q^6 + (a - 2)*q^7 + O(q^8)
```

We demonstrate here how modular abelian varieties may be described by a label, using the string "43B". Continuing the previous code, we have:

```
> A := ModularAbelianVariety("43B");
> A eq D[2];
true
```

136.3 Homology

The homology $H_1(A, R)$ of an abelian variety A with coefficients in a ring R is a free R-module of rank equal to twice the dimension of A. For many purposes, we view abelian varieties as complex tori V/Λ, so there is a canonical isomorphism $\Lambda \cong H_1(A, \mathbf{Z})$. (If the sign of A is ± 1, then the homology command below gives a $\mathbf{Z}$-module of rank $\dim A$.)

136.3.1 Creation

The `Homology` command creates the first homology of a modular abelian variety, which is of type `ModAbVarHomol`. This is the only command for creating homology.

`Homology(A)`

The first integral homology of the modular abelian variety A. (If the sign of A is 1 or -1, then this is $\mathbf{Z}$-module of rank equal to the dimension of A.)

Example H136E44

The homology of the elliptic curve $J_0(14)$ is of dimension 2.

```
> A := JZero(14); A;
Modular abelian variety JZero(14) of dimension 1 and level 2*7 over Q
> Homology(A);
Modular abelian variety homology space of dimension 2
```

If, for efficiency purposes, we work in the $+1$ quotient, then we are only working with half the homology, so the dimension of the homology is 1.

```
> Homology(JZero(14,2 : Sign := +1));
Modular abelian variety homology space of dimension 1
```

136.3.2 Invariants

The only invariant of homology is its dimension. If A is an abelian variety, and H is its first homology, then H has dimension equal to twice the dimension of A. (Except if, for efficiency purposes, we are working with sign $+1$ or -1, in which case the dimension of H is equal to the dimension of A.)

`Dimension(H)`

The dimension of the space H of homology.

Example H136E45

```
> Dimension(Homology(JZero(100)));
14
> Dimension(Homology(JZero(100,2 : Sign := +1)));
7
> Dimension(Homology(JZero(100,2 : Sign := -1)));
7
```

136.3.3 Functors to Categories of Lattices and Vector Spaces

The following commands provide convenient functors from the categories of homology and modular abelian varieties to lattices and vector spaces. Mathematically, these functors are defined using the first homology of the complex manifold underlying the complex points of the abelian variety.

`IntegralHomology(A)`

The lattice underlying the homology of the modular abelian variety A.

`Lattice(H)`

The underlying lattice of the homology space H. This is a free $\mathbf{Z}$-module of rank equal to the dimension of H.

`RationalHomology(A)`

A $\mathbf{Q}$-vector space obtained by tensoring the homology of the modular abelian variety A with $\mathbf{Q}$.

`RealHomology(A)`

A vector space over $\mathbf{R}$ obtained by tensoring the homology of the modular abelian variety A with $\mathbf{R}$.

`RealVectorSpace(H)`

The $\mathbf{R}$-vector space whose dimension is the dimension of the homology space H.

`VectorSpace(H)`

The $\mathbf{Q}$-vector space whose dimension is the dimension of the homology space H.

Example H136E46

The integral, rational and real homology of a modular abelian variety A is $H_1(A, R)$, where $R = \mathbf{Z}, \mathbf{R}, \mathbf{Q}$, respectively. This homology is just a free module over R of dimension twice $\dim(A)$ (unless the sign of A is ± 1, in which case the homology is of dimension $\dim(A)$).

```
> J := JZero(22); J;
Modular abelian variety JZero(22) of dimension 2 and level 2*11 over Q
> IntegralHomology(J);
Standard Lattice of rank 4 and degree 4
> RationalHomology(J);
Full Vector space of degree 4 over Rational Field
> RealHomology(J);
Full Vector space of degree 4 over Real Field
> J := JZero(22, 2, +1); J;
Modular abelian variety JZero(22) of dimension 2 and level 2*11 over Q
with sign 1
> RationalHomology(J);
Full Vector space of degree 2 over Rational Field
```

Example H136E47

The following code demonstrates the above commands applied to the abelian surface attached to the space of cusp forms of level 37 with quadratic character.

```
> G<eps> := DirichletGroup(37);
> Order(eps);
2
> A := ModularAbelianVariety(eps); A;
Modular abelian variety of dimension 2 and level 37 over Q
> Decomposition(A);
[
    Modular abelian variety image(37A[18]) of dimension 2, level
    37 and conductor 37^2 over Q
]
> IntegralHomology(A);
Standard Lattice of rank 4 and degree 4
> H := Homology(A); H;
Modular abelian variety homology space of dimension 4
> Lattice(H);
Standard Lattice of rank 4 and degree 4
> RationalHomology(A);
Full Vector space of degree 4 over Rational Field
> RealHomology(A);
Full Vector space of degree 4 over Real Field
> RealVectorSpace(H);
Full Vector space of degree 4 over Real Field
> VectorSpace(H);
```

```
Full Vector space of degree 4 over Rational Field
```

Example H136E48

The code below illustrates that the lattice need not just be the free lattice on $\dim(H)$ generators. For efficiency reasons many internal computations only require knowing $H_1(A, \mathbf{Q})$, which is sometimes all that gets computed, and the lattice returned by this command is $H_1(A, \mathbf{Z})$ written with respect to a basis for $H_1(A, \mathbf{Q})$. Thus `Lattice` should be viewed as giving an integral structure of $H_1(A, \mathbf{Q})$.

```
> J := JZero(37);
> A := J(1);
> Lattice(Homology(A));
Lattice of rank 2 and degree 2
Basis:
( 1  1)
( 1 -1)
> IntegralHomology(JOne(17));
Lattice of rank 10 and degree 10
Basis:
( 0  0  1  0  0  0  1  0  0  0)
( 0  0  1  0  0  0  0  0 -1  0)
( 0  0  0  1  0  0  0  1  0  0)
( 0  0  0  1  0  0  0 -1  0  0)
( 0  0  0  0  1  0  0  0 -1  0)
( 0  0  0  0  0  1  0  0  0  1)
( 0  0  0  0  0  1  0  0  0 -1)
( 0  0  0  0  0  0  1  0 -1  0)
( 0  2  1  0  0  0  0  0  0  0)
( 2 -1  0  0  0  0  1 -1  0  1)
```

136.3.4 Modular Structure

If H is the homology of an abelian variety that is attached to a space of modular symbols, then H remembers that space of modular symbols. The following two functions decide if H is attached to modular symbols, and if so provide the corresponding spaces of modular symbols. The reason that `ModularSymbols` returns a sequence instead of a single modular symbols space is that arbitrary finite products of abelian varieties are allowed, so corresponding direct sums of modular symbols spaces must be allowed, which are represented as sequences because MAGMA currently doesn't have a facility for taking direct sums of modular symbols spaces.

`IsAttachedToModularSymbols(H)`

Return `true` if the homology space H is presented as being attached to a sequence of spaces of modular symbols.

`ModularSymbols(H)`

If the space of homology H is attached to a sequence of spaces of modular symbols, then this is that sequence. Otherwise an error occurs.

Example H136E49

In this example, we create the product $J_0(23) \times J_0(11)$, and find that its homology is attached modular symbols, since both $J_0(23)$ and $J_0(11)$ are attached to modular symbols. We then display the corresponding spaces of modular symbols.

```
> A := JZero(23) * JZero(11);
> H := Homology(A); H;
Modular abelian variety homology space of dimension 6
> IsAttachedToModularSymbols(H);
true
> ModularSymbols(H);
[
    Modular symbols space for Gamma_0(23) of weight 2 and
    dimension 4 over Rational Field,
    Modular symbols space for Gamma_0(11) of weight 2 and
    dimension 2 over Rational Field
]
```

136.3.5 Additional Examples

Example H136E50

The following example illustrates each of the above intrinsics for the homology of $J_0(23)$.

```
> A := JZero(23); A;
Modular abelian variety JZero(23) of dimension 2 and level 23 over Q
> H := Homology(A); H;
Modular abelian variety homology space of dimension 4
```

Notice that homology has its own type:

```
> Type(H);
ModAbVarHomol
```

In this case, the homology is attached to a space of modular symbols, since $J_0(23)$.

```
> IsAttachedToModularSymbols(H);
true
> ModularSymbols(H);
[
    Modular symbols space for Gamma_0(23) of weight 2 and
    dimension 4 over Rational Field
]
> Dimension(H);
```

```
4
> Lattice(H);
Standard Lattice of rank 4 and degree 4
> RealVectorSpace(H);
Full Vector space of degree 4 over Real Field
> VectorSpace(H);
Full Vector space of degree 4 over Rational Field
```

We can also obtain various homologies of A more directly.

```
> IntegralHomology(A);
Standard Lattice of rank 4 and degree 4
> RationalHomology(A);
Full Vector space of degree 4 over Rational Field
> RealHomology(A);
Full Vector space of degree 4 over Real Field
```

Example H136E51

The following example illustrates that a factor of $J_0(37)$ is not presented as something associated to a space of modular symbols. Also notice that the two lattices are different.

```
> J := JZero(37);
> D := Decomposition(J);
> H1 := Homology(D[1]);  H2 := Homology(D[2]);
> IsAttachedToModularSymbols(H1);
false
> Lattice(H1);
Lattice of rank 2 and degree 2
Basis:
( 1  1)
( 1 -1)
> Lattice(H2);
Standard Lattice of rank 2 and degree 2
```

136.4 Homomorphisms

136.4.1 Creation

The commands below create the multiplication by n map on an abelian variety, for any n. Other ways to create homomorphisms are described in other sections of this chapter. These include computing Hecke operators, Atkin-Lehner operators, and computing the full endomorphism and homomorphism rings, and choosing elements in them.

`IdentityMap(A)`

The identity homomorphism from the modular abelian variety A to A.

`ZeroMap(A)`

The zero homomorphism from the modular abelian variety A to A.

`nIsogeny(A, n)`

The multiplication by n isogeny on the modular abelian variety A, where n is a rational number or an integer.

Example H136E52

```
> A := JZero(23);
> IdentityMap(A);
Homomorphism from JZero(23) to JZero(23) given on integral homology by:
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
> ZeroMap(A);
Homomorphism from JZero(23) to JZero(23) given on integral homology by:
[0 0 0 0]
[0 0 0 0]
[0 0 0 0]
[0 0 0 0]
> nIsogeny(A,3);
Homomorphism from JZero(23) to JZero(23) given on integral homology by:
[3 0 0 0]
[0 3 0 0]
[0 0 3 0]
[0 0 0 3]
> nIsogeny(A,1/3);
Homomorphism from JZero(23) to JZero(23) (up to isogeny) on integral
homology by:
[1/3   0   0   0]
[  0 1/3   0   0]
[  0   0 1/3   0]
[  0   0   0 1/3]
```

136.4.2 Restriction, Evaluation, and Other Manipulations

Suppose A is an abelian variety, B is an abelian subvariety of A, and ϕ is a homomorphism from A. Then the `Restriction` command computes the restriction of ϕ to B. If, moreover, ϕ is an endomorphism of A (i.e., also has codomain A) and $\phi(B)$ is contained in B, then `RestrictEndomorphism` computes the endomorphism of B induced by ϕ.

If f is a polynomial over the integers or rational numbers and ϕ is an endomorphism of an abelian variety, then the `Evaluate` command computes the endomorphism $f(\phi)$ (if f has denominators, then $f(\phi)$ might only be a morphism on abelian varieties up to isogeny). Together with the `Kernel` command, `Evaluate` is useful for cutting out subvarieties of an abelian variety.

The `SurjectivePart`, `DivideOutIntegers`, and `UniversalPropertyOfCokernel` commands can also all be useful in various contexts for constructing homomorphisms.

`Restriction(phi, B)`

The restriction of the map of abelian varieties ϕ to a morphism from the abelian variety B to the codomain of ϕ, if this obviously makes sense.

`RestrictEndomorphism(phi, B)`

The restriction of the map of abelian varieties ϕ to an endomorphism of the abelian variety B, if this obviously makes sense. If B is not left invariant by ϕ, an error may occur.

`RestrictEndomorphism(phi, i)`

Suppose ϕ is an endomorphism of an abelian variety A and $i : B \to A$ is an injective morphism of abelian varieties such that $i(B)$ is invariant under ϕ. This intrinsic computes the endomorphism ψ of B induced by ϕ. If $i(B)$ is not left invariant by ϕ, an error may occur.

`RestrictionToImage(phi, i)`

Suppose $i : A \to D$ and $\phi : D \to B$ are morphisms of abelian varieties. This intrinsic computes the restriction of ϕ to the image of i. The resulting map is an endomorphism of the image of i.

`Evaluate(f, phi)`

The endomorphism $f(\phi)$ of A, where f is a univariate polynomial and ϕ is an endomorphism of a modular abelian variety A.

`DivideOutIntegers(phi)`

If $\phi : A \to B$ is a homomorphism of abelian varieties, find the largest integer n such that $\psi = (1/n) * \phi$ is also a homomorphism from A to B and return ψ and n.

`SurjectivePart(phi)`

Let $\phi : A \to B$ be a homomorphism. This intrinsic returns the *surjective* homomorphism $\pi : A \to \phi(A)$ induced by ϕ.

`UniversalPropertyOfCokernel(pi, f)`

Uses the universal property of the cokernel to find the unique morphism with a certain property. More precisely, suppose $\pi : B \to C$ is the cokernel of a morphism, so π is surjective with kernel K. Suppose $f : B \to D$ is a morphism whose kernel contains K. By definition of cokernel, there exists a unique morphism $\psi : C \to D$ such that $\pi * \psi = f$. This intrinsic returns ψ. If we only have that the identity component of $\ker(\pi)$ is contained in `ker(f)`, then ψ will only be a homomorphism in the category of abelian varieties up to isogeny, i.e., it will have a nontrivial denominator.

Example H136E53

We use the `Evaluate` and `Kernel` commands to cut out a 2-dimensional abelian subvariety of $J_0(65)$.

```
> J := JZero(65);
> R<x> := PolynomialRing(RationalField());
> T2 := HeckeOperator(J,2);
> Factorization(CharacteristicPolynomial(T2));
[
    <x + 1, 2>,
    <x^2 - 3, 2>,
    <x^2 + 2*x - 1, 2>
]
> phi := Evaluate(x^2-3,T2);
> _,A := Kernel(phi);
> A;
Modular abelian variety of dimension 2 and level 5*13 over Q
```

Example H136E54

This example illustrates the universal property of the cokernel. We decompose $J = J_0(65)$ as a product of simples A, B, and C, of dimensions 1, 2, and 2, respectively. Then we let π be a homomorphism from J onto $B + C$, and f a homomorphism from J onto B. The universal property supplies a morphism ψ from $B + C$ to B such that $\pi * \psi = f$ (i.e., $f(x) = \psi(\pi(x))$ for all x).

```
> J := JZero(65);
> A,B,C := Explode(Decomposition(J));
> pi := NaturalMap(J,B+C);
> IsSurjective(pi);
true
> f := NaturalMap(J,B);
```

```
> psi := UniversalPropertyOfCokernel(pi,f); psi;
Homomorphism from modular abelian variety of dimension 4 to 65B
(up to isogeny) on integral homology by:
 (not printing 8x4 matrix)
> Matrix(psi);
[ 1/2    0    0 -1/2]
[ 1/2    0 -1/2  1/2]
[   0 -1/2  1/2    0]
[   0    0 -1/2    1]
[ 1/2 -1/2 -1/2  1/2]
[ 1/2    0 -1/2  1/2]
[   0  1/2    0    0]
[   0    0  1/2    0]
> pi*psi eq f;    // apply pi then psi is the same as applying f.
true
> Denominator(psi);
2
```

Since ψ has a denominator of 2, it is only a morphism in the category of abelian varieties up to isogeny. This is because only the connected component of the kernel of π is contained in the kernel of f.

```
> G := Kernel(pi); G;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2, 2, 2 ]
> H, K := Kernel(f);
> H;
{ 0 }: finitely generated subgroup of abelian variety with
invariants []
> G subset K;
false
```

Example H136E55

Next we illustrate dividing out by integers, by dividing the 10 out of $10T_3$ acting on $J_0(23)$. Note that this division occurs in the full endomorphism ring, not just the Hecke algebra.

```
> phi := 10*HeckeOperator(JZero(23),3); phi;
Homomorphism from JZero(23) to JZero(23) given on integral homology by:
[-10 -20  20   0]
[  0 -30  20 -20]
[ 20 -40  30 -20]
[ 20 -20   0  10]
> DivideOutIntegers(phi);
Homomorphism from JZero(23) to JZero(23) given on integral homology by:
[-1 -2  2  0]
[ 0 -3  2 -2]
[ 2 -4  3 -2]
[ 2 -2  0  1]
```

```
10
```

Example H136E56

Next we illustrate the restriction commands using factors of $J_0(65)$.

```
> J := JZero(65);
> A := Decomposition(J)[2]; A;
Modular abelian variety 65B of dimension 2, level 5*13 and
conductor 5^2*13^2 over Q
> T := HeckeOperator(J,3);
> Factorization(CharacteristicPolynomial(T));
[
    <x + 2, 2>,
    <x^2 - 2*x - 2, 2>,
    <x^2 - 2, 2>
]
> Restriction(T,A);
Homomorphism from modular abelian variety of dimension 2 to
JZero(65) given on integral homology by:
[-1  0  0  1  0 -1  0  0  0  0]
[-1  3 -1  1 -3 -1  1  2 -1 -2]
[-1  1 -1  3 -1 -1 -1  0  1 -2]
[-1  0  0  3  0 -1 -2  0  2 -2]
> TonA := RestrictEndomorphism(T,A); TonA;
Homomorphism from 65B to 65B given on integral homology by:
[-1  0  0  1]
[-1  3 -1  1]
[-1  1 -1  3]
[-1  0  0  3]
> Factorization(CharacteristicPolynomial(TonA));
[
    <x^2 - 2*x - 2, 2>
]
```

Finally, we illustrate the `SurjectivePart` command on the non-surjective morphism $T_3 + 2$ of $J_0(65)$.

```
> phi := T+2;
> IsSurjective(phi);
false
> pi := SurjectivePart(phi);
> IsSurjective(pi);
true
> Codomain(pi);
Modular abelian variety of dimension 4 and level 5*13 over Q
```

136.4.3 Kernels

The category of abelian varieties is not an abelian category because kernels need not exist in this category. More precisely, if ϕ is a homomorphism $A \to B$ of abelian varieties, then the kernel of ϕ is usually not an abelian variety because it is rarely connected. Instead, the kernel fits into an exact sequence

$$0 \to C \to \ker(\phi) \to G \to 0,$$

where C is an abelian variety and G is a finite group, both defined over the same field as ϕ.

The `ConnectedKernel` command returns C.

The `ComponentGroupOfKernel` command returns G as a subgroup of A/C.

The `Kernel` command returns a finite subgroup of A that maps to G, the abelian variety C, and a map from C into A.

Note that if $C \neq 0$ then the finite group that the `Kernel` command returns is *not canonical*, since it is just some finite group that maps onto G via quotienting out by C. For the canonical component group, use the `ComponentGroupOfKernel` command, which gives a group defined over the same base field as ϕ, whose main drawback is that the component group is not contained in A.

`ComponentGroupOfKernel(phi)`

Component group of $\ker(\phi)$ where ϕ is a homomorphism of abelian varieties.

`ConnectedKernel(phi)`

The connected component C of $\ker(\phi)$ and a morphism from C to the domain of ϕ where ϕ is a homomorphism of abelian varieties.

`Kernel(phi)`

Let ϕ be a homomorphism of abelian varieties. This intrinsic returns a finite subgroup G of A (the domain of ϕ) as a subgroup of an abelian variety, an abelian variety C such that $\ker(\phi)$ equals $f(C) + G$, and an injective map f from C to A. If $C = 0$, then G has the same field of definition as ϕ; otherwise, G is only known to be defined over the algebraic closure.

Example H136E57

The kernel of $T_2 - 3$ on $J_0(65)$ is an extension of an abelian surface by a finite group isomorphic to $(\mathbf{Z}/2\mathbf{Z})^4$.

```
> J := JZero(65);
> T := HeckeOperator(J,2);
> phi := T^2-3;
> ConnectedKernel(phi);
Modular abelian variety of dimension 2 and level 5*13 over Q
Homomorphism from modular abelian variety of dimension 2 to
JZero(65) given on integral homology by:
```

```
[ 1  0  0  0  0  1 -1  0  1 -1]
[ 0  1  0  0 -1  0  0  1  0 -1]
[ 0  0  1  0  0  0 -1  1  1 -1]
[ 0  0  0  1  0  0 -1  0  1 -1]
> Kernel(phi);
Finitely generated subgroup of abelian variety with
invariants [ 2, 2, 2, 2 ]
Modular abelian variety of dimension 2 and level 5*13 over Q
Homomorphism from modular abelian variety of dimension 2 to
JZero(65) given on integral homology by:
[ 1  0  0  0  0  1 -1  0  1 -1]
[ 0  1  0  0 -1  0  0  1  0 -1]
[ 0  0  1  0  0  0 -1  1  1 -1]
[ 0  0  0  1  0  0 -1  0  1 -1]
> G := ComponentGroupOfKernel(phi); G;
Finitely generated subgroup of abelian variety with
invariants [ 2, 2, 2, 2 ]
> FieldOfDefinition(G);
Rational Field
```

Though G is defined over $\mathbf{Q}$, the ambient variety of G is the quotient of $J_0(65)$ by the two dimensional connected component of the kernel of $T_2 - 3$.

```
> AmbientVariety(G);
Modular abelian variety of dimension 3 and level 5*13 over Q
```

On the other hand, the group returned by the `Kernel` command is a subgroup of $J_0(65)$.

```
> H, C := Kernel(phi);
> H;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2 ]
> FieldOfDefinition(H);
Algebraically closed field with no variables
> AmbientVariety(H);
Modular abelian variety JZero(65) of dimension 5 and level 5*13
over Q
```

136.4.4 Images

These commands compute the image of a modular abelian variety or a finite group under a homomorphism ϕ of modular abelian varieties. Using `@@`, one can also compute a group lifting a given group. Note that this lift is not canonical unless ϕ has finite kernel, in which case `G@@phi` is the full inverse image of G.

`A @ phi`

`phi(A)`

The image of the abelian variety A under the map ϕ of abelian varieties, if this makes sense, i.e., if A is the domain of ϕ, or A has dimension 0, or one of the embeddings of A has codomain equal to the domain of ϕ.

`G @ phi`

`phi(G)`

The image of the subgroup G of an abelian variety under the map ϕ of abelian varieties, if this makes sense. If A is the ambient variety of G, then this makes sense if A is the domain of ϕ, or A has dimension 0, or one of the embeddings of A has codomain equal to the domain of ϕ.

`Image(phi)`

The image C of the morphism ϕ of abelian varieties, which is a modular abelian subvariety contained in the codomain of ϕ, a morphism from C to the codomain of ϕ, and a surjective morphism from the domain of ϕ to C.

`G @@ phi`

A finite group whose image under ϕ, a morphism of abelian varieties, is equal to the subgroup G of a modular abelian variety, if possible. If ϕ has finite kernel, then this is the exact inverse image of G under ϕ. If not, then this is a group generated by a choice of torsion inverse image for each generator of G, which may not be canonical.

Example H136E58

The image of $J_0(37)$ under T_2 is an elliptic curve.

```
> J := JZero(37);
> phi := HeckeOperator(J,2);
> phi(J);
Modular abelian variety of dimension 1 and level 37 over Q
> Image(phi);
Modular abelian variety of dimension 1 and level 37 over Q
Homomorphism from modular abelian variety of dimension 1 to
JZero(37) given on integral homology by:
[ 1 -1  1  0]
[ 1 -1 -1  1]
Homomorphism from JZero(37) to modular abelian variety of dimension
1 given on integral homology by:
[ 0 -1]
[ 1  0]
[-1  1]
```

```
[ 0  0]
```

The Hecke operator T_2 maps the 2-torsion subgroup of $J_0(37)$ maps onto the 2-torsion subgroup of the image of T_2.

```
> G := nTorsionSubgroup(J,2); G;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2 ]
> phi(G);
Finitely generated subgroup of abelian variety with invariants
[ 2, 2 ]
```

The homomorphism $T_2 - 1$ is surjective, and the inverse image of the 2-torsion is a subgroup isomorphic to $(\mathbf{Z}/2\mathbf{Z})^2 \times (\mathbf{Z}/6\mathbf{Z})^2$.

```
> IsSurjective(phi-1);
true
> psi := phi-1;
> H := G@@(psi); H;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 6, 6 ]
> psi(H);
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2 ]
> H := G@@psi; H;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 6, 6 ]
> psi(H);
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2 ]
```

136.4.5 Cokernels

`Cokernel(phi)`

The cokernel of the morphism ϕ of abelian varieties and a morphism from the codomain of ϕ to the cokernel.

Example H136E59

We compute a 2-dimensional quotient of the 3-dimensional abelian variety $J_0(33)$ using the Hecke operator T_2 and the `Cokernel` command.

```
> J := JZero(33);
> T := HeckeOperator(J,2);
> Factorization(CharacteristicPolynomial(T));
[
    <x - 1, 2>,
    <x + 2, 4>
```

```
]
> phi := T + 2;
> A, pi := Cokernel(phi);
> A;
Modular abelian variety of dimension 2 and level 3*11 over Q
> pi;
Homomorphism from JZero(33) to modular abelian variety of dimension
2 (not printing 6x4 matrix)
```

136.4.6 Matrix Structure

Homomorphisms are stored and worked with internally using the linear maps they induce on homology. The commands below provide access to those matrices.

`Matrix(phi)`

The matrix on the chosen basis of rational homology that defines the morphism ϕ of abelian varieties.

`Eltseq(phi)`

The `Eltseq` of the underlying matrix that defines the morphism ϕ of abelian varieties. This is a sequence of integers or rational numbers.

`Ncols(phi)`

The number of columns of the matrix which defines the morphism ϕ of abelian varieties. This is also the dimension of the homology of the codomain of ϕ.

`Nrows(phi)`

The number of rows of the matrix that defines the morphism ϕ of abelian varieties. This is also the dimension of the homology of the domain of ϕ.

`Rows(phi)`

The sequence rows of the matrix that defines the morphism ϕ of abelian varieties.

`IntegralMatrix(phi)`

The matrix which defines the morphism ϕ of abelian varieties, written with respect to integral homology.

`IntegralMatrixOverQ(phi)`

The matrix which defines the morphism ϕ of abelian varieties, written with respect to integral homology.

`RealMatrix(phi)`

The matrix which defines the morphism ϕ of abelian varieties, written with respect to real homology.

Example H136E60

The following example demonstrates each of the commands for the Hecke operator T_2 on $J_0(23)$.

```
> phi := HeckeOperator(JZero(23),2); phi;
Homomorphism T2 from JZero(23) to JZero(23) given on integral homology by:
[ 0  1 -1  0]
[ 0  1 -1  1]
[-1  2 -2  1]
[-1  1  0 -1]
> Eltseq(phi);
[ 0, 1, -1, 0, 0, 1, -1, 1, -1, 2, -2, 1, -1, 1, 0, -1 ]
> IntegralMatrix(phi);
[ 0  1 -1  0]
[ 0  1 -1  1]
[-1  2 -2  1]
[-1  1  0 -1]
> Parent($1);

> Rows(phi);
[
    ( 0  1 -1  0),
    ( 0  1 -1  1),
    (-1  2 -2  1),
    (-1  1  0 -1)
```

```
]
```

136.4.7 Arithmetic

MAGMA supports many standard arithmetic operations with homomorphisms of abelian varieties, including composition, addition, subtraction, and exponentiation.

`Inverse(phi)`

The inverse of ϕ and an integer d such that $d*\phi^{-1}$ is a morphism of abelian varieties. More precisely, if ϕ is an isogeny, then the inverse of ϕ is a morphism in the category of abelian varieties up to isogeny. This intrinsic returns such a morphism or the actual inverse of ϕ if ϕ has degree 1.

`phi * psi`

The composition of the homomorphisms ϕ and ψ of abelian varieties.

`a * phi`

The product of the rational number or integer a and the homomorphism ϕ of abelian varieties. The result might only be a homomorphism, up to isogeny.

`phi * psi`

The product of the matrix that defines the morphism ϕ of abelian varieties and the matrix ψ.

`psi * phi`

The product of the matrix ψ and the matrix that defines the morphism ϕ of abelian varieties.

`phi ^ n`

The n-fold composition ϕ^n of the endomorphism ϕ of an abelian variety with itself. If $n = -1$, then this is the inverse of ϕ, in which case ϕ must be an isogeny or an error occurs.

`phi + psi`

The sum of the homomorphisms ϕ and ψ

`n + phi`

The sum of the morphism multiplication by the rational number or integer n and the endomorphism ϕ of an abelian variety.

`phi + n`

The sum of the endomorphism ϕ of an abelian variety and the endomorphism multiplication-by-n where n is an integer.

`phi + psi`

The sum of the matrix that defines the morphism ϕ of abelian varieties and the matrix ψ.

`psi + phi`

The sum of the matrix ψ and the matrix which defines the morphism ϕ of abelian varieties.

`phi - psi`

The difference between the homomorphisms ϕ and ψ of abelian varieties.

`n - phi`

The difference between the morphism multiplication-by-n, where n is a rational number or an integer, and the endomorphism ϕ of an abelian variety.

`phi - n`

The difference between the endomorphism ϕ of an abelian variety and the endomorphism multiplication-by-n where n is a rational number or an integer.

`phi - psi`

The difference between the matrix that defines the morphism ϕ of abelian varieties and the matrix ψ.

`psi - phi`

The difference between the matrix ψ and the matrix which defines the morphism ϕ of abelian varieties.

Example H136E61

We illustrate several arithmetic operations use the Hecke operators T_2 and T_3 on $J_0(23)$.

```
> J := JZero(23);
> phi := HeckeOperator(J,2);
> psi := HeckeOperator(J,3);
> Matrix(phi)*Matrix(psi);
[-2  1 -1  0]
[ 0 -1 -1  1]
[-1  2 -4  1]
[-1  1  0 -3]
> phi*psi;
Homomorphism from JZero(23) to JZero(23) given on integral homology by:

[ 0  8 -3  3]
[-3  6 -1  3]
[-3  3  0  2]
1
```

136.4.8 Polynomials

The polynomial commands compute the characteristic and minimal polynomials of endomorphisms of modular abelian varieties. Each command requires that the input homomorphism be a genuine homomorphism (not just a morphism up to isogeny). The same computation could be done by first extracting the matrix of the endomorphism and using the analogous command on the matrix. However, in some special cases there may be special techniques which can be used to do the computation more quickly, so there can be some advantage to using the commands below.

`CharacteristicPolynomial(phi)`

The characteristic polynomial of the endomorphism ϕ of an abelian variety. We can sometimes use extra information about ϕ (e.g., how it was constructed, Deligne bounds) to gain an answer faster.

`FactoredCharacteristicPolynomial(phi)`

The factorization of the characteristic polynomial of the endomorphism ϕ of an abelian variety. We can sometimes use extra information about ϕ (e.g., how it was constructed, Deligne bounds), to gain an answer faster. These factored polynomials are cached.

`MinimalPolynomial(phi)`

The minimal polynomial of the endomorphism ϕ of an abelian variety. We can sometimes use extra information about ϕ (e.g., how it was constructed, Deligne bounds), to gain an answer faster.

Example H136E62

This example illustrates each of the polynomial commands for the Hecke operator T_2 on $J_0(66)$.

```
> J := JZero(66);
> phi := HeckeOperator(J,2);
> R<x> := PolynomialRing(RationalField());
> CharacteristicPolynomial(phi);
x^18 + 4*x^17 + 8*x^16 + 8*x^15 + 6*x^14 - 20*x^12 - 56*x^11 -
    55*x^10 - 4*x^9 + 36*x^8 + 48*x^7 + 104*x^6 + 128*x^5 -
    32*x^4 - 192*x^3 - 112*x^2 + 64*x + 64
> CharacteristicPolynomial(Matrix(phi));
x^18 + 4*x^17 + 8*x^16 + 8*x^15 + 6*x^14 - 20*x^12 - 56*x^11 -
    55*x^10 - 4*x^9 + 36*x^8 + 48*x^7 + 104*x^6 + 128*x^5 -
    32*x^4 - 192*x^3 - 112*x^2 + 64*x + 64
> FactoredCharacteristicPolynomial(phi);
[
    <x - 1, 4>,
    <x + 1, 2>,
    <x^2 - x + 2, 2>,
    <x^2 + 2*x + 2, 4>
```

```
]
> MinimalPolynomial(phi);
x^6 + x^5 + x^4 + x^3 + 2*x^2 - 2*x - 4
> Factorization(MinimalPolynomial(phi));
[
    <x - 1, 1>,
    <x + 1, 1>,
    <x^2 - x + 2, 1>,
    <x^2 + 2*x + 2, 1>
]
```

136.4.9 Invariants

It is possible to retrieve the domain and codomain of homomorphisms between abelian varieties. The degrees of such homomorphisms can be computed. Denominators of homomorphisms can be determined and cleared. A field over which a homomorphism is defined is available. The rank, nullity and trace of a homomorphism can also be computed.

`Domain(phi)`

The domain of the morphism ϕ of abelian varieties.

`Codomain(phi)`

The codomain of the morphism ϕ of abelian varieties.

`Degree(phi)`

The degree of the morphism ϕ of abelian varieties, i.e. the cardinality of the kernel of ϕ. If the kernel of ϕ is not finite, then the degree is defined to be 0.

`Denominator(phi)`

Given a morphism ϕ of abelian varieties return the smallest positive integer n such that $n * \phi$ is a homomorphism. This is also the denominator of the matrix that defines ϕ.

`ClearDenominator(phi)`

Return the morphism $n * \phi$ where ϕ is a morphism of abelian varieties and n is positive and the smallest such that $n * \phi$ is a genuine homomorphism.

`FieldOfDefinition(phi)`

A field of definition of the morphism ϕ of abelian varieties. This is only some field over which ϕ is defined, it is not guaranteed to be minimal.

`Nullity(phi)`

The dimension of the kernel of the morphism ϕ of abelian varieties.

`Rank(phi)`

The dimension of the kernel of the morphism ϕ of abelian varieties.

`Trace(phi)`

The trace of any matrix which represents the action of the morphism ϕ of abelian varieties on integral homology. For example, the trace of multiplication by n on A is $2n\dim(A)$.

Example H136E63

```
> phi := NaturalMap(JZero(11),JZero(33));
> Codomain(phi);
Modular abelian variety JZero(33) of dimension 3 and level 3*11 over Q
> Domain(phi);
Modular abelian variety JZero(11) of dimension 1 and level 11 over Q
> Degree(phi);
1
> Denominator(1/5*phi);
5
> FieldOfDefinition(phi);
Rational Field
> Nullity(phi);
0
> Rank(phi);
1
> Trace(HeckeOperator(JZero(33),2));
-6
> Trace(nIsogeny(JZero(33),5));
30
```

136.4.10 Predicates

A range of predicates are provided allowing a morphism to be checked for whether it is an actual morphism or not, whether its kernel is finite, and whether it is injective or surjective or an isogeny. There are also commands for testing equality of homomorphisms and inclusion in a list.

`IsMorphism(phi)`

Return `true` if and only if the map ϕ between abelian varieties is a morphism in the category of abelian varieties (not just in the category of abelian varieties up to isogeny).

`OnlyUpToIsogeny(phi)`

Return `true` if the map ϕ between abelian varieties is not a homomorphism, but $n*\phi$ is a homomorphism for some positive integer n, i.e., ϕ is only a homomorphism in the category of abelian varieties up to isogeny.

`HasFiniteKernel(phi)`

Return `true` if the kernel of the homomorphism ϕ of abelian varieties is finite.

`IsInjective(phi)`

Return `true` if the map ϕ between abelian varieties is an injective homomorphism.

`IsSurjective(phi)`

Return `true` if the homomorphism ϕ between abelian varieties is surjective.

`IsEndomorphism(phi)`

Return `true` if the morphism ϕ between abelian varieties is an endomorphism, i.e., the domain and codomain of ϕ are equal.

`IsInteger(phi)`

Return `true` if the morphism ϕ between abelian varieties is multiplication by n for some integer n. If so, returns that n as well, otherwise, returns `false`.

`IsIsogeny(phi)`

Return `true` if the morphism ϕ between abelian varieties is a surjective homomorphism with finite kernel. Note that this definition differs from the one in Silverman's books on elliptic curves, agrees with the one in Milne's articles, and is an equivalence relation.

`IsIsomorphism(phi)`

Return `true` if the morphism ϕ between abelian varieties is an isomorphism of abelian varieties.

`IsOptimal(phi)`

Return `true` if the morphism ϕ between abelian varieties is an optimal quotient map, i.e., ϕ is surjective and has connected kernel.

`IsHeckeOperator(phi)`

Returns `true` if the morphism ϕ between abelian varieties was computed using the `HeckeOperator` command, and the argument n passed to the `HeckeOperator` command when ϕ was created, otherwise `false`.

`IsZero(phi)`

Return `true` if the morphism ϕ of abelian varieties is the zero morphism.

`phi eq psi`

Return `true` if the two homomorphisms of abelian varieties ϕ and ψ are equal.

`n eq phi`

`phi eq n`

Return `true` if the morphism ϕ between abelian varieties is equal to multiplication by the integer n.

`phi in X`

Return `true` if the morphism ϕ between abelian varieties is one of the homomorphisms in the list X of homomorphisms.

Example H136E64

```
> phi := HeckeOperator(JZero(65),2)-1;
> HasFiniteKernel(phi);
true
> IsEndomorphism(phi);
true
> IsHeckeOperator(phi);
false 0
> IsInjective(phi);
false
> IsInteger(phi);
false
> IsIsogeny(phi);
true
> IsIsomorphism(phi);
false
> IsMorphism(phi);
true
> IsMorphism(1/2*phi);
false
> IsSurjective(phi);
true
> IsZero(phi);
false
> OnlyUpToIsogeny(phi);
false
> 2 eq phi;
false
> phi eq 2;
false
> 2 eq nIsogeny(JZero(65),2);
true
> phi eq nIsogeny(JZero(65),2);
```

```
false
> phi in [* phi, nIsogeny(JZero(65),2) *];
true
> IsIsomorphism(NaturalMap(JZero(11),JOne(11)));
false
> IsIsomorphism(NaturalMap(JZero(11)^2,JZero(22)));
false
> IsIsomorphism(NaturalMap(JZero(11),JZero(11)));
true
```

136.5 Endomorphism Algebras and Hom Spaces

136.5.1 Creation

Let A and B be modular abelian varieties. Then one can create the finite-rank free abelian group of homomorphisms from A to B or the vector space of homomorphisms in the category of abelian varieties up to isogeny. It is also possible to create the endomorphism algebra of an abelian variety. Such creations do non-trivial computations until further information is requested of the structures, such as rank or basis. In particular, such creations do not compute $\mathrm{Hom}(A, B)$.

`Hom(A, B)`

`Hom(A, B, oQ)`

Return the group of homomorphisms from the abelian variety A to the abelian variety B. If the argument oQ is given and is `true`, return the vector space generated by such homomorphisms.

`End(A)`

`End(A, oQ)`

The endomorphism ring of the abelian variety A. If oQ is given and is `true`, return the endomorphism algebra.

`BaseExtend(H, R)`

The space $H \otimes R$, where H is a group of homomorphisms of a modular abelian variety and R is the rational numbers or integers. When $R = \mathbf{Q}$, this is the space of homomorphisms in the category of abelian varieties up to isogeny.

`HeckeAlgebra(A)`

The Hecke algebra associated to the abelian variety A, which is a commutative subring of $\mathrm{End}(A)$ generated by Hecke operators. For an abelian variety attached to modular symbols, this is the algebra induced by Hecke operators acting on modular symbols (homology). For a general abelian variety, let $\pi : J \to A$ and $e : A \to J$ be the modular parameterization and embedding of A. Then this is the ring of endomorphisms obtained by pulling back the Hecke algebra on J to A using π and e, i.e., it is $e * T * \pi$, where T is the Hecke ring of J. For example, since $J_1(N)$ is represented as a quotient of $J_0(N)$, the Hecke algebra is not what you might expect but may differ by some finite index.

Example H136E65

```
> A := JZero(11); B := JZero(33);
> Hom(A,B);
Group of homomorphisms from JZero(11) to JZero(33)
> Hom(A,B,true);
Group of homomorphisms from JZero(11) to JZero(33) in the category of
abelian varieties up to isogeny
> End(A);
Group of homomorphisms from JZero(11) to JZero(11)
> End(A,true);
Group of homomorphisms from JZero(11) to JZero(11) in the category of
abelian varieties up to isogeny
> BaseExtend(Hom(A,B),RationalField());
_Q: Group of homomorphisms from JZero(11) to JZero(33) in the category
of abelian varieties up to isogeny
> HeckeAlgebra(A);
HeckeAlg(JZero(11)): Group of homomorphisms from JZero(11) to JZero(11)
```

136.5.2 Subgroups and Subrings

Subgroups of $\mathrm{Hom}(A, B)$ can also be formed as well as subrings of $\mathrm{End}(A, B)$. MAGMA provides the computation of saturations of subgroups of $\mathrm{Hom}(A, B)$ where A and B are abelian varieties.

`Subgroup(X)`

The group of homomorphisms from the abelian variety A to the abelian variety B generated by the homomorphisms of abelian varieties in the sequence X.

`Subgroup(X, oQ : parameters)`

`IsBasis` BoolElt *Default :* `false`

The group of homomorphisms generated by homomorphisms of abelian varieties in the sequence X. If the parameter `IsBasis` is `true`, then it is assumed that the elements of X are a basis for their span. If the argument oQ is `true`, return the vector space generated by such homomorphisms.

`Subring(X)`

`Subring(X, oQ)`

The ring of endomorphisms of a modular abelian variety generated by the endomorphisms in the sequence X. It does not need to contain unity. If the argument oQ is given and is `true`, return the algebra generated by such endomorphisms.

`Subring(phi)`

The ring of endomorphisms generated by the endomorphism ϕ of an abelian variety. It does not need to contain unity.

`Saturation(H)`

The saturation of the group H of homomorphisms of abelian varieties in all homomorphisms. Suppose A and B are abelian varieties and H is a subgroup of $\mathrm{Hom}(A, B)$. Then $\mathrm{Hom}(A, B)$ is a free $\mathbf{Z}$-module, and the saturation of H in $\mathrm{Hom}(A, B)$ is a group H' that contains H with finite index such that the quotient of `Hom(A,B)` by H' is torsion free.

`RingGeneratedBy(H)`

The ring of endomorphisms generated by the endomorphisms in the group H of homomorphisms between abelian varieties.

Example H136E66

In this example we use the `Saturation` command to find the integers N up to 60 such that the Hecke algebra of $J_0(N)$ is not saturated in the full ring of endomorphisms.

```
> function ind(N)
>    H := HeckeAlgebra(JZero(N));
>    return Index(Saturation(H),H);
> end function;
> for N in [2..60] do
>    i := ind(N);
>    if i gt 1 then N, i; end if;
> end for;
44 2
46 2
54 3
56 2
```

```
60 2
```

Note that multiplicity one fails at 3 for $J_0(54)$. It might be interesting to find a precise relationship between failure of multiplicity one and the index of the Hecke algebra T in its saturation.

Example H136E67

This example illustrates constructing a subgroup.

```
> J := JZero(33);
> E := End(J); E;
Group of homomorphisms from JZero(33) to JZero(33)
> H := Subgroup([E.1, E.3]); H;
Group of homomorphisms from JZero(33) to JZero(33)
> Rank(H);
2
```

Example H136E68

We compute the subring generated by T_2 on $J_0(100)$.

```
> T2 := HeckeOperator(JZero(100),2);
> R := Subring(T2); R;
Group of homomorphisms from JZero(100) to JZero(100)
> Rank(R);
3
```

Example H136E69

The Hecke operator T_2 and the main Atkin-Lehner involution together generate a commutative ring of rank 10 over $\mathbf{Z}$.

```
> J := JZero(100);
> T2 := HeckeOperator(J,2);W := AtkinLehnerOperator(J,100);
> R := Subring([End(J) | T2,W]);
> Dimension(R);
10
> Dimension(End(J));
13
> IsRing(R);
true
> IsCommutative(R);
false
```

136.5.3 Pullback and Pushforward of Hom Spaces

A homomorphism of abelian varieties induces a map from one space of homomorphisms into another. The three commands below compute the image of such maps.

`Pullback(H, phi)`

Given a space of homomorphisms H in $\mathrm{Hom}(A, B)$ and a morphism $\phi : B \to C$, compute the image of H in $\mathrm{Hom}(A, C)$ via the map that sends f to $f * \phi$.

`Pullback(phi, H)`

Given a space of homomorphisms H in $\mathrm{Hom}(A, B)$ and a morphism $\phi : C \to A$, compute the image of H in $\mathrm{Hom}(C, B)$ via the map that sends f to $\phi * f$.

`Pullback(phi, H, psi)`

Suppose H is a space of homomorphisms $A \to B$ and $\phi : C \to A$ and $\psi : B \to D$. Then this intrinsic computes and returns the ring of homomorphisms of A of the form $\phi * f * \psi$, where f is in H.

Example H136E70

```
> H := Hom(JZero(11),JZero(22));
> phi := NaturalMap(JZero(22),JZero(33));
> psi := NaturalMap(JZero(33),JZero(11));
> Pullback(H,phi);
Group of homomorphisms from JZero(11) to JZero(33)
> Pullback(psi,H);
Group of homomorphisms from JZero(33) to JZero(22)
> Pullback(psi,H,phi);
Group of homomorphisms from JZero(33) to JZero(33)
```

136.5.4 Arithmetic

The + and `meet` command compute the sum and intersection of two subgroups of $\mathrm{Hom}(A, B)$.

`H1 + H2`

The subgroup generated by H_1 and H_2, where H_1 and H_2 are assumed to both be subgroups of $\mathrm{Hom}(A, B)$, for abelian varieties A and B.

`H1 meet H2`

The intersection of H_1 and H_2, where H_1 and H_2 are assumed to both be subgroups of $\mathrm{Hom}(A, B)$, for abelian varieties A and B.

Example H136E71

```
> J := JZero(33);
> E := End(J);
> H1 := HeckeAlgebra(J); H1;
HeckeAlg(JZero(33)): Group of homomorphisms from JZero(33) to JZero(33)
> H2 := Subgroup([E.1,E.2]); H2;
Group of homomorphisms from JZero(33) to JZero(33)
> Dimension(E);
5
> Dimension(H1);
3
> Dimension(H2);
2
> Dimension(H1 meet H2);
1
> Dimension(H1 + H2);
4
```

136.5.5 Quotients

If H_1 and H_2 are subspaces of $\mathrm{Hom}(A, B)$ then the index of H_1 in H_2 can be computed. The quotient H_2/H_1 can also be taken.

`Index(H2, H1)`

The index of H_1 in H_2, where H_1 and H_2 are both subgroups of $\mathrm{Hom}(A, B)$, for abelian varieties A and B. If H_1 is contained in H_2, this is just the cardinality of H_2/H_1, or 0 if this cardinality is infinite. If H_1 is not contained in H_2, then the index is by definition the generalized lattice index $[H_1 + H_2 : H_1]/[H_1 + H_2 : H_2]$, assuming the denominator is nonzero, i.e., that H_2 has finite index in $H_1 + H_2$ (an error occurs if H_2 does not have finite index in $H_1 + H_2$).

`Quotient(H2, H1)`

`H2 / H1`

The abelian group quotient H_2/H_1, a map from H_2 to this quotient, and a lifting map from this quotient to H_2, where H_1 and H_2 are subgroups of $\mathrm{Hom}(A, B)$ and A and B are abelian varieties.

Example H136E72

We define the subgroup of $\mathrm{End}(J_0(54))$ generated by T_1, T_2, T_3, and T_4, find that it has infinite index in the full Hecke algebra, and compute the quotient, which is $\mathbf{Z}$.

```
> J := JZero(54);
> T := HeckeAlgebra(J);
> Dimension(T);
4
> S := Subgroup([HeckeOperator(J,n) : n in [1..4]]);
> Dimension(S);
3
> Index(T,S);
0
> Quotient(T,S);
Abelian Group isomorphic to Z
Defined on 1 generator (free)
Mapping from: HomModAbVar: T to Abelian Group isomorphic to Z
Defined on 1 generator (free) given by a rule [no inverse]
Mapping from: Abelian Group isomorphic to Z
Defined on 1 generator (free) to HomModAbVar: T given by a rule
[no inverse]
> G := T/S; G;
Abelian Group isomorphic to Z
Defined on 1 generator (free)
```

We compute the subgroup generated by T_3, T_4, T_5, and T_{10}, and find that it has index 6 in its saturation.

```
> S := Subgroup([HeckeOperator(J,n) : n in [3,4,5,10]]);
> Sat := Saturation(S);
> Index(Sat,S);
6
> Index(S,Sat);
1/6
> Invariants(Sat/S);
[ 6 ]
```

136.5.6 Invariants

Domain and codomain of the homomorphisms in a space of homomorphisms of abelian varieties can both be retrieved from the space as well as a field which all homomorphisms in a space are defined over.

A possibly time consuming computation is that of the discriminant of a space of homomorphisms. Discriminants of Hecke algebras are particularly interesting to compute because they are closely related to congruences between eigenforms.

`Domain(H)`

The domain of the homomorphisms in the group H of homomorphisms between modular abelian varieties.

`Codomain(H)`

The codomain of the homomorphisms in the group H of homomorphisms between modular abelian varieties.

`FieldOfDefinition(H)`

A field over which all homomorphisms in the group H of homomorphisms of abelian varieties are defined. It is not guaranteed to be minimal.

`Discriminant(H)`

The discriminant of the space H of homomorphisms of abelian varieties with respect to the trace pairing matrix. This is the trace of endomorphisms acting on homology, not left multiplication on themselves, so, e.g., the discriminant of the Hecke algebra will be 2^d times as big as it would be otherwise (if the sign is 0), where d is the dimension of A. If H is over $\mathbf{Q}$, this function returns the discriminant of the lattice of elements in H that are homomorphisms.

Example H136E73

```
> H := Hom(JZero(11),JZero(33));
> Domain(H);
Modular abelian variety JZero(11) of dimension 1 and level 11 over Q
> Codomain(H);
Modular abelian variety JZero(33) of dimension 3 and level 3*11 over
Q
> FieldOfDefinition(H);
Rational Field
> A := BaseExtend(JZero(11),ComplexField());
> H := End(A);
> FieldOfDefinition(H);
Complex Field
```

Though $H = \mathbf{Z}$, so the discriminant of the abstract ring H is 1, the discriminant of the trace pairing of H acting on homology is 2:

```
> Discriminant(H);
2
[2]
```

The prime $p = 389$ is the only known example where p divides the discriminant of the Hecke algebra of $J_0(p)$.

```
> T := HeckeAlgebra(JZero(389,2 : Sign := +1));
> d := Discriminant(T);
> J := JZero(389,2,+1);
```

```
> T := HeckeAlgebra(J);
> d := Discriminant(T);
> d mod 389;
0
> Factorization(d);
[ <2, 53>, <3, 4>, <5, 6>, <31, 2>, <37, 1>, <389, 1>, <3881, 1>,
<215517113148241, 1>, <477439237737571441, 1> ]
```

All the "action" at 389 comes from the 20-dimensional simple factor.

```
> A := J(5); A;
Modular abelian variety 389E of dimension 20, level 389 and
conductor 389^20 over Q with sign 1
> Factorization(Discriminant(HeckeAlgebra(A)));
[ <2, 98>, <5, 41>, <389, 1>, <215517113148241, 1>,
<477439237737571441, 1> ]
```

136.5.7 Structural Invariants

The following commands provide access to a basis and generators for spaces of homomorphisms.

`Basis(H)`

`Generators(H)`

A basis for the space H of homomorphisms of abelian varieties.

`Dimension(H)`

`Rank(H)`

The rank of the space H of homomorphisms of abelian varieties as a $\mathbf{Z}$-module or $\mathbf{Q}$-vector space.

`Ngens(H)`

The number of generators of the space H of homomorphisms of abelian varieties.

`H . i`

The ith generator of the space H of homomorphisms of abelian varieties.

Example H136E74

The following example illustrates each of the commands for $\mathrm{Hom}(J_0(11), J_0(33))$.

```
> H := Hom(JZero(11),JZero(33));
> Basis(H);
[
    Homomorphism from JZero(11) to JZero(33) given on integral homology
    by:
    [ 0  2 -1 -2  0  1]
    [ 1  0 -1 -1  1  1],
    Homomorphism from JZero(11) to JZero(33) given on integral homology
    by:
    [ 1  0 -2  2 -3  0]
    [ 1 -1  0  1 -2  1]
]
> Dimension(H);
2
> Ngens(H);
2
> Rank(H);
2
> H.1;
Homomorphism from JZero(11) to JZero(33) given on integral homology by:
[ 0  2 -1 -2  0  1]
[ 1  0 -1 -1  1  1]
```

136.5.8 Matrix and Module Structure

The following commands associate lattices, vector spaces, matrix algebras, and matrix spaces to subspaces H of $\mathrm{Hom}(A, B)$.

`Lattice(H)`

`VectorSpace(H)`

A lattice or vector space with basis obtained from the components of the matrices of a basis for the space H of homomorphisms of abelian varieties. This free **Z**-module is constructed from the `Eltseq`s of the all of the basis elements of H.

`MatrixAlgebra(H)`

The matrix algebra generated by the underlying matrices of all elements in the space H of homomorphisms of abelian varieties, acting on homology.

`RMatrixSpace(H)`

The matrix space whose basis is the generators for the space H of homomorphisms of abelian varieties.

`RModuleWithAction(H)`

A module over the ring R generated by the space H of homomorphisms of abelian varieties equipped with the action of H, where H must be a ring of endomorphisms.

`RModuleWithAction(H, p)`

A module over H tensor F_p equipped with the action of H tensor F_p, where H must be a ring of endomorphisms of an abelian variety that has not been tensored with $\mathbf{Q}$.

Example H136E75

We first demonstrate some of the commands with $\mathrm{Hom}(J_0(11), J_0(33))$.

```
> H := Hom(JZero(11),JZero(33));
> Lattice(H);
Lattice of rank 2 and degree 12
Basis:
( 0  2 -1 -2  0  1  1  0 -1 -1  1  1)
( 1  0 -2  2 -3  0  1 -1  0  1 -2  1)
> RMatrixSpace(H);
RMatrixSpace of 2 by 6 matrices and dimension 2 over Integer Ring
> RMatrixSpace(BaseExtend(H,RationalField()));
KMatrixSpace of 2 by 6 matrices and dimension 2 over Rational
Field
> VectorSpace(H);
Vector space of degree 12, dimension 2 over Rational Field
User basis:
( 1  0 -2  2 -3  0  1 -1  0  1 -2  1)
( 0 -2  1  2  0 -1 -1  0  1  1 -1 -1)
```

Next we consider the endomorphism algebra of $J_0(22)$.

```
> H := End(JZero(22));
> MatrixAlgebra(H);
Matrix Algebra of degree 4 with 4 generators over Integer Ring
> RModuleWithAction(H);
RModule(IntegerRing(), 4)
Action:
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
[ 0  1  0  1]
[ 0  0  0  0]
[ 1  0  1 -1]
[ 0  1  0  1]
[ 0  1  0 -1]
[ 0  1  0  0]
[-1  2 -1  1]
```

```
[-1  1  0  0]
[ 0  1 -2  1]
[-1  2 -1  0]
[-1  0  1 -1]
[ 0 -1  1 -1]
```

Example H136E76

The following example illustrates that `MatrixAlgebra` computes the algebra generated by H, even if H is not itself an algebra.

```
> H := Subgroup([HeckeOperator(JZero(33),2)]); H;
Group of homomorphisms from JZero(33) to JZero(33)
> A := MatrixAlgebra(H); A;
Matrix Algebra of degree 6 with 1 generator over Integer Ring
> Dimension(A);
2
> Dimension(H);
1
```

136.5.9 Predicates

These commands determine whether a space of homomorphisms is a ring, if it's commutative, if it's a field (and what field), if it was created using the `HeckeAlgebra` command, whether it has been tensored with $\mathbf{Q}$, or whether it is saturated in the full ring of endomorphisms. Equality and inclusion can also be tested.

`IsRing(H)`

Return `true` if the space H of homomorphisms of abelian varieties is a ring. (Note that a ring does not have to contain unity.)

`IsField(H)`

Return `true` if the space H of homomorphisms of abelian varieties is a field, and if so returns that field, a map from the field to H, and a map from H to the field.

`IsCommutative(H)`

Return `true` if and only if the space H of homomorphisms of abelian varieties is a commutative ring.

`IsHeckeAlgebra(H)`

Return `true` if the space H of homomorphisms of abelian varieties was constructed using the `HeckeAlgebra` command.

`IsOverQ(H)`

Return `true` if the space H of homomorphisms of abelian varieties is a $\mathbf{Q}$-vector space instead of just a $\mathbf{Z}$-module, i.e., a space of homomorphisms up to isogeny.

`IsSaturated(H)`

Return `true` if the space H of homomorphisms of abelian varieties is equal to its saturation, i.e., the quotient of the ambient $\mathrm{Hom}(A, B)$ by H is torsion free.

`H1 eq H2`

Return `true` if the spaces H_1 and H_2 of homomorphisms of abelian varieties are equal.

`H1 subset H2`

Return `true` if the spaces H_1 and H_2 of homomorphisms of abelian varieties are both subgroups of a common $\mathrm{Hom}(A, B)$, and in addition H_1 is a subset of H_2.

Example H136E77

We illustrate several of the commands for the endomorphism ring of $J_0(33)$.

```
> H := End(JZero(33));
> IsCommutative(H);
false
> IsField(H);
false 0 0 0
> IsHeckeAlgebra(H);
false
> IsOverQ(H);
false
> IsOverQ(BaseExtend(H,RationalField()));
true
> IsRing(H);
true
> IsSaturated(H);
true
```

Next we compare the endomorphism ring with the Hecke algebra of $J_0(33)$.

```
> T := HeckeAlgebra(JZero(33));
> T eq H;
false
> T subset H;
true
> IsSaturated(T);
true
> IsRing(T);
true
> IsHeckeAlgebra(T);
```

```
true
> IsCommutative(T);
true
> IsField(BaseExtend(T,RationalField()));
false 0 0 0
```

The Hecke algebra of $J_0(33)$ is actually a product of 3 fields, so it is not a field. In contrast, the Hecke algebra of $J_0(23)$ is a field.

```
> T := HeckeAlgebra(JZero(23));
> IsField(T);
false 0 0 0
```

In the following code, the answer you get might be different, since computation of the defining polynomial for the number field involves a randomized algorithm.

```
> IsField(BaseExtend(T,RationalField()));
true Number Field with defining polynomial x^2 + 11*x + 29 over
the Rational Field
Mapping from: Number Field with defining polynomial x^2 + 11*x +
    29 over the Rational Field to HeckeAlg(JZero(23))_Q: Group of
homomorphisms from JZero(23) to JZero(23) in the category of abelian
varieties up to isogeny  given by a rule [no inverse]
Mapping from: HeckeAlg(JZero(23))_Q: Group of homomorphisms from
JZero(23) to JZero(23) in the category of abelian varieties up to
isogeny  to Number Field with defining polynomial x^2 + 11*x + 29
over the Rational Field given by a rule [no inverse]
```

136.5.10 Elements

Elements of spaces of homomorphisms exist as maps between abelian varieties as discussed in Section 136.4.

`H ! x`

Coerce x into the space H of homomorphisms of abelian varieties. For this coercion to be successful x must be a homomorphism between 2 abelian varieties, an integer or a rational number or a matrix coercible into the matrix space of H base extended to the rational numbers.

Example H136E78

```
> H := End(JZero(22));
> H ! Matrix(Integers(), 4, 4,
>              [9, -4, 0, 2, 0, 6, 0, 0, 2, -6, 11, -2, 3, -4, -0, 8]);
Homomorphism from JZero(22) to JZero(22) given on integral homology by:
[ 9 -4  0  2]
[ 0  6  0  0]
[ 2 -6 11 -2]
```

```
[ 3 -4  0  8]
```

136.6 Arithmetic of Abelian Varieties

136.6.1 Direct Sum

One can take arbitrary finite direct sums of modular abelian varieties. We do not write `A+B` for the direct sum, since it is already used for the sum of A and B inside a common ambient abelian variety, and this sum need not be direct, unless $A \cap B = 0$.

`DirectSum(A, B)`

`DirectProduct(A, B)`

`A * B`

The direct sum D of abelian varieties A and B, together with the embedding maps from A into D and B into D, respectively, and the projection maps from D onto A and B, respectively. It is not possible to take the direct sum of abelian varieties with different signs.

`DirectSum(X)`

`DirectProduct(X)`

The direct sum D of the sequence X of modular abelian varieties, together with a list containing the embedding maps from each modular abelian variety of X into D and a list containing the projection maps from D onto each modular abelian variety in X. It is not possible to take the direct sum of abelian varieties with different signs.

`A ^ n`

The direct sum of n copies of the abelian variety A. If $n = 0$, the zero subvariety of A. If n is negative, the $(-n)$-th power of the dual of A.

Example H136E79

Using the product operator we can take the direct product of any two modular abelian varieties, even ones of different weights or levels. We first illustrate taking the product of two abelian subvarieties of $J_0(65)$, then taking the product of one of the subvarieties of $J_0(65)$ with the weight 4 motive $J_1(11, 4)$.

```
> J := JZero(65);
> D := Decomposition(J); D;
[
    Modular abelian variety 65A of dimension 1, level 5*13 and
    conductor 5*13 over Q,
    Modular abelian variety 65B of dimension 2, level 5*13 and
    conductor 5^2*13^2 over Q,
```

```
    Modular abelian variety 65C of dimension 2, level 5*13 and
    conductor 5^2*13^2 over Q
]
> A := D[1];
> B := D[2];
> A*B;
Modular abelian variety 65A x 65B of dimension 3 and level 5*13
over Q
Homomorphism from 65A to 65A x 65B given on integral homology by:
[1 0 0 0 0 0]
[0 1 0 0 0 0]
Homomorphism from 65B to 65A x 65B given on integral homology by:
[0 0 1 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
Homomorphism from 65A x 65B to 65A (not printing 6x2 matrix)
Homomorphism from 65A x 65B to 65B (not printing 6x4 matrix)
> M := JZero(11,4);M;
Modular motive JZero(11,4) of dimension 2 and level 11 over Q
> P := A*M; P;
Modular motive 65A x JZero(11,4) of dimension 3 and level 5*11*13 over Q
```

The product also returns inclusions of each factor into the product and projection from the product onto each factor.

```
> C,f,g := A*B;
> f;
[*
Homomorphism from 65A to 65A x 65B given on integral homology by:
[1 0 0 0 0 0]
[0 1 0 0 0 0],
Homomorphism from 65B to 65A x 65B given on integral homology by:
[0 0 1 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
*]
```

Here we compare direct sums of abelian varieties to the sum of of abelian varieties in a common ambient abelian variety. Thus if A is as above, then

```
> Dimension(A);
1
> Dimension(A*A);
2
> Dimension(A+A);
```

```
1
```

If you take a direct sum of abelian varieties that are defined over different base rings, then MAGMA will first attempt to express them over a common over-ring.

```
> A := JZero(11);
> B := BaseExtend(JZero(14),CyclotomicField(3));
> C := A*B; C;
Modular abelian variety JZero(11) x JZero(14) of dimension 2 and level
2*7*11 over Q(zeta_3)
```

The above would not work if `CyclotomicField(3)` were replaced by `GF(3)`, since the base ring $\mathbf{Q}$ of A is not contained in `GF(3)`.

136.6.2 Sum in an Ambient Variety

The sum `A+B` is the sum of A and B inside a common ambient abelian variety. This sum need not be direct, unless the intersection of A and B is 0.

`A + B`

The sum of the images of the abelian varieties A and B in a common ambient abelian variety.

`SumOf(X)`

The sum of the modular abelian varieties in the sequence X.

`SumOfImages(phi, psi)`

The sum D of the images of the morphisms ϕ and ψ of abelian varieties in their common codomain, a morphism from D into their common codomain, and a list containing a morphism from the domain of each of ϕ and ψ to D. If the codomains are not the same, then the homomorphisms are replaced by homomorphisms into an appropriate direct sum of codomains.

`SumOfMorphismImages(X)`

The sum D of the images of the morphisms of abelian varieties in the list X in their common codomain, a morphism from D into their common codomain, and a list containing a morphism from the domain of each morphism in X to D. If not all codomains of the elements of X are the same, then the homomorphisms are replaced by homomorphisms into an appropriate direct sum of codomains.

`FindCommonEmbeddings(X)`

Return `true` and a list of embeddings into a common abelian variety, if one can be found using `Embeddings(A)` for all abelian varieties A in the sequence X.

136.6.3 Intersections

Two abelian varieties cannot, by themselves, by intersected without choosing an embedding of both varieties in a common ambient abelian variety. The algorithm for computing an intersection is to compute the kernel of a certain homomorphism.

Intersections are computed in MAGMA by finding a homomorphism whose kernel is isomorphic to the intersection. For example, if $f : A \to C$ and $g : B \to C$ are injective homomorphisms, then the intersection of their images is isomorphic to the kernel of $f - g$.

As mentioned above, kernels of morphisms of abelian varieties are frequently not themselves abelian varieties. Instead a kernel is an extension of an abelian variety by a finite group of components. Likewise, intersections of abelian varieties are often not abelian varieties.

The intersection commands also take a sequence of abelian varieties or list of morphisms in order to facilitate computation of n-fold intersections, for any positive integer n.

`A meet B`

`Intersection(X)`

Given abelian varieties A and B or a sequence X of abelian varieties, compute a finite lift G of the component group of the intersection, the *connected* component of the intersection C, and a map from the abelian variety that contains C to the abelian variety that contains G. The relevant intersection is $C + G$. The elements of X are replaced by their images via their modular embedding map. All the elements of X must be embedded in the same abelian variety.

`IntersectionOfImages(X)`

Given a sequence X of morphisms from abelian varieties into a common abelian variety, compute a finite lift G of the component group of the intersection, the *connected* component C of the intersection, and a map from the abelian variety that contains C to the abelian variety that contains G. The morphisms in X do not have to be injective.

`ComponentGroupOfIntersection(A, B)`

`ComponentGroupOfIntersection(X)`

Given abelian varieties A and B or a sequence X of abelian varieties compute the group of components of the intersection of A and B or the varieties in X. (For more details, see the discussion of kernels in Section 136.4.3).

Example H136E80

The intersection of the three simple newform abelian subvarieties of $J_0(65)$ is a group isomorphic to $\mathbf{Z}/2\mathbf{Z}$.

```
> D := Decomposition(JZero(65));
> G := ComponentGroupOfIntersection(D); G;
Finitely generated subgroup of abelian variety with
invariants [ 2 ]
```

```
> FieldOfDefinition(G);
Rational Field
```

The quotient of D[1] by this subgroup of order 2 is an elliptic curve over $\mathbf{Q}$ isogenous to D[1], but not isomorphic to D[1].

```
> B  := D[1]/G; B;
Modular abelian variety of dimension 1 and level 5*13 over Q
> IsIsomorphic(D[1],B);
false
```

Next we compute some non-finite intersections.

```
> A := D[1] + D[2];
> B := D[1] + D[3];
> A meet B;
Finitely generated subgroup of abelian variety with invariants [ 2, 2, 2 ]
Modular abelian variety of dimension 1 and level 5*13 over Q
Homomorphism from modular abelian variety of dimension 1 to
modular abelian variety of dimension 6 given on integral homology
by:
[ 1 -1  0  0  0  0  1 -1  0  0  0 -1]
[ 0  0  1 -1  1 -1  0  0  1 -1  1  0]
Homomorphism from modular abelian variety of dimension 6 to
JZero(65) (not printing 12x10 matrix)
```

We can also intersect images of morphisms.

```
> f := ModularEmbedding(A);
> g := ModularEmbedding(B);
> _, C := IntersectionOfImages([* f, g *]);
> C eq D[1];
true
```

Example H136E81

The following example illustrates failure of multiplicity one for $J_0(p)$ for a prime number p. This is the first such example known, and it was discovered by Lloyd Kilford using MAGMA [Kil02]. There are two elliptic curve factors A and B inside $J_0(431)$. The eigenforms associated to A and B are congruent modulo 2, but the intersection of A and B is trivial.

```
> J := JZero(431);
> IsPrime(431);
true
> A := Decomposition(J)[1];
> B := Decomposition(J)[2];
> G, C := A meet B;
> G;
{ 0 }: finitely generated subgroup of abelian variety with
invariants []
> C;
```

```
Modular abelian variety ZERO of dimension 0 and level 431 over Q
> Newform(A) - Newform(B);
-2*q^3 + 4*q^5 + 2*q^6 - 4*q^7 + O(q^8)
```

136.6.4 Quotients

If B is an abelian subvariety of A (or some natural image of B lies in A), then the quotient A/B is an abelian variety. Also, the cokernel of a homomorphism of abelian varieties is an abelian variety.

`A / B`

The quotient of the abelian variety A by a natural image B' of the abelian variety B. Here B' is the image of B under the modular embedding composed with the modular parameterization to A.

`Cokernel(phi)`

The cokernel of the morphism ϕ of abelian varieties and a morphism from the codomain of ϕ to the cokernel.

Example H136E82

We compute a 2-dimensional quotient of the 3-dimensional abelian variety $J_0(33)$ using the Hecke operator T_2.

```
> J := JZero(33);
> T := HeckeOperator(J,2);
> Factorization(CharacteristicPolynomial(T));
[
    <x - 1, 2>,
    <x + 2, 4>
]
> C := ConnectedKernel(T-1);
> B,psi := J/C;
> B;
Modular abelian variety of dimension 2 and level 3*11 over Q
```

136.7 Decomposing and Factoring Abelian Varieties

By the Poincare reducibility theorem, every abelian variety is isogenous to a product of simple abelian subvarieties. If A is a modular abelian variety over $\mathbf{Q}$, then A is isogenous to a product of simple abelian varieties A_f attached to newforms. The `Decomposition` and `Factorization` commands compute such decompositions.

136.7.1 Decomposition

`Decomposition(A)`

Given an abelian variety A, return a sequence $[B_i]$ of simple modular abelian varieties, whose product is isogenous to A. Each B_i is equipped with an embedding into A such that the sum of the images of the B_i is equal to A. This embedding is the first element of the output of `Embeddings` on page 4547, given a B_i.

`A(n)`

The nth factor in `Decomposition(A)`, denoted $A(n)$ where A is an abelian variety.

Example H136E83

We decompose $A = J_0(37) \times J_0(22)$, then find the embedding into A of a factor which is isogenous to $J_0(11)$.

```
> A := JZero(37) * JZero(22);
> D := Decomposition(A); D;
[
    Modular abelian variety 37A of dimension 1, level 2*11*37 and
    conductor 37 over Q,
    Modular abelian variety 37B of dimension 1, level 2*11*37 and
    conductor 37 over Q,
    Modular abelian variety N(11,814,1)(11A) of dimension 1,
    level 2*11*37 and conductor 11 over Q,
    Modular abelian variety N(11,814,2)(11A) of dimension 1,
    level 2*11*37 and conductor 11 over Q
]
> B := D[3];
> Embeddings(B);
[*
Homomorphism from N(11,814,1)(11A) to JZero(37) x JZero(22) given on
integral homology by:
[ 0  0  0  0  1  0 -1  3]
[ 0  0  0  0  0  1 -2  3]
*]
```

136.7.2 Factorization

`Factorisation(A)`

`Factorization(A)`

Given an abelian variety A, compute pairwise non-isogenous simple newform abelian varieties A_f whose product, with multiplicities, is isomorphic to A. A list of pairs $\langle B, [\phi, \ldots] \rangle$ is returned, where B is an isogeny simple abelian variety and $[\phi, \ldots]$ is a sequence of maps from B into A (whose length is the "multiplicity"), such that the product of all images of all B is isogenous to A, and the sum of the dimensions of the images of B is the dimension of A. Moreover, the B are pairwise non-isogenous. To obtain a list of the images of the B canonically embedded into A, use `Decomposition(A)`.

Example H136E84

```
> A := JZero(37) * JZero(22);
> Factorization(A);
[*
<Modular abelian variety 37A of dimension 1, level 37 and
conductor 37 over Q, [
    Homomorphism N(37,814,1) from 37A to JZero(37) x JZero(22) given on
    integral homology by:
    [ 1 -1  1  0  0  0  0  0]
    [ 1 -1 -1  1  0  0  0  0]
]>,
<Modular abelian variety 37B of dimension 1, level 37 and
conductor 37 over Q, [
    Homomorphism N(37,814,1) from 37B to JZero(37) x JZero(22) given on
    integral homology by:
    [1 1 1 0 0 0 0 0]
    [0 0 0 1 0 0 0 0]
]>,
<Modular abelian variety 11A of dimension 1, level 11 and
conductor 11 over Q, [
    Homomorphism N(11,814,1) from 11A to JZero(37) x JZero(22) given on
    integral homology by:
    [ 0  0  0  0  0  1 -2  3]
    [ 0  0  0  0  1 -1  1  0],
    Homomorphism N(11,814,2) from 11A to JZero(37) x JZero(22) given on
    integral homology by:
    [ 0  0  0  0 -1  0  2 -2]
    [ 0  0  0  0 -1  2 -1  0]
]>
*]
```

136.7.3 Decomposition with respect to an Endomorphism or a Commutative Ring

The following commands use the elements of a commutative subring of endomorphisms to decompose a modular abelian variety A into a direct sum of abelian subvarieties by taking kernels (which are analogous to generalized eigenspaces).

`DecomposeUsing(R)`

Decompose an abelian variety A using the commutative ring of endomorphisms generated by the space of homomorphisms R of A.

`DecomposeUsing(phi)`

Decompose an abelian variety A using the endomorphism ϕ of A.

Example H136E85

```
> T2 := HeckeOperator(JZero(100),2);
> DecomposeUsing(T2);
[
    Modular abelian variety of dimension 1 and level 2^2*5^2 over Q,
    Modular abelian variety of dimension 5 and level 2^2*5^2 over Q,
    Modular abelian variety of dimension 1 and level 2^2*5^2 over Q
]
> W := AtkinLehnerOperator(JZero(100),100);
> DecomposeUsing(W);
[
    Modular abelian variety of dimension 3 and level 2^2*5^2 over Q,
    Modular abelian variety of dimension 4 and level 2^2*5^2 over Q
]
```

136.7.4 Additional Examples

Example H136E86

We compute a decomposition of $J_0(46)$ as a product of simple abelian subvarieties.

```
> J := JZero(46); J;
Modular abelian variety JZero(46) of dimension 5 and level 2*23 over Q
> Decomposition(J);
[
    Modular abelian variety 46A of dimension 1, level 2*23 and
    conductor 2*23 over Q,
    Modular abelian variety N(23,46,1)(23A) of dimension 2, level
    2*23 and conductor 23^2 over Q,
    Modular abelian variety N(23,46,2)(23A) of dimension 2, level
    2*23 and conductor 23^2 over Q
```

```
]
```

Thus J decomposes as a product $E \times A \times B$, where E is an elliptic curve of conductor 46, and A and B are two isogenous images of $J_0(23)$.

```
> J(1);
Modular abelian variety 46A of dimension 1, level 2*23 and
conductor 2*23 over Q
> Conductor(J(1));
46
> Factorization(Conductor(J(2)));
[ <23, 2> ]
```

The `Factorization` command gives an explicit decomposition with embeddings of each factor into $J_0(46)$.

```
> Factorization(Conductor(J(2)));
[ <23, 2> ]
> Factorization(J);
[*
<Modular abelian variety 46A of dimension 1, level 2*23 and
conductor 2*23 over Q, [
    Homomorphism from 46A to JZero(46) given on integral homology
    by:
    [ 1  0 -2 -1 -1  1  1  1 -2  1]
    [ 0  1 -1 -1  0  0  0  1 -1  0]
]>,
<Modular abelian variety 23A of dimension 2, level 23 and
conductor 23^2 over Q, [
    Homomorphism N(23,46,1) from 23A to JZero(46) given on integral
    homology by:
    [-1  1 -1  1  0 -1 -1  1 -1  2]
    [ 0  0 -1  2 -2 -1  0  0  1  0]
    [ 0  0  0  1 -2  0  0  1  0  0]
    [ 0  1  0 -1  0  0  1  0  0  0],
    Homomorphism N(23,46,2) from 23A to JZero(46) given on integral
    homology by:
    [ 0 -1  0  0  1 -1  0  1  0  0]
    [-1  0  0  0  0 -1  2 -1  1 -1]
    [-1  1 -1  0  0  0  2 -2  2 -2]
    [ 0  0 -1  2 -1  0  0  0  0 -1]
]>
*]
```

136.8 Building blocks

The abelian variety $A_f/\mathbf{Q}$ associated to a newform f is isogenous over $\overline{\mathbf{Q}}$ to a power ${B_f}^r$ of some simple variety B_f, which is called a "building block". This section is concerned with computations related to the field of definition of B_f, and its endomorphism algebra.

The functions in this section take spaces of modular symbols, and *must have sign* +1. For instance, the modular symbols of level N, weight 2 and sign +1 are obtained from `ModularSymbols(N,2,1)`. (These spaces have the same dimension as the corresponding spaces of modular forms.) Furthermore, the space of symbols is expected to be *cuspidal, new and irreducible over* $\mathbf{Q}$ (in other words, the corresponding space of cusp forms is spanned by a single Galois orbit of newforms).

Acknowledgement: This section was contributed by Jordi Quer. For more details of the theory, and some tables, see [Que09].

136.8.1 Background and Notation

Let $f = \sum_{n=1}^{\infty} a_n q^n \in S_2^{new}(N, \varepsilon)$ be a newform of weight 2, level N and Nebentypus ε. Let E be the number field generated by the coefficients a_n, and let F be the field generated by the numbers $\mu_p := a_p^2/\varepsilon(p)$ for primes p not dividing N.

The abelian variety $A_f/\mathbf{Q}$ attached to f (that is, associated to the space spanned by f and its conjugates) is a variety of dimension equal to the degree $[E : \mathbf{Q}]$ with endomorphism algebra $\mathrm{End}_{\mathbf{Q}}(A_f) \otimes \mathbf{Q}$ isomorphic to E.

The variety A_f has complex multiplication if there is a nontrivial character χ (necessarily of order 2) such that $a_p = \chi(p)a_p$ for all p not dividing N, and in this case the variety B_f is an elliptic curve with complex multiplication by the quadratic field fixed by the kernel of χ.

We assume for the rest of this section that A_f has no complex multiplication. Then, the field F is totally real, and E/F is an abelian extension. E is totally real when ε is trivial, and otherwise E is a CM field. The endomorphism algebra $\mathrm{End}(B_f) \otimes \mathbf{Q}$ is a division algebra with centre F. It is either equal to F, and then $\dim(B_f) = [F : \mathbf{Q}]$ and $r = [E : F]$, or otherwise is a quaternion algebra over F, and then $\dim(B_f) = 2[F : \mathbf{Q}]$ and $r = [E : F]/2$.

For every element $s \in G_F$ there exists a unique primitive Dirichlet character χ_s, which only depends on the action of s on the field E, such that $a_p^s = \chi_s(p)a_p$ for all p not dividing N. The characters χ_s are called the *inner twists* of the form f.

Let F_δ be the extension of F generated by the square roots of the elements $\mu_p \in F$ (for p not dividing N). Note that $EF_\delta = E(\sqrt{\varepsilon})$, the field obtained by adjoining square roots of the character values, which is either E or a quadratic extension of E. We may associate to each $s \in \mathrm{Gal}(F_\delta/F)$ a primitive quadratic Dirichlet character ψ_s, defined by $\sqrt{\mu_p}^s = \psi_s(p)\sqrt{\mu_p}$ (for p not dividing N). These are called the *quadratic degree characters* of the form f. They are related with the inner twists of f by the identity $\chi_s(p) = \psi_s(p)\sqrt{\varepsilon(p)}^s/\sqrt{\varepsilon(p)}$.

Let $K_P/\mathbf{Q}$ be the field fixed by the kernel of the homomorphism $\delta : G_{\mathbf{Q}} \to F^*/F^{*2}$ that sends $Frob_p$ to μ_p for all p not dividing N with a_p nonzero. (This is enough to determine the homomorphism, because the primes with $a_p = 0$ have density zero). This homomorphism is returned by `DegreeMap` (the syntax uses the notation below).

The Galois group $Gal(K_P/\mathbf{Q})$ is abelian of exponent 2; choose a basis $\sigma_1, ..., \sigma_r$. Let $\psi_1, ..., \psi_r$ be the basis of $\mathrm{Hom}(Gal(K_P/\mathbf{Q}), \mathbf{Z}/2)$ dual to the basis $\{\sigma_i\}$, and consider the ψ_i's as characters on $G_{\mathbf{Q}}$. Also let t_i be a quadratic discriminant such that $\mathbf{Q}(\sqrt{t_i}) \subset K_P$ is the field fixed by the kernel of ψ_i.

Denote by γ_ε the element of $Br(\mathbf{Q})[2]$ given by the two-cocycle sending σ, τ to $\sqrt{\varepsilon(\sigma)}\sqrt{\varepsilon(\tau)}\sqrt{\varepsilon(\sigma\tau)}^{-1}$. Then the class in $Br(F)[2]$ of the endomorphism algebra $\mathrm{End}^0(B_f)$ is the restriction to F of $\gamma_\varepsilon \prod(t_i, \delta(\sigma_i))$. This is computed by `BrauerClass`.

In general the smallest fields of definition up to isogeny for B_f are quadratic extensions of K_P. It is sometimes possible to "descend" B_f (up to isogeny) to the field K_P. The obstruction to this descent lies in $Br(K_P)[2]$, and is given by the restriction of γ_ε to K_P. This is computed by `ObstructionDescentBuildingBlock`.

`BoundedFSubspace(epsilon, k, degrees)`

A sequence containing the irreducible subspaces of the modular symbols of weight k and Nebentypus character ϵ corresponding to non-CM newforms for which the degree $[F : \mathbf{Q}]$ of the centre of the endomorphism algebra (of the associated abelian variety) is in the sequence *degrees*.

`HasCM(M : parameters)`

`IsCM(M : parameters)`

`Proof` BoolElt *Default :* `false`

Return `true` if and only if the modular abelian variety attached to the given space of modular symbols has complex multiplication. When the level is larger than 100, an unproved bound is used in the computation, unless `Proof` is set to `true`.

`InnerTwists(A : parameters)`

`InnerTwists(M : parameters)`

`Proof` BoolElt *Default :* `false`

The inner twists of the newform $f = \sum a_n q^n$ corresponding to the given space of modular symbols, or to the given modular abelian variety. This should be irreducible over $\mathbf{Q}$, and f should not have CM, and only spaces of modular symbols with sign $+1$ are accepted.

The inner twists are Dirichlet characters satisfying $\chi_s(p) = a_p^s/a_p$ (for primes p not dividing the level), where s is in the absolute Galois group of $\mathbf{Q}$.

Warning: when the level is larger than 100, a non-rigorous bound is used in the computation, unless `Proof` is set to `true`. Even in that case, the returned twists are only checked to be inner twists up to precision 10^{-5}.

`DegreeMap(M : parameters)`

`Proof` BoolElt *Default :* `false`

The homomorphism $\delta : G_{\mathbf{Q}} \to F^*/F^{*2}$ (as defined in the introduction), attached to the given space M of modular symbols (which should be new, irreducible over $\mathbf{Q}$, and have sign $+1$). The second object returned is F. The first object returned is a sequence of tuples $< t_i, f_i >$, where $t_i \in \mathbf{Q}$ are quadratic discriminants and $f_i \in F$. The t_i determine a basis σ_i of $\mathrm{Gal}(K_P/\mathbf{Q})$ as in the introduction, and δ is the map sending σ_i to f_i.

`BrauerClass(M)`

Given a space of modular symbols M corresponding to a newform f, this function computes the Brauer class of the endomorphism algebra of the associated abelian variety A_f (or motive M_f). The endomorphism algebra is either a number field F (in which case an empty sequence is returned), or a quaternion algebra over a number field F. The corresponding class in the Brauer group $Br(F)[2]$ is specified by returning the sequence of places of F that ramify in the quaternion algebra.

The given space M should be irreducible over $\mathbf{Q}$, and have sign $+1$, and f should not have CM.

`ObstructionDescentBuildingBlock(M)`

Given a space of modular symbols M corresponding to a newform f, this function computes the obstruction to "descending" the building block B_f to the field K_P (for definitions, see the introduction). The obstruction to the existence of a building block over K_P isogenous to B_f is an element of the Brauer group $Br(K_P)[2]$. (More precisely, for any field L there exists such a building block over L if and only if L is an extension of K_P over which this Brauer element splits.) The Brauer class is specified by returning the sequence of places of K_P where the class is not locally trivial.

The given space M should be irreducible over $\mathbf{Q}$, and have sign $+1$, and f should not have CM.

Example H136E87

The lowest level where a nontrivial obstruction occurs is 28, with a character of order 6. We find that the space of modular symbols (with sign 1) for this character has dimension 2 over the field of character values.

```
> Chi28 := FullDirichletGroup(28);
> chi := Chi28.1*Chi28.2;
> Chi28;
Group of Dirichlet characters of modulus 28
   over Cyclotomic Field of order 6 and degree 2
> Order(Chi28), Order(chi);
12 6
>  M28chi := CuspidalSubspace( ModularSymbols(chi, 2, 1));
> M28chi;
```

```
Modular symbols space of level 28, weight 2, character $.1*$.2, and dimension
2 over Cyclotomic Field of order 6 and degree 2
> qEigenform(M28chi);
q + (1/3*(-zeta_6 - 1)*a - zeta_6)*q^2 + a*q^3 + 1/3*(4*zeta_6 - 2)*a*q^4 +
    (zeta_6 - 2)*q^5 + (-zeta_6*a + (2*zeta_6 - 1))*q^6 + 1/3*(-zeta_6 - 4)*a*q^7
    + O(q^8)
> Parent(Coefficients(qEigenform(M28chi))[2]);
Univariate Quotient Polynomial Algebra in a
   over Cyclotomic Field of order 6 and degree 2
   with modulus a^2 + 3*zeta_6
```

So the q-eigenform is defined over a quadratic extension of $\mathbf{Q}(\zeta_6)$, In fact, this extension is $\mathbf{Q}(\zeta_6, i)$. Since the space `M28chi` has dimension 2 over $\mathbf{Q}(\zeta_6)$, it is irreducible over $\mathbf{Q}(\zeta_6)$. The corresponding abelian variety over $\mathbf{Q}$ therefore has dimension 4.

```
> A := ModularAbelianVariety(M28chi);
> A;
Modular abelian variety of dimension 4 and level 2^2*7 over Q with sign 1
> delta, F := DegreeMap(M28chi);
> F;
Rational Field
```

This means that A is isogenous to B^2 for some abelian variety B over $\overline{\mathbf{Q}}$ of dimension 2, and that the endomorphism algebra of B is a quaternion algebra over $F = \mathbf{Q}$.

```
> BrauerClass(M28chi);
[ 2, 3 ]
```

This means the endomorphism algebra of B is the quaternion algebra over $\mathbf{Q}$ ramified only at 2 and 3. Now we determine the possible fields of definition of B.

```
> delta;  // This came from DegreeMap, above.
[ <-7, 3> ]
```

In particular, this tells us that $K_P = \mathbf{Q}(\sqrt{-7})$.

```
> ObstructionDescentBuildingBlock(M28chi);
[ Place at Prime Ideal
Two element generators:
    [2, 0]
    [0, 1],
Place at Prime Ideal
Two element generators:
    [2, 0]
    [3, 1] ]
> Universe($1);  // What are these places elements of?
Set of Places of Number Field with defining polynomial x^2 + 7
over the Rational Field
```

The obstruction is given as a list of places of $\mathbf{Q}(\sqrt{-7})$. Recall that B can be defined over any extension of K_P for which the obstruction is trivial. In this case, any extension of $\mathbf{Q}(\sqrt{-7})$ which splits the quaternion algebra over $\mathbf{Q}(\sqrt{-7})$ ramified at the two primes above 2.

136.9 Orthogonal Complements

136.9.1 Complements

The following two commands find a complement of an abelian subvariety of an abelian variety. Existence of a complement is guaranteed by the Poincare reducibility theorem (if we were just working with n-dimensional complex tori, then there need not be complements of subtori). MAGMA computes a complement using the module-theoretic structure of the ambient variety.

`Complement(A : parameters)`

`IntPairing` BOOLELT *Default :* `false`

The complement of the image of the abelian variety A under the first embedding of A (the first map in the sequence returned by `Embeddings` on page 4547). If the parameter `IntPairing` is set to `true`, the intersection pairing is used to compute the homology complement.

`ComplementOfImage(phi : parameters)`

`IntPairing` BOOLELT *Default :* `false`

Suppose $\phi : A \to B$ is a morphism of abelian varieties. By the Poincare reducibility theorem, there is an abelian variety C such that $\phi(A) + C = B$ and the intersection of $\phi(A)$ with C is finite. This intrinsic returns a choice of C and an embedding of C into B. If the parameter `IntPairing` is set to `true`, the intersection pairing is used to compute the homology complement.

Example H136E88

We compute a decomposition of $J_0(33)$ as a product of simples, then find a decomposition of the complement of one of the factors.

```
> J := JZero(33);
> D := Decomposition(J); D;
[
    Modular abelian variety 33A of dimension 1, level 3*11 and
    conductor 3*11 over Q,
    Modular abelian variety N(11,33,1)(11A) of dimension 1, level
    3*11 and conductor 11 over Q,
    Modular abelian variety N(11,33,3)(11A) of dimension 1, level
    3*11 and conductor 11 over Q
]
> A := D[3];
> B := Complement(A);
> B;
Modular abelian variety of dimension 2 and level 3*11 over Q
> Decomposition(B);
[
    Modular abelian variety image(33A) of dimension 1, level 3*11
```

```
    and conductor 3*11 over Q,
    Modular abelian variety image(11A) of dimension 1, level 3*11
    and conductor 11 over Q
]
```

Here we compute a somewhat random map from $J_0(11)$ to $J_0(33)$, and compute the complement of the image.

```
> phi := 2*NaturalMap(JZero(11),JZero(33),1) - 3*NaturalMap(JZero(11),
>                         JZero(33),3);
> phi;
Homomorphism from JZero(11) to JZero(33) given on integral homology by:
[ 2  6 -7 -2 -6  3]
[ 5 -2 -3 -1 -1  5]
> C,pi := ComplementOfImage(phi);
> C;
Modular abelian variety of dimension 2 and level 3*11 over Q
> Decomposition(C);
[
    Modular abelian variety image(33A) of dimension 1, level 3*11
    and conductor 3*11 over Q,
    Modular abelian variety image(11A) of dimension 1, level 3*11
    and conductor 11 over Q
]
```

136.9.2 Dual Abelian Variety

It is possible to compute an abelian variety which is dual to a given variety in many of the cases that are of interest. Let A be an abelian variety and suppose the modular map $A \to J$ is injective, where J is attached to a space of modular symbols and J is isomorphic to its dual (e.g., $J = J_0(N)$). To compute the dual of A, we find a complement B of A in J whose homology is orthogonal to the homology of A with respect to the intersection pairing. This can frequently be accomplished (e.g., when A is attached to a newform) without using the intersection pairing by finding a complement B such that the rational homology of B as a module over the Hecke algebra has no simple factors in common with that of A. Then J/B is isomorphic to the dual of A.

`IsDualComputable(A)`

Return `true` if the dual of the abelian variety A can be computed, and the dual. Otherwise, return `false` and a message.

`Dual(A)`

The dual abelian variety of the abelian variety A. The modular map to a modular symbols abelian variety must be injective.

`ModularPolarization(A)`

The polarization on the abelian variety A induced by pullback of the theta divisor.

Example H136E89

We compute the dual of a 2-dimensional newform abelian variety of level 43, and note that it is isomorphic to itself.

```
> J := JZero(43);
> A := Decomposition(J)[2]; A;
Modular abelian variety 43B of dimension 2, level 43 and
conductor 43^2 over Q
> Adual := Dual(A); Adual;
Modular abelian variety of dimension 2 and level 43 over Q
> IsIsomorphic(A,Adual);
true Homomorphism from 43B to modular abelian variety of
dimension 2 given on integral homology by:
[-1  1 -1  1]
[-1  0  1  0]
[-1  0  0  0]
[ 0  0 -1  1]
```

Next we compute the dual of a 2-dimensional newform abelian variety of level 69, and find that it is not isomorphic to itself.

```
> A := Decomposition(JZero(69))[2]; A;
Modular abelian variety 69B of dimension 2, level 3*23 and
conductor 3^2*23^2 over Q
> Adual := Dual(A); Adual;
Modular abelian variety of dimension 2 and level 3*23 over Q
> IsIsomorphic(A,Adual);
false
```

One can show that the natural map from A to its dual is a polarization of degree 484.

```
> phi := NaturalMap(A,Adual);
> phi;
Homomorphism N(1) from 69B to modular abelian variety of
dimension 2 given on integral homology by:
[  3   1   5  -7]
[ -1   5  -1   1]
[ -6   4  -1   7]
[ 11  -7   6 -12]
> Degree(phi);
484
> Factorization(484);
[ <2, 2>, <11, 2> ]
1
```

136.9.3 Intersection Pairing

These commands compute the matrix of the intersection pairing on homology with respect to the fixed basis for rational or integral homology. If A is not a modular symbols abelian variety (such as $J_0(N)$), then the intersection pairing on homology computed below *is the one obtained by pulling back from the pairing on the codomain of the modular embedding* of A. This may not be what you expect, but is easy to compute in great generality.

Computation of intersection pairings is currently only implemented for weight 2.

`IntersectionPairing(H)`

The intersection pairing matrix on the basis of the homology H of an abelian variety.

`IntersectionPairing(A)`

The intersection pairing matrix on the basis for the rational homology of the abelian variety A, pulled back using the modular embedding.

`IntersectionPairingIntegral(A)`

The intersection pairing matrix on the basis for the integral homology of the abelian variety A, pulled back using the modular embedding.

Example H136E90

The intersection pairing on $J_0(11)$ is very simple.

```
> J := JZero(11);
> IntersectionPairing(J);
[ 0 -1]
[ 1  0]
> IntersectionPairingIntegral(J);
[ 0 -1]
[ 1  0]
```

The intersection pairing associated to $J_0(33)$ is more interesting. Note that the representing matrix is skew symmetric and has determinant 1.

```
> I := IntersectionPairingIntegral(JZero(33)); I;
[ 0  1  0  1  0  1]
[-1  0  0  1  0  1]
[ 0  0  0  1  0  1]
[-1 -1 -1  0  0  1]
[ 0  0  0  0  0  1]
[-1 -1 -1 -1 -1  0]
> Determinant(I);
1
```

The intersection pairing on **33A** is surprising, because it is pulled back from the intersection pairing on $J_0(33)$. Thus instead of having determinant 1, it has determinant 9.

```
> A := ModularAbelianVariety("33A");  A;
Modular abelian variety 33A of dimension 1 and level 3*11 over Q
```

```
> I := IntersectionPairingIntegral(A); I;
[ 0  3]
[-3  0]
> Determinant(I);
9
```

136.9.4 Projections

Suppose ϕ is a homomorphism from A to B. Then the image $\phi(A)$ is an abelian subvariety of B. The commands below compute a map π in the endomorphism algebra of B whose image is $\phi(A)$ and such that $\pi^2 = \pi$, i.e., π is projection onto $\phi(A)$. A projection map is not canonical, unless it is required to respect the intersection pairing.

`ProjectionOnto(A` : *parameters*`)`

`ProjectionOntoImage(phi` : *parameters*`)`

`IntPairing` BoolElt *Default :* `false`

Given a morphism $\phi : A \to B$ return a projection onto $\phi(A)$ as an element of $E \otimes \mathbf{Q}$, where E is the endomorphism ring of B. If the optional parameter `IntPairing` is set to `true`, then the projection is also required to respect the intersection pairing, which uniquely determines π.

Example H136E91

```
> pi := ProjectionOnto(ModularAbelianVariety("33A"));  pi;
Homomorphism pi from JZero(33) to JZero(33) (up to isogeny) on
integral homology by:
 (not printing 6x6 matrix)
> Matrix(pi);
[ 2/3  1/3 -1/3  1/3    0 -2/3]
[ 1/3  2/3 -2/3  2/3    0 -1/3]
[ 1/3  1/3 -1/3  1/3    0 -1/3]
[   0  2/3 -2/3  2/3    0    0]
[   0  1/3 -1/3  1/3    0    0]
[-1/3  1/3 -1/3  1/3    0  1/3]
> pi^2 eq pi;
true
> Rank(pi);
1
```

Example H136E92

```
> phi := NaturalMap(JZero(11),JZero(44));
> pi := ProjectionOntoImage(phi); pi;
Homomorphism pi from JZero(44) to JZero(44) (up to isogeny) on
integral homology by:
 (not printing 8x8 matrix)
> A := Image(5*pi); A;
Modular abelian variety of dimension 1 and level 2^2*11 over Q
> IsIsomorphic(JZero(11),A);
true Homomorphism from JZero(11) to modular abelian variety of
dimension 1 given on integral homology by:
[ 0 -1]
[-1  1]
```

136.9.5 Left and Right Inverses

Left and right inverses of homomorphisms in the category of abelian varieties up to isogeny can be computed. A left or right inverse times a minimal integer can be computed instead so that the result is a homomorphism.

MAGMA computes a right inverse of a finite-degree homomorphism ϕ by finding the projection map onto the complement of the image of ϕ, and composing with a inverse from the image. To find a left inverse of a surjective homomorphism $\phi : A \to B$, MAGMA computes the complement C of the kernel of ϕ and inverts ϕ restricted to C. This complement C is an abelian subvariety of A that maps isomorphically onto B.

`LeftInverse(phi : parameters)`

`IntPairing` BOOLELT *Default :* `false`

Given a surjective homomorphism $\phi : A \to B$ of abelian varieties return a homomorphism $\psi : B \to A$ of minimal degree in the category of abelian varieties up to isogeny such that $\psi * \phi$ is the identity map on B and an integer d such that $d * \psi$ is a homomorphism.

If the parameter `IntPairing` is `true` then the intersection pairing is used to compute the homology complement.

`LeftInverseMorphism(phi : parameters)`

`IntPairing` BOOLELT *Default :* `false`

Given a surjective homomorphism $\phi : A \to B$ of abelian varieties, return a homomorphism $\psi : B \to A$ of minimal degree such that $\psi * \phi$ is multiplication by an integer.

If the parameter `IntPairing` is `true` then the intersection pairing is used to compute the homology complement.

`RightInverse(phi : parameters)`

`IntPairing` BoolElt *Default :* `false`

Given a homomorphism $\phi : A \to B$ of abelian varieties with finite kernel, return a map $\psi : B \to A$ in the category of abelian varieties up to isogeny such that $\phi * \psi : A \to A$ is the identity map.

If the parameter `IntPairing` is `true` then the intersection pairing is used to compute the homology complement.

`RightInverseMorphism(phi : parameters)`

`IntPairing` BoolElt *Default :* `false`

Given a homomorphism $\phi : A \to B$ of abelian varieties with finite kernel return a minimal-degree homomorphism $\psi : B \to A$ such that $\phi * \psi : A \to A$ is multiplication by an integer.

If the parameter `IntPairing` is `true` then the intersection pairing is used to compute the homology complement.

Example H136E93

First we compute the difference ϕ of the two natural degeneracy maps $J_0(11) \to J_0(33)$, which has as kernel a group of order 5 (called the Shimura subgroup in this case).

```
> J11 := JZero(11);  J33 := JZero(33);
> d1 := NaturalMap(J11,J33,1);
> d3 := NaturalMap(J11,J33,3);
> phi := d1-d3;
> Degree(phi);
5
```

A right inverse of ϕ is a homomorphism up to isogeny from $J_0(33)$ to $J_0(11)$.

```
> RightInverse(phi);
Homomorphism from JZero(33) to JZero(11) (up to isogeny) on integral
homology by:
 (not printing 6x2 matrix)
15
> RightInverseMorphism(phi);
Homomorphism from JZero(33) to JZero(11) (not printing 6x2 matrix)
> phi*RightInverseMorphism(phi);
Homomorphism from JZero(11) to JZero(11) given on integral homology by:
[15  0]
[ 0 15]
```

Finally we find a left inverse of a map from $J_0(33)$ to $J_0(11)$.

```
> psi := NaturalMap(J33,J11,1) - NaturalMap(J33,J11,3);
> IsSurjective(psi);
true
> LeftInverse(psi);
```

```
Homomorphism from JZero(11) to JZero(33) (up to isogeny) on integral
homology by:
[ 1/5    0 -2/5  2/5 -3/5    0]
[ 1/5 -1/5    0  1/5 -2/5  1/5]
5
> LeftInverseMorphism(psi);
Homomorphism from JZero(11) to JZero(33) given on integral homology by:
[ 1  0 -2  2 -3  0]
[ 1 -1  0  1 -2  1]
> LeftInverseMorphism(psi)*psi;
Homomorphism from JZero(11) to JZero(11) given on integral homology by:
[5 0]
[0 5]
```

136.9.6 Congruence Computations

The congruence modulus and the modular degree are each an integer which measures "congruences" between an abelian variety and other abelian varieties. These two quantities are related because if a prime divides the modular degree, then it divides the congruence modulus, though the converse need not be true (see the example below).

`CongruenceModulus(A)`

Given $A = A_f$, an abelian variety attached to a newform f, return the congruence modulus of the newform f, taken in the space $S_2(N, \epsilon)$, where ϵ is the character of the newform, which is an integer that measures congruences between f and nonconjugate forms in the Peterson complement of f. More precisely, if $f \in S_k(N, \varepsilon)$, which is the direct sum of the spaces of modulus forms with character a Galois conjugate of ε, then we define the congruence modulus of f to be the order of the group $S_k(N, \varepsilon; \mathbf{Z})/(W + W^{\perp})$, where W is the intersection of $S_k(N, \varepsilon; \mathbf{Z})$ with the span of the Galois conjugates of f.

`ModularDegree(A)`

The modular degree of the abelian variety A. This is the square root of the degree of the map from A to its dual A' induced by virtue of A being modular. In some cases where no algorithm is implemented for computing A', a message is printed and the square of the degree of the composition of the modular embedding with the modular parameterization is computed. When any weight of a factor of A is bigger than 2 the square root is not taken.

Example H136E94

The modular degree and congruence modulus of one of the two elliptic curves of conductor 54 are interesting because they are not equal. This is the smallest level of an elliptic curve where these two invariants differ. (For more details, see [AS04].)

```
> J := JZero(54);
> A,B := Explode(Decomposition(NewSubvariety(J)));
> ModularDegree(A);
6
> CongruenceModulus(A);
6
> ModularDegree(B);
2
> CongruenceModulus(B);
6
```

The modular degree and congruence modulus are 4 for a certain abelian surface A of level 65. We also compute the kernel of the modular map and see that it is $A[2]$.

```
> J := JZero(65);
> A := J(2); A;
Modular abelian variety 65B of dimension 2, level 5*13 and
conductor 5^2*13^2 over Q
> CongruenceModulus(A);
4
> ModularDegree(A);
4
> phi := NaturalMap(A,Dual(A));
> Invariants(Kernel(phi));
[ 2, 2, 2, 2 ]
```

136.10 New and Old Subvarieties and Natural Maps

136.10.1 Natural Maps

Suppose M and N are positive integers and M divides N. There are natural maps in both directions between $J_0(N)$ and $J_0(M)$ (and likewise for J_1, etc.), for each divisor of $t = N/M$, which correspond to maps of the form $f(q) \mapsto f(q^t)$ and their duals. Since any modular abelian variety A in MAGMA is equipped with a map $A \to J_e$ and $J_p \to A$, where J_e and J_p are attached to modular symbols, the problem of defining natural maps between A and B is reduced to defining natural maps between modular abelian varieties attached to modular symbols.

`NaturalMap(A, B, d)`

Given abelian varieties A and B and an integer d return the natural map from A to B induced, in a potentially complicated way, from the map $f(q) \mapsto f(q^d)$ on modular forms. In situations where the modular forms associated to A and B have nothing to do with each other, then we define this map to be the zero map.

`NaturalMap(A, B)`

The natural map from the abelian variety A to the abelian variety B induced by the identity on modular forms, or the zero map if there is none.

`NaturalMaps(A, B)`

Given abelian varieties A and B return a sequence of the natural maps from A to B for all divisors d of the level of A over the level B, or the level of B over the level A.

Example H136E95

```
> A := JZero(11)*JZero(22);
> B := JZero(11)*JZero(33);
> phi := NaturalMap(A,B);
> phi;
Homomorphism N(1) from JZero(11) x JZero(22) to JZero(11) x JZero(33) (not
printing 6x8 matrix)
> Nullity(phi);
1
> f := NaturalMap(A,B,3); f;
Homomorphism N(3) from JZero(11) x JZero(22) to JZero(11) x JZero(33) (not
printing 6x8 matrix)
> Nullity(f);
2
> NaturalMaps(JZero(11),JZero(33));
[
    Homomorphism N(1) from JZero(11) to JZero(33) given on integral
    homology by:
    [ 1  0 -2  2 -3  0]
    [ 1 -1  0  1 -2  1],
    Homomorphism N(3) from JZero(11) to JZero(33) given on integral
    homology by:
    [ 0 -2  1  2  0 -1]
    [-1  0  1  1 -1 -1]
]
```

If we take a product of several copies of $J_0(11)$ and of several copies of $J_0(22)$, the `NaturalMaps` command still only returns 2 natural maps, one for each divisor of the quotient of the levels.

```
> A := JZero(11)^2;
> B := JZero(22)^3;
```

```
> NaturalMaps(A,B);
[
    Homomorphism N(1) from JZero(11) x JZero(11) to JZero(22) x JZero(22) x
    JZero(22) given on integral homology by:
    [ 0  1 -2  3  0  1 -2  3  0  1 -2  3]
    [ 1 -1  1  0  1 -1  1  0  1 -1  1  0]
    [ 0  1 -2  3  0  1 -2  3  0  1 -2  3]
    [ 1 -1  1  0  1 -1  1  0  1 -1  1  0],
    Homomorphism N(2) from JZero(11) x JZero(11) to JZero(22) x JZero(22) x
    JZero(22) given on integral homology by:
    [-1  0  2 -2 -1  0  2 -2 -1  0  2 -2]
    [-1  2 -1  0 -1  2 -1  0 -1  2 -1  0]
    [-1  0  2 -2 -1  0  2 -2 -1  0  2 -2]
    [-1  2 -1  0 -1  2 -1  0 -1  2 -1  0]
]
```

136.10.2 New Subvarieties and Quotients

These commands compute the new and r-new subvarieties and quotients of an abelian variety A of level N. The *r-new subvariety* of A is the intersection of the kernels of all natural maps from A to modular abelian varieties of level N/r. The *new subvariety* is the intersection of the r-new subvarieties over all prime divisors r of N. The *r-new quotient* of A is the quotient of A by the sum of all images in A under all natural maps of abelian varieties of level N/r.

`NewSubvariety(A, r)`

The r-new subvariety of the abelian variety A.

`NewSubvariety(A)`

The new subvariety of the abelian variety A.

`NewQuotient(A, r)`

The r-new quotient of the abelian variety A.

`NewQuotient(A)`

The new quotient of the abelian variety A.

Example H136E96

```
> J := JZero(33);
> Dimension(J);
3
> Dimension(NewSubvariety(J,3));
1
> Dimension(NewSubvariety(J));
1
> Dimension(NewSubvariety(J,11));
3
> Dimension(NewQuotient(J));
1
> Dimension(OldSubvariety(J));
2
> Dimension(OldSubvariety(J,3));
2
```

136.10.3 Old Subvarieties and Quotients

These commands compute the old and r-old subvarieties and quotients of an abelian variety A of level N. The *r-old subvariety* of A is the sum of the images of all natural maps from modular abelian varieties of level N/r to A. The *old subvariety* is the sum of the r-old subvarieties as r varies over the divisors of N. The r-old quotient of A is the quotient of A by its r-new subvariety.

`OldSubvariety(A, r)`

The r-old subvariety of the abelian variety A.

`OldSubvariety(A)`

The old subvariety of the abelian variety A.

`OldQuotient(A, r)`

The r-old quotient of the abelian variety A.

`OldQuotient(A)`

The old quotient of the abelian variety A.

Example H136E97

We compute the old subvariety and old quotient of $J_0(100)$, both of which have dimension 6.

```
> J := JZero(100); J;
Modular abelian variety JZero(100) of dimension 7 and level 2^2*5^2
over Q
> J_old := OldSubvariety(J); J_old;
Modular abelian variety JZero(100)_old of dimension 6 and level
2^2*5^2 over Q
> phi := Embeddings(J_old)[1];
> Codomain(phi);
Modular abelian variety JZero(100) of dimension 7 and level 2^2*5^2
over Q
> Jold := OldQuotient(J); Jold;
Modular abelian variety JZero(100)^old of dimension 6 and level
2^2*5^2 over Q
```

The new subvariety and new quotient of $J_0(100)$ intersect in a finite subgroup isomorphic to $\mathbf{Z}/12\mathbf{Z} \times \mathbf{Z}/12\mathbf{Z}$.

```
> J_new := NewSubvariety(J); J_new;
Modular abelian variety JZero(100)_new of dimension 1 and level
2^2*5^2 over Q
> G, A := J_new meet J_old; G;
Finitely generated subgroup of abelian variety with invariants
[ 12, 12 ]
> Dimension(A);
0
```

136.11 Elements of Modular Abelian Varieties

We represent torsion points on modular abelian varieties as follows. Suppose A is an abelian variety defined over the complex numbers $\mathbf{C}$. Then $A(\mathbf{C})$ is canonically isomorphic to $H_1(A, \mathbf{R})/H_1(A, \mathbf{Z})$, and the torsion subgroup of $A(\mathbf{C})$ is isomorphic to $H_1(A, \mathbf{Q})/H_1(A, \mathbf{Z})$. We represent a torsion element of $A(\mathbf{C})$ by giving a representative element of $H_1(A, \mathbf{Q})$. The functions below provide basic arithmetic operations with such elements, application of homomorphisms, and conversion functions.

Sometimes it is useful to consider elements of $H_1(A, \mathbf{R})$, given by floating point vectors (i.e., over `RealField()`). These represent certain points of infinite order, but without further information we do not know exactly what point they represent, or even whether such a point is 0.

Elements can only be created independently of other elements by coercion, see Section 136.2.14.

136.11.1 Arithmetic

The following commands describe the basic arithmetic operations available for elements of modular abelian varieties. Operations include addition, subtraction, and multiplication by an integer, rational number, or real number.

`a * x`

Product of the integer, rational or real number a by the element x of a modular abelian variety.

`x * a`

Product of the element x of a modular abelian variety by the integer, rational or real number a.

`x + y`

The sum of elements x and y of a modular abelian variety.

`x - y`

The difference of elements x minus y of a modular abelian variety.

Example H136E98

In this example, we construct $J_0(23)$, and consider the finite subgroup $\ker(T_3 - 5)$, which has order 400. We then do various arithmetic operations with some of its elements.

```
> A := JZero(23);
> t3 := HeckeOperator(A,3);
> Factorization(CharacteristicPolynomial(t3));
[
    <x^2 - 5, 2>
]
> G := Kernel(t3-5);
> #G;
400
> Generators(G);
[
    Element of abelian variety defined by [1/10 0 1/10 1/5] modulo homology,
    Element of abelian variety defined by [0 0 0 -5/2] modulo homology,
    Element of abelian variety defined by [1/10 -1/10 0 -1/5] modulo homology,
    Element of abelian variety defined by [1 -3/2 2 1] modulo homology
]
> x := G.1;
> 1.5*x;
Element of abelian variety defined by [0.14999999999999999999999999998 0.E-28
0.14999999999999999999999999998
0.29999999999999999999999999996] modulo homology
> (3/2)*x;
Element of abelian variety defined by [3/20 0 3/20 3/10] modulo homology
> 10*x;
```

```
0
> x*1.5;
Element of abelian variety defined by [0.14999999999999999999999999998 0.E-28
0.14999999999999999999999999998
0.29999999999999999999999999996] modulo homology
> 1.5*x eq x*1.5;
true
> x*(3/2);
Element of abelian variety defined by [3/20 0 3/20 3/10] modulo homology
> x*5;
Element of abelian variety defined by [1/2 0 1/2 1] modulo homology
> G.1 + G.2;
Element of abelian variety defined by [1/10 0 1/10 -23/10] modulo homology
> G.1 - G.2;
Element of abelian variety defined by [1/10 0 1/10 27/10] modulo homology
```

136.11.2 Invariants

These commands compute information about the order of an element, the degree of the homology of the parent variety, and a field that the point is defined over.

`Order(x)`

Given an element of a modular abelian variety x, return the order of x, if x is known exactly. Otherwise an error occurs.

`ApproximateOrder(x)`

Given a point x on a modular abelian variety return the exact order of x, if x is known exactly as a torsion point, and if not the order of an approximation of x by a torsion point, obtained using continued fractions.

`Degree(x)`

The dimension of the homology of the parent of x, where x is an element of a modular abelian variety.

`FieldOfDefinition(x)`

A field that x is defined over, which need not be minimal, where x is an element of a modular abelian variety.

Example H136E99

We compute a 2-torsion point on the elliptic curve $J_0(11)$, compute some approximate orders, and compute the degree.

```
> A := JZero(11);
> G := Kernel(nIsogeny(A,2));
> G;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2 ]
> x := G.1;
> ApproximateOrder(Sqrt(2)*x);
175568277047523
> ApproximateOrder(1.000000000000001*x);
2
> Degree(x);
2
```

Notice that `FieldOfDefinition(x)` is valid, but far from optimal. It would be better to return the number field generated by the 2-torsion point.

```
> FieldOfDefinition(x);
Algebraically closed field with no variables
> FieldOfDefinition(0*x);
Rational Field
> Order(x);
2
```

136.11.3 Predicates

These are commands for testing equality, inclusion, whether an element is 0, and whether an element is known exactly, (i.e., as an element of $H_1(A, \mathbf{Q})$, or just as an element of $H_1(A, \mathbf{R})$).

`x eq y`

Return `true` if the elements x and y of a modular abelian variety are equal.

`x in X`

Return `true` if the element x of a modular abelian variety is an element of the list X.

`IsExact(x)`

Return `true` if the element x of a modular abelian variety is known exactly, i.e., x is defined by an element of the rational homology.

IsZero(x)

Return `true` if the element x of a modular abelian variety is known exactly and is equal to 0. If x is not known exactly, return `true` if a real homology vector that represents x is "very close" to an element of the integral homology, where very close means that the distance is within $1/10^n$, where n is `M‘point_precision` and M is the parent of x.

Example H136E100

We demonstrate each of these commands using elements of the 2-torsion subgroups of the two elliptic curves of conductor 37.

```
> J := JZero(37);
> A, B := Explode(Decomposition(J));
> A;
Modular abelian variety 37A of dimension 1, level 37 and
conductor 37 over Q
> B;
Modular abelian variety 37B of dimension 1, level 37 and
conductor 37 over Q
> A2 := Kernel(nIsogeny(A,2));
> B2 := Kernel(nIsogeny(B,2));
> x := A2.1;
> y := B2.2;
> x eq y;
false
> x in [* x, y *];
true
> IsZero(x);
false
> IsZero(0*x);
true
> IsExact(1.00000000000000000001*x);
false
> IsExact((2/3)*x);
true
```

For non-exact elements, `IsZero` means "is quite close to 0".

```
> IsZero(0.0001*x);
false
> IsZero(0.00001*x);
true
> IsZero(0.000000000001*x);
true
> A‘point_precision;
10
```

136.11.4 Homomorphisms

There are two notations for applying a homomorphism to an element. One can find an inverse image of an element using the @@ command.

```
x @ phi
```

```
phi(x)
```

The image of the element x of a modular abelian variety under the homomorphism ϕ of abelian varieties.

```
x @@ phi
```

An inverse image of the element x of a modular abelian variety under the homomorphism ϕ of abelian varieties.

Example H136E101

Let $\phi = T_3 - 5$ acting on the abelian surface $J_0(23)$. We apply ϕ to an element of the kernel G of ϕ, and get 0. We also find an element y such that $\phi(y)$ is a certain element of G.

```
> A := JZero(23);
> phi := HeckeOperator(A,3) - 5;
> G := Kernel(phi);
> x := G.1;
> Order(x);
10
> phi(x);
0
> zero := A!0;
> z := zero@@phi; z;
0
> y := x@@phi; y;
Element of abelian variety defined by [-1/20 1/20 -1/20 -1/20] modulo homology
> phi(y) in G;
true
> y@phi eq phi(y);
true
```

136.11.5 Representation of Torsion Points

An exact torsion point representation of an element of a modular abelian variety can be found using continued fractions to find good rational approximations for each coordinate of a representative real homology class. A representative element of the homology can also be retrieved.

The `Eltseq` command gives the sequence of entries of the vector returned by `Element`.

`ApproximateByTorsionPoint(x : parameters)`

`Cutoff` RngIntElt *Default :* 10^3

If the modular abelian variety element x is defined by an element z in the real homology $H_1(A, R)$, find an element of $H_1(A, \mathbf{Q})$ which approximates z, using continued fractions, and return the corresponding point.

`Element(x)`

The vector in homology which represents the element x of a modular abelian variety.

`LatticeCoordinates(x)`

A vector over the rational or real field which represents the element x with respect to the basis for integral homology of the parent abelian variety of x.

`Eltseq(x)`

The `Eltseq` of `LatticeCoordinates(x)` where x is an element of a modular abelian variety.

Example H136E102

This code illustrates each of the commands for a 3-torsion point in $J_0(33)$.

```
> A := JZero(33);
> x := A![1/3,0,0,0,0,0];
> x;
Element of abelian variety defined by [1/3 0 0 0 0 0] modulo homology
> Order(x);
3
> ApproximateByTorsionPoint(1.001*x);
Element of abelian variety defined by [1001/3000 0 0 0 0 0] modulo homology
> Element(x);
(1/3   0   0   0   0   0)
> Eltseq(x);
[ 1/3, 0, 0, 0, 0, 0 ]
> LatticeCoordinates(x);
(1/3   0   0   0   0   0)
```

The `Element` and `LatticeCoordinates` can differ when the integral structure on the homology is complicated. This is common when the weight is bigger than 2.

```
> A := JZero(11,4); A;
```

```
Modular motive JZero(11,4) of dimension 2 and level 11 over Q
> x := A![1/3,0,0,0];
> Element(x);
(  1/8  1/24 -1/24 -1/24)
> Eltseq(x);
[ 1/3, 0, 0, 0 ]
> LatticeCoordinates(x);
(1/3   0   0   0)
> x;
Element of abelian variety defined by [1/3 0 0 0] modulo homology
```

136.12 Subgroups of Modular Abelian Varieties

136.12.1 Creation

Subgroups can be created from a sequence of elements of a modular abelian variety which generate it. It is also possible to create n-torsion subgroups $A[n]$ and to create subgroups as kernels of homomorphisms or by taking an image of the difference of two cusps.

If a subgroup G contains elements that are not known exactly (i.e., they are defined by floating point approximations to real homology elements), a group of torsion points that approximates G can be found.

`Subgroup(X)`

The subgroup of A generated by the nonempty sequence X of elements of modular abelian variety A.

`ZeroSubgroup(A)`

The zero subgroup of the abelian variety A.

`nTorsionSubgroup(A, n)`

The kernel $A[n]$ of the multiplication by n isogeny on the modular abelian variety A.

`nTorsionSubgroup(G, n)`

The kernel $G[n]$ of the multiplication by n homomorphism on the subgroup G of a modular abelian variety.

`ApproximateByTorsionGroup(G : parameters)`

`Cutoff` RngIntElt *Default :* 10^3

The subgroup generated by torsion approximations of a set of generators of the subgroup G of a modular abelian variety.

Example H136E103

First we list the elements of the 2-torsion subgroup of the elliptic curve 100A, then we compute the 0 subgroup.

```
> A := ModularAbelianVariety("100A"); A;
Modular abelian variety 100A of dimension 1 and level 2^2*5^2
over Q
> G := nTorsionSubgroup(A,2); G;
Finitely generated subgroup of abelian variety with invariants [ 2, 2 ]
> Elements(G);
[
    0,
    Element of abelian variety defined by [1/2 0] modulo homology,
    Element of abelian variety defined by [0 1/2] modulo homology,
    Element of abelian variety defined by [1/2 1/2] modulo homology
]
> ZeroSubgroup(A);
{ 0 }: finitely generated subgroup of abelian variety with
invariants []
```

We can also use the `nTorsionSubgroup` command on subgroups.

```
> nTorsionSubgroup(G,2);
Finitely generated subgroup of abelian variety with
invariants [ 2, 2 ]
> nTorsionSubgroup(G,3);
{ 0 }: finitely generated subgroup of abelian variety with
invariants []
```

One of the 2-torsion elements generates a subgroup H of order 2.

```
> G.1;
Element of abelian variety defined by [0 1/2] modulo homology
> H := Subgroup([G.1]); H;
Finitely generated subgroup of abelian variety
> #H;
2
```

To illustrate the approximation command, we consider the subgroup generated by an approximation to one of the 2-torsion elements.

```
> K := Subgroup([1.00001*G.1]);
> L := ApproximateByTorsionGroup(K);
Finitely generated subgroup of abelian variety with
invariants [ 2 ]
> L eq H;
true
```

136.12.2 Elements

These commands enumerate elements of a finite subgroup of a modular abelian variety and allow access to the generators.

`Elements(G)`

A sequence of all elements of the finite subgroup G of a modular abelian variety.

`Generators(G)`

A sequence of generators for the subgroup G of a modular abelian variety. These correspond to generators for the underlying abelian group.

`Ngens(G)`

The number generators of the subgroup G of a modular abelian variety.

`G . i`

The i-th generator of the subgroup G of a modular abelian variety.

Example H136E104

We illustrate each of the commands using the kernel of the Hecke operator T_3 acting on $J_0(67)$.

```
> J := JZero(67);
> T := HeckeOperator(J,3);
> G := Kernel(T);
> #G;
4
> Elements(G);
[
    0,
    Element of abelian variety defined by [0 0 1/2 0 0 -1/2 -1/2 0 1/2 0] modulo
    homology,
    Element of abelian variety defined by [1/2 -1/2 0 0 -1/2 0 0 -1/2 1/2 0]
    modulo homology,
    Element of abelian variety defined by [1/2 -1/2 1/2 0 -1/2 -1/2 -1/2 -1/2 1 0]
    modulo homology
]
> Generators(G);
[
    Element of abelian variety defined by [1/2 -1/2 0 0 -1/2 0 0 -1/2 1/2 0]
    modulo homology,
    Element of abelian variety defined by [0 0 1/2 0 0 -1/2 -1/2 0 1/2 0]
    modulo homology
]
> Ngens(G);
2
> G.1;
Element of abelian variety defined by [1/2 -1/2 0 0 -1/2 0 0 -1/2 1/2 0] modulo
homology
```

```
> G.2;
Element of abelian variety defined by [0 0 1/2 0 0 -1/2 -1/2 0 1/2 0] modulo
homology
```

136.12.3 Arithmetic

Quotients of abelian varieties by finite subgroups can be formed, finite subgroups can be intersected with other finite subgroups or abelian varieties, and the group generated by two subgroups can be computed.

For several of the arithmetic operations below, finite groups or abelian varieties are replaced by their image in a common abelian variety, so the operation makes sense. This common abelian variety is the one returned by `FindCommonEmbeddings` on page 4594. Note that the "embedding" is only guaranteed to be an embedding up to isogeny.

`Quotient(A, G)`

The quotient of the abelian variety A by the finite subgroup G of A, the isogeny $A \to A/G$ and an isogeny $A/G \to A$, such that composition of the two isogenies is multiplication by the exponent of G.

`Quotient(G)`

The quotient A/G, where A is the ambient variety of the subgroup G of an abelian variety, an isogeny from A to A/G with kernel G, and an isogeny from A/G to A such that the composition of the two isogenies is multiplication by the exponent of G.

`A / G`

Given an abelian variety A and a subgroup G of an abelian variety return the quotient A/G, the isogeny $A \to A/G$ with kernel G, and an isogeny $A/G \to A$ where A is not necessarily the ambient variety of G.

`A meet G`
`G meet A`

The intersection of the finite subgroup G of an abelian variety B with the abelian variety A. If A is not equal to B, then G and A are replaced by their image in a common abelian variety.

`G1 + G2`

The sum of the subgroups G_1 and G_2 of abelian varieties A_1 and A_2. If A_1 is not equal to A_2, then G_1 and G_2 are replaced by their image in a common abelian variety.

`G1 meet G2`

The intersection of the finite subgroups G_1 and G_2 of an abelian variety. If their ambient varieties are not equal, G_1 and G_2 are replaced by their image in a common abelian variety.

Example H136E105

We illustrate these commands using the 2-torsion of $J_0(67)$. First we compute the kernel of T_3, which is a 2-torsion group of order 4.

```
> J := JZero(67); J;
Modular abelian variety JZero(67) of dimension 5 and level 67 over Q
> T := HeckeOperator(J,3);
> Factorization(CharacteristicPolynomial(T));
[
    <x + 2, 2>,
    <x^2 - x - 1, 2>,
    <x^2 + 3*x + 1, 2>
]
> G := Kernel(T); #G;
4
```

Next we quotient $J_0(67)$ out by this subgroup of order 4.

```
> A := Quotient(J,G); A;
Modular abelian variety of dimension 5 and level 67 over Q
```

The result is, of course, isogenous to $J_0(67)$. Unfortunately, testing of isomorphism in this generality is not yet implemented.

```
> IsIsogenous(A,J);
true
> Degree(ModularParameterization(A));
4
```

If the `Quotient` command is given only one argument then the variety being quotiented out by is the ambient variety.

```
> B := Quotient(G); B;
Modular abelian variety of dimension 5 and level 67 over Q
> Degree(ModularParameterization(B));
4
```

We can also use the divides notation for quotients.

```
> C := J/G; C;
Modular abelian variety of dimension 5 and level 67 over Q
```

Next we list the 2-torsion subgroups of the simple factors of $J_0(67)$. Interestingly, the sum of the 2-torsion subgroups of these simple factors is much smaller than the full 2-torsion subgroup $J_0(67)[2]$.

```
> D := Decomposition(J); D;
[
    Modular abelian variety 67A of dimension 1, level 67 and
    conductor 67 over Q,
    Modular abelian variety 67B of dimension 2, level 67 and
    conductor 67^2 over Q,
```

```
    Modular abelian variety 67C of dimension 2, level 67 and
    conductor 67^2 over Q
]
> for A in D do print #(A meet G); end for;
4
1
1
> G2 := nTorsionSubgroup(D[2],2);
> G3 := nTorsionSubgroup(D[3],2);
> H := G + G2 + G3;
> #H;
64
> H eq nTorsionSubgroup(J,2);
false
> #nTorsionSubgroup(J,2);
1024
> G2 eq G3;
true
> G meet G2;
{ 0 }: finitely generated subgroup of abelian variety with invariants []
```

136.12.4 Underlying Abelian Group and Lattice

`AbelianGroup(G)`

Let G be a finitely generated subgroup of an abelian variety A. Return an abstract abelian group H which is isomorphic to G along with isomorphisms in both directions.

`Lattice(G)`

Let G be a finite torsion subgroup of its ambient abelian variety A whose elements are all known exactly, i.e. G is generated by elements of $H_1(A, \mathbf{Q})/H_1(A, \mathbf{Z})$. Return the lattice L in the rational homology of A generated by $H_1(A, \mathbf{Z})$ and all x such that G can be viewed as a set of equivalence classes of the form $x + H_1(A, \mathbf{Z})$.

Example H136E106

This examples illustrate these commands for the 3-torsion subgroup of $J_0(11)$.

```
> A := JZero(11);
> G := nTorsionSubgroup(A,3);
> H,f,g := AbelianGroup(G);
> H;
Abelian Group isomorphic to Z/3 + Z/3
Defined on 2 generators
Relations:
    3*H.1 = 0
```

```
    3*H.2 = 0
```

The lattice of G is $1/3$ times the integral homology.

```
> Lattice(G);
Lattice of rank 2 and degree 2
Basis:
[Identity matrix]
Basis Denominator: 3
> L := IntegralHomology(A); L;
Standard Lattice of rank 2 and degree 2
> Lattice(G)/L;
Abelian Group isomorphic to Z/3 + Z/3
Defined on 2 generators
Relations:
    3*$.1 = 0
    3*$.2 = 0
```

136.12.5 Invariants

`AmbientVariety(G)`

Let G be a finitely generated subgroup of an abelian variety. Return the abelian variety whose elements were used to create G.

`Exponent(G)`

Given a finitely generated subgroup G of an abelian variety, return the smallest positive integer e which kills G, i.e. such that $eG = 0$. We assume G is finite.

`Invariants(G)`

Given a finitely generated subgroup of an abelian variety, return the invariants of an abstract abelian group isomorphic to G.

`Order(G)`

`#G`

Given a finitely generated subgroup G of an abelian variety, return the number of elements in G, when G is known to be finite (an error occurs otherwise).

`FieldOfDefinition(G)`

Given a finitely generated subgroup G of an abelian variety return a field over which the group G is defined. This is a field K such that if σ is an automorphism that fixes K, then $\sigma(G) = G$. Note that K *is not guaranteed to be minimal.*

Example H136E107

We illustrate each command using the kernel of T_3 on $J_0(67)$.

```
> A := JZero(67);
> T3 := HeckeOperator(A,3);
> G := Kernel(T3); G;
Finitely generated subgroup of abelian variety with
[ 2, 2 ]
> AmbientVariety(G);
Modular abelian variety JZero(67) of dimension 5 and level 67 over Q
> Exponent(G);
2
> Invariants(G);
[ 2, 2 ]
> Order(G);
4
> #G;
4
```

The field of definition of G is $\mathbf{Q}$, since G is the kernel of a homomorphism defined over $\mathbf{Q}$ (a Hecke operator).

```
> FieldOfDefinition(G);
Rational Field
```

However, the field of definition of the subgroup of G generated by one of the elements of G could take significant extra work to determine. Currently MAGMA simply chooses the easiest answer, which is $\overline{\mathbf{Q}}$.

```
> H := Subgroup([G.1]);
> FieldOfDefinition(H);
Algebraically closed field with no variables
```

136.12.6 Predicates and Comparisons

A subgroup G of an abelian variety is finite exactly when every element of G is known exactly, since then all elements are torsion and G is finitely generated.

Abelian varieties and subgroups thereof can be tested for inclusion and equality. Equality and subset testing is liberal, in that if the ambient varieties containing the two groups are not equal, then MAGMA attempts to find a natural embedding of both subgroups into a common ambient variety, and checks equality or inclusion there.

`IsFinite(G)`

Return `true` if the subgroup G of a modular abelian variety is known to be finite, i.e., generated by torsion elements. If G is not known exactly, i.e., has elements defined by floating point approximations to homology, then return `false`.

`G1 subset G2`

Return `true` if $G1$ is a subset of $G2$, where $G1$ and $G2$ are both subgroups of modular abelian varieties.

`G subset A`

Return `true` if the subgroup G is a subset of the abelian variety A. If A is not the ambient variety of G, then G and A are first mapped to a common ambient variety and compared.

`A subset G`

Return `true` if the abelian variety A is a subset of the finitely generated subgroup G of a modular abelian variety. This is true only if A is a point, i.e., the 0 dimensional abelian variety.

`G1 eq G2`

Return `true` if the subgroups G_1 and G_2 of modular abelian varieties are equal.

Example H136E108

We work with $J_0(389)$, but work in the $+1$ quotient of homology for efficiency. First we let A and B be the first and fifth factors in the decomposition of J, and let G and H be the corresponding 5-torsion subgroups.

```
> J := JZero(389,2,+1);
> D := Decomposition(J);
> A := D[1];
> B := D[5];
> G := nTorsionSubgroup(A,5);
> H := nTorsionSubgroup(B,5);
```

Note that the torsion subgroups aren't as big because we are working in the $+1$ quotient.

```
> #G;
5
> #H;
95367431640625
```

We now demonstrate each of the above commands for A, B, G, and H.

```
> IsFinite(G);
true
> A subset G;
false
> ZeroModularAbelianVariety() subset G;
true
> G subset A;
true
> G subset B;
true
> H subset A;
```

```
false
```

Since the ambient varieties of G and H are A and B, respectively, the following commands implicitly embed G and H into $J_0(389)$ and make comparisons there.

```
> G subset H;
true
> G eq H;
false
> G eq G;
true

> J := JZero(37);
> A, B := Explode(Decomposition(J));
> A2 := Kernel(nIsogeny(A,2));
> B2 := Kernel(nIsogeny(B,2));
> A2 eq B2;
true
> x := A2.1;
> x in B2;   // uses embedding of both into $J_0(37)$.
true
```

136.13 Rational Torsion Subgroups

The following functions are used for computing information about certain torsion points on modular abelian varieties.

136.13.1 Cuspidal Subgroup

For simplicity, assume A is a modular abelian variety and $\pi : J_0(N) \to A$ is the modular parameterization (the case when $J_0(N)$ is replaced by a more general modular abelian variety is similar). The *cuspidal subgroup* of $J_0(N)$ is the finite torsion group generated by all classes of differences of cusps on $X_0(N)$. The *cuspidal subgroup* of $A(\overline{\mathbf{Q}})$ is the image under π of the cuspidal subgroup of $J_0(N)$. The *rational cuspidal subgroup* is the subgroup generated by differences of cusps that are defined over $\mathbf{Q}$. (Computation of the rational points in the cuspidal subgroup has not yet been implemented.) One important use of the rational cuspidal subgroup is that it gives a lower bound on the cardinality (and structure) of the torsion subgroup of $A(\mathbf{Q})$, which is important in computations involving the Birch and Swinnerton-Dyer conjecture.

`CuspidalSubgroup(A)`

The subgroup of the abelian variety A generated by all differences of cusps, where we view A as a quotient of a modular symbols abelian variety. Note that this subgroup need not be defined over $\mathbf{Q}$.

`RationalCuspidalSubgroup(A)`

Return the finite subgroup of the abelian variety A generated by all differences of $\mathbf{Q}$-rational cusps, where we view A in some way as a quotient of a modular symbols abelian variety.

Example H136E109

We compute the cuspidal and rational cuspidal subgroups of $J_0(100)$.

```
> J := JZero(100);
> G := CuspidalSubgroup(J); G;
Finitely generated subgroup of abelian variety with invariants
[ 6, 30, 30, 30, 30 ]
> [Eltseq(x) : x in Generators(G)];
[
    [ 29/30, -2/5, 16/15, 121/30, -2, -61/30, 3/5, 31/15, 1,
    -89/30, -7/2, -3/2, -3, -1 ],
    [ 1, -5/6, 0, -1, -1, 2/3, -3/2, 0, -2, 0, 2, 5/3, 5/6, 0 ],
    [ -2, 17/15, 1/10, -29/15, 89/30, 26/15, 7/10, -2, 2/5, 2,
    -3/10, -7/30, 59/30, -1/2 ],
    [ 29/30, -1, 1/2, 67/15, -2, -3/2, 14/15, 91/30, 1, -3,
    -38/15, -29/30, -91/30, 1/2 ],
    [ 31/30, -31/30, 2/5, 67/15, -29/15, -43/30, 5/6, 3, 1, -3,
    -13/5, -31/30, -91/30, 0 ]
]
> H := RationalCuspidalSubgroup(J); H;
Finitely generated subgroup of abelian variety with invariants
[ 3, 15, 30 ]
```

Next we compute the cuspidal and rational subgroups for the optimal new elliptic curve of conductor 100.

```
> D := Decomposition(J); A := D[1];
> CuspidalSubgroup(A);
Finitely generated subgroup of abelian variety with invariants
[ 2, 2 ]
> Generators(CuspidalSubgroup(A));
[
    Element of abelian variety defined by [0 1/2] modulo homology,
    Element of abelian variety defined by [1/2 0] modulo homology
]
> RationalCuspidalSubgroup(A);
Finitely generated subgroup of abelian variety with invariants []
> TorsionMultiple(A);
2
```

Because the torsion multiple is 2, some of the cuspidal subgroup can not be defined over $\mathbf{Q}$.

136.13.2 Upper and Lower Bounds

Let A be an abelian variety over a number field K. MAGMA can compute upper and lower bounds on the cardinality of the torsion subgroup of $A(K)$ in the form of a multiple and a divisor of this cardinality.

`TorsionLowerBound(A)`

Given an abelian variety A return a divisor of the cardinality of the K-rational torsion subgroup of $A(K)$. Currently, to compute a bound we require that A be the base extension of an abelian variety B over $\mathbf{Q}$, and the lower bound is simply the cardinality of the rational cuspidal subgroup of $B(\mathbf{Q})$.

`TorsionMultiple(A)`

`TorsionMultiple(A, n)`

Given an abelian variety A return a multiple of the cardinality of the K-rational torsion subgroup of A over K. If n is not given it is assumed to be 50.

This multiple is usually fairly sharp, and is computed as follows. For each good prime $p \leq n$ with $[K : Q] + 1 < p$ and such that p does not divide the level of A, MAGMA computes $\#A(k)$, where k varies over residue class fields of K of characteristic p. Since reduction on torsion is injective for such primes, the greatest common divisor of the $\#A(k)$ is a multiple of the order of the torsion subgroup of $A(K)$. MAGMA computes $\#A(k)$ by using Hecke operators to find the characteristic polynomial of Frobenius on a Tate module of A, and uses this characteristic polynomial to deduce $\#A(k)$. For details, see [AS05].

Example H136E110

```
> J := JZero(100);
> TorsionLowerBound(J);
1350
> #RationalCuspidalSubgroup(J);
1350
> TorsionMultiple(J);
16200
> 16200/1350;
12
> J2 := BaseExtend(J,QuadraticField(2));
> TorsionMultiple(J2);
129600
> 129600/16200;
8
```

136.13.3 Torsion Subgroup

`TorsionSubgroup(A)`

Let A be an abelian variety over a field K. Attempt to compute the subgroup of torsion elements in $A(K)$. Return either `false` and a subgroup of the torsion subgroup, or `true` and the exact torsion subgroup of A over the base field.

Example H136E111

```
> TorsionSubgroup(JZero(11));
true Finitely generated subgroup of abelian variety with invariants [ 5 ]
> TorsionSubgroup(JZero(33));
false Finitely generated subgroup of abelian variety with
invariants [ 10, 10 ]
> TorsionSubgroup(BaseExtend(JZero(11),QuadraticField(5)));
true Finitely generated subgroup of abelian variety with
invariants [ 5 ]
> TorsionSubgroup(ChangeRing(JZero(11),GF(5)));
false { 0 }: finitely generated subgroup of abelian variety with
invariants []
> TorsionSubgroup(JZero(100));
false Finitely generated subgroup of abelian variety with
invariants [ 3, 15, 30 ]
> TorsionSubgroup(JZero(125));
true Finitely generated subgroup of abelian variety with
invariants [ 25 ]
```

136.14 Hecke and Atkin-Lehner Operators

136.14.1 Creation

These commands compute endomorphisms induced by the Atkin-Lehner and Hecke operators on modular abelian varieties. The Atkin-Lehner involution W_q is defined for each positive integer q that exactly divides the level (and is divisible by the conductor of any relevant character).

`AtkinLehnerOperator(A, q)`

The Atkin-Lehner operator W_q of index q induced on the abelian variety A by virtue of A being modular. In general W_q need not be a morphism except in the category of abelian varieties up to isogeny so this intrinsic also returns an integer d such that $d * W_q$ is an endomorphism of A, and when W_q doesn't leave A invariant, returns $d = 0$. If the ambient modular symbols space of A contains a space with character of conductor r, then currently an error occurs unless r divides q.

`AtkinLehnerOperator(A)`

The morphism (or morphism tensor Q) on (or from) the abelian variety A induced by the Atkin-Lehner operator.

`HeckeOperator(A, n)`

The Hecke operator T_n of index n induced on the abelian variety A by virtue of its morphism to a modular symbols abelian variety. In general T_n need not be a morphism. Also, if A is contained in e.g., $J_0(N)$, then the T_n on $J_0(N)$ need not even leave A invariant. In that case this command composes T_n with a map back to A to obtain an endomorphism of A. For the exact Hecke operators induced by their action on $J_0(N)$, say, use the `RestrictEndomorphism` command.

Example H136E112

We compute the main Atkin-Lehner operator and the Hecke operator T_2 on $J_0(23)$.

```
> A := JZero(23);
> AtkinLehnerOperator(A,23);
Homomorphism W23 from JZero(23) to JZero(23) given on integral homology by:
[-1  0  0  0]
[ 0 -1  0  0]
[ 0  0 -1  0]
[ 0  0  0 -1]
> HeckeOperator(A,2);
Homomorphism T2 from JZero(23) to JZero(23) given on integral homology by:
[ 0  1 -1  0]
[ 0  1 -1  1]
[-1  2 -2  1]
[-1  1  0 -1]
```

Next we compute w_4 and w_{25} on J_{100}, and note that their product equals w_{100}.

```
> A := JZero(100); A;
Modular abelian variety JZero(100) of dimension 7 and
level 2^2*5^2 over Q
> w4 := AtkinLehnerOperator(A,4);
> Factorization(CharacteristicPolynomial(w4));
[
    <x - 1, 4>,
    <x + 1, 10>
]
> w25 := AtkinLehnerOperator(A,25);
> Factorization(CharacteristicPolynomial(w25));
[
    <x - 1, 8>,
    <x + 1, 6>
]
> w4*w25 eq AtkinLehnerOperator(A);
```

```
true
```

Next we compute W_{25} acting on $J_1(25)$.

```
> A := Js(17);
> B := BaseExtend(A,CyclotomicField(17));
> w := AtkinLehnerOperator(B);
> Factorization(CharacteristicPolynomial(w));
[
    <x - 1, 4>,
    <x + 1, 6>
]
```

Finally we compute Hecke operators on the quotient of a simple factor of $J_0(65)$ by a finite subgroup.

```
> A := Decomposition(JZero(65))[2]; A;
Modular abelian variety 65B of dimension 2, level 5*13 and conductor
5^2*13^2 over Q
> G := nTorsionSubgroup(A,2); G;
Finitely generated subgroup of abelian variety with invariants
[ 2, 2, 2, 2 ]
> H := Subgroup([G.1]); H;
Finitely generated subgroup of abelian variety with invariants [ 2 ]
> B := A/H; B;
Modular abelian variety of dimension 2 and level 5*13 over Qbar
> T2 := HeckeOperator(B,2); T2;
Homomorphism from modular abelian variety of dimension 2 to
modular abelian variety of dimension 2 (up to isogeny) on
integral homology by:
[ -2 1/2   0   0]
[ -2   2   0   0]
[ -2   1  -2   1]
[ -6   1  -1   2]
> FactoredCharacteristicPolynomial(T2);
[
    <x^2 - 3, 2>
]
```

136.14.2 Invariants

Intrinsics are provided which compute characteristic polynomials, factored characteristic polynomials and minimal polynomials of Hecke operators.

`HeckePolynomial(A, n)`

The characteristic polynomial of the Hecke operator T_n acting on the abelian variety A.

`FactoredHeckePolynomial(A, n)`

The factored characteristic polynomial of the Hecke operator T_n acting on the abelian variety A. This can be faster than first computing T_n, then computing the characteristic polynomial, and factoring, because we can take into account information about the decomposition of A, in order to avoid factoring.

`MinimalHeckePolynomial(A, n)`

The minimal polynomial of the Hecke operator T_n acting on the abelian variety A.

Example H136E113

```
> FactoredHeckePolynomial(JZero(65),2);
[
    <x + 1, 2>,
    <x^2 - 3, 2>,
    <x^2 + 2*x - 1, 2>
]
> HeckePolynomial(JZero(65),2);
x^10 + 6*x^9 + 5*x^8 - 32*x^7 - 62*x^6 + 28*x^5 + 130*x^4 +
    48*x^3 - 51*x^2 - 18*x + 9
> MinimalHeckePolynomial(JZero(65),2);
x^5 + 3*x^4 - 2*x^3 - 10*x^2 - 3*x + 3
```

136.15 L-series

136.15.1 Creation

The `LSeries` command creates the L-series $L(A, s)$ associated to a modular abelian variety A over $\mathbf{Q}$ or a cyclotomic field. No actual computation is performed.

`LSeries(A)`

The L-series associated to the abelian variety A.

Example H136E114

```
> A := JZero(23);
> L := LSeries(A);
> L;
L(JZero(23),s): L-series of Modular abelian variety JZero(23) of
dimension 2 and level 23 over Q
> LSeries(ModularAbelianVariety("65B"));
L(65B,s): L-series of Modular abelian variety 65B of dimension 2
and level 5*13 over Q
```

You can create L-series of abelian varieties over cyclotomic fields, but currently no interesting functionality is implemented for them.

```
> LSeries(BaseExtend(JZero(11),CyclotomicField(5)));
L(JZero(11),s): L-series of Modular abelian variety JZero(11) of
dimension 1 and level 11 over Q(zeta_5)
```

136.15.2 Invariants

`CriticalStrip(L)`

Let L be the L-function of some modular abelian variety A. This function returns integers x and y such that the critical strip for L is the set of complex numbers with real part strictly between x and y. If W is the set of weights of newforms that give rise to factors of A, then this command returns 0 and `Max(W)`.

`ModularAbelianVariety(L)`

The abelian variety the L-series L is associated to.

Example H136E115

We define several L-functions of modular abelian varieties and modular motives, and compute their critical strip (which is from 0 to k, where k is the weight).

```
> L := LSeries(JZero(37));
> CriticalStrip(L);
0 2
> L := LSeries(JZero(37,6));
> CriticalStrip(L);
0 6
> J := JOne(11,3);  J;
Modular motive JOne(11,3) of dimension 5 and level 11 over Q
> CriticalStrip(LSeries(J));
0 3
> A_delta := JZero(1,12);
> L := LSeries(A_delta);
> CriticalStrip(L);
```

```
0 12
> ModularAbelianVariety(L);
Modular motive JZero(1,12) of dimension 1 and level 1 over Q
```

136.15.3 Characteristic Polynomials of Frobenius Elements

Let A be a modular abelian variety. The characteristic polynomials of Frobenius elements acting on the ℓ-adic Tate modules of A define the local L-factors of $L(A, s)$.

`FrobeniusPolynomial(A : parameters)`

`Factored` BoolElt *Default :* `false`

The characteristic polynomial of Frobenius on the abelian variety A defined over a finite field. If `Factored` is set to `true`, return a factorization instead of a polynomial.

`FrobeniusPolynomial(A, p : parameters)`

`Factored` BoolElt *Default :* `false`

The characteristic polynomial of Frob_p acting on any ℓ-adic Tate module of the abelian variety A over a number field, where p and ℓ do not divide the level of A. If the base ring has degree bigger than 1, then return a sequence of characteristic polynomials, one for each prime lying over p, sorted by degree. If `Factored` is set to `true`, return a factorization instead of a polynomial.

`FrobeniusPolynomial(A, P)`

The characteristic polynomial of Frobenius at the nonzero prime ideal P of a number field on the modular abelian variety A, where P is assumed to be a prime of good reduction for A, and A is defined over a field that contains the prime P.

Example H136E116

```
> A := JZero(23);
> FrobeniusPolynomial(A,2);
x^4 + x^3 + 3*x^2 + 2*x + 4
> A := JZero(23) * JZero(11,4) * JOne(13);
> FrobeniusPolynomial(A,2);
x^12 + 2*x^11 + 17*x^10 + 40*x^9 + 145*x^8 + 362*x^7 + 798*x^6 +
    1408*x^5 + 2104*x^4 + 2528*x^3 + 2528*x^2 + 1792*x + 1024
> Factorization($1);
[
    <x^4 - 2*x^3 + 14*x^2 - 16*x + 64, 1>,
    <x^4 + x^3 + 3*x^2 + 2*x + 4, 1>,
    <x^4 + 3*x^3 + 5*x^2 + 6*x + 4, 1>
]
> A := BaseExtend(JZero(23),CyclotomicField(22));
> FrobeniusPolynomial(A,2);
```

```
[
    x^4 + 25*x^3 - 327*x^2 + 25600*x + 1048576
]
```

These characteristic polynomials are used in the algorithm to compute the number of points on modular abelian varieties over finite fields.

```
> A := ChangeRing(JZero(23),GF(2^10));
> NumberOfRationalPoints(A);
1073875 1073875
> Factorization($1);
[ <5, 3>, <11, 2>, <71, 1> ]
```

136.15.4 Values at Integers in the Critical Strip

MAGMA allows evaluation of L-series at integers lying within the critical strip.

There exist algorithms for computing $L(A, s)$ for any complex number s, but these are not currently implemented in MAGMA.

`L(s)`

`Evaluate(L, s)`

`Evaluate(L, s, prec)`

The value of L-series L at s, where s must be an integer that lies in the critical strip for L, computed using *prec* terms of the power series or 100 if *prec* is not given. The power series used are the q-expansions of modular forms corresponding to differentials on A. It is not clear, a priori, what the relation is between *prec* and the precision of the real number output by this command. (It is theoretically possible to give bounds, but we have not done this.) In practice, one can increase *prec* and see how the output result changes.

`LRatio(A, s)`

`LRatio(L, s)`

Given an abelian variety A over $\mathbf{Q}$ attached to a newform or an L-series L of an abelian variety and an integer s, return the ratio $L(A, s) * (s-1)!/((2\pi)^{s-1} * \Omega_s)$, where s is a "critical integer", and Ω_s is the integral (Neron) volume of the group of real points on the optimal quotient A' associated to A when s is odd, and the volume of the -1 eigenspace for conjugation when s is even.

`IsZeroAt(L, s)`

Given an L-series L of a modular abelian variety and an integer s in the critical strip for L return `true` is $L(A, s)$ is zero. In contrast to the output of the `Evaluate` command above, the result returned by this command is provably correct.

Example H136E117

First we demonstrate each evaluation command for the L-series of $J_0(23)$.

```
> L := LSeries(JZero(23));
> L(1);
0.24843186659059928468330576929 0 +  0.E-29*i
> Evaluate(L,1);
0.24843186659059928468330576929 0 +  0.E-29*i
> Evaluate(L,1,200);
0.24843186659059968120725033907 4 +  0.E-29*i
> LRatio(L,1);
1/11
> L := LSeries(JZero(23));
> L(1);
0.24843186659059928468330577047 6 +  0.E-29*i
> Evaluate(L,1,200);
0.24843186659059968120725034014 4 +  0.E-29*i
```

Next we compute the L-series of the motive attached to the weight 12 level 1 modular form Δ.

```
> A := JZero(1,12);
> L := LSeries(A);
> Evaluate(L,1);
0.037441281268515541738770315844 3
> L(5);
0.666709188434003643826130221 64
> Evaluate(L,1,200);
0.037441281268515541738770315844 3
> LRatio(L,1);
11340/691
> LRatio(L,2);
24
> LRatio(L,3);
7
```

We compute some ratios for $J_1(N)$ and factors of $J_1(N)$.

```
> LRatio(JOne(13),1);
1/361
> J := JOne(23);
> Evaluate(LSeries(J),1);
0.000000080777697074785775420090700066 +
0.000000053679621277482217773207669332*i
```

It looks kind of like $L(J_1(23), 1)$ is zero. However, this is not the case! We can not compute `LRatio` for $J_1(23)$, since it not attached to a newform. We can, however, compute `LRatio` for each simple factor.

```
> LRatio(J(1),1);
1/11
```

```
> LRatio(J(2),1);
1/1382426761
```

Each simple factor has nonzero `LRatio`, so $L(J,1) \neq 0$.

136.15.5 Leading Coefficient

The L-function $L(A,s)$ has a Taylor expansion about any critical integer. The leading coefficient and order of vanishing of $L(A,s)$ about a critical integer can be computed.

`LeadingCoefficient(L, s, prec)`

Given an L-series L associated to a modular abelian variety A and an integer s in the critical strip for L return the leading coefficient of the Taylor expansion about s and the order of vanishing of L at s. At present, A must have weight 2 and trivial character (so $s = 1$). It does not have to be attached to a newform. The argument *prec* is the number of terms of the power series which are used.

Example H136E118

```
> LeadingCoefficient(LSeries(JZero(37)),1,100);
0.24426406492583898134986778296 5
> LeadingCoefficient(LSeries(JZero(37)(1)) ,1,100);
0.30599977380008529004409407572 5
> J := JZero(3^5);
> LeadingCoefficient(LSeries(J),1,100);
15.140660788463628991688955015326 +  0.E-27*i 4
```

The order of vanishing of 4 for $J_0(3^5)$ comes from an elliptic curve and a 3-dimensional abelian variety that have order of vanishing 1 and 3, respectively.

```
> LeadingCoefficient(LSeries(J(1)),1,100);
1.4192096493382156160031880842 81
> LeadingCoefficient(LSeries(J(5)),1,100);
1.2280519528591420520347698584 45 3
```

Example H136E119

We give a few more examples.

```
> L := LSeries(ModularAbelianVariety("389A",+1));
> LeadingCoefficient(L,1,100);
0.75931650029224679065762600319 2
>
> A := JZero(65)(2); A;
Modular abelian variety 65B of dimension 2, level 5*13 and
conductor 5^2*13^2 over Q
> L := LSeries(A);
> LeadingCoefficient(L,1,100);
```

```
0.91225158869818984109351402175 +  0.E-29*i 0
> A := JZero(65)(3); A;
Modular abelian variety 65C of dimension 2, level 5*13 and
conductor 5^2*13^2 over Q
> L := LSeries(A);
> LeadingCoefficient(L,1,100);
0.45206792176803106991748613500 0 +  0.E-29*i 0
```

136.16 Complex Period Lattice

136.16.1 Period Map

Let A be a modular abelian variety. The period mapping of A is a map from the rational homology of A to a complex vector space.

`PeriodMapping(A, prec)`

The complex period mapping from the rational homology of the abelian variety A to $\mathbf{C}^d$, where $d = \dim A$, computed using *prec* terms of q-expansions.

136.16.2 Period Lattice

`Periods(A, n)`

Given an abelian variety A and an integer n return generators for the complex period lattice of A, computed using n terms of q-expansions. We use the map from A to a modular symbols abelian variety to define the period mapping (so this map must be injective).

136.17 Tamagawa Numbers and Component Groups of Neron Models

136.17.1 Component Groups

Suppose A is a newform modular abelian variety over $\mathbf{Q}$ over level N. For any prime p that exactly divides N, the order of the component group of A over the algebraic closure of $\mathbf{F}_p$ can be computed. The nontrivial algorithm is described in [CS01] and [KS00]. It is an open problem to compute the structure of the component group or the order under more general hypothesis.

`ComponentGroupOrder(A, p)`

The order of the component group of the special fiber of the Neron model of A over the algebraic closure of $\mathbf{F}_p$. The abelian variety A must be attached to a newform.

Example H136E120

```
> J := JZero(65); J;
Modular abelian variety JZero(65) of dimension 5 and level 5*13 over Q
> A := Decomposition(J)[3];
> ComponentGroupOrder(A,13);
1
> ComponentGroupOrder(A,5);
7
```

136.17.2 Tamagawa Numbers

Suppose A is an abelian variety over $\mathbf{Q}$ that is attached to a newform. A divisor and an integer some power of which is a multiple of the Tamagawa number of A at a prime p can be determined. When p^2 divides the level, the reduction is additive, we use the Lenstra-Oort bound from [LO85].

`TamagawaNumber(A, p)`

A divisor of the Tamagawa number of the abelian variety A at the prime p and an integer some power of which is a multiple of the Tamagawa number of A at p. Also return `true` if the divisor of the Tamagawa number is provably equal to the Tamagawa number of A. The abelian variety A must be attached to a newform.

`TamagawaNumber(A)`

Let c be the product of the Tamagawa numbers of A at primes of bad reduction, where A is an abelian variety over $\mathbf{Q}$ attached to a newform. This command returns a divisor of c, an integer some power of which is a multiple of c, and `true` if the divisor is provably equal to c.

Example H136E121

```
> J := JZero(65);
> TamagawaNumber(J(2),5);
2 2 false
> TamagawaNumber(J(2),13);
3 3 true
> TamagawaNumber(J(3),5);
7 7 true
> TamagawaNumber(J(3),13);
2 2 false
>
> J := JZero(5^2*7);
> TamagawaNumber(J(1));
2 30 false
> TamagawaNumber(J(1),5);
```

```
1 30 false
> TamagawaNumber(J(1),7);
2 2 false
```

136.18 Elliptic Curves

136.18.1 Creation

Modular abelian varieties of dimension 1 are elliptic curves. Given a modular abelian variety A over $\mathbf{Q}$ of dimension 1, MAGMA can compute an elliptic curve that is isogenous over $\mathbf{Q}$ to A. Given an elliptic curve E over $\mathbf{Q}$, a modular abelian variety over $\mathbf{Q}$ that is isogenous to E can be constructed.

It would be very desirable to make these commands more precise, and to extend them to work over other fields. For example, modular abelian varieties should (conjecturally) be associated to $\mathbf{Q}$-curves and their restriction of scalars.

`EllipticCurve(A)`

An elliptic curve isogenous to the modular abelian variety A over the rational field, if there is an elliptic curve associated to A. For A of weight greater than 2 use the `EllipticInvariants` command.

`ModularAbelianVariety(E)`

`Sign` RNGINTELT *Default :* 0

A modular abelian variety isogenous to the elliptic curve E. Note that elliptic curves with small coefficients can have quite large conductor, hence computing the massive modular abelian variety that has E as quotient, which is one thing this function does, could take some time.

Example H136E122

We apply the above two commands to the elliptic curve $J_0(49)$.

```
> A := JZero(49);
> E := EllipticCurve(A); E;
Elliptic Curve defined by y^2 + x*y = x^3 - x^2 - 2*x - 1 over
Rational Field
> B := ModularAbelianVariety(E); B;
Modular abelian variety 'Cremona 49A' of dimension 1 and level
7^2 over Q
```

To see how A and B compare, we first test equality and see they are not equal (since they were constructed differently). However, they are isomorphic.

```
> B eq A;
false
> IsIsomorphic(A,B);
```

```
true Homomorphism from JZero(49) to 'Cremona 49A' given on integral
homology by:
[1 0]
[0 1]
> phi := NaturalMap(A,B);
> Degree(phi);
1
> phi;
Homomorphism N(1) from JZero(49) to 'Cremona 49A' given on integral
homology by:
[1 0]
[0 1]
```

Thus B is embedded in A via the identity map.

136.18.2 Invariants

Let A be an abelian variety over $\mathbf{Q}$ of dimension 1. The following two functions use standard iterative algorithms (see Cremona's book) to compute the invariants c_4, c_6, j, and generators of the period lattice of the optimal quotient of $J_0(N)$ associated to A.

`EllipticInvariants(A, n)`

Invariants c_4, c_6, j, and an elliptic curve, of the one dimensional modular abelian variety A, computed using n terms of q-expansion.

`EllipticPeriods(A, n)`

Elliptic periods w_1 and w_2 of the $J_0(N)$-optimal elliptic curve associated to the modular abelian variety A, computed using n terms of the q-expansion. The periods have the property that w_1/w_2 has positive imaginary part.

Example H136E123

```
> A := ModularAbelianVariety("100A");
> c4,c6,j,E := EllipticInvariants(A,100);
> c4;
1600.052318304045803306867849111720 8 +  0.E-25*i
> c6;
-44002.166592330033618811790218678607 +  0.E-24*i
> j;
3276.801127299202275905948170653 93 +  0.E-25*i
> E;
Elliptic Curve defined by y^2 = x^3 +
(-43201.412594209236689285431925551172 +  0.E-24*i)*x +
(2376116.995985821815415836671800373 00 +  0.E-22*i) over Complex
Field
> jInvariant(E);
```

```
3276.80112729920227590594817070563 +  0.E-25*i
> w1,w2 := EllipticPeriods(A,100);
> w1;
1.26308870071276069371281657330245009108 8 +  0.E-38*i
> w2;
 0.E-38 - 1.01702927066995984919787906165005620863321*i
> w1/w2;
 0.E-38 + 1.24193937887422962244668740609486508404 97*i
```

137 HILBERT MODULAR FORMS

Chapter 137
HILBERT MODULAR FORMS

137.1 Introduction

The first version of this package was released in V2.15 (December 2008). It has been developed further in each subsequent release, and is still under development. We encourage users to send feedback regarding the package, and desirable features or improvements.

The package contains implementations of two separate algorithms. The primary focus is on parallel weight 2. Higher weight spaces (including non-parallel weight) are also handled; however some features are only available for weight 2, and the main routines are better optimized in weight 2. All levels $\Gamma_0(N)$ are allowed; some spaces with nontrivial character are also handled.

The main purposes of the current functionality are to efficiently compute Hecke operators on these spaces, to decompose spaces into newforms, and to efficiently obtain large numbers of eigenvalues for newforms (at least those having small degree). Some additional features such as Atkin-Lehner operators are also included.

137.1.1 Definitions and Background

Hilbert modular forms are a generalization of classical modular forms where the modular group is replaced by a subgroup of $\mathrm{GL}_2(\mathbf{Z}_F)$ where $\mathbf{Z}_F$ is the ring of integers in a totally real number field. This section gives a brief and partly informal introduction to Hilbert modular forms. The sections about the algorithms also introduce quaternionic modular forms and the Jacquet-Langlands theory in order to use the package!

The books by Freitag [Fre90] and Garrett [Gar90] are good references for standard material on Hilbert modular forms.

Let F be a totally real field of degree n over $\mathbf{Q}$, with ring of integers $\mathbf{Z}_F$. Let $v_1, \ldots, v_n$ be the embeddings of F into $\mathbf{R}$. For $x \in F$, we write x_i as a shorthand for $v_i(x)$. Each embedding v_i induces an embedding $v_i : \mathrm{Mat}_2(\mathrm{F}) \hookrightarrow \mathrm{Mat}_2(\mathbf{R})$. Extending our shorthand to matrices, for $\gamma \in \mathrm{Mat}_2(\mathrm{F})$ we write γ for $v_i(\gamma)$. Let

$$\mathrm{GL}_2^+(F) = \{\gamma \in \mathrm{GL}_2(F) : \mathrm{det}\gamma_\mathrm{i} > 0 \text{ for all i}\}.$$

The group $\mathrm{GL}_2^+(F)$ acts on the cartesian product H^n by the rule

$$\gamma(\tau, \ldots, \tau_n) = (\gamma\tau_1, \ldots, \gamma\tau_n)$$

where as usual $\mathrm{GL}_2^+(\mathbf{R})$ acts on H by linear fractional transformations.

Let $\gamma = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{GL}_2(\mathbf{R})$ and $\tau \in \mathrm{H}$. We define

$$j(\gamma, \tau) = c\tau + d \in \mathbf{C}.$$

For a *weight* $k = (k_1, \ldots, k_n) \in (\mathbf{Z}_{>0})^n$, we define a right *weight-k action* of $\mathrm{GL}_2^+(F)$ on the space of complex-valued functions on H^n by

$$(f|_k\gamma)(\tau) = f(\gamma\tau)\prod_{i=1}^{n}(\det\gamma)^{\mathrm{k_i}/2}\mathrm{j}(\gamma,\tau_\mathrm{i})^{-\mathrm{k_i}}$$

for $f : \mathrm{H}^n \to \mathbf{C}$ and $\gamma \in \mathrm{GL}_2^+(F)$. The center $F^\times$ of $\mathrm{GL}_2^+(F)$ acts trivially on such f. Therefore, the weight-k action descends to an action of $\mathrm{PGL}_2^+(F) = \mathrm{GL}_2^+(F)/F^\times$.

Now let N be a (nonzero) ideal of $\mathbf{Z}_F$. Define

$$\Gamma_0(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{GL}_2^+(\mathbf{Z}_F) : c \in N \right\}.$$

A *Hilbert modular cusp form of weight-k and level* $\Gamma_0(N)$ is an analytic function $f : \mathrm{H}^n \to \mathbf{C}$ such that $f|_k\gamma = f$ for all $\gamma \in \Gamma_0(N)$ and such that f vanishes at the cusps of $\Gamma_0(N)$.

When F has narrow class number 1, it is possible to define double coset operators in the same way as for classical modular forms; among these are Hecke operators, Atkin-Lehner operators and degeneracy maps. More precisely, the definitions work for primes in the trivial ideal class. In the general case, the adelic definition of Hilbert modular forms is more convenient for the purpose of defining operators, among other considerations. We refer to the book by Freitag [Fre90].

137.1.2 Algorithms and the Jacquet-Langlands Correspondence

Two separate algorithms are implemented for computing the Hecke action on cuspidal spaces of Hilbert modular forms. Both rely on the *Jacquet-Langlands correspondence*, which states that the Hecke action on a space of Hilbert cusp forms is the same as the Hecke action on a space of automorphic forms on some order in a suitable quaternion algebra. See [Hid06] for definitions of quaternionic automorphic forms and the correspondence.

Let F be a totally real field of degree n over $\mathbf{Q}$. Algorithm I uses a definite quaternion algebra over F (ramified at all n infinite places). Algorithm II uses the Shimura curve associated to a quaternion algebra ramified at exactly $n-1$ infinite places. By default, the algorithm (and the quaternion order to be used) are selected automatically, but can also be specified by the user. The essential requirement is that the quaternion order can be ramified only at primes p for which the space is p-new. The required conditions are stated fully in the descriptions of the commands `HilbertCuspForms` and `NewSubspace`. It is worth noting that a different algorithm and order may be selected for a newspace than for the space containing it. In fact, there is more freedom for a new space; in particular, over $\mathbf{Q}$ neither algorithm can compute full spaces, but can compute new subspaces for nonsquare levels.

Algorithm II is implemented only for parallel weight 2 (weight $[2, 2, \ldots, 2]$). In the current implementation, Algorithm I is more optimized than Algorithm II, and therefore should be preferred in most cases. For spaces over odd degree fields with level not divisible by any small primes, Algorithm II may be preferable.

An exposition of both algorithms is given in [DV12], in addition to the references mentioned in the following two sections.

137.1.3 Algorithm I (Using Definite Quaternion Orders)

This algorithm, described in [Dem07] and [DD08], is an efficient formulation of the Brandt module approach to computing modular forms.

A key advantage of this algorithm is that the most expensive steps come in the precomputation phase (computations depending only on the quaternion algebra). This means that for a given number field, forms of many different levels and weights can be computed based on the same precomputation.

137.1.4 Algorithm II (Using Indefinite Quaternion Orders)

This algorithm, described in [GV11], is based on computing the homology of a Shimura curve (and therefore is closer to the usual modular symbols algorithm over **Q** than Algorithm I). Voight's algorithm ([Voi09]) for the fundamental domain of the action of the Fuchsian group on the upper half plane is applied. The algorithm simultaneously determines a fundamental domain and generators and relations for the fundamental group. From this a description of the homology is obtained, in such a way that the Hecke action on it can then be explicitly calculated.

137.1.5 Categories

The MAGMA category for spaces of Hilbert modular forms is `ModFrmHil`, while elements in these spaces have type `ModFrmHilElt`.

137.1.6 Verbose Output

To see some information printed during computation about what the program is doing, use `SetVerbose("ModFrmHil",n)`, where `n` is 0 (silent, by default), 1 (prints concise information), 2 or 3 (which may display bulky data).

137.2 Creation of Full Cuspidal Spaces

In the current implementation only cusp forms are supported. In future releases it will be possible to compute Eisenstein series, and create the full space of Hilbert modular forms of given weight and level.

```
HilbertCuspForms(F, N, k)
```

```
HilbertCuspForms(F, N)
```

`QuaternionOrder` ALGASSVORD *Default :*

This creates the space of Hilbert modular forms over the field F (a number field or the rationals) on $\Gamma_0(N)$ with weight k. Here the level N should be an ideal in the maximal order of F, and k should be a sequence of $\deg(\mathrm{F}/\mathbf{Q})$ integers, all at least 2 and all of the same parity. If not specified, the weight is taken to be parallel weight 2, ie. [2, 2, ..., 2].

Computations in the space will be done by realising it as a space of automorphic forms on an order in a suitable quaternion algebra (as explained in the introduction).

This choice is made automatically (in most cases), when it is needed, and is hidden from the user; however the user may specify the order to be used by providing the optional argument `QuaternionOrder`. The quaternion algebra may be definite (ramified at all infinite places of F) or indefinite (ramified at all infinite places except one); this determines which of the two algorithms will be used (see the introduction). Indefinite algebras may only be used for spaces of parallel weight 2. The algebra must be unramified at all finite primes (for full cuspidal spaces, although often a different algebra may be used to compute a `NewSubspace`). In the definite case the order must be maximal, while in the indefinite case it must be an Eichler order with discriminant equal to the level N.

Example H137E1

Here we create some spaces of modular forms over $\mathbf{Q}(\sqrt{85})$.

```
> _<x> := PolynomialRing(Rationals());
> F := NumberField(x^2-85);
> level := 1*Integers(F);
> H := HilbertCuspForms(F, level);
> H;
Cuspidal space of Hilbert modular forms over Number Field with defining polynomial
x^2 - 85 over the Rational Field
   Level = Ideal of norm 1 generated by ( [1, 0] )
   Weight = [ 2, 2 ]
```

This returns instantly because no nontrivial computations have been done yet. We can find out which quaternion order will be used internally to do computations.

```
> QO := QuaternionOrder(H);
> A := Algebra(QO);
> A;
Quaternion Algebra with base ring F
> A.1^2, A.2^2, A.3^2;
-1 -1 -1
> IsMaximal(QO);
true
```

So the order is a maximal order in Hamilton's quaternion algebra over F. We now define a space with level equal to one of the split primes dividing 3.

```
> level := Factorization(3*Integers(F))[1][1];
> Norm(level);
3
> weight := [3,5];
> H := HilbertCuspForms(F, level, weight);
```

If we wish, we may tell Magma to use the same quaternion order. (This would avoid some of the time-consuming computations being done twice.)

```
> H := HilbertCuspForms(F, level, weight : QuaternionOrder:=QO);
```

137.3 Basic Properties

`BaseField(M)`

The field on which the space M was defined.

`Weight(M)`

The weight of the space M.

`CentralCharacter(M)`

The central character of the weight representation defining the space M of Hilbert modular forms. This is of significance only for higher weight spaces (not parallel weight 2).

`Level(M)`

The level of the space M.

`DirichletCharacter(M)`

The nebentypus of the space M of Hilbert modular forms.

`IsCuspidal(M)`

This is true if the space M was created as (a subspace of) a space of cusp forms. In the current implementation this is always `true`.

`IsNew(M)`

This is true if the space M was created as (a subspace of) a new space, for instance using `NewSubspace` or `NewformDecomposition`, or if the space is known to satisfy `NewLevel(M) = Level(M)`.

`NewLevel(M)`

This returns the level at which M is known to be new. (See `NewSubspace`.)

`Dimension(M)`

`UseFormula` BoolElt *Default :* `true`

This computes the dimension of the space M of Hilbert modular forms.

The dimension is determined either by using "dimension formulae" or else by explicitly constructing the space. By default, formulae are used when available and when considered cheap to evaluate. The optional argument `UseFormula` can be set `true` or `false` to override the default.

Dimension formulae are implemented for spaces of parallel weight 2. These formulae are sums over certain cyclotomic extensions of the base field of F.

The results by formula are guaranteed only under GRH, since they may involve class numbers that are calculated conditionally. If at some later point, the space is explicitly computed, the dimension is will then be verified unconditionally.

`QuaternionOrder(M)`

This returns the quaternion order that is used internally to compute the space M of Hilbert modular forms.

`IsDefinite(M)`

This indicates which of the two algorithms is used to compute the space M of Hilbert modular forms. It is equivalent to `IsDefinite(Algebra(QuaternionOrder(M)))`. Note that calling this causes a `QuaternionOrder` for M to be chosen (if it has not been set already).

Example H137E2

We continue with the first example above.

```
> _<x> := PolynomialRing(Rationals());
> F := NumberField(x^2-85);
> OF := Integers(F);
> H := HilbertCuspForms(F, 1*OF);
> Norm(Level(H));
1
> Weight(H);
[ 2, 2 ]
> time Dimension(H);
6
Time: 2.580
> IsDefinite(H);
true
```

This indicates that Algorithm I (described in the introduction) was used to compute the dimension.

```
> level := Factorization(3*OF)[1][1];
> H3 :=  HilbertCuspForms(F, level);
> Level(H3);
Prime Ideal of OF
Two element generators:
    [3, 0]
    [2, 2]
> time Dimension(H3);
14
Time: 2.370
> H3 :=  HilbertCuspForms(F, level : QuaternionOrder:=QuaternionOrder(H) );
> time Dimension(H3);
14
Time: 0.270
```

It is much faster when we recycle the same quaternion order used for the space of level 1. This is because the harder computations involved depend only on the quaternion order, not on the level.

137.4 Elements

The current implementation does not provide functionality for manipulating elements in spaces of Hilbert modular forms. Note that, unlike classical modular forms in MAGMA, Hilbert modular forms are allowed to be defined over extensions of the base field of their parent space.

`Parent(f)`

The space of Hilbert modular forms containing f.

`BaseField(f)`

The field over which the Hilbert modular form f is defined. This is either equal to, or an extension of, the base field of `Parent(f)`.

137.5 Operators

Operators on spaces of Hilbert modular forms are returned as matrices with respect to a basis of M. For spaces of parallel weight 2, operators are matrices over $\mathbf{Q}$, and the basis of M is permanently fixed. For all other weights, two finite extensions of $\mathbf{Q}$ may arise:

(i) The field that is used for the raw computations; operators are originally computed as matrices over this field.

(ii) The minimal field F for which there exists a basis of M such that operators are matrices with entries in F. For all parallel weights, this minimal field is $\mathbf{Q}$. We refer to such a basis as a "rational basis" of M.

Changing the basis can be expensive for large spaces, so for some spaces a "rational basis" is not computed by default. In these cases, Hecke operators are returned as matrices over the "raw" field, with respect to a basis which remains fixed until `SetRationalBasis(M)` is invoked by the user. When that occurs, the basis of the space is changed to a "rational basis" which is then permanently fixed; as a result, the operators also change (they are now given as matrices with respect to the new basis).

A space M is guaranteed to have a "rational basis" (which is permanently fixed) in any of the following circumstances:

(i) M has parallel weight,

(ii) M was constructed using `NewSubspace` (unless `RationalBasis` was set to `false`), or was constructed using `NewformDecomposition`,

(iii) `SetRationalBasis(M)` has been invoked.

`HeckeOperator(M, P)`

This returns a matrix representing the Hecke operator T_P on the space M of Hilbert modular forms.

Example H137E3

```
> R<x> := PolynomialRing(IntegerRing());
> F<a> := NumberField(x^2-2);  OF := Integers(F);
> M3 := HilbertCuspForms(F, 3*OF, [2,4]);
> Dimension(M3);
1
> P2 := Factorization(2*OF)[1][1];
> Norm(P2);
2
> HeckeOperator(M3, P2);
[2]
```

Since the space has dimension 1, it consists of a single eigenform, whose eigenvalues can be read from the Hecke matrices. We now consider the space of level 5, which has dimension 3. The Hecke matrices are given with respect to the basis used to compute the space, over the extension K displayed here.

```
> M5 := HilbertCuspForms(F, 5*OF, [2,4] : QuaternionOrder:=QuaternionOrder(M3) );
> Dimension(M5);
3
> T2 := HeckeOperator(M5, P2);
> K<b> := BaseRing(T2);
> K;
Number Field with defining polynomial $.1^2 + 1 over F
> T2;
[       0    8*a*b -2*b - 2]
[-1/2*a*b        2        0]
[   b - 1        0        0]
```

`AtkinLehnerOperator(M, P)`

This returns a matrix representing the Atkin-Lehner operator w_P on the space M of Hilbert modular forms.

`DegeneracyOperator(M, P, Q)`

This computes degeneracy maps in the "downward" direction as maps from M to itself. Here M is a space of Hilbert modular forms of level N, P is a prime dividing N, and Q either equals P or the unit ideal (1). The function returns a matrix representing a map from M to M whose image equals a copy of the space of level N/P.

When $Q = (1)$, this is double coset operator defined by cosets of an element with determinant 1 (which can be seen as a "norm" map); when $Q = P$, it is the double coset operator defined by cosets of an element with determinant Norm(P).

`DeleteHeckePrecomputation(O)`

`DeleteHeckePrecomputation(O, P)`

These procedures delete data obtained during the precomputation phase of the "definite" algorithm. This data is used in the computation of Hecke operators (and other operators) for given primes, and the same data can be re-used for all spaces that are computed with the some quaternion order O. (Often this is the same for spaces of all weights and levels over a particular number field.) Since the data is the most expensive part of the Hecke computation, it is stored by default. However it is very expensive in memory; these procedures allow the user to reclaim this memory when necessary.

137.6 Creation of Subspaces

`NewSubspace(M)`

`NewSubspace(M, I)`

`QuaternionOrder` AlgAssVOrd *Default :*

Given a cuspidal space M of Hilbert modular forms of level N, and an ideal I dividing N, this constructs the subspace of M consisting of forms that are new at the ideal I (or that are new at N, if I is not given). More precisely, this is the complement of the space generated by all images under degeneracy maps of spaces of level N/P for primes P dividing I. In the current implementation, I must be squarefree and coprime to N/I.

The `NewSubspace` of M is not necessarily represented as an explicit subspace of M: doing so is not always possible, or may not be optimal. (These choices are internal: the difference is not visible in the output.) In many cases new subspace is obtained as an explicit subspace by computing degeneracy maps. In other case it is computed independently of M, using a quaternion order which is chosen automatically. When the optional argument `QuaternionOrder` is specified, this will always be used (overriding other considerations). The allowable orders are similar to those for full cuspidal spaces (see `HilbertCuspForms` above), with the difference that here the quaternion algebra is allowed to be ramified at finite primes dividing I. When the algebra is indefinite, the finite primes where it is ramified must be precisely those dividing I.

In the non-parallel weight case, work may be saved by setting the optional argument `RationalBasis` to `false`. This defers the computation of a "rational basis" of the new space (this is explained below). By default, a rational basis is computed for `NewSubspace(M)`, and (equivalently) `NewSubspace(M)` where I equals `Level(M)`. If it is defered, one may later set a "rational basis" for the new space using `SetRationalBasis`.

`SetRationalBasis(M)`

This is a procedure which changes the basis of M. A full explanation is given in the first part of Section 137.5.

If the basis of M is already known to be a "rational basis", then nothing is done; the basis of M is not modified. In particular, this has no effect on spaces of parallel weight 2.

After this has been invoked, the basis of M is never modified again.

Example H137E4

We investigate new forms and old forms with level dividing 3 over $\mathbf{Q}(\sqrt{10})$.

```
> _<x> := PolynomialRing(Rationals());
> F := NumberField(x^2-10);
> OF := Integers(F);
> primes := [tup[1] : tup in Factorization(3*OF)];
> #primes;
2
> M1 := HilbertCuspForms(F, 1*OF);
> Dimension(M1);
2
> M3 := HilbertCuspForms(F, primes[1]);
> Dimension(M3);
4
```

Hence $M3$ must contain only oldforms (since there are two degeneracy maps $M1 \to M3$, whose images must be linearly independent). We confirm this now:

```
> Dimension(NewSubspace(M3));
0
```

Next we consider level (3).

```
> M9 := HilbertCuspForms(F, 3*OF);
> Dimension(M9);
18
> Dimension(NewSubspace(M9, primes[1]));
14
> Dimension(NewSubspace(M9, primes[2]));
14
> Dimension(NewSubspace(M9));
10
```

The dimensions indicate that the four degeneracy maps $M1 \to M9$ have independent images.

Example H137E5

This illustrates that new subspaces may be computed independently, not using the same algorithm as for the full space. We compute forms over the real subfield of $\mathbf{Q}(\zeta_7)$, which has degree 3.

```
> _<x> := PolynomialRing(Rationals());
```

```
> _<zeta7> := CyclotomicField(7);
> F<a> := NumberField(MinimalPolynomial(zeta7 + 1/zeta7));
> F;
Number Field with defining polynomial x^3 + x^2 - 2*x - 1 over the Rational Field
```

We consider forms of level 3 (which generates a prime ideal in F).

```
> M := HilbertCuspForms(F, 3*Integers(F));
> M;
Cuspidal space of Hilbert modular forms over
Number Field with defining polynomial x^3 + x^2 - 2*x - 1 over the Rational Field
   Level = Ideal of norm 27 generated by ( [3, 0, 0] )
   Weight = [ 2, 2, 2 ]
> Mnew := NewSubspace(M);
> Dimension(M);
1
> Dimension(Mnew);
1
```

So in fact M equals its new subspace, and consists of just one newform. However, different algorithms have been chosen to compute them, as indicated below. (Algorithm I is chosen automatically for the new subspace because it is much faster. It cannot be used for the full space, since over an odd degree field there is no quaternion algebra ramified at precisely the infinite places.)

```
> IsDefinite(M);
false
> IsDefinite(Mnew);
true
```

We now compute some eigenvalues of the newform generating the space, using both algorithms. (The computations for M_{new} are entirely independent from those for M.)

```
> primes := PrimesUpTo(20,F);
> [Norm(P) : P in primes];
[ 7, 8, 13, 13, 13 ]
> time for P in primes do HeckeOperator(Mnew,P); end for;
[-5]
[-4]
[1]
[1]
[1]
Time: 0.810
> time HeckeOperator(M, primes[1]);
[-5]
Time: 38.800
```

137.7 Eigenspace Decomposition and Eigenforms

`HeckeEigenvalueBound(M, P)`

Returns a bound on the absolute value of the Hecke eigenvalue at the prime P which must hold for all newforms in the space M of Hilbert modular forms.

`NewformDecomposition(M)`

Given a space M of Hilbert modular forms which was created as a `NewSubspace`, this decomposes M into subspaces that are irreducible modules under the Hecke action.

`NewformsOfDegree1(M)`

This constructs the list of new eigenforms in M that have rational eigenvalues, i.e. corresponding to the 1-dimensional components in the `NewformDecomposition`. The space M is not required to be a new space. The algorithm avoids constructing the new subspace of M, and makes use of bounds on the eigenvalues.

`Eigenform(M)`

This constructs an eigenform contained in the space M of Hilbert modular forms (which should be an irreducible module under the Hecke action, for instance a space obtained using `NewformDecomposition`).

`Eigenforms(M)`

This is a list containing an eigenform from each space in `NewformDecomposition(M)`.

`HeckeEigenvalueField(M)`

Given a space M constructed using `NewformDecomposition`, this returns the number field over which the `Eigenform` of M is defined.

`HeckeEigenvalue(f, P)`

The computes the eigenvalue of the Hecke operator T_P acting on the eigenform f (which should be a Hilbert modular form constructed using `Eigenform`).

Example H137E6

We compute the newforms corresponding to elliptic curves over $\mathbf{Q}(\sqrt{2})$ of conductor 11, and find there is only the one coming from $\mathbf{Q}$.

```
> R<x> := PolynomialRing(IntegerRing());
> F := NumberField(x^2-2);  OF := Integers(F);
> M := HilbertCuspForms(F, 11*OF);
> Dimension(M);
6
> time decomp := NewformDecomposition(NewSubspace(M)); decomp;
Time: 11.130
[*
```

```
    New cuspidal space of Hilbert modular forms of dimension 1 over
    Number Field with defining polynomial x^2 - 2 over the Rational Field
       Level = Ideal of norm 121 generated by ( [11, 0] )
       Weight = [ 2, 2 ],
    New cuspidal space of Hilbert modular forms of dimension 5 over
    Number Field with defining polynomial x^2 - 2 over the Rational Field
       Level = Ideal of norm 121 generated by ( [11, 0] )
       Weight = [ 2, 2 ]
*]
```

We look at the first few eigenvalues of the 1-dimension piece (at split primes).

```
> f := Eigenform(decomp[1]);
> primes := [P : P in PrimesUpTo(40,F) | IsOdd(Norm(P)) and IsPrime(Norm(P))];
> for P in primes do
>   Norm(P),  HeckeEigenvalue(f,P);
> end for;
7 -2
7 -2
17 -2
17 -2
23 -1
23 -1
31 7
31 7
```

Happily, they agree with the eigenvalues of the elliptic cusp form of conductor 11 over $\mathbf{Q}$:

```
> fQ := Newforms(CuspForms(11))[1][1];
> for P in primes do
>   p := Norm(P);
>   p,  Coefficient(fQ, p);
> end for;
7 -2
7 -2
17 -2
17 -2
23 -1
23 -1
31 7
31 7
```

The 5-dimensional piece conjecturally corresponds to an abelian variety over F of dimension 5, which would be absolutely irreducible and have real multiplication by the following field.

```
> K := HeckeEigenvalueField(decomp[2]);
> K;
Number Field with defining polynomial $.1^5 - 8*$.1^3 + 10*$.1 + 4 over F
> IsTotallyReal(K);
true
```

137.8 Further Examples

Example H137E7

```
> R<x> := PolynomialRing(IntegerRing());
> F := NumberField(x^2-15);  OF := Integers(F);
> M := HilbertCuspForms(F, 1*OF, [2,4]);
> M;
Cuspidal space of Hilbert modular forms over Number Field with defining polynomial
x^2 - 15 over the Rational Field
   Level = Ideal of norm 1 generated by ( [1, 0] )
   Weight = [ 2, 4 ]
> Dimension(M);
2
> T2 := HeckeOperator(M, Factorization(2*OF)[1][1] );
> BaseRing(T2);
Number Field with defining polynomial $.1^2 + 1 over F
```

So the basis used to compute M is over this extension of F. We now replace this with a F-rational basis (this is implemented for new spaces, in particular spaces of level 1).

```
> IsNew(M);
true
> SetRationalBasis(M);
> for P in PrimesUpTo(7,F) do
>    Norm(P), HeckeOperator(M,P);
> end for;
2
[  0   1]
[-20   0]
3
[0 0]
[0 0]
5
[  0   4]
[-80   0]
7
[0 0]
[0 0]
7
[0 0]
[0 0]
> #NewformDecomposition(M);
1
```

In general the Hecke matrices would be over F, however for this space there is a basis where they have entries in $\mathbf{Z}$. The program was able to discover this because the basis is chosen by putting one of the matrices in rational canonical form.

Example H137E8

It is possible to use this package to compute classical modular forms (although this will usually be much slower). Here we compute the newform of level 14 three times independently. First we wish to use Algorithm 1, so we choose the quaternion algebra over $\mathbf{Q}$ ramified at 2 and infinity. (Note: Algorithm I is not implemented over `Rationals()`, so we must work over a number field isomorphic to $\mathbf{Q}$ instead!)

```
> QQ := RationalsAsNumberField();
> ZZ := Integers(QQ);
> M := HilbertCuspForms(QQ, 14*ZZ);
> A := QuaternionAlgebra(2*ZZ, InfinitePlaces(QQ) : Optimized);
> M14 := NewSubspace(M : QuaternionOrder:=MaximalOrder(A) );
> Dimension(M14);
1
> f := Eigenform(NewformDecomposition(M14)[1]);
> primes := PrimesUpTo(50);
> time eigenvalues1:= [ <p, HeckeEigenvalue(f,p*ZZ)> : p in primes ];
Time: 0.220
> eigenvalues1;
[ <2, -1>, <3, -2>, <5, 0>, <7, 1>, <11, 0>, <13, -4>, <17, 6>, <19, 2>, <23, 0>,
  <29, -6>, <31, -4>, <37, 2>, <41, 6>, <43, 8>, <47, -12> ]
```

Now we use Algorithm 2, choosing the indefinite quaternion algebra over $\mathbf{Q}$ ramifed at 2 and 7.

```
> Q := Rationals();
> M := HilbertCuspForms(Q, 14);
> A := QuaternionAlgebra(14 : Al:="Smallest" );
> A.1^2, A.2^2;
7, -2
> M14 := NewSubspace(M : QuaternionOrder:=MaximalOrder(A) );
> IsDefinite(M14); // Not definite means Algorithm 2
false
> Dimension(M14);
1
> f := Eigenform(NewformDecomposition(M14)[1]);
> time eigenvalues2 := [ <p, HeckeEigenvalue(f,p)> : p in primes |
>                                                     GCD(p,14) eq 1];
Time: 2.750
> eigenvalues2;
[ <3, -2>, <5, 0>, <11, 0>, <13, -4>, <17, 6>, <19, 2>, <23, 0>,
  <29, -6>, <31, -4>, <37, 2>, <41, 6>, <43, 8>, <47, -12> ]
```

Finally we check both results agree with the standard modular forms package.

```
> M14 := CuspForms(14);
> time eigenvalues := [ <p, HeckeOperator(M14,p)[1,1]> : p in primes ];
Time: 0.160
> assert eigenvalues1 eq eigenvalues;
> assert eigenvalues2 subset eigenvalues;
```

138 MODULAR FORMS OVER IMAGINARY QUADRATIC FIELDS

Chapter 138
MODULAR FORMS OVER IMAGINARY QUADRATIC FIELDS

138.1 Introduction

This package deals with cuspidal spaces of weight 2 modular forms on $\Gamma_0(N)$, over any imaginary quadratic field. In the current version, one can compute Hecke operators for principal ideals on these spaces, and determine the newforms. The package will be developed further in the future.

We will refer to modular forms over imaginary quadratic fields as *Bianchi modular forms*. These are defined similarly to classical modular forms, with the modular group $SL(2, \mathbf{Z})$ is replaced by $SL(2, O_F)$, where O_F is the ring of integers in an imaginary quadratic field F. This group acts on $\mathbf{H_3}$, 3-dimensional hyperbolic space, and Bianchi modular forms (of weight $k \geq 2$) are functions on $\mathbf{H_3}$ that satisfy a natural automorphy relation under this action.

For an ideal N of O_F, the congruence subgroup $\Gamma_0(N)$ of $GL(2, O_F)$ is defined as the subgroup of matrices that are upper triangular modulo N. The space of *Bianchi modular forms on F of level N* is defined as the space of functions satisfying the automorphy relation on the subgroup $\Gamma_0(N)$.

For precise definitions see [EGM98].

There exist several previous implementations of weight 2 Bianchi modular forms, each for specific fields F. These projects are described in [Cre84] and references cited there for Euclidean fields, [Whi90] for fields of class number one, [Byg99] for $\mathbf{Q}(\sqrt{-5})$ and [Lin05] for $\mathbf{Q}(\sqrt{-23})$ and $\mathbf{Q}(\sqrt{-31})$.

138.1.1 Algorithms

A theorem of Franke states that for algebraic group $\mathbf{G}$ defined over $\mathbf{Q}$ and arithmetic subgroup Γ,

$$H^*(\Gamma; E) \simeq H^*(g, K; A(\Gamma, G) \otimes E)$$

where $A(\Gamma, G)$ denotes the space of automorphic forms. Thus we can think of the cohomology $H^*(\Gamma; E)$ as a concrete realization of certain automorphic forms.

Ash, Gunnells, and Lee-Szczarba [LS78, Ash94, Gun00] define a homology complex $S^*(\Gamma)$ known as the *sharbly complex*. A theorem of Borel-Serre [BS73] gives

$$H^{\nu-k}(\Gamma; \mathbf{C}) \simeq H_k(S_*(\Gamma)),$$

where $\nu = \mathrm{vcd}(\Gamma)$ is the *virtual cohomological dimension* of Γ.

There is a natural Hecke action on this complex which agrees with the Hecke action on the automorphic forms.

The space of positive definite binary Hermitian forms over F form an open cone in a real vector space. There is a natural decomposition of this cone into polyhedral cones corresponding to the facets of the Voronoi polyhedron [Gun99, Koe60, Ash77]. These facets are in 1-1 correspondence with perfect forms over F. The polyhedral cones give rise to ideal polytopes in $\mathbf{H_3}$, 3-dimensional hyperbolic space.

The structure of the polytopes allows us to find a finite (modulo Γ) spanning set for the sharbly complex. This is the analogue of unimodular symbols in the classical case. The modular symbol algorithm, for describing the action of Hecke operators, can now be replaced by a 0-sharbly reduction algorithm. An advantage of this is, compared with a straightforward generalization of the usual modular symbols algorithm, is that the number field does not need to be Euclidean.

Given an imaginary quadratic field F, we compute the structure of the Voronoi polyhedron by computing a complete set of $\mathrm{GL}_2(\mathcal{O})$-class representatives of perfect forms. Given a level $n \subseteq \mathcal{O}$ defining the level of the congruence subgroup, the polyhedron is used to compute $H^2(\Gamma_0(n))$. Given a prime ideal $p \subset \mathcal{O}$, the 0-sharbly reduction algorithm is used to compute the action of the Hecke operator T_p on $H^2(\Gamma_0(n))$.

The algorithm described in [Gun99] is an efficient algorithm for computing the Voronoi polyhedron and provides a replacement for the modular symbol algorithm for computing the action of Hecke operators.

One advantage of this algorithm is that the most expensive steps come in the precomputation phase (computations depending only on the imaginary quadratic field). This means that for a given field, forms of many different levels can be computed based on the same precomputation.

The cohomology, regarded as a module for the algebra generated by the Hecke operators T_p, decomposes into an Eisenstein piece and a cuspidal piece. The cuspidal piece is the same as the cuspidal subspace of modular forms (regarding both as Hecke modules). The Eisenstein part is recognisable by looking at Hecke eigenvalues of the eigenforms contained in it. By this means, we strip away the Eisenstein part; the space returned is the cuspidal subspace only.

138.1.2 Categories

Spaces of Bianchi modular forms in MAGMA are objects of type `ModFrmBianchi`. This is functionally the same as the type `ModFrmHil`: functions for Hilbert modular forms (see Chapter 137) can also be applied to Bianchi spaces, for example `NewformDecomposition`.

138.1.3 Verbose Output

To see some information printed during computation about what the program is doing, use `SetVerbose("Bianchi",n)`, where `n` is 0 (silent, by default), 1 (for concise information), 2, 3 or 4 (which may display bulky data).

138.2 Creation

In the current implementation only cusp forms are supported.

`BianchiCuspForms(F, N)`

`VorData` REC *Default :*

This creates the cuspidal subspace of the space of Bianchi modular forms over the field F (an imaginary quadratic field) on $\Gamma_0(N)$ with weight 2. The level N should be an ideal in the maximal order of F.

The optional argument `VorData` may be set equal to `VoronoiData(M)` where `M` is a previously computed space of forms over the same field. This avoids repeating the time-consuming precomputations that depend only on the field.

138.3 Attributes

`BaseField(M)`

The field on which the space M of Bianchi modular forms was defined.

`Level(M)`

The level of the space M.

`Dimension(M)`

The dimension of the space M. Dimension formulas are not available, so the dimension is computed by explicit construction of the space.

`VoronoiData(M)`

This returns a record containing technical data that is computed in the precomputation phase of the algorithm. This depends only on the base field of M, and the data can be reused when computing spaces of different levels over the same field.

Example H138E1

We create spaces of modular forms over $\mathbf{Q}(\sqrt{-14})$ for various levels.

```
> _<x> := PolynomialRing(Rationals());
>  F := NumberField(x^2+14);
>  OF := Integers(F);
>  level := 1*OF;
>  M := BianchiCuspForms(F, level);
>  M;
Cuspidal space of Bianchi modular forms over
    Number Field with defining polynomial x^2 + 14 over the Rational Field
    Level = Ideal of norm 1 generated by ( [1, 0] )
    Weight = 2
>  time Dimension(M);
0
```

```
Time: 4.980
```

We now define a space with level equal to the square of one of the split primes dividing 3.

```
> level := (Factorization(3*OF)[1][1])^2;
> Norm(level);
9
> time M9 := BianchiCuspForms(F, level);
Time: 7.300
> M9;
Cuspidal space of Bianchi modular forms over
    Number Field with defining polynomial z^2 + 14 over the Rational Field
    Level = Ideal of norm 9 generated by ( [9, 0], [5, 2] )
    Weight = 2
```

If we wish, we may tell Magma to use the same Voronoi data (to avoid repeating the time-consuming precomputation):

```
> time M9 := BianchiCuspForms(F, level : VorData := VoronoiData(M) );
Time: 0.100
> M9;
Cuspidal space of Bianchi modular forms over
    Number Field with defining polynomial z^2 + 14 over the Rational Field
    Level = Ideal of norm 9 generated by ( [9, 0], [5, 2] )
    Weight = 2
>  Level(M9);
Ideal
Two element generators:
    [9, 0]
    [5, 2]
>  time Dimension(M9);
1
Time: 24.540
```

138.4 Hecke Operators

The computations are done essentially on the cohomology of $\Gamma\backslash\mathbf{H_3}$, and so the for a non-principal ideal P, the Hecke operator T_P does not act on this space, but sometimes the Hecke action can be deduced from the action of principal Hecke operators. See for instance [Lin05]. Specifically, suppose p is a prime ideal that is prime to the level. There exists an ideal a, prime to p and the level, such that a^2p is principal. Then the composition $T_{a,a}T_p$ acts on the cohomology.

`HeckeOperator(M, P)`

This returns a matrix representing a certain Hecke action T on the space M of Bianchi modular forms, with respect to the fixed basis of M. The ideal P must be principal (but not necessarily prime) or prime and a square in the class group. If P is principal, then T is the Hecke operator T_P. When P is prime and a square in the class group, T is the composition $T_{a,a}T_P$ for a suitably chosen ideal a.

138.5 Newforms

The functions `NewSubspace` and `NewformDecomposition` may be applied to spaces of Bianchi modular forms. (See Chapter 137.)

Example H138E2

We continue the previous example.

```
> _<x> := PolynomialRing(Rationals());
>  F := NumberField(x^2+14);
>  OF := Integers(F);
>  level := (Factorization(3*OF)[1][1])^2;
>  M9 := BianchiCuspForms(F, level);
>  P:=Factorization(23*OF);
>  P[1,1];
Prime Ideal of OF
Two element generators:
    [23, 0]
    [3, 1]
>  HeckeOperator(M9, P[1,1]);
[8]
>  P[2,1];
Prime Ideal of OF
Two element generators:
    [23, 0]
    [20, 1]
>  HeckeOperator(M9, P[2,1]);
[-8]
>  HeckeOperator(M9, 2*OF);
[1]
```

Since this cuspidal space has dimension 1, it consists of a single eigenform, whose eigenvalues can be read from the Hecke matrices:

139 ADMISSIBLE REPRESENTATIONS OF $\mathrm{GL}_2(\mathbf{Q}_p)$

Chapter 139
ADMISSIBLE REPRESENTATIONS OF $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$

139.1 Introduction

This package enables one to do the following. Starting with a cuspidal newform, one may define the local component at p of the associated automorphic representation, and determine its key properties. Furthermore, via the local Langlands correspondence, there exists a related Galois representation on the absolute Galois group of $\mathbf{Q}_p$. One may compute (the restriction to inertia of) that Galois representation.

The algorithms implemented here are described in [LW].

139.1.1 Motivation

Let F be a local non-archimedean field and let G be a reductive group over F. The representation theory of G is a rich subject in its own right but also has fascinating (and often conjectural) connections with the representation theory of the absolute Galois group of F. This package deals with admissible irreducible representations in the case that G is the group GL_2 and F is the p-adic field $\mathbf{Q}_p$. Such objects correspond canonically to two-dimensional representations of the absolute Galois group of F of a certain sort.

There are applications to the study of local properties of (global) Galois representations arising from modular forms. Namely, if f is a cuspidal newform, then there is associated to f a family of ℓ-adic Galois representations $\rho_f : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}_2(\overline{\mathbf{Q}}_\ell)$. For example, for a prime p different from ℓ, one may determine the restriction of ρ_f to the decomposition group at p.

139.1.2 Definitions

Here we introduce the category of admissible irreducible representations of GL_2 over a non-archimedean field, which for our purposes will be $\mathbf{Q}_p$. The first systematic study of admissible representations is [JL70]. For an accessible introduction, see [BH06].

Let G be the locally compact group $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$. An *admissible* representation of G on a complex vector space V is a homomorphism $\pi : G \to \mathrm{AutV}$ which satisfies the properties:

(i) every vector $v \in V$ is fixed by a compact open subgroup of G, and

(ii) for every compact open subgroup $K \subset G$, V^K is finite-dimensional.

The center of G is $\mathbf{Q}_p^\times$. If π is an irreducible admissible representation of G, then it has a unique *central character* $\varepsilon : \mathbf{Q}_p^\times \to \mathbf{C}^\times$ such that $\pi(g)$ acts as the scalar $\varepsilon(g)$ for all $g \in \mathbf{Q}_p^\times$. The *conductor* of an irreducible admissible representation π is a measure of how small a compact open subgroup $K \subset G$ must be before one sees nonzero K-invariant vectors; see [Cas73]. Consider the filtration $K_0(p^n)$ of subgroups of G, where $K_0(p^n)$ is the

subgroup of matrices $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{GL}_2(\mathbf{Z}_\mathrm{p})$ with $c \equiv 0 \pmod{p^n}$. If π admits a nonzero vector fixed by $K_0(1) = \mathrm{GL}_2(\mathbf{Z}_\mathrm{p})$, then π is called *spherical* or *unramified principal series* and has conductor 1. If π admits a nonzero vector v for which $\pi\left(\begin{pmatrix} a & b \\ c & d \end{pmatrix}\right) v = \varepsilon(a)v$ for all $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in K_0(p^n)$, and $n \geq 1$ is minimal for this condition, then the conductor of π is p^n. (Note the similarity with the convention used to define the level of a modular form for $\Gamma_0(N)$.) In both cases the vector v so described is unique up to scaling; see [Cas73]. We shall call v a *new vector* for π.

If χ is a character of $\mathbf{Q}_p^\times$ then let $\pi \otimes \chi$ be the representation $g \mapsto \chi(g)\pi(g)$; such a representation is a *twist* of χ. If π has minimal conductor among all its twists $\pi \otimes \chi$, then π is called *minimal*.

Admissible representations are generally infinite-dimensional, but we will nonetheless be able to present them using Magma infrastructure for representations of finite groups and Dirichlet characters.

139.1.3 The Principal Series

We can directly construct a large class of admissible representations of G. Let χ_1 and χ_2 be two characters of $\mathbf{Q}_p^*$. Let $B \subset G$ be the Borel subgroup of upper triangular matrices. Then $\begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \mapsto |a/d|^{-1/2}\chi_1(a)\chi_2(d)$ is a character χ of B. An admissible representation π is a *principal series* representation if it is a composition factor of the induced representation $\pi(\chi_1, \chi_2) := \mathrm{Ind}_\mathrm{B}^\mathrm{G}\chi$. This induced representation is already irreducible unless $\chi_1\chi_2^{-1}$ equals $|.|^{\pm 1}$, in which case it has length two, with one 1-dimensional and one infinite-dimensional composition factor. For instance, $\mathrm{Ind}_\mathrm{B}^\mathrm{G}1$ has a trivial 1-dimensional submodule and an irreducible infinite-dimensional quotient St_G, the *Steinberg* representation. The unramified principal series representations are either 1-dimensional, in which case they factor through the determinant map, or else they take the form $\pi(\chi_1, \chi_2)$, where χ_1 and χ_2 are unramified characters of $\mathbf{Q}_p^\times$ (meaning they are trivial on $\mathbf{Z}_p^\times$).

The central character of $\pi(\chi_1, \chi_2)$ is $\chi_1\chi_2$, and its conductor is the product of the conductors of the χ_i. Note that $\pi(\chi_1, \chi_2)$ is minimal if and only if one of the characters χ_1, χ_2 is unramified. The Steinberg representation St_G has trivial central character and conductor p.

139.1.4 Supercuspidal Representations

For the purposes of this package, an admissible irreducible representation is *supercuspidal* if it does not belong to the principal series. A supercuspidal representation π has conductor p^c, where $c \geq 2$. There is a convenient, if technical, classification of supercuspidal representations of G. Let π be supercuspidal. By [BH06], Ch. 15, there is a representation Ξ of an open and compact-mod-center subgroup $K \subset G$ for which $\pi = \mathrm{Ind}_\mathrm{K}^\mathrm{G}\Xi$. If c is even, then we may take K to be $\mathbf{Q}_p^\times\mathrm{GL}_2(\mathbf{Z}_\mathrm{p})$, and if c is odd, we may take K to be the

normalizer of the Iwahori subgroup $K_0(p) = \begin{pmatrix} \mathbf{Z}_p^\times & \mathbf{Z}_p \\ p\mathbf{Z}_p & \mathbf{Z}_p^\times \end{pmatrix}$ in G. We call the pair (K, Ξ) a *cuspidal inducing datum.*

139.1.5 The Local Langlands Correspondence

The Local Langlands Correspondence is a canonical bijection $\pi \mapsto \sigma(\pi)$ between irreducible admissible representations of G and local 2-dimensional representations of the absolute Galois group of $\mathbf{Q}_p$ of a certain sort. (Note to purists: the proper Galois-theoretic object to study in this scenario is the Weil-Deligne representation, which consists of the datum of a representation of the Weil group, together with a monodromy operator. See [Tat79].) The bijection manifests as an agreement of L- and ε-factors that one constructs for each category. The foundation for the Local Langlands Correspondence for GL_2 over a non-archimedean field was laid in [JL70]; the work was completed in [Kut80] and [Kut84].

We remark that the conductor of π agrees with the Artin conductor of $\sigma(\pi)$, and that π is principal series (resp., Steinberg, supercuspidal) if and only if $\sigma(\pi)$ is a sum of two characters (resp., reducible but not decomposable, irreducible). We also remark that if $p \neq 2$ and σ is an irreducible 2-dimensional Galois representation of $\mathbf{Q}_p$, then σ must be induced from a character χ of a quadratic field extension $E/\mathbf{Q}_p$. Then (E, χ) is called an *admissible pair* (see [BH06], Ch. 18).

139.1.6 Connection with Modular Forms

The classical theory of modular forms has a modern interpretation in terms of *cuspidal automorphic representations.* These are representations Π of the adele group $\mathrm{GL}_2(\mathbf{A_Q})$ which appear in the Hilbert space of square-integrable cuspidal functions $L_0^2(\mathrm{GL}_2(\mathbf{Q})\backslash\mathrm{GL}_2(\mathbf{A_Q}), \varepsilon)$, where ε is a Dirichlet character. Let f be a cuspidal newform for $\Gamma_0(N)$ with Dirichlet character ε. Then there is associated to f a cuspidal automorphic representation Π_f, see [Gel75]. This is a restricted tensor product $\bigotimes_{p \leq \infty} \pi_{f,p}$, where if p is a finite prime, $\pi_{f,p}$ is an admissible representation of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$. There is also the Galois representation ρ_f attached to f constructed by Deligne. By [Car83] there is a straightforward relationship between $\sigma(\pi_{f,p})$ and the restriction of ρ_f to the decomposition group at p. Therefore to determine the local properties of ρ_f it is enough to compute the local components $\pi_{f,p}$. These are almost always unramified principal series; the only challenge is to compute $\pi_{f,p}$ when p divides N.

139.1.7 Category

In MAGMA, admissible representations are objects of type `RepLoc`.

139.1.8 Verbose Output

To see information about computations in progress, enter `SetVerbose("RepLoc", 1)`.

139.2 Creation of Admissible Representations

One starts with a classical cuspidal eigenform, given as a space of modular symbols.

`LocalComponent(M, p)`

This returns the admissible representation of $\mathrm{GL}(\mathbf{Q}_\mathrm{p})$ associated to the cuspidal eigenform specified by M. Here M must be a space of modular symbols that is cuspidal and contains only a single Galois conjugacy class of newforms. (Such spaces are created using `NewformDecomposition`).

Example H139E1

We create the local component at 11 of the representation associated to the newform of level 11 and weight 2. We specify the newform as a space of modular symbols of level 11, weight 2 and sign +1.

```
> S11 := CuspidalSubspace(ModularSymbols(11, 2, 1));
> newform_spaces := NewformDecomposition(S11);
> newform_spaces;
[
    Modular symbols space for Gamma_0(11) of weight 2 and dimension 1 over Q
]
> Eigenform(newform_spaces[1]);
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
> LocalComponent(newform_spaces[1], 11);
Steinberg Representation of GL(2,Q_11)
```

139.3 Attributes of Admissible Representations

`CentralCharacter(pi)`

The central character of π, where π is an admissible representation on $\mathrm{GL}(\mathbf{Q}_\mathrm{p})$. This is a Dirichlet character of p-power conductor.

`Conductor(pi)`

The conductor of π, written multiplicatively.

`DefiningModularSymbolsSpace(pi)`

The space of modular symbols from which π was created.

`IsMinimal(pi)`

Given a representation π of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$, returns `true` if the conductor of π cannot be lowered by twisting by a character of $\mathbf{Q}_p^\times$. If π is not minimal, the function also returns a minimal representation π' together with a Dirichlet character χ, such that π is the twist of π' by χ.

This is true iff `IsMinimalTwist(DefiningModularSymbolsSpace(pi))` is true.

Example H139E2

We continue the previous example.

```
> S11 := CuspidalSubspace(ModularSymbols(11, 2, 1));
> E11 := NewformDecomposition(S11)[1];
> E11;
Modular symbols space for Gamma_0(11) of weight 2 and dimension 1 over Q
> pi := LocalComponent(E11, 11);
> pi;
Steinberg Representation of GL(2,Q_11)
> DefiningModularSymbolsSpace(pi) eq E11;
true
> Conductor(pi);
11
> IsTrivial(CentralCharacter(pi));
true
```

139.4 Structure of Admissible Representations

`IsPrincipalSeries(pi)`

This is `true` iff the admissible representation π belongs to the principal series.

`IsSupercuspidal(pi)`

This is `true` iff the admissible representation π is supercuspidal.

`PrincipalSeriesParameters(pi)`

Given a principal series representation π of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$, this returns two Dirichlet characters of p-power conductor which represent the restriction to $\mathbf{Z}_p^\times \times \mathbf{Z}_p^\times$ of the character of the split torus of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$ associated to π.

`CuspidalInducingDatum(pi)`

Given a minimal supercuspidal representation π of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$, this returns a cuspidal inducing datum that gives rise to π.

Recall (from Section 139.1.4) that a cuspidal inducing datum (K, Ξ) consists of a subgroup K of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$ and a representation Ξ of K that gives rise to π via induction. Importantly, Ξ factors through some finite quotient K/K_1 of K. This function returns such a representation of K/K_1. From this one can deduce the representation on K, and hence π.

139.5 Local Galois Representations

`GaloisRepresentation(pi)`

`WeilRepresentation(pi)`

`Precision` RngIntElt *Default :* 10

Given a minimal representation π of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$, this returns the representation of the Weil group associated to π under the local Langlands correspondence. (See Section 139.1.5.)

More precisely, the objects returned are G, α, L and ρ. $L/\mathbf{Q}_p$ is a finite Galois extension which the representation factors through, G is an abstract group and α is a bijective map identifying G with $\mathrm{Gal}(\mathrm{L}/\mathbf{Q}_\mathrm{p})$, and ρ is a G-module. In this way ρ describes the Weil representation on $\mathrm{Gal}(\mathrm{L}/\mathbf{Q}_\mathrm{p})$.

(See Chapter 90 for information about group modules in Magma.)

`AdmissiblePair(pi)`

Given an ordinary minimal supercuspidal representation π of $\mathrm{GL}_2(\mathbf{Q}_\mathrm{p})$, this returns the associated admissible pair (E, χ). (See Section 139.1.5.) Two objects are returned: a quadratic field extension $E/\mathbf{Q}_p$, and a map χ which is a character of the unit group of E.

139.6 Examples

Example H139E3

We consider a newform of weight 5 and level 7, whose local representation at 7 is principal series.

```
> S := CuspidalSubspace(ModularSymbols(Gamma1(7), 5, 1));
> newforms := NewformDecomposition(S);
> Eigenform(newforms[1], 15);
q + q^2 - 15*q^4 + 49*q^7 - 31*q^8 + 81*q^9 - 206*q^11 + 49*q^14 + O(q^15)
> pi := LocalComponent(newforms[1], 7);
> pi;
Ramified Principal Series Representation of GL(2,Q_7)
> chi := CentralCharacter(pi);
> Conductor(chi);
7
> parameters := PrincipalSeriesParameters(pi);
```

These are Dirichlet characters on $\mathbf{Z}/7\mathbf{Z}$ (the trivial character and the character of order 2):

```
> Conductor(parameters[1]), Order(parameters[1]);
1 1
> Conductor(parameters[2]), Order(parameters[2]);
```

```
7 2
```

The principal series representation π is the induction up to $\mathrm{GL}_2(\mathbf{Q}_7)$ of a character of the Borel subgroup inflated from a character of the diagonal group $\mathbf{Q}_7^\times \times \mathbf{Q}_7^\times$. The restriction of this character to $\mathbf{Z}_7^\times \times \mathbf{Z}_7^\times$ gives the pair of Dirichlet characters above. We now compute the Galois representation.

```
> G, map, F, rho := WeilRepresentation(pi);
> F;
Totally ramified extension defined by the polynomial
x^6 + 7*x^5 + 21*x^4 + 35*x^3 + 35*x^2 + 21*x + 7
over 7-adic ring mod 7^10
> IsAbelian(G);
true
```

The Weil representation is simply the sum of the two characters above, considered as characters of the Galois group of $\mathbf{Q}_7$ via local class field theory.

```
> IsIrreducible(rho);
false
GModule of dimension 1 over Cyclotomic Field of order 6 and degree 2
GModule of dimension 1 over Cyclotomic Field of order 6 and degree 2
```

Example H139E4

We consider a supercuspidal representation of conductor 121, associated to a newform of weight 2 and level 121.

```
> S := CuspidalSubspace(ModularSymbols(Gamma0(121), 2, 1));
> newforms := NewformDecomposition(S);
> newforms;
[
    Modular symbols space for Gamma_0(121) of weight 2 and dimension 1 over Q,
    Modular symbols space for Gamma_0(121) of weight 2 and dimension 1 over Q,
    Modular symbols space for Gamma_0(121) of weight 2 and dimension 1 over Q,
    Modular symbols space for Gamma_0(121) of weight 2 and dimension 1 over Q,
    Modular symbols space for Gamma_0(121) of weight 2 and dimension 2 over Q
]
> Eigenform(newforms[2], 11);
q + q^2 + 2*q^3 - q^4 + q^5 + 2*q^6 - 2*q^7 - 3*q^8 + q^9 + q^10 + O(q^11)
> pi := LocalComponent(newforms[2], 11);
> pi;
Supercuspidal Representation of GL(2,Q_11)
```

This means the representation of the Weil group associated to pi is irreducible.

```
> Conductor(pi);
121
> W := CuspidalInducingDatum(pi);
> W;
```

```
GModule W of dimension 10 over Rational Field
```

W is a module over a group which is a quotient of $\mathrm{GL}_2(\mathbf{Z}_{11})$, namely $\mathrm{GL}_2(\mathbf{Z}/11\mathbf{Z})$. The representation π is induced from some extension of W to the open subgroup $\mathbf{Q}_{11}^{\times}\mathrm{GL}_2(\mathbf{Z}_{11})$.

```
> Group(W);
MatrixGroup(2, IntegerRing(11)) of order 2^4 * 3 * 5^2 * 11
Generators:
    [2 0]
    [0 1]

    [1 1]
    [0 1]

    [ 0  1]
    [10  0]
> Group(W) eq GL(2, Integers(11));
true
> G, alpha, L, rho := WeilRepresentation(pi);
```

This gives the Weil representation attached to π up to multiplication by an unramified twist. This consists of a permutation group G, an isomorphism `alpha` identifying G with the automorphisms of the local field $L/\mathbf{Q}_p$, and a 2-dimensional G-module `rho`.

```
> G;
Permutation group G acting on a set of cardinality 6
Order = 6 = 2 * 3
    Id(G)
    (1, 2, 4)(3, 6, 5)
    (1, 3)(2, 5)(4, 6)
> bool := IsIsomorphic(G, DihedralGroup(3));
> bool;
true
> L;
Totally ramified extension defined by the polynomial x^3 + 11
 over Unramified extension defined by the polynomial x^2 + 7*x + 2
 over 11-adic field mod 11^10
```

Example H139E5

We consider a supercuspidal representation of conductor 3^3, associated to a newform of weight 4 and level 27.

```
> S := CuspidalSubspace(ModularSymbols(Gamma0(27), 4, 1));
> newforms := NewformDecomposition(S);
> Eigenform(newforms[1], 14);
q + 3*q^2 + q^4 + 15*q^5 - 25*q^7 - 21*q^8 + 45*q^10 - 15*q^11 + 20*q^13 + O(q^14)
> pi:=LocalComponent(newforms[1], 3);
> pi;
Supercuspidal Representation of GL(2,Q_3)
```

```
> W:=CuspidalInducingDatum(pi);
> W;
GModule W of dimension 2 over Rational Field
> Group(W);
MatrixGroup(2, IntegerRing(9)) of order 2^2 * 3^5
Generators:
    [1 1]
    [0 1]

    [2 0]
    [0 1]

    [1 0]
    [0 2]

    [1 0]
    [3 1]
```

These matrices generate (topologically) the Iwahori subgroup of $\mathrm{GL}_2(\mathbf{Z}_3)$ consisting of matrices which are upper-triangular modulo 3. W is an irreducible two-dimensional G-module. The representation π is induced from some extension of W to the normalizer of the Iwahori in $\mathrm{GL}_2(\mathbf{Q}_3)$.

```
> E, chi:=AdmissiblePair(pi);
> E;
Totally ramified extension defined by the polynomial x^2 - 3
 over 3-adic ring mod 3^10
> E.1^2;
3
> chi(1+E.1);
zeta_3
```

Note that `chi` can only be evaluated on units of E, so that `chi(E.1)` would result in an error.

```
> G, alpha, L, rho := WeilRepresentation(pi);
> L;
Totally ramified extension defined by the polynomial x^6 - 12*x^4 - 12*x^2 - 3
 over Unramified extension defined by the polynomial x + 2
 over 3-adic field mod 3^10
```

140 SIMPLICIAL HOMOLOGY

Chapter 140
SIMPLICIAL HOMOLOGY

140.1 Introduction

This chapter presents the category of finite simplicial complexes.

We define an abstract simplicial complex K to be a subset of the power set of some set V of vertices, with the property that if $S \in K$ and $T \subset S$ then $T \in K$.

For detailed reading on simplicial complexes and their homology, we refer to [Hat02] and [Arm83].

Simplicial complexes may be defined over any `SetEnum`, however, many of the construction methods operate over `SetEnum[RngIntElt]`. The handbook refers to such simplicial complexes as *normalized*.

A simplicial complex carries the category name `SmpCpx`. Constructors and package internal functions guarantee that the closure under subsets relation is kept intact.

140.2 Simplicial Complexes

The module supports creation of simplicial complexes from lists of faces, as well as a few preprogrammed complex types. Furthermore, several standard techniques for modifying and recombining simplicial complexes are available.

`SimplicialComplex(f)`

Constructs an abstract simplicial complex with the faces in the list f. The argument should be a sequence of sets. There is no requirement on the type of the elements in the face sets, however several of the constructions require the sets to have integer entries. See `Normalization` on page 4696 for automated renumbering of the face set elements.

Example H140E1

We give a simplicial complex by listing the facets, or also redundant faces if we want to.

```
> sc := SimplicialComplex([{1,2,3},{1,2,4},{1,3,4},{2,3,4},{1,5},{2,5}]);
```

We can view the facets (faces not included in any other faces) of the complex, or by giving the `:Maximal` output flag, we can view all faces.

```
> sc;
Simplicial complex
[
    { 2, 3, 4 },
    { 1, 2, 3 },
    { 1, 2, 4 },
```

```
    { 2, 5 },
    { 1, 5 },
    { 1, 3, 4 }
]
> sc:Maximal;
Simplicial complex
{
    {},
    { 4 },
    { 2, 3, 4 },
    { 2, 3 },
    { 3, 4 },
    { 1, 3 },
    { 3 },
    { 1 },
    { 1, 4 },
    { 1, 2, 3 },
    { 2 },
    { 1, 2 },
    { 1, 2, 4 },
    { 2, 5 },
    { 1, 5 },
    { 5 },
    { 2, 4 },
    { 1, 3, 4 }
}
```

`SimplicialComplex(G)`

Constructs a 1-dimensional simplicial complex isomorphic to the graph G.

`FlagComplex(G)`

`CliqueComplex(G)`

Constructs a simplicial complex with an n-simplex for each n-clique in the graph G.

`Dimension(X)`

Returns the dimension of the highest dimensional face of the simplicial complex X. Note that there is a difference between degrees and dimensions of faces. A face is said to have degree n if there are n elements in the face as a set, and it is said to have dimension n if there are $n + 1$ elements in the face as a set.

Example H140E2

The recently defined simplicial complex has top dimension 2.

```
> Dimension(sc);
2
```

`Faces(X, d)`

Returns the faces of one degree d of the simplicial complex X. Recall that the degree of a face is the number of elements in the face as a set, and one more than the dimension of the face.

The order of faces returned for each degree is also the correspondence between faces and the basis of the corresponding module in a chain complex constructed from the simplicial complex.

If the complex does not possess any faces of the requested degree, an empty sequence is returned.

Example H140E3

We can list faces of any degree in the defined simplicial complex.

```
> Faces(sc,2);
[
    { 2, 3 },
    { 3, 4 },
    { 1, 3 },
    { 1, 4 },
    { 1, 2 },
    { 2, 5 },
    { 1, 5 },
    { 2, 4 }
]
> Faces(sc,5);
[]
```

`Facets(X)`

Returns the facets of the simplicial complex X. The facets of a simplicial complex are the faces that are not themselves subsets of another face. This is what the normal printing mode for a simplicial complex outputs.

Example H140E4

We can read the facets both by fetching the sequence of facets and by printing the complex as such.

```
> Facets(sc);
[
    { 2, 3, 4 },
    { 1, 2, 3 },
    { 1, 2, 4 },
    { 2, 5 },
    { 1, 5 },
    { 1, 3, 4 }
]
> sc;
Simplicial complex
[
    { 2, 3, 4 },
    { 1, 2, 3 },
    { 1, 2, 4 },
    { 2, 5 },
    { 1, 5 },
    { 1, 3, 4 }
]
```

`Normalization(X)`

`Normalization(~X)`

Relabels the points (elements of the face sets) of the simplicial complex X using $1, 2, 3, \ldots$. This ensures that the simplicial complex is built on subsets of the integers, which is a prerequisite for several functions handling simplicial complexes. We call a simplicial complex on subsets of the integers *normalized* in this handbook.

Note the two calling signatures of this function. The first signature copies the simplicial complex and returns a new complex with the desired modification, whereas the second signature modifies the complex in place.

`Shift(X, n)`

`Shift(~X, n)`

Shifts all integer points in the normalized simplicial complex X by an offset given by n.

Note the two calling signatures of this function. The first signature copies the simplicial complex and returns a new complex with the desired modification, whereas the second signature modifies the complex in place.

Example H140E5

We define a simplicial complex using string labels, normalize it and then shift the labels.

```
> cpx := Boundary(SimplicialComplex([{"a","b","c"}]));
> cpx;
Simplicial complex
[
    { c, a },
    { c, b },
    { b, a }
]
> Normalization(~cpx);
> cpx;
Simplicial complex
[
    { 1, 3 },
    { 2, 3 },
    { 1, 2 }
]
> Shift(~cpx,-2);
> cpx;
Simplicial complex
[
    { -1, 1 },
    { 0, 1 },
    { -1, 0 }
]
```

`Boundary(X)`

Returns the simplicial complex generated by all simplexes that lie in the boundary of the simplicial complex X. This can be used to easily acquire a simplicial complex representing the n-sphere.

Example H140E6

We can determine the boundary of our previously defined simplicial complex, or construct a 4-sphere.

```
> Boundary(sc);
Simplicial complex
[
    { 2, 3 },
    { 3, 4 },
    { 1, 3 },
    { 1, 4 },
    { 1, 2 },
```

```
    { 5 },
    { 2, 4 }
]
> sph4 := Boundary(SimplicialComplex([{1,2,3,4,5,6}]));
> sph4;
Simplicial complex
[
    { 1, 2, 3, 5, 6 },
    { 2, 3, 4, 5, 6 },
    { 1, 3, 4, 5, 6 },
    { 1, 2, 3, 4, 5 },
    { 1, 2, 4, 5, 6 },
    { 1, 2, 3, 4, 6 }
]
```

`S + T`

Returns the topological sum, or disjoint union, of two simplicial complexes. Requires both complexes to be normalized using Normalization on page 4696.

Example H140E7

We can construct a disjoint union of two circles.

```
> sph2 := Boundary(SimplicialComplex([{1,2,3}]));
> sph2 + sph2;
Simplicial complex
[
    { 4, 6 },
    { 2, 3 },
    { 4, 5 },
    { 5, 6 },
    { 1, 3 },
    { 1, 2 }
]
```

`S eq T`

Compares two simplicial complexes. Will not try to find an isomorphism, rather does the comparison by ensuring that the points are in the same universe and then doing a set comparison on the set of faces.

Example H140E8

Shifting a complex, for instance, will break equality, since the labels differ.

```
> sc eq Shift(sc,2);
false
> sc eq Shift(Shift(sc,2),-2);
true
```

Furthermore, isomorphic complexes with different labels will not be equal.

```
> circ1 := Boundary(SimplicialComplex([{1,2,3}]));
> circ2 := Boundary(SimplicialComplex([{"a","b","c"}]));
> circ1 eq circ2;
false
```

`Product(S,T)`

Returns the cartesian product of two simplicial complexes. This will work on any complexes, since the new points will be pairs of points from the component complexes.

Example H140E9

Using the two different circles from the last example, we can now construct a torus.

```
> Product(circ1,circ2);
Simplicial complex
[
    { <3, b>, <1, b>, <3, c> },
    { <1, c>, <3, c>, <1, a> },
    { <2, a>, <3, b>, <3, a> },
    { <3, b>, <1, b>, <1, a> },
    { <1, b>, <2, b>, <2, c> },
    { <2, a>, <3, c>, <3, a> },
    { <1, c>, <1, b>, <3, c> },
    { <3, c>, <2, b>, <2, c> },
    { <1, c>, <1, b>, <2, c> },
    { <3, c>, <3, a>, <1, a> },
    { <2, a>, <3, c>, <2, c> },
    { <3, b>, <3, a>, <1, a> },
    { <2, a>, <1, a>, <2, b> },
    { <2, a>, <1, a>, <2, c> },
    { <1, c>, <1, a>, <2, c> },
    { <3, b>, <3, c>, <2, b> },
    { <1, b>, <1, a>, <2, b> },
    { <2, a>, <3, b>, <2, b> }
```

```
]
```

If we want something less unwieldy – especially after repeated cartesian products – we can always normalize the resulting complexes.

```
> line := SimplicialComplex([{1,2}]);
> square := Product(line,line);
> cube1 := Product(square,line);
> cube2 := Product(line,square);
> cube1 eq cube2;
false
> Normalization(cube1) eq Normalization(cube2);
false
> cube1;
Simplicial complex
[
    { <<1, 2>, 1>, <<1, 2>, 2>, <<1, 1>, 1>, <<2, 2>, 2> },
    { <<2, 1>, 1>, <<2, 2>, 1>, <<1, 1>, 1>, <<2, 2>, 2> },
    { <<1, 2>, 2>, <<1, 1>, 1>, <<1, 1>, 2>, <<2, 2>, 2> },
    { <<1, 2>, 1>, <<2, 2>, 1>, <<1, 1>, 1>, <<2, 2>, 2> },
    { <<1, 1>, 1>, <<1, 1>, 2>, <<2, 1>, 2>, <<2, 2>, 2> },
    { <<2, 1>, 1>, <<1, 1>, 1>, <<2, 1>, 2>, <<2, 2>, 2> }
]
> Normalization(cube1);
Simplicial complex
[
    { 3, 4, 5, 8 },
    { 4, 5, 6, 8 },
    { 1, 3, 4, 5 },
    { 2, 4, 5, 7 },
    { 1, 2, 4, 5 },
    { 4, 5, 6, 7 }
]
```

`Join(S,T)`

`S * T`

Constructs the join of two simplicial complexes. The join of two simplicial complexes is defined as the complex generated by faces on the form $\{x_1, \ldots, x_r, y_1, \ldots, y_s\}$ for $\{x_1, \ldots, x_r\} \in S$ and $\{y_1, \ldots, y_s\} \in T$. Requires both simplicial complexes to be normalized.

Example H140E10

The join of two edges is a 3-simplex.

```
> SimplicialComplex([{1,2}]) * SimplicialComplex([{1,2}]);
Simplicial complex
[
    { 1, 2, 3, 4 }
]
```

`AddSimplex(X, s)`
`AddSimplex(~X, s)`
`AddSimplex(X, s)`
`Addsimplex(~X, s)`

Adds either a single simplex s expressed as a set or a sequence of simplexes to a simplicial complex. The functional versions of the function call return a new complex with the added simplices included, and the procedural change the complex in place.

`Prune(X, f)`
`Prune(~X, f)`

Removes a face f and all faces containing f from a simplicial complex X. If f is not a face of X, then X is returned unchanged.

Note the two calling signatures of this function. The first signature copies the simplicial complex and returns a new complex with the desired modification, whereas the second signature modifies the complex in place.

`Glue(X, e)`
`Glue(~X, e)`

In the simplicial complex X, identify all points identified by pairs in the sequence e.

The sequence e should be a sequence of pairs of elements of the face sets of X. The identification will eliminate the first component of each pair, replacing it with the second component wherever it occurs in X.

Note the two calling signatures of this function. The first signature copies the simplicial complex and returns a new complex with the desired modification, whereas the second signature modifies the complex in place.

Example H140E11

We can, for instance, construct the connected sum of two tori using `Product`, `Prune`, the topological sum and `Glue`.

```
> circ := SimplicialComplex([{1,2},{2,3},{3,1}]);
> torus := Product(circ,circ);
> Normalization(~torus);
> torus;
Simplicial complex
[
    { 2, 3, 6 },
    { 1, 2, 9 },
    { 2, 6, 8 },
    { 4, 7, 8 },
    { 3, 5, 9 },
    { 4, 6, 7 },
    { 1, 8, 9 },
    { 1, 4, 8 },
    { 6, 8, 9 },
    { 2, 7, 8 },
    { 2, 3, 9 },
    { 5, 6, 9 },
    { 1, 3, 5 },
    { 1, 4, 6 },
    { 3, 6, 7 },
    { 1, 5, 6 },
    { 1, 2, 7 },
    { 1, 3, 7 }
]
> oneholetorus := Prune(torus,{1,2,7});
> twoholetorus := Prune(Prune(torus,{1,2,7}),{6,8,9});
> threetori := oneholetorus + twoholetorus + oneholetorus;
> threetorus := Glue(threetori,[<1,10>,<2,11>,<7,16>,<15,19>,<17,20>,<18,25>]);
```

Note that we find the glue data by considering that the maximal point in the original torus had number 9, so for the second added torus, all points will be shifted by 9 and in the third all points will be shifted by 18. Thus, the excised facets $\{1, 2, 7\}$ and $\{6, 8, 9\}$ turn into $\{10, 11, 16\}$ and $\{15, 17, 18\}$, and the excised facet $\{1, 2, 7\}$ in the third torus turns into $\{19, 20, 25\}$.

`BarycentricSubdivision(X)`

Constructs the barycentric subdivision of the simplicial complex X. Abstractly, this is a simplicial complex whose faces are chains $X_1 \subset \ldots \subset X_n$ of faces from X. The new complex has more faces but the same homotopy type as the old complex.

`Skeleton(X, q)`

Returns the q-skeleton of the simplicial complex X. This is the complex consisting of all faces of X of dimension at most q.

`UnderlyingGraph(X)`

Constructs a graph isomorphic, as a graph, to the 1-skeleton of the simplicial complex X.

`Cone(X)`

Constructs a cone over the simplicial complex X. The cone is generated by all faces of the complex, with an additional vertex included into each face. Any cone is acyclic, in other words all homology groups vanish. Requires a normalized simplicial complex.

`Suspension(X)`

Constructs the suspension, or double cone, over the normalized simplicial complex X. The suspension has the added property that all the homology groups occur in it, shifted up by one dimension.

Example H140E12

For computation of the relevant homology, and a demonstration of the stated facts about the cone and suspension operations, please refer to examples in the Section on homology computation.

```
> circ := Boundary(SimplicialComplex([{1,2,3}]));
> Cone(circ);
Simplicial complex
[
    { 1, 3, 4 },
    { 2, 3, 4 },
    { 1, 2, 4 }
]
> Suspension(circ);
Simplicial complex
[
    { 1, 3, 5 },
    { 1, 3, 4 },
    { 1, 2, 5 },
    { 2, 3, 4 },
    { 1, 2, 4 },
    { 2, 3, 5 }
]
```

140.2.1 Standard Topological Objects

`Simplex(n)`

Returns the n-dimensional simplex as a simplicial complex.

`Sphere(n)`

Returns a simplicial complex triangulating the n-sphere.

`KleinBottle()`

Returns a triangulation of the Klein bottle as an abstract simplicial complex.

`Torus()`

Returns a triangulation of a torus as an abstract simplicial complex.

`Cylinder()`

Returns a triangulation of a cylinder as an abstract simplicial complex.

`MoebiusStrip()`

Returns a triangulation of the Moebius strip as an abstract simplicial complex.

`LensSpace(p)`

Constructs the lens space $L(p, 1)$. This has a 1-dimensional homology generator of order p.

`SimplicialProjectivePlane()`

Constructs a triangulation of the projective plane.

Examples for the usage of `LensSpace` and `SimplicialProjectivePlane` will be given in Section 140.3 on homology computation.

140.3 Homology Computation

The code computes exclusively reduced homology of the given simplicial complexes. If you want the non-reduced homology, just add a single free rank to dimension 0 and let it be generated by any single point in the complex.

`Homology(X)`

`Homology(~X)`

`Homology(X,A)`

`Homology(~X, A)`

Calculates the reduced homology of a simplicial complex `X` with coefficients in the ring A. The procedural form of this command caches the results of the calculation in the simplicial complex object. If no ring is given, then the function defaults to integer coefficients.

Example H140E13

The resulting modules are stored in falling dimension, always including the dimension -1 vanishing homology module at the very end.

```
> circ := Boundary(SimplicialComplex([{1,2,3}]));
> Homology(circ,Integers());
[
    Full Quotient RSpace of degree 1 over Integer Ring

> Homology(lens3,Integers())[3];
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 3 ]
```

`HomologyGroup(X, q)`

`HomologyGroup(X, q, A)`

Calculates and returns the qth homology group of X with coefficients in A. If no ring is given, the function defaults to integer coefficients. If the homology is cached in X, the cached results are returned. This function will not compute the entire homology in order to return one homology group.

`BettiNumber(X,q)`

`BettiNumber(X,q,A)`

Returns the qth Betti number, computed as the free rank of the q-dimensional homology group, with coefficients in A. If no ring is given, then the function will default to integer coefficients.

Note that the Betti number computations compensate for the homology computations being reduced. Thus, `BettiNumber(X,0) eq Rank(HomologyGroup(X,0)) + 1`.

`TorsionCoefficients(X, q)`

`TorsionCoefficients(X, q, A)`

Returns the torsion coefficients of the qth homology group of X with coefficients in A. If no ring is given, then the function will default to integer coefficients.

`EulerCharacteristic(X)`

Computes the Euler characteristic of the complex. If homology is cached, this is used for computation, and else the characteristic is computed using the ranks of the chain groups.

`BoundaryMatrix(X, q, A)`

Returns the qth boundary matrix of the corresponding chain complex to the simplicial complex X with coefficients in A.

`ChainComplex(X, A)`

Constructs a reduced chain complex of free A-modules corresponding to the abstract simplicial complex X.

Note that the produced complex includes one extra rank 1 module on each end, with the zero map leading to it, to simulate the maps to and from the zero module that would end a chain complex constructed from a simplicial complex in ordinary cases.

Example H140E14

```
> ChainComplex(SimplicialComplex([{1}]),Integers());
Chain complex with terms of degree 2 down to -1
Dimensions of terms: 1 1 1 1
> BoundaryMaps(ChainComplex(SimplicialComplex([{1}]),Integers()));
[*
    [0],
    [-1],
    [0]
*]
> ChainComplex(SimplicialComplex([{1,2,3}]),GF(3));
Chain complex with terms of degree 4 down to -1
Dimensions of terms: 1 1 3 3 1 1
> BoundaryMaps(ChainComplex(SimplicialComplex([{1,2,3}]),GF(3)));
[*
    [0],
    [1 2 2],
    [1 0 2]
    [0 1 2]
    [1 2 0],
    [2]
    [2]
    [2],
    [0]
*]
```

`HomologyGenerators(X)`

`HomologyGenerators(X, A)`

`HomologyGenerators(H, M, X)`

Prints generators of the homology groups of the simplicial complex X with coefficients in A together with their order, in order of dimension. The latter calling form expects H, M to be the result from `H,M := ChainComplex(A,smp);`. This function will recalculate homology each time unless the homology is already cached in the simplicial complex using `Homology(A, smp)`.

If no ring is given, the function defaults to integer coefficients.

Example H140E15

This function gives a condensed form of the actual bases of the homology groups, as well as mappings back to an actual chain representative for each homology class.

```
> HomologyGenerators(threetorus,Integers());
*** dimension 2 ***
inf: { 21, 23, 27 } - { 4, 6, 16 } - { 20, 24, 26 } + { 20, 25, 26 } -
  { 14, 19, 25 } + { 12, 14, 25 } + { 3, 6, 11 } - { 10, 14, 19 } +
  { 19, 20, 27 } - { 3, 9, 11 } - { 10, 13, 20 } + { 10, 13, 19 } -
  { 10, 12, 14 } - { 12, 16, 19 } - { 11, 19, 20 } - { 13, 16, 20 } +
  { 21, 24, 25 } + { 24, 26, 27 } - { 20, 21, 24 } - { 19, 22, 26 } -
  { 3, 10, 16 } - { 4, 6, 10 } - { 22, 25, 26 } + { 11, 16, 20 } +
  { 4, 8, 16 } - { 5, 6, 9 } + { 4, 8, 10 } - { 11, 12, 19 } - { 3, 5, 9 } +
  { 11, 12, 25 } + { 8, 9, 10 } + { 20, 21, 27 } + { 3, 6, 16 } +
  { 10, 11, 25 } + { 19, 22, 24 } - { 9, 10, 11 } + { 3, 5, 10 } +
  { 10, 20, 25 } - { 8, 11, 16 } - { 19, 26, 27 } - { 19, 23, 24 } +
  { 10, 12, 16 } - { 19, 21, 23 } - { 6, 8, 9 } + { 13, 16, 19 } +
  { 19, 21, 25 } + { 23, 24, 27 } - { 22, 24, 25 } + { 5, 6, 10 } +
  { 6, 8, 11 }
*** dimension 1 ***
inf: -1*{ 10, 13 } + { 3, 5 } - { 8, 9 } - { 8, 16 } - { 19, 22 } +
  { 20, 26 } + { 9, 11 } - { 3, 16 } + { 5, 10 } + { 22, 26 } + { 11, 20 } +
  2*{ 10, 20 } + { 13, 19 } - 2*{ 10, 11 }
inf: { 3, 9 } - { 3, 5 } - { 9, 11 } - { 5, 10 } + { 10, 11 }
inf: -1*{ 26, 27 } - { 11, 19 } + 2*{ 19, 22 } - { 20, 26 } -
  2*{ 22,  26 } + { 11, 20 } + { 19, 21 } - { 21, 27 }
inf: { 10, 13 } + { 11, 19 } - { 11, 20 } - { 10, 20 } - { 13, 19 }
inf: -1*{ 11, 19 } + { 19, 22 } - { 20, 26 } - { 22, 26 } + { 11, 20 }
inf: { 11, 20 } + { 10, 20 } - { 10, 11 }
```

The six found generators are the generators of each of the contained torus homology groups. Notice that each generator is printed out with a prefix. This gives the order of the generator - so that for instance torsion elements of homology may be recognized. Thus, we see with the projective plane:

```
> HomologyGenerators(SimplicialProjectivePlane(),Integers());
*** dimension 1 ***
  2: { 3, 6 } + { 2, 3 } - { 2, 6 }
```

We can further take this opportunity to verify the claims about `Cone` and `Suspension` with regard to the homology.

```
> HomologyGenerators(Cone(SimplicialProjectivePlane()),Integers());
Complex is acyclic.
> HomologyGenerators(Suspension(SimplicialProjectivePlane()),Integers());
*** dimension 2 ***
  2: { 1, 5, 7 } - { 1, 4, 7 } + { 1, 2, 5 } + { 1, 5, 8 } - { 2, 3, 8 } -
  { 3, 5, 7 } - { 1, 2, 8 } + { 5, 6, 8 } + { 1, 4, 5 } - { 4, 6, 8 } +
  { 3, 4, 7 } + { 2, 3, 5 } - { 4, 5, 6 } - { 3, 4, 8 }
```

141 FINITE PLANES

Chapter 141
FINITE PLANES

141.1 Introduction

In this chapter we will present the categories of finite projective and affine planes.

The category names for projective and affine planes are `PlaneProj` and `PlaneAff` respectively. Within each of these categories we have what we will call *classical* planes — those which are defined by a vector space of dimension 2 (for affine planes) or 3 (for projective planes).

Some functions documented here apply to all types of planes, others are specific to projective, affine or classical planes. It should be clear which is the case for each entry.

141.1.1 Planes in Magma

A point of a plane is considered to be a special object, and so points are given their own special type, `PlanePt`, in MAGMA. This allows the points of a plane to be defined over any type of MAGMA object, and also improves the efficiency of the code.

A special structure called the *point–set* acts as the parent structure for points. A point is created by coercing an appropriate MAGMA object into the point–set. It is also possible the get the i-th point, or a random point, from the point–set.

Similarly, lines of a plane have a special type `PlaneLn`, and the *line–set* acts as their parent structure. Lines can be created by coercing a suitable object into the line–set, or by asking for the i-th line, or a random line, from the line–set.

141.2 Construction of a Plane

All functions which create a plane return three values:

(i) the plane itself;

(ii) the point–set of the plane;

(iii) the line–set of the plane.

These "sets" ((ii) and (iii)) are used as the parent structures for points and lines respectively, and are explained more fully in the next section.

`FiniteProjectivePlane< v | X : parameters >`

`FiniteProjectivePlane< V | X : parameters >`

`Check` BOOLELT *Default :* `true`

Construct the projective plane P having as point set the indexed set V (or $\{@1, 2, \ldots . v@\}$ if an integer v is given), and as line set $L = \{L_1, L_2, \ldots, L_b\}$ given by the list X. The value of X must be either:

(a) A list of subsets of the set V.

(b) A sequence, set or indexed set of subsets of V.

(c) A list of lines of an existing plane.

(d) A sequence, set or indexed set of lines of an existing plane.

(e) A combination of the above.

(f) A $v \times b$ $(0,1)$-matrix A, where A may be defined over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the plane P.

(g) A set of codewords of a linear code with length v. The line set of P is taken to be the set of supports of the codewords.

The optional boolean argument `Check` indicates whether or not to check that the given data satisfies the projective plane axioms.

```
FiniteProjectivePlane(W)
FiniteProjectivePlane(F)
FiniteProjectivePlane(q)
```

Given a 3–dimensional vector space W defined over the field $F = \mathbf{F}_q$, construct the classical projective plane defined by the one–dimensional and two–dimensional subspaces of W.

```
FiniteAffinePlane< v | X : parameters >
FiniteAffinePlane< V | X : parameters >
```

`Check` BoolElt *Default :* `true`

Construct the affine plane P having as point set the indexed set V (or $\{@1, 2, \ldots . v@\}$ if an integer v is given), and as line set $L = \{L_1, L_2, \ldots, L_b\}$ given by the list X. The value of X must be either:

(a) A list of subsets of the set V.

(b) A sequence, set or indexed set of subsets of V.

(c) A list of lines of an existing plane.

(d) A sequence, set or indexed set of lines of an existing plane.

(e) A combination of the above.

(f) A $v \times b$ $(0,1)$-matrix A, where A may be defined over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the plane P.

(g) A set of codewords of a linear code with length v. The line set of P is taken to be the set of supports of the codewords.

The optional boolean argument `Check` indicates whether or not to check that the given data satisfies the affine plane axioms.

`FiniteAffinePlane(W)`

`FiniteAffinePlane(F)`

`FiniteAffinePlane(q)`

Given a 2–dimensional vector space W defined over the field $F = \mathbf{F}_q$, construct the classical affine plane defined by the cosets of the subspaces of W.

Example H141E1

The classical projective plane of order 3 can be constructed by the following statement:

```
> P, V, L := FiniteProjectivePlane(3);
> P;
Projective Plane PG(2, 3)
> V;
Point-set of Projective Plane PG(2, 3)
> L;
Line-set of Projective Plane PG(2, 3)
```

A non-classical affine plane of order 2 can be constructed in the following way:

```
> A := FiniteAffinePlane< 4 | Setseq(Subsets({1, 2, 3, 4}, 2)) >;
> A: Maximal;
Affine Plane of order 2
Points: {@ 1, 2, 3, 4 @}
Lines:
    {1, 3},
    {1, 4},
    {2, 4},
    {2, 3},
    {1, 2},
    {3, 4}
```

To demonstrate the use of the `Check` argument, we recreate the classical projective plane of order 16 with `Check := true` (the default) and `Check := false`.

```
> P, V, L := FiniteProjectivePlane(16);
> time P2 := FiniteProjectivePlane<
>     Points(P) | {Set(l): l in L} : Check := true >;
Time: 10.769
> time P2 := FiniteProjectivePlane<
>     Points(P) | {Set(l): l in L} : Check := false >;
Time: 0.030
```

141.3 The Point-Set and Line-Set of a Plane

141.3.1 Introduction

An affine or projective plane in MAGMA consists of three objects: the plane P itself, the *point–set* V of P, and the *line–set* L of P.

Although called the point–set and line–set, V and L are not actual MAGMA sets. They simply act as the parent structures for the points and lines (respectively) of the plane P, enabling easy creation of these objects via the `!` and `.` operators.

The point–set V belongs to the MAGMA category `PlanePtSet`, and the line–set L to the category `PlaneLnSet`.

In this section, the functions used to create point–sets, line–sets and the points and lines themselves are described.

141.3.2 Creating Point-Sets and Line-Sets

As mentioned above, the point–set and line–set are returned as the second and third arguments of any function which creates a plane. They can also be created via the following two functions.

`PointSet(P)`

Given a plane P, return the point–set V of P.

`LineSet(P)`

Given a plane P, return the line–set L of P.

141.3.3 Using the Point-Set and Line-Set to Create Points and Lines

For efficiency and clarity, the points and lines of a plane are given special types in MAGMA. The category names for points and lines are `PlanePt` and `PlaneLn` respectively. They can be created in the following ways.

`V . i`

Given the point–set V of a plane P and an integer i, return the i-th point of P.

`V ! [a, b, c]`

Given the point–set V of a classical projective plane $P = PG_2(K)$, and elements a, b, c of the finite field K, create the projective point $(a : b : c)$ in the plane P.

`V ! [a, b]`

Given the point–set V of a classical affine plane $P = AG_2(K)$, and elements a, b of the finite field K, create the point (a, b) in the plane P.

`V ! x`

Given the point–set V of a plane P, return the point of P corresponding to the element x, which should be coercible into the underlying point set for P. (In the case of classical planes, x should be coercible to a vector.)

`Representative(V)`
`Rep(V)`

Given the point–set V of a plane P, return a representative point of P.

`Random(V)`

Given the point–set V of a plane P, return a random point of P.

`L . i`

Given the line–set L of a plane P and an integer i, return the i-th line of P.

`L ! [a, b, c]`

Given the line set L of a classical plane P defined over a finite field K, and elements a, b, c of K, create the line $\langle a : b : c \rangle$ (i.e. the line given by the equation $ax+by+cz = 0$ if P is projective, or $ax + by + c = 0$ if P is affine).

`L ! [m, b]`

Given the line set L of a classical affine plane $P = AG_2(K)$, and elements m, b of the finite field K, create the affine line $y = mx + b$ in P.

`L ! S`

Given the line–set L of a plane P and a set or sequence S of collinear points of P, return the line containing the points of S.

`L ! l`

Given the line–set L of a plane P and a line l of a (possibly) different plane (generally a subplane of P), return the line of P corresponding to l.

`Representative(L)`
`Rep(L)`

Given the line–set L of a plane P, return a representative line of P.

`Random(L)`

Given the line–set L of a plane P, return a random line of P.

Example H141E2

The following example shows how points and lines of a plane can be created. First we study a classical projective plane.

```
> P, V, L := FiniteProjectivePlane(5);
> V;
Point-set of Projective Plane PG(2, 5)
> L;
Line-set of Projective Plane PG(2, 5)
```

Create the third point of P:

```
> V.3;
( 0 : 0 : 1 )
```

Create the point $(1 : 2 : 3)$ of P:

```
> V![1, 2, 3];
( 1 : 2 : 3 )
```

Choose a random point of P:

```
> Random(V);
( 1 : 0 : 0 )
> Random(V);
( 0 : 0 : 1 )
```

Create the sixth line of P:

```
> L.6;
< 1 : 1 : 3 >
```

Create the line of P given by the equation $4x + 3y + 2z = 0$:

```
> L![4, 3, 2];
< 1 : 2 : 3 >
```

Create the line of P containing the points $(0 : 0 : 1)$ and $(0 : 1 : 0)$:

```
> L![ V | [0, 0, 1], [0, 1, 0] ];
< 1 : 0 : 0 >
```

Get a representative from the line-set of P, and a random line:

```
> Rep(L);
< 1 : 0 : 0 >
> Random(L);
< 1 : 2 : 4 >
```

Now we look at a non-classical plane.

```
> V := {2, 4, 6, 8};
> A, P, L := FiniteAffinePlane< SetToIndexedSet(V) | Setseq(Subsets(V, 2)) >;
> A: Maximal;
Affine Plane of order 2
```

```
Points: {@ 2, 4, 6, 8 @}
Lines:
    {6, 8},
    {2, 6},
    {2, 8},
    {2, 4},
    {4, 6},
    {4, 8}
> P;
Point-set of Affine Plane of order 2
> L;
Line-set of Affine Plane of order 2
```

Get the third point of A:

```
> P.3;
6
```

Create the point of A given by the integer 4:

```
> P!4;
4
```

Get a representative from the point–set of A:

```
> Rep(P);
2
```

Get the third line of A:

```
> L.3;
{2, 8}
```

Create the line of A containing the integers 2 and 6:

```
> L![2, 6];
{2, 6}
```

Choose a random line from A:

```
> Random(L);
{6, 8}
```

141.3.4 Retrieving the Plane from Points, Lines, Point-Sets and Line-Sets

The `ParentPlane` function allows you to access the plane to which a point, line, point–set or line–set belongs.

`ParentPlane(V)`

The plane P for which V is the point–set.

`ParentPlane(L)`

The plane P for which L is the line–set.

`ParentPlane(p)`

The plane P for which p is a point.

`ParentPlane(l)`

The plane P for which l is a line.

141.4 The Set of Points and Set of Lines

It may sometimes be desirable to have an explicitly enumerated set of the points or lines of a plane, as opposed to the point–set and line–set, which aren't true MAGMA sets. The following functions have been provided for this purpose.

`Points(P)`

An indexed set E whose elements are the points of the plane P. Note that this creates a standard indexed set and not the point–set of P, in contrast to the function `PointSet`.

`Lines(P)`

An indexed set containing the lines of the plane P. In contrast to the function `LineSet`, this function returns the collection of lines of P in the form of a standard indexed set.

141.5 The Defining Points of a Plane

Points of a plane have their own special type in MAGMA (`PlanePt`). However it may sometimes be necessary to return to the objects used to define the points. These are the elements of the indexed set originally used to create the plane, or, in the case of a classical plane, the vector space elements which define the points of the plane.

The functions listed in this section provide the means to do this.

`Support(P)`

An indexed set E which is the underlying point set of the plane P (i.e. the elements of the set have their "real" types; they are no longer a "PlanePt" of P).

`Support(l)`

The set of underlying points contained in the line l of a plane P (i.e. the elements of the set have their "real" types; they are no longer a "PlanePt" of P).

`Support(P, p)`

`Support(p)`

The MAGMA object corresponding to the point p of a plane P.

Example H141E3

The following code shows the difference between the `Points` and `Support` functions.

```
> A := FiniteAffinePlane< {@ 3, 4, 5, 6 @} | {3, 4}, {3, 5}, {3, 6},
>                                            {4, 5}, {4, 6}, {5, 6} >;
> Pts := Points(A);
> Supp := Support(A);
> Pts, Supp;
{@ 3, 4, 5, 6 @}
{@ 3, 4, 5, 6 @}
```

These sets look the same, but the elements have different types:

```
> Universe(Pts);
Point-set of Affine Plane of order 2
> Universe(Supp);
Integer Ring
```

The classical plane case is slightly different. Here the support is a set of vectors.

```
> P, V, L := FiniteProjectivePlane(2);
> Points(P);
{@ ( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 1 : 1 : 0 ),
   ( 0 : 1 : 1 ), ( 1 : 1 : 1 ), ( 1 : 0 : 1 ) @}
> Support(P);
{@
    (1 0 0),
    (0 1 0),
```

```
    (0 0 1),
    (1 1 0),
    (0 1 1),
    (1 1 1),
    (1 0 1)
@}
> Universe(Points(P));
Point-set of Projective Plane PG(2, 2)
> Universe(Support(P));
Full Vector space of degree 3 over GF(2)
> l := Random(L);
> l;
< 0 : 0 : 1 >
> Support(l);
{
    (1 0 0),
    (0 1 0),
    (1 1 0)
}
```

141.6 Subplanes

The `sub` constructor allows subplanes of a projective or affine plane to be created. For classical planes, the `SubfieldSubplane` function is also provided.

`sub< P | L >`

Given a plane P, construct the subplane of P generated by the points specified by L, where L is a list of one or more items of the following types:

(a) A point of P;

(b) A set or sequence of points of P;

(c) A subplane of P;

(d) A set or sequence of subplanes of P.

The set S of points defined by the list L must include a quadrangle if P is a projective plane and three non-collinear points if P is an affine plane. The function returns the smallest subplane of P containing S.

`SubfieldSubplane(P, F)`

The plane obtained from the classical plane P by taking only those points of P which have all coordinates lying in F, where F must be a subfield of `Field(P)`.

Example H141E4

In the plane $PG_2(4)$, the points $(1:0:0), (0:1:0), (0:0:1)$ and $(1:w:1)$, where w is a primitive element of $\mathbf{F}_4$, form a quadrangle. We form the subplane of $PG_2(4)$ generated by this quadrangle.

```
> K<w> := GF(4);
> P, V, L := FiniteProjectivePlane(K);
> S := sub< P | [ V | [1, 0, 0], [0, 1, 0], [0, 0, 1], [1, w, 1] ] >;
> S: Maximal;
Projective Plane of order 2
Points: {@ ( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 1 : w : 0 ),
( 1 : 0 : 1 ), ( 1 : w : 1 ), ( 0 : 1 : w^2 ) @}
Lines:
    {( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 0 : 1 : w^2 )},
    {( 1 : 0 : 0 ), ( 0 : 0 : 1 ), ( 1 : 0 : 1 )},
    {( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 1 : w : 0 )},
    {( 1 : 0 : 0 ), ( 1 : w : 1 ), ( 0 : 1 : w^2 )},
    {( 0 : 1 : 0 ), ( 1 : 0 : 1 ), ( 1 : w : 1 )},
    {( 0 : 0 : 1 ), ( 1 : w : 0 ), ( 1 : w : 1 )},
    {( 1 : w : 0 ), ( 1 : 0 : 1 ), ( 0 : 1 : w^2 )}
```

We next form the subplane of $AG_2(4)$ over $\mathbf{F}_2$.

```
> A := FiniteAffinePlane(4);
> S := SubfieldSubplane(A, GF(2));
> S: Maximal;
Affine Plane AG(2, 2)
> S subset A;
true
```

141.7 Structures Associated with a Plane

There are a number of structures naturally associated with a plane. This section lists some functions for accessing or creating them.

`VectorSpace(P)`

The vector space underlying the classical plane P.

`Field(P)`

The field over which the classical plane P is defined.

`IncidenceMatrix(P)`

The incidence matrix of the plane P.

`Dual(P)`

The dual of the projective plane P.

Example H141E5

The functions in this section are illustrated by the following example.

```
> A := FiniteAffinePlane(4);
> VectorSpace(A);
Full Vector space of degree 2 over GF(2^2)
> Field(A);
Finite field of size 2^2
>
> P := FiniteProjectivePlane< 7 | {1, 3, 5}, {1, 2, 7}, {1, 4, 6}, {2, 3, 6},

> IncidenceMatrix(D) eq Transpose(IP);
true
```

141.8 Numerical Invariants of a Plane

`Order(P)`

The order of the plane P.

`NumberOfPoints(P)`

`#V`

The cardinality v of the point–set V of the plane P.

`NumberOfLines(P)`

`#L`

The cardinality v of the line–set L of the plane P.

`pRank(P)`

The p-rank of the plane P of order p^t.

`pRank(P, p)`

The p-rank of the plane P.

Example H141E6

We demonstrate some of the above functions with the plane $PG_2(8)$.

```
> P := FiniteProjectivePlane(8);
> NumberOfLines(P);
73
> Order(P);
8
> pRank(P);
28
> pRank(P, 2);
28
> pRank(P, 3);
72
> pRank(P, 5);
73
```

141.9 Properties of Planes

`IsDesarguesian(P)`

Returns `true` if and only if the plane P is a desarguesian plane.

`IsSelfDual(P)`

Returns `true` if and only if the projective plane P is self–dual.

141.10 Identity and Isomorphism

Two planes are considered equal if their point sets are equal and they have the same lines.

`P eq Q`

Return `true` if the planes P and Q are equal, otherwise `false`.

`P ne Q`

Return `true` if the planes P and Q are not equal, otherwise `false`.

`IsIsomorphic(P, Q:` *parameters*`)`

`AutomorphismGroups` MonStgElt *Default :* "*None*"

Return `true` if the planes P and Q are isomorphic, otherwise `false`. If the planes are isomorphic, an isomorphism f from P onto Q is also returned. The function first computes none, one, or both of the automorphism groups of the left and right planes. This may assist the isomorphism testing. The parameter `AutomorphismGroups`, with valid string values `"Both"`, `"Left"`, `"Right"`, `"None"`, may be used to specify which of the automorphism groups should be constructed first if not already known. The default is `"None"`.

`P subset Q`

Returns `true` if P is a subplane of Q, otherwise `false`.

141.11 The Connection between Projective and Affine Planes

There exist natural mathematical constructions to form a projective plane from an affine plane and vice versa. The functions in the this section provide a quick and easy way to do this in MAGMA.

`FiniteAffinePlane(P, l)`

The affine plane obtained by removing the line l from the projective plane P, together with the point set and line set of the affine plane, plus the embedding map from the affine plane to P.

`ProjectiveEmbedding(P)`

The projective completion of the affine plane P, together with the point set and line set of the projective plane, plus the embedding map from P to the projective plane.

Example H141E7

We begin with the classical affine plane A of order 3, and take the projective embedding P of A. We then remove a randomly selected line from P, and show that the affine plane produced by this action is isomorphic to the original affine plane A.

```
> A := FiniteAffinePlane(3);
> P := ProjectiveEmbedding(A);
> P;
Projective Plane of order 3
> A2 := FiniteAffinePlane(P, Random(LineSet(P)));
> A2;
Affine Plane of order 3
> iso, map := IsIsomorphic(A, A2);
> is_iso, map := IsIsomorphic(A, A2);
> is_iso;
true
> map;
Mapping from: PlaneAff: A to PlaneAff: A2
```

We demonstrate the use of the embedding map to get the correspondence between the points of the affine and projective planes.

```
> K<w> := GF(4);
> A, AP, AL := FiniteAffinePlane(K);
> P, PP, PL, f := ProjectiveEmbedding(A);
```

Now take a point of the affine plane and map it into the projective.

```
> AP.5;
```

```
( 1, w )
> AP.5 @ f;
5
```

Our point corresponds to `PP.5`, which in the affine plane is the pair `(1, w)`. The map `f` can be applied to any point or line of the affine plane to get the corresponding point or line of the projective plane. Given any point or line of the projective plane, provided that it is not on the adjoined line at infinity, the preimage in the affine plane can be found.
The line at infinity is always the last line in the line set of the projective plane created by `ProjectiveEmbedding`. We will call this line `linf`:

```
> linf := PL.#PL;
> linf;
{17, 18, 19, 20, 21}
> SetSeed(1, 3);
> p := Random(PP);
> p in linf;
false
> p @@ f;
( w, 1 )
> l := Random(PL);
> l eq linf;
false
> l @@ f;
< 1 : 1 : 0 >
> $1 @ f eq l;
true
```

Since neither `p` nor `l` were infinite we could find their preimages under `f`. Of course, when we map a line from `P` to `A` and back, we get the line we started with.
When an embedding is constructed by `FiniteAffinePlane(P, l)`, then `l` is the line at infinity for this embedding.

141.12 Operations on Points and Lines

All the usual equality, membership and subset functions are provided along with a collection of deconstruction functions and others.

141.12.1 Elementary Operations

`p eq q`

Returns `true` if the points p and q are equal, otherwise `false`.

`p ne q`

Return `true` if the points p and q are not equal, otherwise `false`.

`l eq m`

Return `true` if the lines l and m are equal, otherwise `false`.

`l ne m`

Return `true` if the lines l and m are not equal, otherwise `false`.

`p in l`

Return `true` if point p lies on the line l, otherwise `false`.

`p notin l`

Return `true` if point p does not lie on the line l, otherwise `false`.

`S subset l`

Given a subset S of the point set of the plane P and a line l of P, return `true` if the subset S of points lies on the line l, otherwise `false`.

`S notsubset l`

Given a subset S of the point set of the plane P and a line l of P, return `true` if the subset S of points does not lie on the line l, otherwise `false`.

`l meet m`

The unique point common to the lines l and m.

`Representative(l)`

`Rep(l)`

Given a line l of the plane P, return a representative point of P which is incident with l.

`Random(l)`

Given a line l of the plane P, return a random point of P which is incident with l.

141.12.2 Deconstruction Functions

`Index(P, p)`

Given a point p from the point–set V of a plane P, return the index of p, i.e. the integer i such that p is `V.i`.

`Index(P, l)`

Given a line l, return the index of l in the plane P, i.e. the integer i such that l is $L.i$ (where L is the line–set of P).

`p[i]`

The i-th coordinate of the point p, which must be from a classical plane. If p is from a projective plane, then i must satisfy $1 \leq i \leq 3$; if p is from an affine plane, then i must satisfy $1 \leq i \leq 2$.

`l[i]`

The i-th coordinate of the line l, which must be from a classical plane. The integer i must satisfy $1 \leq i \leq 3$. Recall that in a classical plane $\langle a : b : c \rangle$ (where $a, b, c \in K$) represents the line given by the equation $ax + by + cz = 0$ in a projective plane or $ax + by + c = 0$ in an affine plane.

`Coordinates(P, p)`

Given a point $p = (a : b : c)$ from a classical projective plane P (or $p = (a, b)$ from a classical affine plane P), return the sequence $[a, b, c]$ (or $[a, b]$ in the affine case) of coordinates of p.

`Coordinates(P, l)`

Given a line $l = \langle a : b : c \rangle$ from a classical plane P (projective or affine), return the sequence $[a, b, c]$ of coordinates of l.

`ElementToSequence(p)`

`Eltseq(p)`

Given a point $p = (a : b : c)$ from a classical projective plane P (or $p = (a, b)$ from a classical affine plane P), return the sequence $[a, b, c]$ (or $[a, b]$ in the affine case) of coordinates of p.

`ElementToSequence(l)`

`Eltseq(l)`

Given a line $l = \langle a : b : c \rangle$ from a classical plane P (projective or affine), return the sequence $[a, b, c]$ of coordinates of l.

`Set(l)`

The set of points contained in the line l.

Example H141E8

The following example illustrates the use of some of the elementary and deconstruction functions on lines and points discussed in the previous two subsections.

```
> K<w> := GF(4);
> P, V, L := FiniteProjectivePlane(K);
```

Create the line $x + z = 0$:

```
> l := L![1, 0, 1];
> l;
< 1 : 0 : 1 >
```

Look at the points on the line l:

```
> Set(l);
{  ( 0 : 1 : 0 ), ( 1 : w^2 : 1 ), ( 1 : 0 : 1 ),
```

```
   ( 1 : w : 1 ), ( 1 : 1 : 1) }
```

Get the coordinates of the line l:

```
> Coordinates(P, l);
[ 1, 0, 1 ]
> l[1];
1
```

Find the index of the line l in the line–set L of P, and check it:

```
> Index(P, l);
8
> l eq L.8;
true
```

Test if a point is on the line l:

```
> V![1, 0, 1] in l;
true
```

Test a set of points for containment in l:

```
> S := {V.1, V.2};
> S;
{  ( 1 : 0 : 0 ), ( 0 : 1 : 0 ) }
> S subset l;
false
```

Create the line containing the points in S:

```
> l2 := L!S;
> l2;
< 0 : 0 : 1 >
> S subset l2;
true
```

And finally, find the point common to the lines l and $l2$:

```
> p := l meet l2;
> p;
( 0 : 1 : 0 )
> p[3];
0
```

141.12.3 Other Point and Line Functions

`IsCollinear(P, S)`

Return `true` if the set S of points of the plane P are collinear, otherwise `false`. If the points are collinear, the line which they define is also returned.

`IsConcurrent(P, R)`

Return `true` if the set R of lines of the plane P are concurrent, otherwise `false`. If the lines are concurrent, their common point is returned as a second value.

`ContainsQuadrangle(P, S)`

Return `true` if the set S of points of a plane P contains a quadrangle.

`Pencil(P, p)`

The pencil of lines passing through the point p in the plane P.

`Slope(l)`

The slope of the line l of a classical affine plane P.

`IsParallel(P, l, m)`

Return `true` if the line l is parallel to the line m in the affine plane P.

`ParallelClass(P, l)`

The parallel class containing the line l of an affine plane P.

`ParallelClasses(P)`

The partition into parallel classes of the lines of the affine plane P.

Example H141E9

We use the affine plane $AG_2(3)$ to demonstrate some of the above functions.

```
> A, V, L := FiniteAffinePlane(3);
```

Create the line $y = 2x + 1$ in A, and check its slope:

```
> l := L![2, 1];
> l;
< 1 : 1 : 2 >
> Slope(l);
2
```

Find the lines parallel to l:

```
> ParallelClass(l);
{
    < 1 : 1 : 0 >,
    < 1 : 1 : 1 >,
    < 1 : 1 : 2 >
```

```
}
> [Slope(m): m in ParallelClass(l)];
[ 2, 2, 2 ]
```

Get the pencil of lines through a point of l:

```
> p := Rep(l);
> p;
( 1, 0 )
> Pencil(A, p);
{
    < 1 : 0 : 2 >,
    < 1 : 1 : 2 >,
    < 1 : 2 : 2 >,
    < 0 : 1 : 0 >
}
```

141.13 Arcs

A *k–arc* in a projective or affine plane P is a set of k points of P, no three of which are collinear. A k–arc is *complete* if it cannot be extended to a $(k+1)$–arc by the addition of another point. A *tangent* to an arc A is a line which meets A exactly once; a *secant* is a line which meets A exactly twice; and a *passant*, or *external line*, is a line which does not meet A at all.

`kArc(P, k)`

Return a k–arc for the plane P.

`CompleteKArc(P, k)`

Return a complete k–arc for the plane P (if one exists).

`IsArc(P, A)`

Returns `true` if the set of points A is an arc in the plane P, i.e. no three points of A are collinear.

`IsComplete(P, A)`

Returns `true` if the k–arc A is complete in the plane P.

`Conic(P, S)`

Given a set S of five points belonging to a classical projective plane P of order $n > 3$ and being in general position, construct the unique conic that passes through them.

`QuadraticForm(S)`

Given a set S of five points belonging to a classical projective plane of order $n > 3$ that are in general position, return the quadratic form defining the conic containing the five points.

`Tangent(P, A, p)`

Given an arc A in the plane P, and a point p on A, return a tangent to A at p.

`AllTangents(P, A)`

Given an arc A in the plane P, return the set of tangent lines to A.

`AllSecants(P, A)`

Given an arc A in the plane P, return the set of secant lines to A.

`ExternalLines(P, A)`
`AllPassants(P, A)`

Given an arc A in the plane P, return the set of external lines to A.

`Knot(P, C)`

Given a conic C in the projective plane P of even order, return the knot of the conic C, i.e the intersection point of the tangents to C.

`Exterior(P, C)`

Given a conic C in the projective plane P of odd order, return the exterior points of C, i.e. the points of P that lie on two tangents of C.

`Interior(P, C)`

Given a conic C in the projective plane P of odd order, return the interior points of C, i.e. the points of P that do not lie on any tangent of C.

Example H141E10

The following sequence of instructions constructs an oval design from $PG_2(16)$.

```
> P, V, L := FiniteProjectivePlane(16);
> oval := kArc(P, 18);
> pts := Points(P) diff oval;
> lns := ExternalLines(P, oval);
> I := IncidenceStructure< SetToIndexedSet(pts) | [l meet pts : l in lns] >;
> D := Design(Dual(I), 2);
> D;
2-(120, 8, 1) Design with 255 blocks
```

The next example uses various functions discussed so far, and shows the relationship between a plane and its subplanes.

```
> K<w> := GF(9);
```

```
> P, V, L := FiniteProjectivePlane(K);
> c := kArc(P, 5);
> c;
{  ( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 1 : 2 : w^3 ),
   ( 1 : w : w) }
> C := Conic(P, c);
> C;
{  ( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 1 : 2 : w^3 ),
   ( 1 : w : w), ( 1 : w^5 : w^6 ), ( 1 : w^7 : 2 ), ( 1 : w^2 : 1 ),
   ( 1 : w^3 : w^5 ), ( 1 : w^6 : w^2 ) }
> #C;
10
> #Interior(P, C);
36
>
> S, SV, SL := SubfieldSubplane(P, GF(3));
> S subset P;
true
> a := kArc(S, 4);
> IsArc(S, a);
true
> IsArc(P, a);
true
> IsComplete(S, a);
true
> IsComplete(P, a);
false
> a;
{ ( 1 : 0 : 0 ), ( 0 : 1 : 0 ), ( 0 : 0 : 1 ), ( 1 : 2 : 1 ) }
> S2 := sub< P | a >;
> S2;
Projective Plane of order 3
> S2 eq S;
true
> p := Random(a);
> p;
( 1 : 2 : 1 )
> Tangent(S, a, p);
< 1 : 2 : 1 >
> AllTangents(S, a);
{
    < 1 : 2 : 0 >,
    < 0 : 1 : 2 >,
    < 1 : 2 : 1 >,
    < 1 : 0 : 1 >
}
> AllTangents(P, a);
{
```

```
    < 1 : w^5 : w^6 >,
    < 1 : 0 : w >,
    < 1 : w^2 : w >,
    < 1 : 0 : w^6 >,
    < 1 : 0 : 1 >,
    < 1 : w^6 : w^3 >,
    < 1 : w^6 : 0 >,
    < 0 : 1 : w^6 >,
    < 1 : 2 : 0 >,
    < 0 : 1 : 2 >,
    < 1 : 2 : 1 >,
    < 1 : w^3 : w^5 >,
    < 1 : 0 : w^7 >,
    < 1 : 0 : w^2 >,
    < 1 : w : 0 >,
    < 0 : 1 : w >,
    < 1 : 0 : w^5 >,
    < 1 : 0 : w^3 >,
    < 1 : w : w^7 >,
    < 1 : w^3 : 0 >,
    < 0 : 1 : w^3 >,
    < 1 : w^7 : w^2 >,
    < 1 : w^5 : 0 >,
    < 0 : 1 : w^5 >,
    < 1 : w^7 : 0 >,
    < 0 : 1 : w^7 >,
    < 1 : w^2 : 0 >,
    < 0 : 1 : w^2 >
}
```

141.14 Unitals

A unital in the classical projective plane $PG_2(q^2)$ is a set of $q^3 + 1$ points such that every line meeting two of these points meets exactly $q + 1$ of them.

`IsUnital(P, U)`

Given a set of points U belonging to a projective plane P defined over a field of cardinality q^2, return `true` if U is a unital.

`AllTangents(P, U)`

Given a unital set of points U in the projective plane P, return the set of tangents to the points of U.

`UnitalFeet(P, U, p)`

The set of intersections of the unital set of points U with the tangents to U in the plane P which pass through the point p.

Example H141E11

The following code computes the Hermitian unital given by the equation $x^{q+1} + y^{q+1} + z^{q+1} = 0$ in $PG_2(q^2)$ for $q = 3$.

```
> q := 3;
> F<w> := GaloisField(q ^ 2);
> P, V, L := FiniteProjectivePlane(F);
>
> hu := { V | [x,y,z] : x, y, z in F |
>                x^(q+1) + y^(q+1) + z^(q+1) eq 0 and {x, y, z} ne {0} };
>
> IsUnital(P, hu);
true
> UnitalFeet(P, hu, V.1);
{  ( 0 : 1 : w ), ( 0 : 1 : w^3 ), ( 0 : 1 : w^5 ), ( 0 : 1 : w^7 ) }
```

Since this set has more than one element, `V.1` must not be in *hu*:

```
> V.1 in hu;
false
```

For a point in *hu*:

```
> UnitalFeet(P, hu, Rep(hu));
{  ( 1 : 0 : w^7 ) }
```

Now we construct the design given by *hu*.

```
> blks := [blk : lin in L | #blk eq (q+1) where blk is lin meet hu ];
> D := Design< 2, SetToIndexedSet(hu) | blks >;
> D;
2-(28, 4, 1) Design with 63 blocks
```

141.15 The Collineation Group of a Plane

The automorphism group (or collineation group) A of a plane P is always presented as a permutation group G acting on the standard support $\{1, ..v\}$, where v is the number of points of P. The reasons for this include the fact that if the group is represented as acting on a set of objects relating to the plane, printed permutations are often unreadable.

So the collineation group G of P does not act directly on P. Instead, G–sets are used to transfer the action of G to various sets associated with P. The two most important G–sets, corresponding to action of G on the point set and on the line set, are returned by each of the functions provided for constructing the collineation group or some specified subgroup of it.

In some circumstances, rather than viewing collineations as group elements, it is desirable to view them is as mappings of P into itself. Associated with each incidence structure is a mapping structure, Aut(P), which denotes the set of collineations of P. Note that Aut(P) is the *parent* of the collineations of G so that the function `Aut(P)` simply creates a

shell structure rather than the actual collineation group of P. A transfer map is provided to convert a permutation of the collineation group G into a mapping belonging to $Aut(P)$.

141.15.1 The Collineation Group Function

`CollineationGroup(P)`

`AutomorphismGroup(P)`

`PointGroup(P)`

Construct the collineation group G of the plane P. The group G is returned as a permutation group on the standard support $\{1 \dots v\}$, where v is the number of points of P. The function also returns: a G–set Y being the point set of P acted on by G; a G–set W being the line set of P acted on by G; a power structure S; a transfer map t. Given a permutation g from G, one can create a map $f = t(g)$ which represents the automorphism g as a mapping in S from P to P (which maps both point sets and line sets). The G–sets Y and W should be used if one wishes to compute stabilizers or similar such subgroups of G so that the appropriate action is used.

`LineGroup(P)`

Construct the collineation group G of the plane P in its action on the lines of P. The group G is returned as a permutation group on the standard support $\{1 \dots l\}$, where l is the number of lines of P. A power structure S and transfer map t are also returned, so that, given a permutation g from G, one can create a map $f = t(g)$ which represents the automorphism g as a mapping in S from L to L, where L is the line set of P.

`CollineationGroupStabilizer(P, k)`

A subgroup G of the collineation group of the plane P which stabilizes the first k base points, together with the points G–set, the lines G–set, the power structure A of all automorphisms of P, and the transfer map t from G into A.

`CollineationSubgroup(P)`

A subgroup G of the collineation group of the plane P generated by one element, together with the points G–set, the lines G–set, the power structure A of all automorphisms of P, and the transfer map t from G into A.

141.15.2 General Action of Collineations

The collineation group G of a plane P is given in its action on the standard support. This support may be regarded as the indices of the points of P. The action of G on P is obtained using the G–set mechanism. The two basic G–sets associated with P correspond to the action of G on the set of points V and the set of lines L of P. These two G–sets are given as return values of the function `AutomorphismGroup`. Additional G–sets associated with P may be built using the G–set constructors. Given a G–set Y for G, the action of G on Y may be studied using the permutation group functions that allow a G–set as an argument. In this section, only a few of the available functions are described: see the chapter on permutation groups for a complete list.

The action of the collineation group on the plane may also be obtained using the ^ operator.

`y ^ g`

Let G be a subgroup of the collineation group for the plane P and suppose $g \in G$. Given an element y that is either a point or line of P, return the image of y under g.

`y ^ G`

Let G be a subgroup of the collineation group for the plane P. Given an element y that is either a point or line of P, return the orbit of y under G.

`Image(g, Y, y)`

Let G be a subgroup of the collineation group for the plane P and let Y be a G–set for G. Given an element y belonging either to Y or to a G–set derived from Y, find the image of y under G.

`Orbit(G, Y, y)`

Let G be a subgroup of the collineation group for the plane P and let Y be a G–set for G. Given an element y belonging either to Y or to a G–set derived from Y, construct the orbit of y under G.

`Orbits(G, Y)`

Let G be a subgroup of the collineation group for the plane P and let Y be a G–set for G. This function constructs the orbits of the action of G on Y.

`Stabilizer(G, Y, y)`

Let G be a subgroup of the collineation group for the plane P and let Y be a G–set for G. Given an element y belonging either to Y or to a G–set derived from Y, construct the stabilizer of y in G.

`Action(G, Y)`

Given a subgroup G of the collineation group of the plane P, and a G–set Y for G, construct the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the set Y. The function returns:

(a) The natural homomorphism $\phi : G \to L$;

(b) The induced group L;

(c) The kernel of the action (a subgroup of G).

`ActionImage(G, Y)`

Given a subgroup G of the collineation group of the plane P, and a G–set Y for G, construct the permutation group L giving the action of G on the set Y.

`ActionKernel(G, Y)`

Given a subgroup G of the collineation group of the plane P, and a G–set Y for G, construct the kernel of the action of G on the set Y.

Example H141E12

We illustrate the use of the G–sets returned by the `CollineationGroup` function.

```
> P := FiniteProjectivePlane(3);
> G, Y, W := CollineationGroup(P);
```

Compute the stabilizer of the first point of P:

```
> H := Stabilizer(G, Y, Points(P)[1]);
> H;
Permutation group H acting on a set of cardinality 13
    (3, 9)(5, 7)(6, 11)(8, 12)
    (2, 8, 12)(3, 9)(4, 6, 7, 10, 5, 11)
    (2, 9)(3, 4)(5, 8)(10, 13)
    (2, 8)(3, 9)(4, 5)(6, 10)
    (2, 3)(4, 13)(6, 8)(9, 10)
    (2, 13, 8)(3, 6, 4)(5, 10, 9)
    (2, 3)(4, 9)(7, 12)(10, 13)
> H eq CollineationGroupStabilizer(P, 1);
true
> lines := {m : m in Lines(P) | Points(P)[1] in m};
> l := Random(lines);
> l ^ H;
GSet{
  < 0 : 1 : 0 >,
  < 0 : 0 : 1 >,
  < 0 : 1 : 2 >,
  < 0 : 1 : 1 >
```

```
}
```

Compute the stabilizer of the first line of P:

```
> Stabilizer(G, W, Lines(P)[1]);
Permutation group acting on a set of cardinality 13
    (1, 8, 12, 4, 7, 9)(2, 3, 5)(6, 13)
    (3, 5, 11)(6, 7, 9)(8, 12, 13)
    (4, 10)(5, 11)(6, 7)(8, 12)
    (1, 10, 6, 7)(2, 11)(3, 5)(4, 13, 9, 12)
    (5, 11)(6, 12)(7, 8)(9, 13)
    (1, 10)(3, 5)(6, 7)(12, 13)
    (1, 4, 10)(3, 11)(6, 13, 9, 8, 7, 12)
```

Example H141E13

The following function `Bundle` returns a projective bundle in $PG_2(q)$.

```
> Bundle := function(q)
>     K<w> := GF(q^3);
>     P, V, L := FiniteProjectivePlane(q^3);
>     G, Y := CollineationGroup(P);
>     S := Support(P);  // normalized vectors
>     sig := sub< G |
>                [Index(P, V ! [S[i][1], S[i][2]^q, S[i][3]^q]) : i in [1..#V]]>;
>                        // group of planar collineations of order 3
>     p := V ! [1, w^2, w];
>     T := Orbit(sig, Y, p);
>     e2 := V![0, 1, 0];
>     e3 := V![0, 0, 1];
>     S := Points(SubfieldSubplane(P, GF(q)));
>     c23 := Conic(P, T join {e2, e3}) meet S;
>     e1 := Rep(S diff c23);
>     c12 := (Conic(P, T join {e1, e2}) meet S) diff { e1 };
>     c13 := (Conic(P, T join {e1, e3}) meet S) diff { e1 };
>     bundle := [ Conic(P, T join {e1, e}) meet S : e in c23 ] cat
>               [ Conic(P, T join {v1, v2}) meet S : v2 in c13, v1 in c12 ];
>     return FiniteProjectivePlane< S | bundle >;
>
> end function;
>
> PB := Bundle(3);
> PB;
Projective Plane of order 3
```

Example H141E14

The function `BaerDerivation` below uses a Baer subplane to construct an affine plane.

```
> BaerDerivation := function(q)
> //--------------------------
> // Construct an affine plane by the technique of derivation using
> // Baer subplanes
>
>    Fq2< w > := FiniteField(q^2);
>    V := VectorSpace(Fq2, 3);
>    Plane, Pts, Lns := FiniteProjectivePlane(V);
>    G, Y := CollineationGroup(Plane);
```

Construct a Baer subplane:

```
>    Subplane := SubfieldSubplane(Plane, GF(q));
```

The Baer segment consists of those points of the Baer subplane that lie on the line at infinity. Take the line $x = 0$ as the line at infinity.

```
>    LineInf := Lns![1, 0, 0];
>
>    BaerSeg := Points(Subplane) meet LineInf;
```

We now find the subgroup of the collineation group that fixes the Baer segment. The translates of the Baer subplane under this subgroup will give us those Baer subplanes that contain the set `BaerSeg`. We use the G–set `Y` to specify the action of `G` on the points of `Plane`.

```
>    StabSeg := Stabilizer(G, Y, BaerSeg);
```

Rather than computing the translates of the entire Baer subplane, we compute the translates of `Subplane - BaerSeg` so that we get exactly those sets which become new affine lines.

```
>    BaerLines := Orbit(StabSeg, Y, Points(Subplane) diff BaerSeg);
```

We complete the new plane by taking those lines of $PG(2, q^2)$ which intersect the line at infinity at points other than those in the Baer segment. Upon removing the intersection point with `LineInf`, each such line becomes a line of the new affine plane.

```
>    AffLines := BaerLines join { Set(l) diff LineInf : l in Lns |
>                                 (BaerSeg meet l) eq {} };
>    return FiniteAffinePlane< SetToIndexedSet(&join(AffLines)) | Setseq(AffLines)
>                                          : Check := false >;
> end function; /*BaerDerivation*/
```

141.15.3 Central Collineations

Let p be a point and l a line of a projective plane P. A (p, l)–*central collineation* is a collineation α of P which fixes l pointwise and p linewise. The line l is called the *axis* of α and the point p is called the *centre* of α.

`CentralCollineationGroup(P, p, l)`

The group G of (p, l)–central collineations of a projective plane P. A power structure S and transfer map t are also returned, so that, given a permutation g from G, one can create a map $f = t(g)$ which represents the permutation g as a mapping in S from P to P. (which maps both point sets and line sets).

`CentralCollineationGroup(P, p)`

The group of central collineations with centre p of a projective plane P. A power structure S and transfer map t are also returned, so that, given a permutation g from G, one can create a map $f = t(g)$ which represents the permutation g as a mapping in S from P to P. (which maps both point sets and line sets).

`CentralCollineationGroup(P, l)`

The group of central collineations with axis l of a projective plane P. A power structure S and transfer map t are also returned, so that, given a permutation g from G, one can create a map $f = t(g)$ which represents the permutation g as a mapping in S from P to P. (which maps both point sets and line sets).

`IsCentralCollineation(P, g)`

Returns `true` iff the collineation g of the projective plane P is a central collineation; if `true`, also returns the centre and axis of g. The support of the parent of g must be the point set of P or the standard support $\{1 \dots v\}$, where v is the number of points of P.

Example H141E15

We find a group of central collineations of a plane P, and check that a random element of the group is in fact a central collineation and has the correct axis and centre.

```
> P, V, L := FiniteProjectivePlane< 13 |
>     {1, 2, 3, 4}, {1, 5, 6, 7}, {1, 8, 9, 10},
>     {1, 11, 12, 13}, {2, 5, 8, 11}, {2, 6, 9, 12},
>     {2, 7, 10, 13}, {3, 5, 9, 13}, {3, 6, 10, 11},
>     {3, 7, 8, 12}, {4, 5, 10, 12}, {4, 6, 8, 13},
>     {4, 7, 9, 11} >;
> p := V!3;
> l := L.1;
> G := CentralCollineationGroup(P, p, l);
> G;
Permutation group G acting on a set of cardinality 13
Order = 3
```

```
    (5, 13, 9)(6, 11, 10)(7, 12, 8)
> g := Random(G);
> g;
(5, 9, 13)(6, 10, 11)(7, 8, 12)
> is_cent_coll, centre, axis := IsCentralCollineation(P, g);
> is_cent_coll;
true
> centre eq p;
true
> axis eq l;
true
```

Any line through the centre of a central collineation must be fixed by the collineation.

```
> lines := {m : m in Lines(P) | p in m};
> m := Random(lines);
> m;
{3, 7, 8, 12}
> m ^ G;
GSet{
  {3, 7, 8, 12}
}
```

141.15.4 Transitivity Properties

`IsPointTransitive(P)`

`IsTransitive(P)`

Return `true` iff the collineation group of the plane P acts transitively on the points of P.

`IsLineTransitive(P)`

Return `true` iff the collineation group of the plane P acts transitively on the lines of P.

Example H141E16

We check the transitivity of the collineation group of $AG_2(4)$.

```
> P := FiniteAffinePlane(4);
> IsPointTransitive(P);
true
> IsLineTransitive(P);
true
```

141.16 Translation Planes

The following functions may be used to construct translation planes by derivation. The original code is due to Jenny Key.

`BaerDerivation(q2)`

An affine plane constructed by the technique of derivation with respect to a Baer subplane, where $q2$ is an even power of a prime.

`BaerSubplane(P)`

A Baer subplane of the projective plane P.

`OvalDerivation(q: parameters)`

`HallOval`	BoolElt	*Default :* `false`
`Print`	BoolElt	*Default :* `false`

A translation plane from $\mathrm{PG}(2, q)$, where q is a power of 2, computed by derivation with respect to an oval. By default, the oval chosen is that defined by the points of the conic $y^2 = xz$ together with the nucleus, in $\mathrm{PG}(2, q)$. In the case $q = 16$, a Hall oval in the plane may be requested by assigning the parameter `HallOval` the value `true`. If the parameter `Print` is assigned the value `true`, then some information is printed during the computation.

141.17 Planes and Designs

Projective and affine planes can be viewed as special kinds of designs. The following functions convert between designs and planes.

`Design(P)`

The design corresponding to the points and lines of the plane P.

`FiniteAffinePlane(D)`

The affine plane corresponding to the incidence structure D.

`FiniteProjectivePlane(D)`

The projective plane corresponding to the incidence structure D.

Example H141E17

The development of a Singer difference set provides a design which satisfies the projective plane axioms, and thus can be converted to a projective plane in MAGMA.

```
> sds := SingerDifferenceSet(2, 3);
> sds;
{ 0, 1, 3, 9 }
> sdv := Development(sds);
> sdv;
2-(13, 4, 1) Design with 13 blocks
> spp := FiniteProjectivePlane(sdv);
> spp: Maximal;
Projective Plane of order 3
Points: {@ 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 @}
Lines:
    {0, 1, 3, 9},
    {1, 2, 4, 10},
    {2, 3, 5, 11},
    {3, 4, 6, 12},
    {0, 4, 5, 7},
    {1, 5, 6, 8},
    {2, 6, 7, 9},
    {3, 7, 8, 10},
    {4, 8, 9, 11},
    {5, 9, 10, 12},
    {0, 6, 10, 11},
    {1, 7, 11, 12},
    {0, 2, 8, 12}
> Universe(Support(spp));
Residue class ring of integers modulo 13
```

141.18 Planes, Graphs and Codes

MAGMA provides the following functions to create the graphs and codes naturally associated to a projective or affine plane.

`LineGraph(P)`

The line graph of the plane P.

`IncidenceGraph(P)`

The incidence graph of the plane P. This bipartite graph has as vertex set the union of the point set V and line set L of P. A vertex $p \in V$ is adjacent to a vertex $l \in L$ whenever $p \in l$.

`LinearCode(P, K)`

Given a plane P with v points and a finite field K, this function returns the linear code C of length v generated by the characteristic functions of the lines of P considered as vectors of the K-space $K^{(v)}$.

Example H141E18

```
> P, V, L := FiniteAffinePlane(3);
> #V, #L;
9 12
> IncidenceGraph(P);

142 INCIDENCE GEOMETRY

Chapter 142
INCIDENCE GEOMETRY

142.1 Introduction

This chapter presents the functions designed for constructing and computing with incidence geometries and coset geometries.

We recall the basic definitions and notation in the field of Incidence Geometry. We refer to the *Handbook of Incidence Geometry* [Bue95], edited by Francis Buekenhout, or to Antonio Pasini's book *Diagram Geometries* [Pas94], for a more detailed overview of the subject.

Let X and I be two finite sets. Let $t : X \to I$ be a mapping from X onto I. Let $\sim$ be a reflexive and symmetric relation such that $\forall x, y \in X$, $x \sim y$ and $t(x) = t(y) \Rightarrow x = y$. The four-tuple $\Gamma(X, \sim, t, I)$ is what we call an *Incidence Geometry* in MAGMA. Remark that it is not a geometry in the sense of Buekenhout since we do not impose that every flag (i.e. clique of the incidence graph) of Γ must be contained in a chamber (i.e. a clique containing one element of each type). If the latter condition is satisfied, then an incidence geometry is a geometry in the sense of Buekenhout. The set X contains the *elements* of the geometry, while I is called the set of *types*. The function t is called the *type function* and $\sim$ is called the *incidence relation* of Γ. The cardinality of I is the *rank* of Γ.

It is possible to construct incidence geometries from a group and some of its subgroups using an algorithm first introduced by Jacques Tits in 1962 [Tit62]. Let G be a group and let I be a finite set. Let $\{G_i, i \in I\}$ be a set of subgroups of G. Define $X = \{G_i g, g \in G, i \in I\}$ to be the set of elements of Γ. Define the type function as $t : X \to I : G_i g \to i$ and the incidence relation as follows: $G_i g \sim G_j h$ iff $G_i g \cap G_j h \neq \emptyset$. The subgroups $\{G_i, i \in I\}$ are called the *maximal parabolic subgroups*. The subgroup $\cap_{i \in I} G_i$ is called the *Borel subgroup*. Finally, the subgroups $\{\cap_{j \in I \setminus \{i\}} G_j, i \in I\}$ are called the *minimal parabolic subgroups*. These geometries are called *Coset Geometries* in MAGMA to remind the user that they are constructed from a group. Again, a coset geometry is not a geometry in the sense of Buekenhout. If every flag of the coset geometry is contained in a chamber, then it is a Buekenhout geometry. We will see that, using coset geometries, it is easy to build huge incidence geometries by giving very little data.

The category names for the incidence geometries and coset geometries are:

- Incidence Geometry : `IncGeom`
- Coset Geometry : `CosetGeom`

142.2 Construction of Incidence and Coset Geometries

142.2.1 Construction of an Incidence Geometry

`IncidenceGeometry(G)`

Construct the incidence geometry IG having as incidence graph the (labelled) graph G.

If G is an unlabelled graph, then the set of elements of IG is the set of vertices and edges of G, the set of types is $\{@1, 2@\}$ where elements of type 1 are vertices of G and elements of type 2 are edges of G. An element x of type 1 is incident to an element y of type 2 iff the vertex x in G is on the edge y of G.

If G is a labelled graph, i.e. a graph whose vertices have labels, then the set of elements of IG is the set of vertices of G, the set of types is the set of labels of the vertices of G and the incidence graph is G.

The function returns one value: the incidence geometry IG.

Example H142E1

The Petersen graph, considered as a rank two incidence geometry, may be constructed by the following statement:

```
> gr := Graph<10|
>   {1,2},{1,5},{1,6},{2,7},{2,3},{3,8},{3,4},{4,9},{4,5},{5,10},
>   {6,8},{8,10},{10,7},{7,9},{9,6}>;
> ig := IncidenceGeometry(gr);
> ig;
Incidence geometry ig with 2 types and with underlying graph:
Graph
Vertex  Neighbours
1       11 12 13 ;
2       11 14 15 ;
3       14 16 17 ;
4       16 18 19 ;
5       12 18 20 ;
6       13 21 22 ;
7       15 23 24 ;
8       17 21 25 ;
9       19 22 23 ;
10      20 24 25 ;
11      1 2 ;
12      1 5 ;
13      1 6 ;
14      2 3 ;
15      2 7 ;
16      3 4 ;
17      3 8 ;
18      4 5 ;
```

```
19      4 9 ;
20      5 10 ;
21      6 8 ;
22      6 9 ;
23      7 9 ;
24      7 10 ;
25      8 10 ;
```

Example H142E2

The rank three geometry consisting of the vertices, edges and faces of the cube, with symmetric inclusion as incidence might be encoded in the following way. The first 8 vertices of the graph correspond to the vertices of the cube, the next 12 vertices correspond to the edges of the cube and the last 6 are the faces of the cube.

```
> g := Graph<26|
>    {1,9},{1,12},{1,13},{1,21},{1,22},{1,25},
>    {2,9},{2,10},{2,14},{2,21},{2,22},{2,23},
>    {3,10},{3,11},{3,15},{3,21},{3,23},{3,24},
>    {4,11},{4,12},{4,16},{4,21},{4,24},{4,25},
>    {5,13},{5,18},{5,17},{5,22},{5,25},{5,26},
>    {6,14},{6,19},{6,18},{6,23},{6,22},{6,26},
>    {7,15},{7,19},{7,20},{7,24},{7,26},{7,23},
>    {8,17},{8,20},{8,16},{8,26},{8,24},{8,25},
>    {9,21},{9,22},{10,21},{10,23},{11,21},{11,24},
>    {12,21},{12,25},{13,22},{13,25},{14,22},{14,23},
>    {15,23},{15,24},{16,24},{16,25},{17,25},{17,26},
>    {18,22},{18,26},{19,23},{19,26},{20,24},{20,26}>;
> v := VertexSet(g);
> AssignLabels(v,[1,1,1,1,1,1,1,1,2,2,2,2,2,2,2,2,2,2,2,3,3,3,3,3,3]);
> cube := IncidenceGeometry(g);
> cube;
Incidence geometry cube with 3 types and with underlying graph:
Graph
Vertex  Neighbours

23      2 3 6 7 10 14 15 19 ;
24      3 4 7 8 11 15 16 20 ;
25      1 4 5 8 12 13 16 17 ;
26      5 6 7 8 17 18 19 20 ;
```

Example H142E3

The Hoffman-Singleton graph $HoSi$: the following description is taken from the book *Diagram Geometry*, by A. Cohen and F. Buekenhout [BCon].
Start with the set $X_1 = \binom{7}{3}$ of all triples from 7. There are 30 collections of 7 triples that form the lines of a *Fano plane* with point set 7. The group $Sym(7)$ acts transitively on this set of 30 elements, but the alternating group $Alt(7)$ has two orbits, of cardinality 15 each. Select one and call it X_2. Now consider the following graph Ω constructed from the incidence graph $(X_1 \cup X_2, *)$ by additionally joining two elements of X_1 whenever they have empty intersection. The following lines of MAGMA-code implement the Hoffman-Singleton graph as an incidence geometry of rank 2. We will study it more later.

```
> HoffmanSingletonGraph := function()
>   pentagram := Graph< 5 | { {1,3}, {3,5}, {5,2}, {2,4}, {4,1} } >;
>   pentagon := PolygonGraph(5);
>   PP := pentagram join pentagon;
>   HS := &join [ PP : i in [1..5] ];
>   return HS + { { Vertices(HS) | i + j*10, k*10 + 6 + (i+j*k) mod 5 } :
>                                  i in [1..5], j in [0..4], k in [0..4] };
> end function;
> ig := IncidenceGeometry(HoffmanSingletonGraph());
```

Example H142E4

A rank four geometry constructed from the Hoffman-Singleton graph : the following description is taken from the book *Diagram Geometry*, by A. Cohen and F. Buekenhout.
Take X_1 and $X_{1'}$ to be two copies of the vertex set of $HoSi$. The group $Sym(7)$ acts transitively on the set of maximal cocliques of $HoSi$. The subgroup $Alt(7)$ has two orbits of size 15 each. Let X_2 be one of them and $X_{2'}$ be a copy of X_2. Define incidence $\sim$ for $a \in X_1$, $a' \in X_{1'}$, $b \in X_2$ and $b' \in X_{2'}$, by
$a \sim a' \Leftrightarrow \{a, a'\}$ is an edge of $HoSi$
$a \sim b \Leftrightarrow a \notin b$
$a \sim b' \Leftrightarrow a \in b'$
$a' \sim b \Leftrightarrow a' \notin b$

$a' \sim b' \Leftrightarrow a' \notin b'$
$b \sim b' \Leftrightarrow b \cap b' = \emptyset$
The geometry $\Gamma(X_1 \cup X_{1'} \cup X_2 \cup X_{2'}, \sim)$ is the *Neumaier geometry*. The following lines of MAGMA-code implement this geometry as a rank four incidence geometry. We assume that *ig* is the incidence geometry corresponding to the Hoffman-Singleton graph, as described in the previous example.

```
> gr := HoffmanSingletonGraph();
> ig := IncidenceGeometry(gr);
> aut := AutomorphismGroup(ig);
> n := NormalSubgroups(aut);
> X1 := VertexSet(gr);
> g := CompleteGraph(50);
> e := EdgeSet(gr);
> ebis := [];
> for x in EdgeSet(gr) do
>     for i := 1 to 50 do
>         for j := i+1 to 50 do
>             if VertexSet(gr)!i in x then
>                 if VertexSet(gr)!j in x then
>                     Append(~ebis,[i,j]);
>                 end if;
>             end if;
>         end for;
>     end for;
> end for;
> for i := 1 to #ebis do
>     RemoveEdge(~g,ebis[i][1],ebis[i][2]);
> end for;
> c := MaximumClique(g);
> cbis := [];
> for i := 1 to 50 do
>     if (VertexSet(gr)!i in c) then Append(~cbis,i); end if;
> end for;
> c := Set(cbis);
> X2 := Orbit(n[2]`subgroup,c);
> X2 := SetToSequence(X2);
> e := [];
> for i := 1 to 50 do
>     for j := 1 to 50 do
>         if X1!i in Neighbours(X1!j) then Append(~e,{i,j+50}); end if;
>     end for;
> end for;
> for i :=1 to 50 do
>     for j := 1 to 50 do
>         if not(i in X2[j]) then Append(~e,{i,j+100});end if;
>     end for;
> end for;
```

```
> for i :=1 to 50 do
>     for j := 1 to 50 do
>         if i in  X2[j] then Append(~e,{i,j+150});end if;
>     end for;
> end for;
> for i :=1 to 50 do
>     for j := 1 to 50 do
>         if i in  X2[j] then Append(~e,{i+50,j+100});end if;
>     end for;
> end for;
> for i :=1 to 50 do
>     for j := 1 to 50 do
>         if not(i in  X2[j]) then Append(~e,{i+50,j+150});end if;
>     end for;
> end for;
> for i :=1 to 50 do
>     for j := 1 to 50 do
>         if X2[i] meet X2[j] eq {} then Append(~e,{i+100,j+150});end if;
>     end for;
> end for;
> gr2 := Graph<200|Set(e)>;
> v := VertexSet(gr2);
> labs := [i: j in {1..50}, i in {1..4}];
> AssignLabels(v,labs);
> neumaier := IncidenceGeometry(gr2);
```

142.2.2 Construction of a Coset Geometry

`CosetGeometry(G, S, I)`

Construct the coset geometry CG with set of types I, obtained from the group G and the set S of subgroups of G. The sets S and I must have same cardinality.

If G is a permutation group and S is a set of subgroups of G, the corresponding coset geometry, obtained by using Tits' algorithm (see above) is constructed. If S and I are indexed sets, then the cosets of the subgroup $S[i]$ are elements of type $I[i]$, for all $i \in \{0, \ldots, n-1\}$ where n is the cardinality of S (and I). The function returns one value: the coset geometry CG.

`CosetGeometry(G, S)`

Construct the coset geometry CG obtained from the group G and the set S of subgroups of G.

If G is a permutation group and S is a set of subgroups of G, the corresponding coset geometry, obtained by using Tits' algorithm (see above) is constructed. To every subgroup in S is associated a number from 0 to $n-1$ where n is the cardinality of S. The function returns one value: the coset geometry CG.

Example H142E5

The Petersen graph, considered as a rank two coset geometry, can be implemented in the following way :

```
> g := Sym(5);
> g0 := Stabilizer(g,{1,2});
> g01 := Stabilizer(g,[{1,2},{3,4}]);
> g1 := sub<g|g01,(1,3)(2,4)>;
> cg := CosetGeometry(g,{g0,g1});
> cg;
Coset geometry cg with 2 types
Group:
Symmetric group g acting on a set of cardinality 5
Order = 120 = 2^3 * 3 * 5
    (1, 2, 3, 4, 5)
    (1, 2)
Maximal Parabolic Subgroups:
Permutation group g0 acting on a set of cardinality 5
Order = 12 = 2^2 * 3
    (3, 4)
    (1, 2)
    (4, 5)
Permutation group g1 acting on a set of cardinality 5
Order = 8 = 2^3
    (1, 2)
    (3, 4)
    (1, 3)(2, 4)
Type Set:
{@ 0, 1 @}
```

Example H142E6

The rank three geometry consisting of the vertices, edges and faces of the cube, can be implemented as a coset geometry in the following way, which is much easier than having to give the full incidence graph :

```
> g := sub<Sym(8)|
>     (1,2,3,4)(5,6,7,8), (1,5)(2,6)(3,7)(4,8), (2,4,5)(3,8,6)>;
> g0 := Stabilizer(g,1);
> g1 := Stabilizer(g,{1,2});
> g2 := Stabilizer(g,{1,2,3,4});
> cg := CosetGeometry(g,{g0,g1,g2});
> cg;
Coset geometry cg with 3 types
Group:
Permutation group g acting on a set of cardinality 8
Order = 48 = 2^4 * 3
    (1, 2, 3, 4)(5, 6, 7, 8)
```

```
    (1, 5)(2, 6)(3, 7)(4, 8)
    (2, 4, 5)(3, 8, 6)
Maximal Parabolic Subgroups:
Permutation group acting on a set of cardinality 8
Order = 8 = 2^3
    (1, 2)(3, 4)(5, 6)(7, 8)
    (2, 4)(6, 8)
Permutation group acting on a set of cardinality 8
Order = 6 = 2 * 3
    (2, 4, 5)(3, 8, 6)
    (3, 6)(4, 5)
Permutation group acting on a set of cardinality 8
Order = 4 = 2^2
    (1, 2)(3, 5)(4, 6)(7, 8)
    (1, 2)(3, 4)(5, 6)(7, 8)
Type Set:
{@ 0, 1, 2 @}
```

Example H142E7

The following lines of MAGMA-code construct a coset geometry of rank 6 for the group $Sym(6)$.

```
> g := Sym(6);
> s := [Stabilizer(g,{1..j}) : j in {1..5}];
> cg := CosetGeometry(g,Set(s));
> cg;
Coset geometry cg with 5 types
Group:
Symmetric group g acting on a set of cardinality 6
Order = 720 = 2^4 * 3^2 * 5
    (1, 2, 3, 4, 5, 6)
    (1, 2)
Maximal Parabolic Subgroups:
Permutation group acting on a set of cardinality 6
Order = 48 = 2^4 * 3
    (3, 4)
    (4, 5)
    (5, 6)
    (1, 2)
Permutation group acting on a set of cardinality 6
Order = 48 = 2^4 * 3
    (1, 2)
    (2, 3)
    (3, 4)
    (5, 6)
Permutation group acting on a set of cardinality 6
Order = 36 = 2^2 * 3^2
    (1, 2)
```

```
    (4, 5)
    (5, 6)
    (2, 3)
Permutation group acting on a set of cardinality 6
Order = 120 = 2^3 * 3 * 5
    (2, 3)
    (3, 4)
    (4, 5)
    (5, 6)
Permutation group acting on a set of cardinality 6
Order = 120 = 2^3 * 3 * 5
    (1, 2)
    (2, 3)
    (3, 4)
    (4, 5)
Type Set:
{@ 0, 1, 2, 3, 4 @}
```

142.3 Elementary Invariants

`Points(D)`

`Elements(D)`

Given an incidence geometry D, return the set of elements of D. These elements are the points of the incidence graph of D.

`Types(D)`

Given an incidence geometry D, return the set of types of D.

`Types(C)`

Given a coset geometry C, return the set of types of C.

`Rank(D)`

Given an incidence geometry D, return the rank of D, i.e. the cardinality of the set of types.

`Rank(C)`

Given a coset geometry C, return the rank of C.

`IncidenceGraph(D)`

Given an incidence geometry D, return the incidence graph of D, its vertex set and its edge set.

We remark that this function is not implemented for coset geometries but we may convert a coset geometry into an incidence geometry using `IncidenceGeometry` and then compute its incidence graph.

`Group(C)`

Given a coset geometry C, return the group from which C is constructed.

`MaxParabolics(C)`
`MaximalParabolics(C)`

Given a coset geometry C, return an indexed set containing the maximal parabolics of C.

`MinParabolics(C)`
`MinimalParabolics(C)`

Given a coset geometry C, return an indexed set containing the minimal parabolics of C.

`Borel(C)`
`BorelSubgroup(C)`

Given a coset geometry C, return the *Borel subgroup* of C, i.e. the intersection of all maximal parabolic subgroups of C.

`Kernel(C)`

Given a coset geometry C, return a permutation group which is its kernel, i.e. the subgroup of the Borel subgroup of C that fixes all elements of the geometry C.

`Kernels(C)`

Given a coset geometry C, return a sequence containing the i-kernel K_i of each maximal parabolic subgroup G_i of C. The i-kernel of the subgroup G_i is the subgroup consisting of all the elements of G_i that fix all the elements of the residue of G_i.

`Quotient(C, K)`

Given a coset geometry $C = (G; (G_i)_{i \in I})$ and a permutation group K, return the coset geometry $(G/K; (G_i/K)_{i \in I})$ provided that K is a normal subgroup of G and of all the maximal parabolic subgroups of C.

142.4 Conversion Functions

In this section we describe the functions that are available to convert incidence geometries and coset geometries in other objects.

`IncidenceGeometry(C)`

Construct the incidence geometry IG from the coset geometry C. This is done using Tits' algorithm described in the introduction of this chapter . The function returns one value: the incidence geometry IG.

`CosetGeometry(D)`

Convert the incidence geometry D into a coset geometry.

If D is an incidence geometry that can be converted into a coset geometry, the coset geometry isomorphic to it is constructed in the following way. The group G of the coset geometry CG is the automorphism group of D. MAGMA determines a chamber C of D, that is a clique of the incidence graph of D containing one element of each type. To every element x in C, MAGMA associates a subgroup G_x which is the stabilizer of x in G. The subgroups $(G_x, x \in C)$ are the maximal parabolic subgroups of CG. In order to obtain a coset geometry combinatorially isomorphic to the incidence geometry we started with, the group G must be transitive on every rank two truncation of D. If this condition is satisfied, the function returns a boolean set to the value `true` and the coset geometry CG. Otherwise, the function returns `false`.

`Graph(D)`

If `IsGraph(D)` returns `true`, this function construct the undirected graph corresponding to the incidence geometry D.

`Graph(C)`

If `IsGraph(C)` returns `true`, this function construct the undirected graph corresponding to the coset geometry C.

Example H142E8

Taking back the last example for incidence geometries, we can convert the Neumai er geometry into a coset geometry by typing the following command (`neumaier` is the Neumaier geometry constructed above):

```
> ok,cg := CosetGeometry(neumaier);
> ok;
true
```

This means the conversion has been done successfully. So *cg* is the coset geome try corresponding to `neumaier`.

```
> cg;
Coset geometry cg with 4 types
Group:
```

```
Permutation group acting on a set of cardinality 200
Order = 126000 = 2^4 * 3^2 * 5^3 * 7
Maximal Parabolic Subgroups:
Permutation group acting on a set of cardinality 200
Order = 2520 = 2^3 * 3^2 * 5 * 7
Permutation group acting on a set of cardinality 200
Order = 2520 = 2^3 * 3^2 * 5 * 7
Permutation group acting on a set of cardinality 200
Order = 2520 = 2^3 * 3^2 * 5 * 7
Permutation group acting on a set of cardinality 200
Order = 2520 = 2^3 * 3^2 * 5 * 7
Type Set:
{@ 1, 2, 3, 4 @}
```

142.5 Residues

Let $\Gamma(X, \sim, t, I)$ be an incidence geometry and let F be a flag of Γ (i.e. a clique of the incidence graph of Γ).

We say that an element $x \in F$ is incident to the flag F if and only if x is incident to all elements in F, and we denote it $x \sim F$.

The *residue* Γ_F of the flag F in Γ is the geometry whose set of elements is $\{x \in X : x \sim F\} \backslash F$ and whose set of types is $I \backslash t(F)$, together with the restricted type function and incidence relation.

Let $\Gamma(G; (G_i)_{i \in I})$ be a coset geometry and assume that G acts flag–transitively on Γ. Let F be a flag of Γ. The *residue* of F is the coset geometry $\Gamma_F = \Gamma(\cap_{j \in F} G_j; (G_i \cap (\cap_{j \in F} G_j))_{i \in I \backslash t(F)})$.

`Residue(D, f)`

Given an incidence geometry D and a flag f of D, return the residue of the flag f as an incidence geometry.

`Residue(C, f)`

Given a coset geometry C and a subset f of the set of types of C, return the residue of the flag consisting in the maximal parabolics of C whose type is in f.

142.6 Truncations

Let $\Gamma(X, \sim, t, I)$ be an incidence geometry and let J be a subset of I. Then the *J–truncation* of Γ is the geometry whose set of elements is $t^{-1}(J)$, together with the restricted type function and incidence relation.

Let $J \subseteq I$. The *J–truncation* of the coset geometry $\Gamma(G; (G_i)_{i \in I})$ is the coset geometry $\Gamma(G; (G_j)_{j \in J})$.

`Truncation(D, t)`

Given an incidence geometry D and t a subset of the set of types of D, return the *t–truncation* of D as an incidence geometry.

`Truncation(C, t)`

Given a coset geometry C and t a subset of the set of types of C, return the *t–truncation* of C as a coset geometry.

142.7 Shadows

Let $\Gamma(X, \sim, t, I)$ be an incidence geometry. Let J be a subset of I and let F be a flag of Γ such that $t(F) \cap J = \emptyset$. The *J-shadow* of the flag F, denoted by $\sigma_J(F)$, is the set of flags of type J in the residue of the flag F.

`Shadow(D, I, F)`

Given an incidence geometry D, a subset I of the set of types of D and a flag F of D, return the I-shadow of the flag F as an indexed set of subsets of points of D.

142.8 Shadow Spaces

Let $\Gamma(X, \sim, t, I)$ be an incidence geometry. Let J be a subset of I. The *shadow space* $\Gamma(J)$ of Γ is the incidence structure whose point-set is the set of flags of type J of Γ and whose blocks are the $J-$*shadows* of the flags of Γ.

`ShadowSpace(D,I)`

Given an incidence geometry D and a subset I of the set of types of D, return the shadow space $D(I)$ as an incidence structure.

142.9 Automorphism Group and Correlation Group

These function are currently only available for incidence geometries.

An *automorphism* α of an incidence geometry $\Gamma(X, \sim, t, I)$ is an automorphism of the incidence graph of Γ such that for all $x \in X$, $t(\alpha(x)) = t(x)$. In other words, an automorphism cannot change the type of an element. The *automorphism group* of Γ, denoted $Aut(\Gamma)$, is the group of all automorphisms of Γ.

A *correlation* α of an incidence geometry $\Gamma(X, \sim, t, I)$ is an automorphism of the incidence graph of Γ such that for all $x, y \in X$, $t(x) = t(y) \Rightarrow t(\alpha(x)) = t(\alpha(y))$. The *correlation group* of Γ, denoted $Cor(\Gamma)$, is the group of all correlations of Γ.

It is obvious that $Aut(\Gamma)$ is a subgroup of $Cor(\Gamma)$.

For an incidence geometry Γ, we can compute $Aut(\Gamma)$ and $Cor(\Gamma)$ using the commands described below.

`AutomorphismGroup(D)`

Given an incidence geometry D, return the group of type–preserving automorphisms of D as a permutation group of type `GrpPerm` acting on the set of elements of D.

`CorrelationGroup(D)`

Given an incidence geometry D, return the group of automorphisms of D as a permutation group of type `GrpPerm` acting of the set on elements of D.

142.10 Properties of Incidence Geometries and Coset Geometries

Let us recall definitions of the properties described in this section.

An incidence geometry Γ is *flag–transitive* if for every two flags x, y of the same type of Γ, there exists an element g of $Aut(\Gamma)$ such that $g(x) = y$. We also say that $Aut(\Gamma)$ acts flag–transitively in this case.

Moreover, it is a flag–transitive geometry if it contains at least one chamber.

A coset geometry $\Gamma(G; (G_i)_{i \in I})$ is *flag–transitive* if for every two flags x, y of the same type of Γ, there exists an element g of G such that $g(x) = y$. It is then a flag–transitive geometry since the set $\{(G_i)_{i \in I}\}$ is a chamber of Γ.

`IsFTGeometry(D)`

Given an incidence geometry D, return `true` if and only if the automorphism group of D acts flag–transitively on D and D has at least one chamber.

`IsFTGeometry(C)`

Given a coset geometry C, return `true` if and only if the group of C acts flag–transitively on C.

`IsFirm(X)`

Given either a coset geometry or an incidence geometry X that is flag transitive, return `true` if and only if every flag of X is contained in at least two chambers.

`IsThin(X)`

Given either a coset geometry or an incidence geometry X that is flag transitive, return `true` if and only if every flag of X is contained in exactly two chambers.

`IsThick(X)`

Given either a coset geometry or an incidence geometry X that is flag transitive, return `true` if and only if every flag of the geometry is contained in exactly three chambers.

`IsResiduallyConnected(X)`

`IsRC(X)`

Given either a coset geometry or an incidence geometry X that is flag transitive, return `true` if and only if every residue of rank at least two of X has a connected incidence graph.

`IsGraph(D)`

Given an incidence geometry D, tests if this incidence geometry corresponds to a graph: D must be of rank two and such that for one of the two types, say e, all elements of this type are incident with exactly two elements of the other type. Elements of type e then correspond to edges of an undirected graph and elements of the other type to the vertices of that graph.

`IsGraph(C)`

Given a coset geometry C, tests if this geometry corresponds to a graph: C must be of rank two and one of the two maximal parabolic subgroups, say G_e, must contain the Borel subgroup as a subgroup of index 2. In that case, the cosets of G_e correspond to edges of a graph and the cosets of the other maximal parabolic subgroup correspond to the vertices of this graph.

142.11 Intersection Properties of Coset Geometries

Let $\Gamma(X, *, t, I)$ be an incidence geometry. Given a type $i \in I$, for any flag F of Γ, we define the *i-shadow* $\sigma_i(F)$ as the set of elements of type i incident with F.

We define the intersection property (IP) as it appears in [Bue79].

(IP) for every type i, the intersection of the i-shadows of a variety x and a flag F is empty or it is the i-shadow of a flag incident to x and F. The same holds on the residues.

In earlier works, the second author, together with other persons, among whom are Francis Buekenhout, Michel Dehon and Philippe Cara, imposed a condition called $(IP)_2$. This condition asks that all rank two residues of Γ satisfy (IP).

If Γ is a geometry of rank n, we could define a property $(IP)_k$ in the following way (for $k = 2, \ldots, n$) as suggested by Francis Buekenhout.

$(IP)_k$ for every residue R of rank k of Γ, for every type i in the set of types of R, the intersection of the i-shadows of a variety x and a flag F is empty or it is the i-shadow of a flag incident to x and F.

In [JL04], Pascale Jacobs and Dimitri Leemans have designed good algorithms to test these intersection properties. The Magma implementation is available with the following functions.

`HasIntersectionPropertyN(C,n)`

Given a coset geometry C and a positive integer n, this function determines firstly, whether C satisfies the intersection property of rank n, and secondly, whether C satisfies the weak intersection property of rank n. A boolean value corresponding to each of these cases is returned.

`HasIntersectionProperty(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C satisfies the intersection property.

`HasWeakIntersectionProperty(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C satisfies the weak intersection property.

142.12 Primitivity Properties on Coset Geometries

`IsPrimitive(C)`

`IsPRI(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C is a primitive geometry, i.e. all of its maximal parabolic subgroups are maximal subgroups of its group.

`IsWeaklyPrimitive(C)`

`IsWPRI(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C is a weakly primitive geometry, i.e. at least one of its maximal parabolic subgroups is a maximal subgroup of its group.

`IsResiduallyPrimitive(C)`

`IsRPRI(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C is a primitive geometry and all of its residues are as well.

`IsResiduallyWealyPrimitive(C)`

`IsRWPRI(C)`

`IsRWP(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C is a weakly primitive geometry and all of its residues are as well.

`IsLocallyTwoTransitive(C)`

`Is2T1(C)`

Given a coset geometry C, this function returns the boolean value `true` if and only if C is locally two-transitive, i.e. all of its minimal parabolic subgroups have a two-transitive action on the cosets of the Borel subgroup.

142.13 Diagram of an Incidence Geometry

As Francis Buekenhout defined it in [Bue79], the diagram of a firm, residually connected, flag–transitive geometry Γ is a complete graph K, whose vertices are the elements of the set of types I of Γ, provided with some additional structure which is further described as follows. To each vertex $i \in I$, we attach the order s_i which is $\mid \Gamma_F \mid -1$ where F is any flag of type $I\backslash\{i\}$, and the number n_i of elements of type i of Γ. To every edge $\{i, j\}$ of K, we associate three positive integers d_{ij}, g_{ij} and d_{ji} where g_{ij} (the gonality) is equal to half the girth of the incidence graph of a residue Γ_F of type $\{i, j\}$, and d_{ij} (resp. d_{ji}), the *i–diameter* (resp. *j–diameter*) is the greatest distance from some fixed i–element (resp. j–element) to any other element in Γ_F.

On a picture of the diagram, this structure will often be depicted as follows.

```
i  d_ij  g_ij  d_ji  j
O--------------------O
s_i-1              s_j-1
n_i                  n_j
```

Moreover, when $g_{ij} = d_{ij} = d_{ji} = n \neq 2$, we only write g_{ij} and if $n = 2$, we do not draw the edge $\{i, j\}$.

`Diagram(D)`

`Diagram(C)`

Given a firm, residually connected and flag–transitive incidence geometry D or a coset geometry C, return a complete graph K whose vertices and edges are labelled in the following way. Every vertex i of K is labelled with a sequence of two positive integers, the first one being s_i and the second one being the number of elements of type i in D. Every edge $\{i, j\}$ is labelled with a sequence of three positive integers which are respectively d_{ij}, g_{ij} and d_{ji}.

Observe that both these functions do the same but the second one works much faster than the first one since it uses groups to compute the parameters of the diagram. So when the user has to compute the diagram of an incidence geometry, it is strongly advised that he first converts it into a coset geometry and then computes the diagram of the corresponding coset geometry.

Example H142E9

Back to the Petersen graph : let us now explore a little more the first incidence geometry we constructed. Suppose that *ig* is the rank two incidence geometry corresponding to the Petersen graph. We may test whether it is firm, residually connected and flag–transitive.

```
> IsFirm(ig);
true
> IsRC(ig);
true
> IsFTGeometry(ig);
true
```

Since it satisfies these three properties, we can compute its diagram.

```
> d, v, e := Diagram(ig);
> d;
Graph
Vertex  Neighbours
1       2 ;
2       1 ;
> for x in v do print x, Label(x);end for;
1 [ 1, 10 ]
2 [ 2, 15 ]
> for x in e do print x, Label(x);end for;
{1, 2} [ 5, 5, 6 ]
```

We thus see that the diagram of *ig* can be drawn as follows.

```
1      5  5  6      2
0-------------------0
1                   2
10                 15
```

Example H142E10

Back to the cube: let *ig* be the rank three incidence geometry of the cube as constructed above and compute its diagram.

```
> cube := IncidenceGeometry(g);
> d, v, e := Diagram(cube);
> d;
Graph
Vertex  Neighbours
1       2 3 ;
2       1 3 ;
3       1 2 ;
> for x in v do x, Label(x); end for;
1 [ 1, 8 ]
2 [ 1, 12 ]
3 [ 1, 6 ]
```

```
> for x in e do x, Label(x); end for;
{1, 2} [ 4, 4, 4 ]
{1, 3} [ 2, 2, 2 ]
{2, 3} [ 3, 3, 3 ]
```

So the diagram can be depicted as follows.

```
1         4         2         3         3
0-------------------0-------------------0
1                   1                   1
8                  12                   6
```

Example H142E11

Back to the Hoffman-Singleton graph:

```
> ig := IncidenceGeometry(HoffmanSingletonGraph());
> d, v, e := Diagram(ig); d;
Graph
Vertex  Neighbours
1       2 ;
2       1 ;
> for x in v do print x, Label(x); end for;
1 [ 1, 50 ]
2 [ 6, 175 ]
> for x in e do print x, Label(x); end for;
{1, 2} [ 5, 5, 6 ]
```

So the diagram can be depicted as follows.

```
1      5  5  6      2
0-------------------0
1                   6
50                175
```

Example H142E12

Back to Neumaier's geometry : let *ig* be the rank four incidence geometry of Neumaier, as described above and compute its diagram.

```
>  d, v, e := Diagram(neumaier);
>  d;
Graph
Vertex  Neighbours
1       2 3 4 ;
2       1 3 4 ;
3       1 2 4 ;
4       1 2 3 ;
>  for x in v do print x, Label(x); end for;
1 [ 2, 50 ]
```

```
2 [ 2, 50 ]
3 [ 2, 50 ]
4 [ 2, 50 ]
>  for x in e do print x, Label(x); end for;
{1, 2} [ 4, 4, 4 ]
{1, 3} [ 2, 2, 2 ]
{1, 4} [ 3, 3, 3 ]
{2, 3} [ 3, 3, 3 ]
{2, 4} [ 2, 2, 2 ]
{3, 4} [ 4, 4, 4 ]
```

So the diagram can be depicted as follows.

143 CONVEX POLYTOPES AND POLYHEDRA

Chapter 143
CONVEX POLYTOPES AND POLYHEDRA

143.1 Introduction and First Examples

This is a package with tools to build and analyse finite-dimensional, finitely-generated, rational polyhedra. In general a polyhedron is the Minkowski sum of a rational polytope (the compact, convex hull of finitely many rational points) and a cone (the convex hull of finitely many rational half-lines emanating from the origin).

It is important to note that we are discussing only *rational* polyhedra: their vertices lie in in some finite-dimensional rational vector space $L = \mathbf{Q}^n$ with the supporting hyperplanes represented in its dual (loosely speaking, all faces have rational gradients). There is a natural lattice in this setup: the integral sublattice $\mathbf{Z}^n$ of L. This is a lattice only in the sense of being a $\mathbf{Z}$-module; it does not come with a preferred definite quadratic form (or norm), and so, in particular, lengths of vectors are not defined. (We explain below how volumes are nevertheless defined relative to the integral lattice.) A point of L is called 'integral' if it lies in the integral sublattice, but there is no requirement that vertices of polyhedra be integral. Notwithstanding all these remarks, we refer to such ambient spaces L as 'lattices'.

This chapter is organised so that functions applying to compact polyhedra, namely polytopes, are collected together in coherent blocks as much as possible. Section 143.2 lists various ways of constructing polytopes, cones and polyhedra, including Minkowski sum and other arithmetical and set-theoretical operations. Section 117.10.2 presents the basic combinatorics associated to all polyhedra such as recovering their vertices or faces. The next section, Section 117.10.2, is dedicated to polytopes. Most of the functions described here rely on compactness; they include enumeration of points and triangulation. Then Section 117.10.2 details functions that apply to polyhedra more generally, although this includes some functions that apply to cones in particular: computing the integral generators of $C \cap \mathbf{Z}^n$ as a semigroup, for example, where C is a cone in L. Finally, there is section outlining the functions that operate on the ambient lattices. These functions are not usually required, since for the most part the ambient space is a book-keeping device that the package handles automatically, but they arise as domains and codomains of maps. This provides a mechanism for modifying the integral sublattice, which can be used to change the underlying notion of which points count as integral.

Before starting, we outline the capabilities of the package by extended examples. The first illustrates the basic machinery available for the analysis of polytopes—that is, the compact convex hulls of finitely many points.

Example H143E1

A polytope can be constructed as the convex hull of finitely many points; the points can be denoted simply as sequences of integers (or even rational numbers), although they will be cast as

points of an ambient lattice (that is, a $\mathbf{Q}$-vector space marked with a spanning lattice $\mathbf{Z}^n$). For example, we build a polytope P as the convex hull of the four points $(1,0,0)$, $(0,1,0)$, $(1,-3,5)$ and $(-2,2,-5)$.

```
> P := Polytope([ [0,0,0], [1,0,0], [0,1,0], [1,-3,5], [-2,2,-5] ]);
> P;
3-dimensional polytope P with 5 generators:
    ( 0,  0,  0),
    ( 1,  0,  0),
    ( 0,  1,  0),
    ( 1, -3,  5),
    (-2,  2, -5)
```

No analysis of P has been carried out in its construction. In fact, one of its defining 'generators' is not required, as can be seen from the vertices of P (which after this calculation will set as the default printing information).

```
> Vertices(P);
[
    (1, 0, 0),
    (0, 1, 0),
    (1, -3, 5),
    (-2, 2, -5)
]
> P;
3-dimensional polytope P with 4 vertices:
    ( 1,  0,  0),
    ( 0,  1,  0),
    ( 1, -3,  5),
    (-2,  2, -5)
```

One can extract the combinatorial components of P. Here we recover the facets of P, its faces of codimension 1, each of which is regarded as a polytope in its own right.

```
> Facets(P);
[
    2-dimensional polytope with 3 vertices:
        ( 1, -3,  5),
        (-2,  2, -5),
        ( 0,  1,  0),
    2-dimensional polytope with 3 vertices:
        ( 1, -3,  5),
        (-2,  2, -5),
        ( 1,  0,  0),
    2-dimensional polytope with 3 vertices:
        (1, -3,  5),
        (0,  1,  0),
        (1,  0,  0),
    2-dimensional polytope with 3 vertices:
        (-2,  2, -5),
```

```
        ( 0,  1,  0),
        ( 1,  0,  0)
]
```

Computing the (integral) points contained in a polytope (including points on its boundary) is one of the principal operations for polytopes.

```
> Points(P);
[
    (-2, 2, -5),
    (0, 0, 0),
    (0, 1, 0),
    (1, -3, 5),
    (1, 0, 0)
]
```

The interior points or boundary points can be retrieved separately using `InteriorPoints(P)` and `BoundaryPoint(P)`.
One can also compute the volume of a polytope.

```
> Volume(P);
20
```

The volume is the lattice-normalised volume: $\mathrm{Vol}(P) = n! \times \mathrm{vol}(P)$, where $\mathrm{vol}(P)$ is the Euclidean volume of P.
The polar, or dual, to P can be computed.

```
> D := Polar(P);
> D;
3-dimensional polytope D with 4 vertices:
    ( 3,  -1, -7/5),
    (-1,   3,  9/5),
    (-1,  -1,  1/5),
    (-1,  -1, -3/5)
```

The polar of P is again a polytope in this case (simply because the origin lies in the strict interior of P), although its vertices need not be integral.
The Ehrhart series,

$$\mathrm{Ehr}(D) = \Sigma_{n \geq 0} \# \left(nD \cap \mathbf{Z}^n \right) t^n,$$

computes the number of points in multiples of a polytope.

```
> EhrhartCoefficients(D,10);
[ 1, 7, 33, 91, 193, 355, 585, 899, 1309, 1827, 2469 ]
```

The (infinite) Ehrhart series can be recovered as a rational function.

```
> E<t> := EhrhartSeries(D);
> E;
(t^7 + 4*t^6 + 15*t^5 + 12*t^4 + 12*t^3 + 15*t^2 + 4*t + 1)/(t^8 - 3*t^7 + 3*t^6
    - t^5 - t^3 + 3*t^2 - 3*t + 1)
```

It is possible to make maps of the underlying lattices and apply them to polyhedra.

```
> L := Ambient(P);
```

```
> K := Quotient(L![1,2,3]);
> K;
2-dimensional toric lattice K = (Z^3) / <1, 2, 3>
> f := LatticeMap(L, K, Matrix(3,2,[1,0,0,1,0,0]));
> Q := Image(f,P);
> Vertices(Q);
[
    (1, 0),
    (0, 1),
    (1, -3),
    (-2, 2)
]
```

In this case the image polytope $Q = f(P)$ is not a simplex. We can triangulate it.

```
> Triangulation(Q);
{
    2-dimensional polytope with 3 vertices:
        (1, 0),
        (1, -3),
        (0, 1)
    2-dimensional polytope with 3 vertices:
        (1, -3),
        (-2, 2),
        (0, 1)
}
```

Our second example illustrates the machinery available for cones and polyhedra more generally.

Example H143E2

A ray is a rational half-line $\mathbf{Q}^+v$ from the origin passing through a point $v \in \mathbf{Q}^n$. A cone is the convex hull of finitely many rays.

```
> C := Cone([[2,2],[1,1/2]]);
> C;
Cone C with 2 generators:
    ( 2,   2),
    ( 1, 1/2)
```

Although any non-zero point on a ray is enough to define it, often the non-zero integral point nearest the origin is preferred. As with polytopes, there is no analysis of a cone C on its construction, but the minimal generators are displayed once some function has forced their calculation.

```
> Rays(C);
[
    (1, 1),
    (2, 1)
]
```

```
> C;
2-dimensional simplicial cone C with 2 minimal generators:
    (1, 1),
    (2, 1)
```

A polyhedron is the Minkowski sum (simply denoted by a plus sign) of a polytope and a cone.

```
> P := StandardSimplex(2);
> P + C;
2-dimensional polyhedron with 2-dimensional finite part with 3
vertices:
    (1, 0),
    (0, 1),
    (0, 0)
and 2-dimensional infinite part given by a cone with 2 minimal
generators:
    (2, 1),
    (1, 1)
```

The polyhedron $P + C$ is now subject to standard combinatorial analysis, such as computing its facets; some of these may be (compact) polytopes, while others may themselves be polyhedra described as the sum of a compact, or finite, part and a cone, or infinite part.

```
> Facets(P + C);
[
    1-dimensional polytope with 2 vertices:
        (1, 0),
        (0, 0),
    1-dimensional polyhedron with 0-dimensional finite part with one
    vertex:
        (0, 1)
    and 1-dimensional infinite part given by a cone with one minimal
    generator:
        (1, 1),
    1-dimensional polytope with 2 vertices:
        (0, 1),
        (0, 0),
    1-dimensional polyhedron with 0-dimensional finite part with one
    vertex:
        (1, 0)
    and 1-dimensional infinite part given by a cone with one minimal
    generator:
        (2, 1)
]
```

143.2 Polytopes, Cones and Polyhedra

A *(rational) polytope* (in a lattice $L = \mathbf{Q}^n$) is the convex hull of finitely many points in L. (The points do not need to be integral points.)

A *cone* C (in a lattice L) is the convex hull of finitely many rays (or zero). Precisely, a *ray* is a half line emanating from the origin, but, as is common, we treat rays synonymously with the first integral lattice point on the ray outside the origin—thus, for example, an intrinsic that returns a ray will actually return an primitive integral point of the ambient lattice. Rays that are the intersection of a linear hyperplane with C are called *extreme rays* of C—these are the corner edges of C. A cone is *regular* if it is generated (as a semigroup in the $\mathbf{Z}$-module $\mathbf{Z}^n \subset L$) by its extreme rays (in other words, by the integral vectors on its extreme rays).

Combining all concepts so far, a *(rational) polyhedron* is the Minkowski sum of a polytope and a cone—the latter is the *tail cone* and is unique; the smallest possible polytope is unique but seems not to be used in the theory. We also use the expressions *compact part* and *infinite part* to indicate the polytope and the cone used to define a polyhedron.

143.2.1 Polytopes

`Polytope(Q)`

The polytope defined by taking the convex hull of the sequence of points Q, where the points can be specified as sequences of integers of rational numbers (of some fixed length) or as points of a common lattice.

`RandomPolytope(L,n,k)`

`RandomPolytope(d,n,k)`

A polytope in the toric lattice L (or a toric lattice of dimension d) generated by n random integral points with coefficients of modulus at most the non-negative integer k.

`Polar(P)`

The polar dual polyhedron to the polyhedron P, namely

$$P^\star = \{u \in L^\vee \mid u \cdot v \geq -1 \ \forall v \in P\}\,.$$

`CrossPolytope(L)`

`CrossPolytope(d)`

The maximum dimensional cross-polytope in the lattice L, or of dimension d for an integer d.

`StandardSimplex(L)`

`StandardSimplex(d)`

The simplex given by the standard basis and the origin of the lattice L, or the d-dimensional simplex given by the standard basis and the origin for an integer d.

`CyclicPolytope(L,n)`

`CyclicPolytope(d,n)`

The cyclic polytope generated by n points in the lattice L, or by n points in d-dimensional space for an integer d.

143.2.2 Cones

Cones in lattices are of type `TorCon`.

`Cone(A)`

The cone in a lattice generated by a sequence A of its elements (or simply of sequences of integer or rational coefficients).

`Cone(v)`

The cone in a lattice generated by a single element v of that lattice; namely the single ray $\mathbf{Q}^+ v$.

`ConeWithInequalities(B)`

The cone in a lattice L defined by the set B of elements of the dual lattice $L^\vee$ (or simply by a set of sequences of integer or rational coefficients). The cone is the intersection of half-spaces $v \cdot u \geq 0$ as v runs through B:

$$\bigcap_{v \in B} \{u \in L \mid v \cdot u \geq 0\}\,.$$

`FullCone(L)`

`FullCone(n)`

The cone which is the entire lattice L, or the lattice of dimension n for a positive integer n.

`PositiveQuadrant(L)`

`PositiveQuadrant(n)`

The cone in the lattice L generated by the standard basis vectors of L, or that of the lattice of dimension n for a positive integer n.

`ZeroCone(L)`

`ZeroCone(n)`

The cone which consists of only the origin of the lattice L, or of the lattice of dimension n for a positive integer n.

`Dual(C)`

The dual cone to the cone C, namely

$$C^\vee = \{u \in L^\vee \mid v \cdot u \geq 0 \text{ for all } v \in C\}\,.$$

where C lies in the lattice L.

`NormalisedCone(P)`

A cone C such that the polyhedron P is the intersection of C with a hyperplane at height one, together with the embedding of the ambient lattice of P into the ambient lattice of C.

`ConeInSublattice(C)`

The cone of maximal dimension given by the intersection of the cone C with its linear span. Also gives the embedding of the sublattice in the ambient toric lattice.

`ConeQuotientByLinearSubspace(C)`

The strictly convex cone given by the quotient of the cone C by its maximal linear subspace. Also gives the quotient map.

143.2.3 Polyhedra

Polytopes and polyhedra in lattices are of type `TorPol`.

`Polyhedron(C,H,h)`

`Polyhedron(C,H,h)`

The polyhedron constructed as the slice of the cone C by the hyperplane determined by the primitive dual vector H at height given by the integer or rational number h.

`Polyhedron(C)`

`level` RngIntElt *Default :* 1

The polyhedron arising as the intersection of the cone C with the hyperplane at height one (can be changed via 'level').

`HalfspaceToPolyhedron(v,h)`

`HalfspaceToPolyhedron(Q,h)`

The halfspace $\{u|v \cdot u \geq h\}$ as a polyhedron, where v is a point of a toric lattice (or a sequence of integral or rational numbers that are its coefficients) and $h \in \mathbf{Q}$.

`HyperplaneToPolyhedron(v,h)`

`HyperplaneToPolyhedron(Q,h)`

The hyperplane $\{u|v \cdot u = h\}$ as a polyhedron, where v is a point of a toric lattice (or a sequence of integral or rational numbers that are its coefficients) and $h \in \mathbf{Q}$.

`Polyhedron(C,f,v)`

The polyhedron arising as the preimage of the cone C under the affine map $f + v$.

`EmptyPolyhedron(L)`

The empty polyhedron in the toric lattice L.

`ConeToPolyhedron(C)`

The cone C as a polyhedron.

`PolyhedronInSublattice(P)`

The polyhedron of maximal dimension given by the intersection of the toric lattice containing the polyhedron P with an affine sublattice of dimension equal to the dimension of P. Also gives the affine embedding as a lattice embedding and translation.

`FixedSubspaceToPolyhedron(G)`

`FixedSubspaceToPolyhedron(L,G)`

The subspace (realised as a polyhedron) fixed by the action of the matrix group G on the toric lattice L. G should be a subgroup of either $GL(n, \mathbf{Z})$ or of $SL(n, \mathbf{Z})$, where n is the dimension of L.

Example H143E3

We construct some polyhedra by taking slices of the positive quadrant in 3-space.

```
> C := PositiveQuadrant(3);
> C;
3-dimensional simplicial cone C with 3 minimal generators:
    (1, 0, 0),
    (0, 1, 0),
    (0, 0, 1)
```

We slice using dual vectors, so we recover the dual lattice M to the ambient lattice of C. Some slices are compact, some are not.

```
> M := Dual(Ambient(C));
> P := Polyhedron(C, M ! [1,2,3], 1);
> IsPolytope(P);
true
> Q := Polyhedron(C, M ! [1,-2,3], 1 );
> IsPolytope(Q);
false
> Q;
2-dimensional polyhedron Q with 1-dimensional finite part with 2 vertices:
    ( 1,   -1),
    ( 0, -1/3)
and 2-dimensional infinite part given by a cone with 2 minimal generators:
```

```
    ( 2,   -1),
    ( 0,    1)
```

We can change the level, or height, at which the slice is taken.

```
> R := Polyhedron(C, M ! [1,2,3], -5);
> R;
Empty polyhedron
```

143.2.4 Arithmetic Operations on Polyhedra

`C eq D`

Return `true` if and only if the cones C and D are equal, that is, they lie in the same toric lattice and have identical supports.

`P eq Q`

Return `true` if and only if the polyhedra P and Q are equal, that is, they lie in the same toric lattice and have identical supports.

`C meet D`

The intersection of the cones C and D; the cones must lie in the same toric lattice otherwise an error is reported.

`P meet Q`

The intersection of the polyhedra P and Q; the polyhedra must lie in the same toric lattice otherwise an error is reported.

`P subset Q`

Return `true` if and only if the support of the polyhedron P is contained in that of the polyhedron Q; the polyhedra must lie in the same toric lattice otherwise an error is reported.

`C + D`
`P + Q`

The Minkowski sum of the cones C and D or of the polyhedra P and Q.

`P + C`
`C + P`

The polyhedron constructed as the Minkowski sum of the polytope P and the cone C.

`P * Q`

The convex hull of the Cartesian product of the polyhedra P and Q.

`k * P`

The dilation of the polyhedron P by the rational number k.

`-P`

The negation of the polyhedron P.

143.3 Basic Combinatorics of Polytopes and Polyhedra

Cones, polytopes and polyhedra have similar combinatorial features: they are composed of faces of various dimensions that meet in faces of lower dimensions. Some functions apply to all of these geometrical objects, some do not.

A face of a cone C is the intersection of C with an affine hyperplane whose defining equation is non-negative on C. A facet of a cone C is a codimension 1 face of C. Defintions for polytopes and polyhedra are similar.

143.3.1 Vertices and Inequalities

`Vertices(P)`

A sequence containing the vertices of the polyhedron P.

`NumberOfVertices(P)`

The number of vertices of the polyhedron P.

`Rays(C)`

The sequence of generators of the rays of the cone C (returned as primitive lattice points). If C is strictly convex, this is the same as the minimal **R**-generators.

`Ray(C,i)`

The ith ray of the of the cone C (in the order returned by `Rays(C)`).

`LinearSpanEquations(C)`

`LinearSpanEquations(Q)`

A sequence of equations defining the minimal linear subspace containing the cone C (or the sequence of toric lattice points Q).

`LinearSpanGenerators(C)`

`LinearSpanGenerators(Q)`

A sequence of generators of the minimal linear subspace containing the cone C (or the sequence of toric lattice points Q).

`LinearSubspaceGenerators(C)`

A basis of the maximal linear subspace contained in the cone C.

Inequalities(C)

Inequalities(P)

MinimalInequalities(C)

If the cone C or polyhedron P lies in a toric lattice L, then return a finite sequence of vectors in the dual lattice $\check{L}$ which define supporting hyperplanes of C or P. The list is forced to be minimal for `MinimalInequalities`, but might not be otherwise. If the argument is a polyhedron, then an integer k is returned as a second return value, so that the first k inequalities correspond to the facets of P while the remaining cut out the subspace containing P.

Example H143E4

Build a polytope and recover the inequalities that define it: the second return value, 3, says that all three inequalities define facets of P—we see an example below where this is not the case.

```
> P := Polytope([[1,0],[0,1],[-1,-1]]);
> Inequalities(P);
[
    <(2, -1), -1>,
    <(-1, -1), -1>,
    <(-1, 2), -1>
]
3
```

For each inequality use `HalfspaceToPolyhedron(m,h)` to define the corresponding halfspace, and then intersect them all to recover P—and finally recover the vertices we started with.

```
> PP := &meet  [HalfspaceToPolyhedron(H[1],H[2]) : H in Inequalities(P)];
> PP eq P;
true
> PP;
2-dimensional polytope PP with 3 vertices:
    ( 0,  1),
    (-1, -1),
    ( 1,  0)
```

It can happen that a polytope does not span the ambient toric lattice in which it lies and that some of the inequalities are used to cut out the affine subspace that it does span.

```
> Q := Polytope([[1,0,2],[0,1,2],[-1,0,2],[0,-1,2]]);
> Inequalities(Q);
[
    <(1, -1, 0), -1>,
    <(-1, -1, 0), -1>,
    <(-1, 1, 0), -1>,
    <(1, 1, 0), -1>,
    <(0, 0, 1), 2>,
    <(0, 0, -1), -2>
```

```
]
4
```

In this case the final two inequalities are opposites of one another and cut out the affine hyperplane $z = 2$. The second return value 4 indicates that the first 4 inequalities are cutting out facets of the polytope while the remaining inequalities are cutting out the affine hyperplane.

143.3.2 Facets and Faces

`#fVector(C)`
`fVector(P)`

The f-vector of the polyhedron P or cone C.

`#hVector(C)`
`#hVector(P)`

The h-vector of the polyhedron P or cone C.

`Facets(C)`
`Facets(P)`

A sequence containing all facets of the toric cone C or polyhedron P.

`FacetIndices(P)`

A sequence of sets describing the facets of the polytope P. The jth set gives the indices of the vertices of P which define the jth facet of P.

`NumberOfFacets(P)`

The number of facets of the polyhedron P.

`Faces(C)`
`Faces(P)`
`Faces(C,i)`
`Faces(P,i)`

A sequence containing all face cones of the toric cone C or polyhedron P, or only those of dimension i if an integer i is also specified.

`FaceIndices(P,i)`

A sequence of sets describing the i-dimensional faces of the polyhedron P. The jth set gives the indices of the vertices of P which define the jth i-dimensional face.

`Edges(P)`

A sequence containing all the edges of the polyhedron P.

`EdgeIndices(P)`

A sequence of sets describing the edges of the polhedron P. The jth set gives the indices of the vertices of P which define the jth edge of P.

`Graph(P)`

The graph of the face lattice of the polyhedron P. The vertices of the graph are labeled by the dimension of the corresponding face.

`FaceSupportedBy(C,H)`

The face of the toric cone C supported by the toric lattice element H in the dual lattice to the one containing C (so H is a linear form on the ambient lattice of C).

`IsSupportingHyperplane(v,h,P)`

Return `true` if and only if the hyperplane defined by $v \cdot u = h$ is a supporting hyperplane of the polyhedron P, where v is a lattice point of the dual ambient lattice of P and h is a rational number. If so, also gives the sign τ such the hyperplane is a support of P (i.e. τ in $\{-1, 0, +1\}$ such that $\text{Sign}(v \cdot u - h)$ is either 0 or τ for all u in P). If P is contained within the hyperplane, then τ will be 0.

`SupportingCone(P,v)`

The cone C such that $C + v$ is a supporting cone of the polyhedron P, where v is a vertex of P.

143.4 The Combinatorics of Polytopes

143.4.1 Points in Polytopes

Given a polygon, one might want to know how many integral points it contains, and one might want to list them. These are computed by different algorithms (although one can of course list the points and then count them). For point counting we use the methods of Barvinok and Pommersheim ([BP99]), as described in [DLHTY04]. More generally, one might want to know the number of points in integral dilations of a polytope: these numbers are the coefficients of a generating function, the Ehrhart series; this is discussed in a later section.

`Points(P)`

`InteriorPoints(P)`

`BoundaryPoints(P)`

The integral toric lattice points, the strictly interior lattice points, or the boundary lattice points of the polytope P.

`NumberOfPoints(P)`

The number of integral toric lattice points of the polytope P.

143.4.2 Ehrhart Theory of Polytopes

`EhrhartSeries(P)`

The rational generating function of the Ehrhart series for the polytope P.

`EhrhartPolynomial(P)`

A sequence representing the Ehrhart (quasi-)polynomial for the polytope P. That is, a sequence of polynomials $[p_0, \ldots, p_{r-1}]$ of length r, the quasi-period of the Ehrhart polynomial, so that the number of lattice points of the dilation nP is the value of $p_s(k)$ where $n = kr + s$ is the Euclidean division of n by r; in other words, s is the least residue of n modulo r. Note that since MAGMA indexes sequences from 1, we have that $p_i =$ `EhrhartPolynomial(P)[i+1]`.

`EhrhartCoefficients(P,l)`

The first $l + 1$ coefficients of the Ehrhart series for the polytope P (starting with $0P$ up to and including lP).

`EhrhartCoefficient(P,k)`

The number of lattice points in the (non-negative, integral) dilation kP of the polytope P.

143.4.3 Automorphisms of a Polytope

`AutomorphismGroup(P)`

The subgroup of $GL(n, \mathbf{Z})$ (acting on the ambient lattice) which leaves the polyhedron P unchanged.

Example H143E5

```
> P:=CrossPolytope(2);
> P;
2-dimensional polytope P with 4 vertices:
    ( 1,  0),
    ( 0,  1),
    (-1,  0),
    ( 0, -1)
> AutomorphismGroup(P);
MatrixGroup(2, Integer Ring)
Generators:
    [0 1]
    [1 0]
    [ 0  1]
    [-1  0]
```

143.4.4 Operations on Polytopes

`Triangulation(P)`

A sequence of polytopes that make a triangulation of the polytope P.

`TriangulationOfBoundary(P)`

A sequence of polytopes that make a triangulation of the boundary of the polytope P.

143.5 Cones and Polyhedra

143.5.1 Generators of Cones

`ZGenerators(C)`

`level` RngIntElt *Default : infinity*

If C lies in a toric lattice L, then return a finite sequence of elements of L that generate C as a monoid. If specified, the parameter `level` restricts the search for generators to that given level; this assumes that C is graded.

`RGenerators(C)`

`MinimalRGenerators(C)`

If C lies in a toric lattice L, then return a finite sequence of elements of L that generate C over $\mathbf{Q}_+$. The list is forced to be minimal for `MinimalRGenerators`, but might not be otherwise.

`Points(C,H,h)`

The set of integral lattice points in the cone C contained in the hyperplane given by the section determined by the dual lattice element H at height given by the rational number h. The intersection of H with C is required to be compact.

Example H143E6

Here we find the generators of a cone in the sublattice spanned by its defining lattice points. First build some points in a toric lattice and make the cone they generate.

```
> L := ToricLattice(4);
> B := [ L | [1,2,3,-3], [-1,0,1,0], [1,2,1,-2], [2,0,0,-1], [0,0,2,-1] ];
> L1,f := Sublattice(B);
> Dimension(L1);
3
> C := Cone(B);
> Points(Polytope(B));
{
    (1, 2, 1, -2),
    (2, 0, 0, -1),
```

```
    (-1, 0, 1, 0),
    (1, 2, 3, -3),
    (1, 0, 1, -1),
    (0, 0, 2, -1),
    (0, 1, 1, -1),
    (1, 1, 2, -2)
}
> ZGenerators(C);
[
    (-1, 0, 1, 0),
    (0, 1, 1, -1),
    (1, 2, 1, -2),
    (2, 0, 0, -1)
]
```

Using the embedding map f, pull the cone back to the lattice span of C.

```
> C1 := C @@ f;
```

In the smaller lattice, this cone is nonsingular.

```
> IsNonsingular(C1);
true
```

We can find out which points generate the cone in the smaller lattice and compare them with the generators of the original cone.

```
> B1 := ZGenerators(C1);
> B1;
[
    (-1, 0, 1),
    (1, 1, 0),
    (2, 0, -1)
]
> [ Index(B,Image(f,b)) : b in B1 ];
[ 2, 3, 4 ]
```

143.5.2 Properties of Polyhedra

`CompactPart(P)`

The polytope defined by taking the convex hull of the vertices of the polyhedron P. This is the smallest polytope which can occur as a factor in an expression of P as the Minkowski sum of a polytope and a cone.

`IntegralPart(P)`

The polyhedron defined by taking the convex hull of the integral points contained in the polyhedron P.

`InfinitePart(P)`

The tail cone of the polyhedron P.

`IsEmpty(P)`

Return `true` if and only if the polyhedron P is empty.

Example H143E7

One can build a polytope as the convex hull of a finite sequence of points—these may be elements of a toric lattice or simply sequences of integer or rational coefficients.

```
> P := Polytope([[-4,2,1],[0,3,4],[3,1,-3],[3,0,0],[2,-1,1]]);
```

The polar polyhedron comprises dual vectors that evaluate to at least -1 on P. It is compact if and only if the origin lies in the interior of P.

```
> D := Polar(P);
> D;
3-dimensional polyhedron D with 3-dimensional finite part with 5 vertices:
    ( 1/2,      1,    -1),
    (-1/3,    1/2,   1/6),
    (-1/3,   1/21,  -2/7),
    (-1/3,  -3/13, -1/13),
    (1/67, -37/67, 11/67)
and 3-dimensional infinite part given by a cone with 3 minimal generators:
    (   1,      2,     0),
    (   2,      9,     5),
    (   7,      9,    10)
```

Since D is infinite, there is no intrinsic to list its integral points, but one can determine whether it contains integral points at all.

```
> HasIntegralPoint(D);
true
```

Computing the span of all the integral points of D is possible.

```
> IntegralPart(D);
3-dimensional polyhedron with 3-dimensional finite part with 6 vertices:
    (0,  0,  0),
    (0,  1,  0),
    (0,  2,  1),
    (1,  1,  1),
    (1,  2, -1),
    (2,  2,  3)
and 3-dimensional infinite part given by a cone with 3 minimal generators:
    (1,  2,  0),
    (2,  9,  5),
    (7,  9, 10)
```

The compact and infinite parts of D can be recovered.

```
> cD := CompactPart(D);
```

```
> cD;
3-dimensional polytope cD with 5 vertices:
    ( 1/2,      1,    -1),
    (-1/3,    1/2,   1/6),
    (-1/3,   1/21,  -2/7),
    (-1/3,  -3/13, -1/13),
    (1/67, -37/67, 11/67)
```

Polytopes are special cases of polyhedra (those whose infinite tail cone is the zero cone, or equivalently those that are compact), and the distinction can be determined.

```
> IsPolytope(cD);
true
> IsPolytope(D);
false
```

Example H143E8

```
> C:=Cone([[0,1,0],[0,1,1],[1,1,2],[1,1,4]]);
> P:=Polyhedron(C);
> P;
2-dimensional polyhedron P with 1-dimensional finite part with 2
vertices:
    (1, 2),
    (1, 4)
and 2-dimensional infinite part given by a cone with 2 minimal
generators:
    (1, 0),
    (1, 1)

> CC:=Cone([[1,0],[1,1]]);
> QQ:=Polytope([[1,2],[1,4]]);
> PP:=CC + QQ;
> PP;
2-dimensional polyhedron PP with 1-dimensional finite part with 2
vertices:
    (1, 2),
    (1, 4)
and 2-dimensional infinite part given by a cone with 2 minimal
generators:
    (1, 0),
    (1, 1)
```

But there's a potential catch.

```
> PP eq P;
false
> Ambient(PP);
2-dimensional toric lattice Z^2
```

```
> Ambient(P);
2-dimensional toric lattice ker <1, 0, 0>
> P:=ChangeAmbient(P,Ambient(PP));
> PP eq P;
true
```

The ambients are different simply because of the method of construction of the two polyhedra, but they can be forced into the same space.

`IsMaximalDimension(C)`
`IsMaximalDimension(P)`

Return `true` if and only if the cone C or polyhedron P has dimension equal to that of its ambient lattice.

`IsStrictlyConvex(C)`

Return `true` if and only if the cone C is strictly convex; that is, if there exists a hyperplane H such that C is contained on one side of H and C meets H in single point 0.

`IsSimplicial(C)`
`IsSimplicial(P)`

Return `true` if and only if the cone C or the polyhedron P is simplicial.

`IsSimplex(P)`

Return `true` if and only if the polyhedron P is a simplex.

`IsSimple(P)`

Return `true` if and only if the polyhedron P is simple.

`IsAffineLinear(P)`

Return `true` if and only if the polyhedron P is an affine linear space.

`IsZero(C)`

Return `true` if and only if the cone C is supported at the origin of its ambient toric lattice.

143.5.3 Attributes of Polyhedra

`Dimension(C)`
`Dimension(P)`

The dimension of the toric cone C or polyhedron P.

`Index(C)`

The index of the sublattice generated by the minimal $\mathbf{R}$-generators of the cone C in its linear span.

`IsShellable(P)`

Return `true` if and only if the integral polytope P is shellable; i.e. if there exists a polytope S such that each lattice point $u \in P$ lies on the boundary of $v + i * (S - v)$ for some $0 \leq i \leq k$, where v is the barycentre of the vertices of P. If `true`, also returns S, v, and k.

143.5.4 Combinatorics of Polyhedral Complexes

`Ambient(C)`
`Ambient(P)`

The ambient toric lattice of the toric cone C or polyhedron P.

`ChangeAmbient(C,L)`
`ChangeAmbient(P,L)`

Make a cone or polyhedron identical to the toric cone C or polyhedron P but lying in the toric lattice L; the identification of the existing ambient toric lattice with L is simply by identification of the two standard bases and it requires the dimensions of the two spaces to be equal.

143.6 Toric Lattices

One often begins to study toric geometry by considering a 'lattice' $L = \mathbf{Z}^n$ and discussing polygons or cones in its overlying rational (or real) vector space $L_{\mathbf{Q}} = L \otimes \mathbf{Q}$ whose vertices lie on L; these are examples of so-called 'lattice polytopes'. Anybody who has given a seminar on toric geometry will know the constant frustration of distinguishing between L and $L_{\mathbf{Q}}$ (or worse, a bit later in the story, the duals of these). In MAGMA, we bind these two spaces together in a single object, a *toric lattice*. These spaces lie underneath all the combinatorics. It is not often necessary to be explicit about them, since the package handles them invisibly in the background, but they are useful for the usual parent and data typing purposes: when one creates an empty sequence intended to house elements of a toric lattice, it should be properly typed from the outset, for instance. Toric lattices created as duals record that relationship.

Toric lattices are of type `TorLat` and their elements are of type `TorLatElt`.

143.6.1 Toric Lattices

A toric lattice is a finite-dimensional rational vector space with a distinguished free **Z**-module L that spans it: it is the pair $L \otimes \mathbf{Q} \supset L$ where $L \cong \mathbf{Z}^n$. We usually refer to the toric lattice as L, and although the feeling of using L is that it is simply the given **Z**-module, the covering vector space allows fluent working with non-integral points of L.

`ToricLattice(n)`

Create an n-dimensional toric lattice $\mathbf{Q}^n \supset \mathbf{Z}^n$. The integer n must be non-negative.

`ScalarLattice()`

The unique one-dimensional toric lattice of scalars $\mathbf{Q} \supset \mathbf{Z}$.

Example H143E9

A properly typed sequence of points of a toric lattice can be summed with the usual convention.

```
> L := ToricLattice(3);
> nopoints := [ L | ];
> &+ nopoints;
(0, 0, 0)
```

A toric lattice is really a vector space marked with a finitely-generated **Z**-module that spans it. In particular, its points may well have rational coefficients, although those with integral coefficients are distinguished.

```
> somepoints := [ L | [1/2,2/3,3/4], [1,2,3] ];
> [ IsIntegral(v) : v in somepoints ];
[ false, true ]
```

`Dual(L)`

The dual lattice of the toric lattice L.

Example H143E10

The dual of a toric lattice is also a toric lattice: integrality of dual points is clear.

```
> L := ToricLattice(2);
> L;
2-dimensional toric lattice L = Z^2
> M := Dual(L);
> M;
2-dimensional toric lattice M = (Z^2)^*
```

MAGMA's default printing for toric lattices tries to help keep track of which lattice is which—this becomes more useful when working with toric varieties. The relationship between L and M is preserved, and double-dual returns L.

```
> M eq L;
false
```

```
> L eq Dual(M);
true
```

`L + M`

`DirectSum(L,M)`

`DirectSum(Q)`

The direct sum of the two toric lattices L and M. The following natural maps are also returned: the embedding of L into the sum, the embedding of M, the projection of the sum onto L, and the projection onto M.

The argument can also be a sequence Q of toric lattices. In this case, there are three return values: the direct sum of all lattices in Q, a sequence of inclusion maps of lattices in Q into the sum, and a sequence of projection maps from the sum onto each of the elements of Q in turn.

`L ^ n`

The direct sum of the toric lattice L with itself n times. Also return are a sequence of injections of L as factors into the sum and a sequence of projections of the sum onto its factors. This is identical to `DirectSum([L,L,...,L])` where the sequence has length n.

`Dimension(L)`

The dimension of the toric lattice L.

143.6.2 Points of Toric Lattices

Points of L are interpreted to mean points of $L \otimes \mathbf{Q}$. If the coefficients of a point are in fact integral, then this is recognised: so it is possible to tell whether a point is in fact a point of L, not just the rational span.

The usual rational vector space arithmetic operates on these lattice points.

`L ! [a,b,...]`

`LatticeVector(L,Q)`

`LatticeVector(Q)`

The point $(a, b, \ldots)$ as an element of the toric lattice L, where $Q = [a, b, \ldots]$ is a sequence of rational numbers or integers. (If the toric lattice L is omitted, then it will be created.)

`L . i`

`Basis(L,i)`

The ith standard basis element of the toric lattice L.

`Basis(L)`

The standard basis element of the toric lattice L as a sequence of points of L.

`Form(L,Q)`

The point $(a, b, \ldots)$ as an element of the dual of the toric lattice L, where $Q = [a, b, \ldots]$ is a sequence of rational numbers or integers.

`Zero(L)`

The zero vector in the toric lattice L.

`P + Q`
`P - Q`
`n * P`
`P / n`

The sum and difference of toric lattice points P and Q (or points of the dual), the rational multiple nP and quotient P/n, where $n \in \mathbf{Q}$.

`P eq Q`

Return `true` if and only if the toric lattice points P and Q are the same point of the same lattice.

`AreProportional(P,Q)`

Return `true` if and only if the toric lattice points P and Q are rational multiples of one another; the factor Q/P is returned in that case.

`P / Q`

The rational factor P/Q in the case that the toric lattice points P and Q are rational multiples of one another.

Example H143E11

This simple example builds some points in a toric lattice and performs arithmetic on them.

```
> L := ToricLattice(3);
> a := L ! [1,2,3];
> a;
(1, 2, 3)
> L eq Parent(a);
true
> b := L ! [1/2,1,3/2];
> a + b;
(3/2, 3, 9/2)
> a eq b;
false
> a eq 2*b;
true
```

```
> b/a;
1/2
```

`v in L`

Return `true` if and only if the toric lattice point v lies in the toric lattice L.

`IsZero(v)`

Return `true` if and only if the toric lattice point v is the zero vector.

`IsIntegral(v)`

Return `true` if and only if the coefficients of the toric lattice point v are integral.

`IsPrimitive(v)`

Return `true` if and only if the toric lattice point v is a primitive integral vector; that is, v is not divisible as an integral vector in its ambient toric lattice.

`PrimitiveLatticeVector(v)`

The first toric lattice point on the ray spanned by v.

Example H143E12

A point of a sublattice may be primitive in the sublattice even though it is not primitive in the bigger lattice: treating sublattices as the images of embeddings makes this point transparent. First build a sublattice K of L together with the embedding map.

```
> L := ToricLattice(2);
> K,emb := Sublattice([L | [2,0],[0,2]]);
```

Construct a point in L that is clearly not primitive.

```
> vL := L ! [2,2];
> IsPrimitive(vL);
false
```

Pulling this point back to K shows that it is obviously primitive in K.

```
> vK := vL @@ emb;
> vK;
(1, 1)
> IsPrimitive(vK);
true
```

But notice that coercion of the point of L into K is not the same thing: it simply works with the coefficients of the point and gives an answer that is not what is wanted in this case.

```
> K ! vL;
(2, 2)
> IsPrimitive(K ! vL);
false
```

143.6.3 Operations on Toric Lattices

`L eq K`

Return `true` if and only if the toric lattices L and K are the same object in MAGMA (and not merely isomorphic).

`Sublattice(Q)`

A toric lattice L_1 isomorphic to the sublattice of a toric lattice L generated by the sequence Q of elements of L together with an embedding map of L_1 in L. The MAGMA subobject constructor `sub< L | Q >` can also be used, although the sequence Q must be a sequence of elements of L and cannot be interpreted more broadly.

`ToricLattice(Q)`

The toric sublattice of $\mathbf{Q}^n \supset \mathbf{Z}^n$ (regarded as a toric lattice) generated by the sequences of integers of length n of which the sequence Q comprises.

`Quotient(C)`
`Quotient(Q)`
`Quotient(v)`

A toric lattice isomorphic to the toric lattice that is the quotient of a toric lattice L by the linear span of the cone C, or the elements $v \in L$ that comprise the sequence Q or the single primitive vector $v \in L$. The projection map of L to the quotient is also returned.

`AddVectorToLattice(v)`
`AddVectorToLattice(Q)`

A toric lattice L_1 isomorphic to the toric lattice generated by a toric lattice L together with the vector $v \in L$ (or by a sequence of vectors of L). The inclusion map of L in L_1 is also returned.

`IsSublattice(L)`

Return `true` if and only if the toric lattice L was constructed as a sublattice of another toric lattice.

`IsSuperlattice(L)`

Return `true` if and only if the toric lattice L was constructed as a superlattice of another toric lattice (by the addition of a rational vector).

`IsDirectSum(L)`

Return `true` if and only if the toric lattice L was constructed as the direct sum of other toric lattices.

`IsQuotient(L)`

Return `true` if and only if the toric lattice L was constructed as the quotient of another toric lattice.

`Sublattice(L)`

If the toric lattice L was constructed as the extension of a toric lattice K by the addition of a vector, then return K.

`Superlattice(L)`

If the toric lattice L was constructed as a sublattice of a toric lattice K, then return K.

`Summands(L)`

If the toric lattice L was constructed as a direct sum, return a sequence of the toric lattice summands used (and parallel sequences of their embedding maps in L and the projections from L to them).

Example H143E13

Construct a sublattice of a toric lattice L and compute its natural basis in the original coordinates of L; the user does not have control over the choice of coordinates and inclusion map.

```
> L := ToricLattice(2);
> L1,phi1 := Sublattice([L| [1,2],[2,1]]);
> L1;
2-dimensional toric lattice L1 = sub(Z^2)
> phi1(L1.1), phi1(L1.2);
(1, 2)
(0, 3)
```

A similar calculation for a quotient map.

```
> L2,phi2 := Quotient(L ! [3/2,2]);
> L2;
1-dimensional toric lattice L2 = (Z^2) / <3, 4>
> phi2(L.1), phi2(L.2);
(-4)
(3)
```

And again for an extension of L.

```
> L3,phi3 := AddVectorToLattice(L ! [1/5,2/5]);
> L3;
2-dimensional toric lattice L3 = (Z^2) + <1/5, 2/5>
> phi3(L1.1), phi3(L1.2);
(1, 0)
(2, 5)
```

143.6.4 Maps of Toric Lattices

Maps between toric lattices are of type `TorLatMap`. They can be constructed using the `hom< L -> K | M >` constructor, where M is the matrix of the desired linear map with respect to the standard bases of L and K. The usual evaluation operations `@` and `@@` can be applied, although there are image and preimage intrinsics too. Basic arithmetic of maps (sum, difference and scalar multiple, each taken pointwise) is available.

`ZeroMap(L,K)`

The zero map between toric lattices L and K.

`IdentityMap(L)`

The identity map on the toric lattice L.

`hom< L -> K | M >`

`LatticeMap(L,K,M)`

The map between toric lattices L and K determined by the matrix M (with respect to the standard bases of L and M).

`LatticeMap(L,Q)`

The toric lattice map from toric lattice L to the toric lattice M determined by the sequence Q of toric lattice points, where M is the toric lattice containing the points of Q.

`DefiningMatrix(f)`

The defining matrix of the lattice map f.

`Image(f,C)`

`Image(f,P)`

`Image(f,v)`

The image of the cone C or polyhedron P or lattice element v under the toric lattice map f; the type of the object is preserved under the map.

`Preimage(f,C)`

`Preimage(f,P)`

`Preimage(f,v)`

The preimage of the cone C or polyhedron P or lattice element v by the toric lattice map f; the type of the object is preserved.

`KernelEmbedding(f)`

`KernelEmbedding(v)`

The inclusion of the kernel of the toric lattice map f, regarded as a distinct toric lattice, into the domain of f; or the same for the dual subspace annihilated by lattice element v.

`KernelBasis(f)`

`KernelBasis(v)`

A basis for the kernel of the toric lattice map f or the dual of the sublattice annihilated by the lattice element v.

`ImageBasis(f)`

A basis for the image of the toric lattice map f.

`IsCokernelTorsionFree(f)`

Return `true` if and only if the cokernel of the toric lattice map f is torsion free.

COMBINATORICS

144 ENUMERATIVE COMBINATORICS

Chapter 144
ENUMERATIVE COMBINATORICS

144.1 Introduction

This chapter presents some of the tools provided by MAGMA for enumerative combinatorics.

144.2 Combinatorial Functions

`Factorial(n)`

The factorial $n!$ for non-negative small integer n.

`NumberOfPermutations(n, k)`

The number of permutations of n distinct objects taken k at a time.

`Binomial(n, r)`

The binomial coefficient $\binom{n}{r}$.

`Multinomial(n, [r`$_1$`, ... r`$_n$`])`

Given a sequence $Q = [r_1, \ldots, r_k]$ of positive integers such that $n = r_1 + ... + r_k$, return the multinomial coefficient $\binom{n}{r_1,\ldots,r_k}$.

`Fibonacci(n)`

Given an integer n, this function returns the n-th Fibonacci number F_n, which can be defined via the recursion $F_0 = 0$, $F_1 = 1$, $F_n = F_{n-1} + F_{n-2}$ for all integers n. Note that n is allowed to be negative, and that $F_{-n} = (-1)^{n+1}F_n$.

`Catalan(n)`

Given a small non-negative integer n, this function returns the n-th Catalan number C_n, defined via the recursion $C_0 = 1$, $C_{n+1} = C_n \cdot (4n + 2)/(n + 2)$.

`Lucas(n)`

Given an integer n, this function returns the n-th Lucas number L_n, which can be defined via the recursion $L_0 = 2$, $L_1 = 1$, $L_n = L_{n-1} + L_{n-2}$ for all integers n. Note that n is allowed to be negative, and that $L_{-n} = (-1)^n L_n$.

`GeneralizedFibonacciNumber(g0, g1, n)`

The nth member of the generalized Fibonacci sequence defined by $G_0 = g_0$, $G_1 = g_1$, $G_n = G_{n-1} + G_{n-2}$ for all integers n. Note that n is allowed to be negative. The Fibonacci and Lucas numbers are special cases where $(g_0, g_1) = (0, 1)$ or $(2, 1)$ respectively.

`StirlingFirst(n, k)`

The Stirling number of the first type, $[{n \atop k}]$, where n and k are non-negative integers.

`StirlingSecond(n, k)`

The Stirling number of the second type, $\{{n \atop k}\}$, where n and k are non-negative integers.

`Bell(n)`

The nth Bell number, giving the number of partitions of a set of size n. (Not to be confused with `NumberOfPartitions(n)`, which gives the number of partitions of the *integer* n.) This is equal to the sum of `StirlingSecond(n,k)` for k between 0 and n (inclusive).

`EulerianNumber(n, r)`

The number $E(n, r)$ of permutations p of $\{1, \ldots, n\}$ having exactly r ascents (i.e., places where $p_i < p_{i+1}$)

`HarmonicNumber(n)`

The nth harmonic number $H_n = \Sigma_{i=1}^{n} \frac{1}{i}$.

`BernoulliNumber(n)`

Returns the nth Bernoulli number B_n as a rational number.

`BernoulliApproximation(n)`

Returns a real approximation to the nth Bernoulli number B_n.

`BernoulliPolynomial(n)`

The nth Bernoulli polynomial $B_n(x) = \sum_{k=0}^{n} \binom{n}{k} B_k x^{n-k}$ where B_n is the nth Bernoulli number.

144.3 Subsets of a Finite Set

`Subsets(S)`

The set of all subsets of the set S.

`Subsets(S, k)`

The set of subsets of the set S of size k. If k is larger than the cardinality of S then the result will be empty.

`Multisets(S, k)`

The set of multisets consisting of k not necessarily distinct elements of the set S.

`Subsequences(S, k)`

The set of sequences of length k with elements from the set S.

`Permutations(S)`

The set of permutations (stored as sequences) of the elements of the set S.

`Permutations(S, k)`

The set of permutations (stored as sequences) of each of the subsets of the set S of cardinality k.

Example H144E1

The use of Subsets is illustrated in the construction of the Petersen graph as the third Odd Graph. The nth Odd Graph has its vertices in correspondence with the $(n-1)$-element subsets of $\{1 \ldots 2n-1\}$, and an edge between two vertices if and only if their corresponding sets have empty intersection.

```
> V := Subsets( {1 .. 2*n-1}, n-1) where n is 3;
> V;
{
    { 1, 5 },
    { 2, 5 },
    { 1, 3 },
    { 1, 4 },
    { 2, 4 },
    { 3, 5 },
    { 2, 3 },
    { 1, 2 },
    { 3, 4 },
    { 4, 5 }
}
> E := { {u, v} : u,v in V | IsDisjoint(u, v) };
> Petersen := Graph< V | E >;
```

145 PARTITIONS, WORDS AND YOUNG TABLEAUX

Chapter 145
PARTITIONS, WORDS AND YOUNG TABLEAUX

145.1 Introduction

This chapter presents some of the tools provided by MAGMA for partitions, words and Young tableaux.

145.2 Partitions

A *partition* of a positive integer n is a decreasing sequence $[n_1, n_2, \ldots, n_k]$ of positive integers such that $\sum n_i = n$. The n_i are called the *parts* of the partition.

All partition functions in MAGMA operate only on small, positive integers.

`NumberOfPartitions(n)`

Given a positive integer n, return the total number of partitions of n.

`Partitions(n)`

Given a positive integer n, return the sequence of all partitions of n.

`Partitions(n, k)`

Given positive integers n and k, return the sequence of all the partitions of n into k parts.

`RestrictedPartitions(n, M)`

Given a positive integer n and a set of positive integers M, return the sequence of all partitions of n, where the parts are restricted to being elements of the set M.

`RestrictedPartitions(n, k, M)`

Given positive integers n and k, and a set of positive integers M, return the sequence of all partitions of n into k parts, where the parts are restricted to being elements of the set M.

`IsPartition(S)`

A sequence S is considered to be a partition if it consists of weakly decreasing positive integers. A sequence is allowed to have trailing zeros, and the empty sequence is accepted as a partition (of zero).

`RandomPartition(n)`

Returns a weakly decreasing sequence of positive integers which is random partition of the positive integer n.

`Weight(P)`

Given a sequence of positive integers P which is a partition, return a positive integer which is the sum of it's parts.

`IndexOfPartition(P)`

Given a sequence of positive integers P which is a partition, return its lexicographical order among partitions of the same weight.

Lexicographical ordering of partitions is such that for partitions P_1 and P_2, then $P_1 > P_2$ implies that P_1 is greater in the first part which differs from P_2. The first index is zero.

Example H145E1

The conjugacy classes of the symmetric group on n elements correspond to the partitions of n. The function `PartnToElt` below converts a partition to an element of the corresponding conjugacy class.

```
> PartitionToElt := function(G, p)
>     x := [];
>     s := 0;
>     for d in p do
>         x cat:= Rotate([s+1 .. s+d], -1);
>         s +:= d;
>     end for;
>     return G!x;
> end function;
>
> ConjClasses := function(n)
>     G := Sym(n);
>     return [ PartitionToElt(G, p) : p in Partitions(n) ];
> end function;
>
> ConjClasses(5);
[
    (1, 2, 3, 4, 5),
    (1, 2, 3, 4),
    (1, 2, 3)(4, 5),
    (1, 2, 3),
    (1, 2)(3, 4),
    (1, 2),
    Id($)
]
> Classes(Sym(5));
```

```
Conjugacy Classes
-----------------
[1]     Order 1       Length 1
        Rep Id($)

[2]     Order 2       Length 10
        Rep (1, 2)

[3]     Order 2       Length 15
        Rep (1, 2)(3, 4)

[4]     Order 3       Length 20
        Rep (1, 2, 3)

[5]     Order 4       Length 30
        Rep (1, 2, 3, 4)

[6]     Order 5       Length 24
        Rep (1, 2, 3, 4, 5)

[7]     Order 6       Length 20
        Rep (1, 2, 3)(4, 5)
```

Example H145E2

The number of ways of changing money into five, ten, twenty and fifty cent coins can be calculated using `RestrictedPartitions`. There is also a well known solution using generating functions, which we use as a check.

```
> coins := {5, 10, 20, 50};
> T := [#RestrictedPartitions(n, coins) : n in [0 .. 100 by 5]];
> T;
[ 1, 1, 2, 2, 4, 4, 6, 6, 9, 9, 13, 13, 18, 18, 24, 24, 31, 31, 39, 39, 49 ]
> F<t> := PowerSeriesRing(RationalField(), 101);
> &*[1/(1-t^i) : i in coins];
1 + t^5 + 2*t^10 + 2*t^15 + 4*t^20 + 4*t^25 + 6*t^30 + 6*t^35 + 9*t^40 + 9*t^45
    + 13*t^50 + 13*t^55 + 18*t^60 + 18*t^65 + 24*t^70 + 24*t^75 + 31*t^80 +
    31*t^85 + 39*t^90 + 39*t^95 + 49*t^100 + O(t^101)
```

145.3 Words

In this and following sections, words are considered to be elements of some *ordered* monoid, that is a free monoid whose generators have an explicit ordering. The most important example is the monoid of words generated by the positive integers, though MAGMA also allows the creation of finitely generated ordered monoids. The words in this section are developed in connection with the theory of Young tableaux (see section 145.4), which are defined over some ordered set of labels (generators of an ordered monoid in MAGMA).

The importance of the ordering on the generators is in the definition of an equivalence known as *Knuth* equivalence. Knuth equivalence is defined by the two relations

$$yxz \sim yxz \qquad x < y \leq z$$
$$xzy \sim zxy \qquad x \leq y < z$$

The *plactic* monoid is the quotient of an ordered monoid with respect to Knuth equivalence. This plactic monoid is in fact isomorphic to the monoid of tableaux over the same generators. Elements of the plactic monoid are represented by a canonical representative from the Knuth equivalence class of the ordered monoid. This canonical representative is in fact the *row word* of the corresponding tableau (see section 145.4).

145.3.1 Ordered Monoids

An ordered monoid is a free monoid with an ordered basis. MAGMA has two different types of ordered monoids. The first is the monoid of words over the positive integers, which retain their natural ordering. The second are finitely generated monoids, whose generators may be assigned names.

`OrderedMonoid(n)`

Given a positive integer n, return the monoid with n ordered generators.

`OrderedIntegerMonoid()`

Return the ordered monoid of words over the positive integers.

`Id(O)`
`O ! 1`

Given an ordered monoid O, return its identity element, i.e., the null word.

`O . i`

Given an ordered monoid O and a positive integer i, return the i–th generator of O.

`O ! [w1, ..., wn]`

Given an ordered monoid O, and a sequence of elements from O, return the word $w_1 \cdots w_n$.

`O ! [i1, ..., in]`

Given the ordered monoid O over the positive integers, and a sequence of integers, return the word $i_1 \cdots i_n$.

`w1 eq w2`

Given two words w_1 and w_2 from the same ordered monoid, return `true` if they are equal.

`w1 * w2`

Given two words w_1 and w_2 from the same ordered monoid, return their product under word concatenation.

`IsKnuthEquivalent(w1, w2)`

Two words w_1 and w_2 from the same monoid are Knuth equivalent if they can be transformed into one another using elementary Knuth transformations, (defined in the introduction to this section).

`w[i]`

Given a word w from an ordered monoid, expressed as a product of generators, return the i–th generator in the product.

`ElementToSequence(w)`

`Eltseq(w)`

Given a word w from the ordered monoid of positive integers, return w as a sequence of integers.

`Length(w)`

`#w`

Given a word w from an ordered monoid, return its length.

`Content(w)`

Given a word w from an ordered monoid, return a sequence of non-negative integers denoting its content. The content of a word is a sequence where the i–th position denotes the number of occurrences of the i–th generator in the word.

`IsReverseLatticeWord(w)`

A word w from an ordered monoid is said to be a reverse lattice word (or Yamanouchi word) if for any $n > 0$, the last n letters of w have a content which is a partition.

`MaximalIncreasingSequence(w)`

Given a word w from an ordered monoid, return a weakly increasing subsubsequence of w of maximal length. This sequence is not necessarily unique.

`MaximalIncreasingSequences(w, k)`

Given a word w from an ordered monoid and some positive integer k, return a sequence of k distinct increasing subsequences of the word w, such that the maximal number of entries from w is used. Empty sequences are returned if all entries from w are used. These sequences are not necessarily unique.

Example H145E3

We create the ordered monoid over the positive integers and look at a few elements.

```
> O := OrderedIntegerMonoid();
> O;
The monoid of words over the positive integers
>
> w1 := O ! [3,5,2,8];
> w1;
3 5 2 8
> w2 := O ! [6,7,2,4];
> w2;
6 7 2 4
>
> w2[3];
2
> Eltseq(w1);
[ 3, 5, 2, 8 ]
>
> w1*w2;
3 5 2 8 6 7 2 4
```

Example H145E4

We create a finitely generated ordered monoid and create an element.

```
> O<a,b,c,d> := OrderedMonoid(4);
> O;
The monoid of words over 4 generators: a b c d
>
> w := a*b*a*d*c;
> w;
a b a d c
```

Example H145E5

We take a word of integers and look at weakly increasing subsequences of maximal length.

```
> O := OrderedIntegerMonoid();
> w := O ! [1,3,4,2,3,4,1,2,2,3,3,2];
>
```

```
> MaximalIncreasingSequence(w);
1 1 2 2 2 3
> MaximalIncreasingSequences(w,2);
[ 1 1 2 2 2 3 , 2 3 3  ]
> MaximalIncreasingSequences(w,3);
[ 1 1 2 2 2 3 , 2 3 3 , 3 4 4  ]
> MaximalIncreasingSequences(w,4);
[ 1 1 2 2 2 3 , 2 3 3 , 3 4 4 , Id(0) ]
```

145.3.2 Plactic Monoids

The *plactic monoid* of an ordered monoid is the quotient defined by Knuth equivalence. Elements of a plactic monoid are equivalence classes of words from the original ordered monoid, and are represented by a canonical representative.

`PlacticMonoid(O)`

Given an ordered monoid O, return the plactic monoid obtained by factoring O by Knuth equivalence.

`PlacticIntegerMonoid()`

Return the plactic monoid obtained by factoring the ordered monoid over the positive integers by Knuth equivalence.

`OrderedMonoid(P)`

Given a plactic monoid P, return the ordered monoid on which P is based.

`Id(P)`
`P ! 1`

Given a plactic monoid P, return its identity element which is the null word.

`P . i`

Given a plactic monoid P and a positive integer i, return the i–th generator of P.

`P ! [u`$_1$`, ..., u`$_n$`]`

Given a plactic monoid P, and a sequence of elements from P, return the product $u_1 \cdots u_n$.

`P ! [i`$_1$`, ..., i`$_n$`]`

Given the plactic monoid P over the positive integers, and a sequence of integers, return the element of P corresponding to the Knuth equivalence class of $i_1 \cdots i_n$.

`P ! w`

Given a plactic monoid P, and a word w from the ordered monoid that its based on, return the element of P corresponding to the Knuth equivalence class of w.

`P ! [w1, ..., wn]`

Given a plactic monoid P, and a sequence of elements from the ordered monoid that its based on, return the element of P corresponding to the Knuth equivalence class of $w_1 \cdots w_n$.

`P ! t`

Given a plactic monoid P and a tableau t which are both associated with the same ordered monoid, return the element of P which is uniquely associated to t.

`u1 eq u2`

Given two elements u_1 and u_2 from the same plactic monoid, return `true` if they are equal.

`u1 * u2`

Given two elements u_1 and u_2 belonging to the same plactic monoid, return their product which is inherited from word concatenation in the ordered monoid.

`Length(u)`

`#u`

Given a element u from a plactic monoid, return its length. The length of a word is invariant under Knuth equivalence and so is well defined for elements of the plactic monoid.

`Content(u)`

Given a word u from a plactic monoid, return a sequence of non-negative integers denoting its content. The content of a word is a sequence where the i–th position denotes the number of occurrences of the i–th generator in the word. The content of a word is invariant under Knuth equivalence and so is well defined for elements of the plactic monoid.

Example H145E6

We create both the ordered monoid and plactic monoid over the integers and look at several elements.

```
> O := OrderedIntegerMonoid();
> P := PlacticIntegerMonoid();
>
> w1 := O ! [2,7,4,8,1,5,9];
> w1;
2 7 4 8 1 5 9
> P!w1;
7 2 8 1 4 5 9
```

First we look at a word that is Knuth equivalent to w_1,

```
> w2 := O ! [7,2,1,8,4,5,9];
> w2;
```

```
7 2 1 8 4 5 9
>
> IsKnuthEquivalent(w1,w2);
true
> (P!w1) eq (P!w2);
true
```

and then one that is not Knuth equivalent.

```
> w3 := O ! [7,1,5,8,2,9,4];
> w3;
>
7 1 5 8 2 9 4
> IsKnuthEquivalent(w1,w3);
false
> (P!w1) eq (P!w3);
false
> P!w3;
7 5 8 1 2 4 9
```

Example H145E7

We create a finitely generated ordered monoid, its associated plactic monoid, and look at some properties which are invariant under Knuth equivalence.

```
> O<a,b,c,d,e> := OrderedMonoid(5);
> P := PlacticMonoid(O);
> P;
The plactic monoid of words over 5 generators: a b c d e
>
> w := b*c*e*e*a*d*a*d;
> w;
b c e e a d a d
> Length(w);
8
> Content(w);
[ 2, 1, 1, 2, 2 ]
>
> u := P!w;
> u;
a a b c d d e e
> Length(u);
8
> Content(u);
[ 2, 1, 1, 2, 2 ]
```

145.4 Tableaux

The tableaux module in MAGMA is loosely based on the computational algebra system SYMMETRICA developed by Adalbert Kerber and Axel Kohnert [KKL92]. The main reference for the theory of this section is "Young Tableaux" by William Fulton [Ful97].

A Young diagram, or Ferrers diagram, is a collection of boxes, or cells, arranged in left–justified rows, with a weakly decreasing number of cells in each row. Listing the number of cells in each row gives a partition (its shape) of n, where n is the total number of cells in the diagram. Conversely, each partition corresponds to a unique Young diagram. A numbering of a Young diagram is an assignment of a positive integer to each box. More generally a numbering can be done using any ordered set of labels, in MAGMA this means the generators of some ordered monoid, (see section 145.3).

A Young tableau, or simply tableau, is a numbering of a Young diagram which has (i) weakly increasing entries across each row, and (ii) strictly increasing entries down each column. These tableaux form a monoid with respect to a multiplication which may be defined in either of two ways, Schensted's "bumping" row insertion, or Schützenberger's "sliding" *jeu de taquin*, (see [Ful97] for full details).

A tableau monoid is constructed from an ordered monoid (see section 145.3), the generators of the ordered monoid comprising the tableau labels. A tableau monoid and a plactic monoid derived from the same ordered monoid are in fact isomorphic to one another.

Flipping a diagram over its main diagonal gives the conjugate diagram, its shape being the `ConjugatePartition` of the original shape.

A skew diagram or skew shape is the diagram obtained by deleting a smaller Young diagram from inside a larger one. A skew tableau is a numbering on a skew diagram obeying the same restrictions on its entries.

145.4.1 Tableau Monoids

Let O be an ordered monoid, elements of O are expressed as products of its generators. The generators of O can be used as the set of labels for a family of tableaux M, called a *tableau monoid*.

A tableau monoid has only one defining characteristic, the ordered monoid which specifies its labels.

The most important tableau monoid is the one defined over the set of all positive integers.

`TableauMonoid(O)`

`TableauMonoid(P)`

Given an ordered monoid O or a plactic monoid P, (in which case let O be the ordered monoid on which P is based), then return the tableau monoid of tableaux whose labels are the generators of O.

`TableauIntegerMonoid()`

Return the tableau monoid over the positive integers.

`OrderedMonoid(M)`

Given a tableau monoid M, return the ordered monoid from which M gets its labels.

Example H145E8

We create the tableau monoid over the positive integers. We take a word in the associated ordered monoid and look at its image in the tableau monoid.

```
> M := TableauIntegerMonoid();
> M;
Monoid of Tableaux labelled by the generators of:
The monoid of words over the positive integers
>
> w := OrderedMonoid(M) ! [3,6,2,8,3,9,1];
> w;
3 6 2 8 3 9 1
> M ! w;
Tableau of shape: 4 2 1
1 3 8 9
2 6
3
```

Example H145E9

We create a tableau monoid over a finite set of labels, and look at the image of a word.

```
> O<x,y,z> := OrderedMonoid(3);
> M := TableauMonoid(O);
> M;
Monoid of Tableaux labelled by the generators of:
The monoid of words over 3 generators: x y z
>
> M ! (z*y*x*z*y*y*x*y*x*z);
Tableau of shape: 5 3 2
x x x y z
y y y
z z
```

145.4.2 Creation of Tableaux

Tableaux are created from the words of some ordered monoid. For tableaux over the positive integers, the rows can be input directly as sequences. Words can be used to exactly specify the rows of a tableau, or an entire word can be mapped to a tableau using row insertion.

`Tableau(Q)`

Given a sequence of sequences of non-negative integers Q, return the tableau with the elements of Q as its rows. Zeroes will indicate skew entries. The resulting tableau must have weakly increasing rows and strictly increasing columns.

`Tableau(Q)`

Given a sequence Q of words from some ordered monoid, return the (non-skew) tableau with the words of Q as its rows. The resulting tableau must have weakly increasing rows and strictly increasing columns.

`Tableau(S, Q)`

Given a sequence of nonnegative integers S which is a partition, and a sequence of sequences of positive integers Q. Create a skew tableau with skew (inner) shape given by the partition S, and the non-skew part of each row being given by the entries of Q. The resulting tableau must have weakly increasing rows and strictly increasing columns.

`Tableau(S, Q)`

Given a sequence of nonnegative integers S which is a partition, and a sequence Q of words from some ordered monoid. Create a skew tableau with skew (inner) shape given by the partition S, and the non-skew part of each row being given by the words of Q. The resulting tableau must have weakly increasing rows and strictly increasing columns.

`WordToTableau(w)`
`WordToTableau(u)`

Given a word w from an ordered monoid, return the tableau obtained by row inserting the entries of w (from the left) into the empty tableau.

If given an element u of a plactic monoid, any word of its Knuth equivalence class is used. This map is invariant under Knuth equivalence and so is well defined for elements of the plactic monoid.

It is a surjective homomorphism from the ordered monoid to the tableau monoid, and an isomorphism from the plactic monoid to the tableau monoid.

`M ! w`

Given a tableau monoid M and a word w from its associated ordered monoid, return the tableau corresponding to w through row insertion.

`M ! u`

Given a tableau monoid M and an element u from a plactic monoid associated with the same ordered monoid as M, return the tableau corresponding to u through row insertion.

`M ! [i1, ..., in]`

Given the tableau monoid M over the positive integers, and a sequence of positive integers, return the tableau corresponding to the word $i_1 * \cdots * i_n$.

`M ! Q`

Given the tableau monoid M over the positive integers, and a sequence of sequences of non-negative integers Q, return the tableau with the elements of Q as its rows. Zeroes will indicate skew entries. The resulting tableau must have weakly increasing rows and strictly increasing columns.

`M ! Q`

Given a tableau monoid M, and a sequence Q of words from its associated ordered monoid, return the (non-skew) tableau with the words of Q as its rows. The resulting tableau must have weakly increasing rows and strictly increasing columns.

Example H145E10

We create a tableau over the positive integers in two ways. First we input its rows explicitly, then we use a single word which specifies the tableau. We also create a skew tableau by using zero entries in a sequence of sequences.

```
> O := OrderedIntegerMonoid();
>
> T := Tableau( [ [2,5,5,6], [5,7,9,9], [6,9] ]);
> T;
Tableau of shape: 4 4 2
2 5 5 6
5 7 9 9
6 9
> WordToTableau( O ! [6,9,5,7,9,9,2,5,5,6] );
Tableau of shape: 4 4 2
2 5 5 6
5 7 9 9
6 9
> Tableau([ [0,0,0,3,4,5], [0,1,2,4], [1,6] ]);
Skew tableau of shape: 6 4 2 / 3 1
0 0 0 3 4 5
0 1 2 4
1 6
```

Example H145E11

We create a skew tableau in a tableau monoid with finitely many labels.

```
> O<a,b,c,d> := OrderedMonoid(4);
> T := Tableau( [3,2] , [ a*a*b*d, b*d*d, a*b]);
> T;
Skew tableau of shape: 7 5 2 / 3 2
0 0 0 a a b d
0 0 b d d
a b
```

Example H145E12

We create the ordered, plactic and tableau monoids each over the positive integers, and examine the natural maps between them.

```
> O := OrderedIntegerMonoid();
> P := PlacticIntegerMonoid();
> M := TableauIntegerMonoid();
> w1 := O ! [4,6,2,6,9,6,2,2,1,7];
> w2 := O ! [9,4,2,1,6,2,6,2,6,7];
> w1 eq w2;
false
> IsKnuthEquivalent(w1,w2);
true
```

Knuth equivalence implies equality for the image in both the plactic and tableau monoids.

```
> (P!w1) eq (P!w2);
true
> P!w1;
9 4 2 6 6 1 2 2 6 7
>
> (M!w1) eq (M!w2);
true
> M!w1;
Tableau of shape: 5 3 1 1
1 2 2 6 7
2 6 6
4
9
```

The plactic and tableau monoids are isomorphic. We confirm that the natural image of an equivalence class from the plactic monoid is the same as the natural images of its member words.

```
> M!w1 eq M ! (P!w1);
true
```

145.4.3 Enumeration of Tableaux

Multiple tableaux may be created corresponding to specified parameters.

`StandardTableaux(P)`

`StandardTableaux(M, P)`

Returns the set of all standard tableau from the tableau monoid M of shape P, which is a partition.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must contain enough labels to fill the shape P, (i.e. more than `Weight(`P`)`).

`StandardTableauxOfWeight(n)`

`StandardTableauxOfWeight(M, n)`

Returns the set of all standard tableau from the tableau monoid M and of weight n, which is a positive integer.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must contain at least n labels.

`TableauxOfShape(S, m)`

`TableauxOfShape(M, S, m)`

Given a tableau monoid M, a sequence of positive integers S which is a partition, and a positive integer m, then return the set of all tableau of shape S which use only the first m labels of the tableau monoid M.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must contain at least m labels.

`TableauxOnShapeWithContent(S, C)`

`TableauxOnShapeWithContent(M, S, C)`

Given a tableau monoid M, a sequence of positive integers S which is a partition, and a sequence of non–negative integers C, then return the set of all tableau from M having shape S and *content* C (see section 145.4.6 for definition of content). If C prescribes fewer cells than would completely fill the shape S, then the tableau within the given shape is returned.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must have at least as many labels as C has entries.

`TableauxWithContent(C)`

`TableauxWithContent(M, C)`

Given a tableau monoid M, and a sequence of non-negative integers C, return the set of all tableau from M with *content* C (see section 145.4.6 for definition of content).

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must have at least as many labels as C has entries.

Example H145E13

We create all tableaux of a given shape, then check that the number of tableaux created agrees with the combinatorical result.

```
> P := [ 3, 2];
> S := StandardTableaux( P );
> S;
{ Tableau of shape: 3 2
 1 2 3
 4 5, Tableau of shape: 3 2
 1 3 4
 2 5, Tableau of shape: 3 2
 1 3 5
 2 4, Tableau of shape: 3 2
 1 2 5
 3 4, Tableau of shape: 3 2
 1 2 4
 3 5 }
>
> #S eq NumberOfStandardTableaux( P );
true
```

Example H145E14

We create all tableau over the ordered generators a, b, c, d which have shape $[4, 2]$ and exactly two a's, one b, two c's and one d. There is in fact four of them.

```
> O<a,b,c,d> := OrderedMonoid(4);
> M := TableauMonoid(O);
> TableauxOnShapeWithContent( M, [4,2], [2,1,2,1]);
{ Tableau of shape: 4 2
a a c c
b d , Tableau of shape: 4 2
a a b c
c d , Tableau of shape: 4 2
a a b d
c c , Tableau of shape: 4 2
a a c d
b c  }
```

145.4.4 Random Tableaux

The functions in this section are based on ideas from [GNW84].

`RandomHookWalk(P, i, j)`

`RandomHookWalk(t, i, j)`

A random hook walk is an essential tool for the creation of random tableau. The *hook* of a cell on a Young diagram is the cells to the right and below its position. The Young diagram is specified by either the sequence of positive integers P which is a partition, or the tableau t.

Given positive integers i and j such that (i, j) lies on the shape, the walk proceeds as follows. Starting from the specified (i, j)-th cell, move to another cell chosen at random from its hook. Repeat this process until a outside corner of the Young diagram is reached, and return the two integers representing the coordinates of this final cell.

`RandomTableau(S)`

`RandomTableau(M, S)`

Given a tableau monoid M, and a sequence of positive integers S which is a partition, return a random standard tableau from M of shape S.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must contain enough labels to fill the shape S, (i.e. more than `Weight(`S`)`).

`RandomTableau(n)`

`RandomTableau(M, n)`

Given a tableau monoid M, and a positive integer n, return a (not completely) random standard tableau of weight n. The probability of any specific tableau of shape S being returned is $N_S/n!$, where N_S is the number of standard tableaux of shape S. So tableaux on more populous shapes are more likely to occur.

If a tableau monoid M is not specified then the monoid over the positive integers is used. If M is specified then it must contain at least n labels.

Example H145E15

We numerically test the random creation of tableau of a given shape, by calculating the average percentage difference in the number of each tableau created. We find it to be less than one percent.

```
> P := [4,3,2];
> Runs := 10000;
>
> S := Setseq( StandardTableaux( P ) );
> Count := [0: i in [1..#S]];
>
> for k in [1..Runs] do
>     T := RandomTableau( P );
```

```
>     i := Index(S,T);
>     Count[i] +:= 1;
> end for;
>
> Average :=  Runs/#S;
> Diff := [RealField(2) | Abs( (Count[i] - Average)/Average )
>                       : i in [1..#Count]];
>
> AvgDiff := (&+ Diff)/#Diff;
> AvgDiff;
0.006
```

145.4.5 Basic Access Functions

`Shape(t)`

`OuterShape(t)`

The (outer) shape of a tableau t is the sequence of positive integers denoting the (decreasing) row lengths of its Young Diagram, which results in a partition.

`SkewShape(t)`

`InnerShape(t)`

The Young diagram of a skew tableau t has a smaller Young diagram inside of it deleted. The skew, or inner, shape of a skew tableau is the sequence of positive integers denoting the (decreasing) row lengths of this deleted diagram, which results in a partition.

A non-skew tableau is a special case of a skew tableau, whose skew shape is simply the null sequence.

Trailing zeroes are added to the inner shape of t to give it the same length as the outer shape of t.

`PartitionCovers(P1, P2)`

Given two sequences of integers, P_1 and P_2, which are partitions, return `true` if the Young diagram of P_1 covers the Young diagram of P_2.

`ConjugatePartition(P)`

Given a sequence of integers P which is a partition, return the partition corresponding to the *conjugate* Young diagram of P (see section 145.4 for a full description).

`Weight(t)`

Given a tableau t, return the positive integer which is the number of (non–skew) cells in its Young Diagram.

`SkewWeight(t)`

Given a tableau t, return the positive integer which is the number of skew cells in its Young Diagram.

`NumberOfRows(t)`

Given a tableau t, return a positive integer which is its number of rows.

`NumberOfSkewRows(t)`

Given a tableau t, return a positive integer which is its number of skewed rows.

`Row(t, i)`

Given a tableau t, return the non-skewed entries of the i–th row as a word of an ordered monoid.

`Rows(t)`

Given a tableau t, return a sequence of words from an ordered monoid which are the non-skewed entries of its rows.

`Column(t, j)`

Given a tableau t, return the non-skewed entries of the j–th column as a word of an ordered monoid.

`Columns(t)`

Given a tableau t, return a sequence of words from an ordered monoid which are the non-skewed entries of its columns.

`RowSkewLength(t, i)`

Given a tableau t, return the length of the skewed portion of the i–th row (zero if no skewed portion).

`ColumnSkewLength(t, j)`

Given a tableau t, return the length of the skewed portion of the j–th column (zero if no skewed portion).

`FirstIndexOfRow(t, i)`

Given a tableau t and a positive integer i, return the index of the first non–skew entry of the i–th row of t. If the row has no non–skew entries then the index will be one greater than the length of the row, i.e., out of bounds.

`LastIndexOfRow(t, i)`

`RowLength(t, i)`

Given a tableau t and a positive integer i, return the index of the last entry of the i–th row of t, which is the length of the i–th row.

`FirstIndexOfColumn(t, j)`

Given a tableau t and a positive integer j, return the index of the first non–skew entry of the j–th column of t. If the column has no non–skew entries then the index will be one greater than the length of the column, i.e., out of bounds.

`LastIndexOfColumn(t, j)`

`ColumnLength(t, j)`

Given a tableau t and a positive integer j, return the index of the last entry in the j–th column of t, which is the length of the j–th column.

Example H145E16

Given a skew tableau, we access a number of its structural properties.

```
> T := Tableau( [3,3,2] , [ [4, 6 ] ,[5, 9], [1, 8] ]);
> T;
Skew tableau of shape: 5 5 4 / 3 3 2
0 0 0 4 6
0 0 0 5 9
0 0 1 8
> Shape(T);
[ 5, 5, 4 ]
> Weight(T);
6
> SkewWeight(T);
8
> NumberOfRows(T);
3
> NumberOfSkewRows(T);
3
> RowSkewLength(T, 2);
3
> Row(T, 2);
5 9
> ColumnSkewLength(T, 3);
2
> Column(T, 3);
1
```

145.4.6 Properties

`HookLength(t, i, j)`

`HookLength(P, i, j)`

The *hook* of a cell on a Young diagram comprises the cells to the right and below its position. The Young diagram is specified by either the sequence of positive integers P which is a partition or the tableau t. The number of cells contained in a hook is its *length*.

For positive integers i and j such that (i, j) is the co-ordinates of a cell lying on the specified Young diagram, a positive integer is returned which is the length of the hook of that cell.

`Content(t)`

Given a tableau t, return a sequence of non-negative integers which is its *content*.

The content of t is such that its i–th value denotes the number of times the i–th label occurs in t.

`Word(t)`

`RowWord(t)`

Given a tableau t, its row word is formed by reading its entries from left to right, bottom to top. The result is a word of an ordered monoid.

`ColumnWord(t)`

Given a tableau t, its column word is formed by reading its labels from bottom to top, left to right. The result is a word of an ordered monoid.

`IsStandard(t)`

Given a tableau t of weight n, then t is standard if and only if its entries are exactly the first n labels of its parent monoid. So t is standard if and only if it has a content of the form $[1, 1, \ldots, 1]$.

`IsSkew(t)`

Returns `true` if the tableau t is a skew tableau.

`IsLittlewoodRichardson(t)`

Given a tableau t, then it is a Littlewood–Richardson tableau if the content of t forms a reverse lattice word, (see section 145.3 for a definition of a reverse lattice word).

Example H145E17

We create a tableau which is not standard. Examining its content shows a simple to way to transform it into a standard tableau.

```
> O := OrderedIntegerMonoid();
> T := WordToTableau( O ! [8,1,7,3,6,2,5,9] );
> T;
Tableau of shape: 4 2 1 1
 1 2 5 9
 3 6
 7
 8
> Content(T);
[ 1, 1, 1, 0, 1, 1, 1, 1, 1 ]
> IsStandard(T);
false
>
> RowInsert(~T, 4);
> T;
Tableau of shape: 4 2 1 1 1
 1 2 4 9
 3 5
 6
 7
 8
> Content(T);
[ 1, 1, 1, 1, 1, 1, 1, 1, 1 ]
> IsStandard(T);
true
```

Example H145E18

Given a tableau, check that the row and column words are Knuth equivalent.

```
> T := Tableau( [2, 2], [ [1,2,3], [4,6,6], [1,5], [2,6] ]);
> T;
Skew tableau of shape: 5 5 2 2 / 2 2
0 0 1 2 3
0 0 4 6 6
1 5
2 6
>
> RW := RowWord(T);
> RW;
2 6 1 5 4 6 6 1 2 3
> CW := ColumnWord(T);
> CW;
2 1 6 5 4 1 6 2 6 3
```

```
> IsKnuthEquivalent(RW, CW);
true
```

145.4.7 Operations

Several operations exist to manipulate tableaux and allow them to interact.

`t1 eq t2`

Given two tableaux t_1 and t_2, return `true` if they are equal.

`t1 * t2`

Given two tableaux t_1 and t_2, return another tableau which is their product. The product of two tableaux can be defined using either row insertion or *jeu de taquin*.

`DiagonalSum(t1, t2)`

The `DiagonalSum` of two tableau $t1$ and $t2$ is formed by first building a rectangle of empty cells, with the same number of columns as $t1$ and the same number of rows as $t2$. Then $t1$ is attached below the rectangle and $t2$ attached to right of it.

`Conjugate(t)`

Given a tableau t with strictly increasing rows, the rows and columns of t are transposed to form a new tableau on the conjugate Young diagram.

`JeuDeTaquin(~t, i, j)`

`JeuDeTaquin(t, i, j)`

Given a skew tableau t, and the co-ordinates (i, j) which must be a skew cell that is an *inside corner* (a corner on the skew shape of t). The skewed (i, j)–th cell is removed using *jeu de taquin*.

`JeuDeTaquin(~t)`

`JeuDeTaquin(t)`

`Rectify(~t)`

`Rectify(t)`

Given a tableau t, remove all skewed cells successively using *jeu de taquin*.

`InverseJeuDeTaquin(~t, i, j)`

`InverseJeuDeTaquin(t, i, j)`

Given a tableau t, and co-ordinates (i, j) which must lie on the outside of t resulting in a new and valid shape. A new skew tableau with skew degree one higher than t is created. This is achieved by adding a new skew cell in the (i, j)–th position, then performing *jeu de taquin* in reverse, which moves the new entry to create a valid skew tableau.

`RowInsert(~t, w)`

`RowInsert(t, w)`

`RowInsert(~t, u)`

`RowInsert(t, u)`

Given a tableau t and a word w from the same ordered monoid that t is associated to, insert w into t using Schensted's row insertion algorithm.

If given an element u of a plactic monoid, any word of its Knuth equivalence class is used. This map is invariant under Knuth equivalence and so is well defined for elements of the plactic monoid.

`RowInsert(~t, x)`

`RowInsert(t, x)`

Given a tableau t over the positive integers, and a positive integer x, insert x into t using the Schensted's row insertion algorithm.

`InverseRowInsert(~t, i, j)`

`InverseRowInsert(t, i, j)`

Given a tableau t and positive integers i and j such that (i, j) corresponds to an outside corner cell of the tableau t, then the row insertion algorithm is applied in reverse to remove the specified entry. In the functional form, both the generated tableau and the value of the removed entry as a word of an ordered monoid are returned.

Example H145E19

The order with which the skew entries of a skew tableau are removed using jeu de taquin is irrelevant to the final tableau produced. We give an example of this.

```
> T := Tableau([2,1], [ [2], [3,4] ,[3] ]);
> T1 := T;
> T;
Skew tableau of shape: 3 3 1 / 2 1
 0 0 2
 0 3 4
 3
>
> JeuDeTaquin(~T, 1, 2); T;
Skew tableau of shape: 3 2 1 / 1 1
 0 2 4
 0 3
 3
> JeuDeTaquin(~T, 2, 1); T;
Skew tableau of shape: 3 2 / 1
 0 2 4
 3 3
```

```
> JeuDeTaquin(~T, 1, 1); T;
Tableau of shape: 3 1
 2 3 4
 3
>
> JeuDeTaquin(~T1, 2, 1); T1;
Skew tableau of shape: 3 3 / 2
 0 0 2
 3 3 4
> JeuDeTaquin(~T1, 1, 2); T1;
Skew tableau of shape: 3 2 / 1
 0 2 4
 3 3
> JeuDeTaquin(~T1, 1, 1); T1;
Tableau of shape: 3 1
 2 3 4
 3
>
> T eq T1;
true
```

Example H145E20

We manually compare the two different methods of multiplying tableau.

```
> O<a,b,c,d,e,f,g,h> := OrderedMonoid(8);
> T1 := Tableau( [ a*c*f, d*g]);
> T2 := Tableau( [ b*b*e*f, d*g*h]);
```

First using row insert,

```
> w := Word(T2);
> w;
d g h b b e f
> Res1 := RowInsert(T1, w);
> Res1;
Tableau of shape: 5 4 2 1
a b b e f
c d g h
d f
g
```

and then using JeuDeTaquin.

```
> Res2 := DiagonalSum(T1, T2);
> Res2;
Skew tableau of shape: 7 6 3 2 / 3 3
0 0 0 b b e f
0 0 0 d g h
a c f
```

```
d g
> Rectify(~Res2);
> Res2;
Tableau of shape: 5 4 2 1
a b b e f
c d g h
d f
g
```

Now we check our results.

```
> Res1 eq Res2;
true
> Res1 eq (T1*T2);
true
```

145.4.8 The Robinson-Schensted-Knuth Correspondence

While the map from the plactic monoid to tableaux is an isomorphism, many different words from the original ordered monoid map to the same tableau. However a bijective map exists between an ordered monoid and *pairs* of tableau of the same shape, the second of which being a standard tableau. This is known as the *Robinson correspondence*.

By removing the restriction that the second tableau be standard, this correspondence is extended further to a bijective map with all matrices with non-negative integers. This is known as the Robinson-Schensted-Knuth (RSK) correspondence.

This latter correspondence can also be made to all lexicographically ordered pairs of words (both having the same length).

`LexicographicalOrdering(~w1, ~w2)`

`LexicographicalOrdering(w1, w2)`

Given two words w_1 and w_2 of the same length, place them in increasing lexicographical order (the functional version returns two new words). Lexicographical ordering on the pairs $(w_1[i], w_2[i])$ is determined primarily by the comparison $w_2[i] < w_2[j]$, but if $w_2[i] = w_2[j]$ then the comparison $w_1[i] < w_1[j]$ is taken into account.

`IsLexicographicallyOrdered(w1, w2)`

Given two words w_1 and w_2, return `true` if the pairs $(w_1[i], w_2[i])$ are ordered according to the ordering described in `LexicographicalOrdering`.

`RSKCorrespondence(w)`

Given a word w, use the bijective map described by the Robinson-Schensted-Knuth correspondence to return two tableau t_1 and t_2. The first tableau, t_1, will be labelled by the entries of w, while t_2 is a standard tableau over the positive integers.

The map described by the correspondence is as follows. Map the word w to t_1 by row inserting its entries into the empty tableau, (as is done in `WordToTableau`). As t_1 is being generated, the insertion tableau t_2 is built simultaneously. As $w[k]$ is inserted into t_1, an additional cell is added to its shape. A new cell is added to t_2 in exactly the same place, and it is labelled with the integer k.

`InverseRSKCorrespondenceSingleWord(t1, t2)`

Given a pair of tableaux t_1, t_2, of the same shape, where t_2 is over the positive integers, return the preimage of t_1 and t_2 using the bijective map described by the Robinson-Schensted-Knuth correspondence.

The result is returned as a single word of the ordered monoid of t_1, as described in the single word version of `RSKCorrespondence`.

`RSKCorrespondence(w1, w2)`

Given two lexicographically ordered words w_1 and w_2 of the same length, where w_2 must be over the positive integers, use the bijective map described by the Robinson-Schensted-Knuth correspondence to return two tableau t_1 and t_2. The first tableau, t_1, will be labelled by the entries of w_1, while t_2 will be labelled by the entries of w_2.

The map described by the correspondence is as follows. Map the word w_1 to t_1 by row inserting its entries into the empty tableau, (as is done in `WordToTableau`). As t_1 is being generated, the insertion tableau t_2 is built simultaneously. As $w[k]$ is inserted into t_1, an additional cell is added to its shape. A new cell is added to t_2 in exactly the same place, and it is labelled with the integer $w_2[k]$.

`InverseRSKCorrespondenceDoubleWord(t1, t2)`

Given a pair of tableaux t_1, t_2, of the same shape, where t_2 is over the positive integers, return the preimage of t_1 and t_2 using the bijective map described by the Robinson-Schensted-Knuth correspondence.

The result is returned as words of the ordered monoids of t_1 and t_2 respectively, as described in the double word version of `RSKCorrespondence`.

`RSKCorrespondence(M)`

Given a matrix M of non-negative integers, use the bijective map described by the Robinson-Schensted-Knuth correspondence to return two tableau t_1 and t_2 over the positive integers.

The map described by the correspondence is as follows. Initialise two words over the positive integers, w_1 and w_2, as null words. For the (i, j)–th entry of M, say m_{ij}, append i to w_1 m_{ij} times, and append j to w_2 m_{ij} times. These two words are then used in the correspondence described in the above version of `RSKCorrespondence`.

`InverseRSKCorrespondenceMatrix(t1, t2)`

Given a pair of tableaux t_1, t_2, of the same shape, both over the positive integers, return the preimage of t_1 and t_2 using the bijective map described by the Robinson-Schensted-Knuth correspondence.

The result is a matrix of non-negative integers, as described in the matrix version of `RSKCorrespondence`.

Example H145E21

We take two words from the ordered monoid over the positive integers. Although they correspond to the same tableau under the natural mapping into the tableau monoid, we show they have a different image under the RSK correspondence. That is, they have different *insertion* tableaux.

```
> O := OrderedIntegerMonoid();
> M := TableauMonoid(O);
> a := O ! [4,7,2,8,4,9,2];
> a;
4 7 2 8 4 9 2
> b := O ! [7,4,2,4,2,8,9];
> b;
7 4 2 4 2 8 9
```

Now we will see that a and b have the same image in the tableau monoid, but that they are distinguished under the RSK correspondence.

```
> (M!a) eq (M!b);
true
> Ta1, Ta2 := RSKCorrespondence(a);
> Tb1, Tb2 := RSKCorrespondence(b);
> Ta1 eq Tb1;
true
> Ta2 eq Tb2;
false
> Ta2;
Tableau of shape: 4 2 1
1 2 4 6
3 5
7
> Tb2;
Tableau of shape: 4 2 1
1 4 6 7
2 5
3
```

To check that the map is indeed bijective we find a and b as the pre-images of the created tableaux.

```
> InverseRSKCorrespondenceSingleWord(Ta1,Ta2 );
4 7 2 8 4 9 2
> InverseRSKCorrespondenceSingleWord(Tb1,Tb2 );
```

```
7 4 2 4 2 8 9
```

Example H145E22

We apply the RSK correspondence to two arbitrary words, the first from a finitely generated ordered monoid. The second word must always be over the positive integers. The first step is to put them into lexicographical order.

```
> O1<a,b,c,d,e,f> := OrderedMonoid(6);
> O2 := OrderedIntegerMonoid();
>
> w1 := e*a*e*b*f*d*a;
> w2 := O2 ! [3,8,2,8,3,3,6];
> LexicographicalOrdering(~w1, ~w2);
> w1, w2;
e d e f a a b  2 3 3 3 6 8 8
```

Now we use the correspondence,

```
> T1, T2 := RSKCorrespondence(w1, w2);
> T1;
Tableau of shape: 3 3 1
a a b
d e f
e
> T2;
Tableau of shape: 3 3 1
2 3 3
3 8 8
6
```

and check that the inverse is correct.

```
> InverseRSKCorrespondenceDoubleWord(T1, T2);
e d e f a a b  2 3 3 3 6 8 8
```

Example H145E23

We give an example of the bijective map provided by the RSK correspondence between matrices of non-negative integers and pairs of tableaux of the same shape.

```
> M := Matrix(2,3,[0,0,2,3,1,2]);
> M;
[0 0 2]
[3 1 2]
> T1, T2 := RSKCorrespondence(M);
> T1;
Tableau of shape: 6 2
1 1 1 2 3 3
3 3
```

```
> T2;
Tableau of shape: 6 2
1 1 2 2 2 2
2 2
> InverseRSKCorrespondenceMatrix(T1, T2);
[0 0 2]
[3 1 2]
```

Looking now at preimage of the tableaux in the double word format, the (i, j) co-ordinates of entries of M can clearly be seen with the correct multiplicities.

```
> wj, wi := InverseRSKCorrespondenceDoubleWord(T1, T2);
> wi;
1 1 2 2 2 2 2 2
> wj;
3 3 1 1 1 2 3 3
```

Example H145E24

We illustrate the remarkable property that a permutation p (in image notation) corresponds to the tableaux pair $(T1, T2)$ if and only if the inverse permutation p^{-1} corresponds to the tableaux pair $(T2, T1)$.

```
> O := OrderedIntegerMonoid();
> n := Random([1..100]);
> G := SymmetricGroup(n);
> p := Random(G);
>
> T1, T2 := RSKCorrespondence( O ! Eltseq(p) );
>
> p1 := InverseRSKCorrespondenceSingleWord( T2, T1);
> p1 := G ! Eltseq(p1);
>
> p1 eq p^-1;
true
```

145.4.9 Counting Tableaux

`NumberOfStandardTableaux(P)`

Given a sequence of positive integers P which is a partition, return the number of standard tableaux of shape P. This is the same as the number of Knuth equivalent words corresponding to each standard tableaux of shape P.

`NumberOfStandardTableauxOnWeight(n)`

Given a positive integer n, return the number of standard tableaux having weight n.

`NumberOfTableauxOnAlphabet(P, m)`

Given a sequence of positive integers P which is a partition, return the number of tableau of shape P with entries from $[1, \ldots, m]$.

`KostkaNumber(S, C)`

Given a sequence of positive integers S forming a partition, and a sequence of non-negative integers C, return the number of tableau having shape S and content C. If C prescribes fewer cells than would completely fill the shape S, then the number of tableau within the given shape is returned.

Example H145E25

There is a correspondence between the number of standard tableaux on a given shape, and the number of words associated with each of those tableaux. We manually count the number of words corresponding to a specific standard tableau, and show that this is equal to the number of standard tableaux on that shape.

```
> O := OrderedIntegerMonoid();
> T := Tableau( [ [ 1, 2, 3, 4, 7],
>                 [ 5, 8],
>                 [ 6]    ] );
> T;
Tableau of shape: 5 2 1
 1 2 3 4 7
 5 8
 6
>
> n := Weight(T);
> G := SymmetricGroup(n);
> S := [1..n];
>
> Count := 0;
> for p in G do
>     T1 := WordToTableau( O ! (S^p) );
>     if T1 eq T then
>         Count +:= 1;
>     end if;
> end for;
>
> Count;
64
> NumberOfStandardTableaux( Shape(T) );
64
```

Example H145E26

If a tableaux is constructed of the shape $[1, 1, 1, \ldots, 1]$ then the entries must be strictly increasing, hence non-repeating. So for such a tableau of length n on an alphabet of m symbols, each subset of n symbols will correspond to one single distinct tableau. So the number of tableau will be $\binom{m}{n}$.

```
> m := Random(1,50);
> n := Random(1,m);
>
> Shape := [ 1 : i in [1..n] ];
> Binomial(m,n) eq NumberOfTableauxOnAlphabet(Shape, m);
true
```

146 SYMMETRIC FUNCTIONS

Chapter 146
SYMMETRIC FUNCTIONS

146.1 Introduction

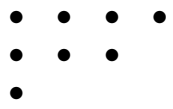
A *symmetric function* is a polynomial which is invariant under permutations of its indeterminates. The symmetric functions over a commutative ring with unity, with an arbitrary number of indeterminates, form an algebra, denoted by Λ.

The symmetric functions of fixed degree n form a submodule of Λ denoted by Λ^n. When analysing and computing with elements of Λ, there are 5 important bases to consider. These are the bases consisting of the *Schur*, *Homogeneous*, *Power Sum*, *Elementary* and *Monomial* symmetric functions. The size of any basis of Λ^n is equal to the number of partitions of weight n, and each basis has its elements indexed by those partitions.

A *partition* is a weakly decreasing sequence of positive integers. So, for example, $[5, 3, 1]$ is a partition of weight 9, and $[3, 1]$ is a partition of weight 4. For more information on partitions see Section 145.2.

MAGMA allows computations with symmetric functions in any of the 5 bases, and any symmetric function can be expressed in any of the different bases. The main reference on the theory of symmetric functions used here is the book of Macdonald [Mac95].

In order to understand the different symmetric function bases, it is necessary to have an understanding of *Young Tableaux*. Firstly, for a given partition let us visualise its *shape* making a diagram. We arrange "boxes" in left-justified rows corresponding to the entries of the partition. So for example, the partition $[4, 3, 1]$ of weight 8 gives



This is known as a *Ferrers diagram*.

Now, to create a Young tableau, we must fill these boxes with integer entries, but subject to some restrictions. We require that each row of the tableau must be weakly increasing, and each column must be strictly increasing. So, for example, a possible tableau of shape $[4, 3, 1]$ would be

$$T \quad = \quad \begin{array}{cccc} 1 & 3 & 3 & 4 \\ 2 & 4 & 5 & \\ 4 & & & \end{array}$$

A tableau can be mapped onto a monomial by treating each entry in the tableau as an indeterminate. So, the above tableau will correspond to the monomial

$$T \mapsto x^T = x_1 x_2 x_3^2 x_4^3 x_5$$

With this connection between tableaux and monomials we are now able to define the bases of an algebra of symmetric functions.

An important point to realise is that when dealing with a symmetric function, the number of indeterminates of the corresponding polynomial is neither fixed nor important. In fact a symmetric function has an image as a symmetric polynomial in an arbitrary number of indeterminates, even an infinite number. MAGMA is only equipped to deal with polynomial rings with finite rank.

Since the partitions of weight n prescribe the symmetric function basis elements of degree n which generate Λ^n, (the symmetric polynomials in n indeterminates), then the number of indeterminates being used will normally be equal to the degree of the symmetric functions considered.

- Schur Functions

  Given a partition $\lambda = [\lambda_1, \lambda_2, \ldots, \lambda_l]$ of weight n, the Schur function s_λ is given by $s_\lambda = \sum_T x^T$ where the sum is taken over all Young tableaux with shape λ, whose entries are all less than or equal to m, (the number of required indeterminates).

- Elementary Functions

  For a positive integer k, define the k-th elementary symmetric function, e_k, as the Schur function of $[1^k]$. Then, for any partition $\lambda = [\lambda_1, \lambda_2, \ldots, \lambda_l]$, we define the elementary symmetric function indexed by λ to be $e_\lambda = \prod_i e_{\lambda_i}$.

- Homogeneous Functions

  For a positive integer k, define the k-th homogeneous symmetric function, h_k, as the Schur function of $[k]$. Then, for any partition $\lambda = [\lambda_1, \lambda_2, \ldots, \lambda_l]$, we define the homogeneous symmetric function indexed by λ to be $h_\lambda = \prod_i h_{\lambda_i}$.

- Monomial Functions

  For a partition $\lambda = [\lambda_1, \lambda_2, \ldots, \lambda_l]$, let x^λ be given by $x_1^{\lambda_1} x_2^{\lambda_2} \cdots x_l^{\lambda_l}$. The monomial symmetric function m_λ is the sum over the orbits of x^λ under the action of the symmetric group. Where the number of indeterminates exceeds the length of the partition, λ can be considered to have trailing zeros.

- Power Sums

  For a positive integer k, define the k-th power sum symmetric function, p_k, as the monomial function of $[k]$. Then, for any partition $\lambda = [\lambda_1, \lambda_2, \ldots, \lambda_l]$, we define the power sum symmetric function indexed by λ to be $p_\lambda = \prod_i p_{\lambda_i}$.

For each of these classes of functions, the set of all functions indexed by partitions of weight n forms a basis for Λ^n. Taking functions indexed by partitions of *all* weights gives a basis of Λ.

It is possible to define an inner product on Λ by requiring that the bases m_λ and h_λ be dual to each other:

$$\langle m_\lambda, h_{\lambda'} \rangle = \delta_{\lambda,\lambda'}$$

With respect to this inner product, the Schur functions are an orthonormal basis of Λ^n and Λ and the power sum basis is an orthogonal basis.

Example H146E1

We give an example illustrating the correspondence between symmetric functions written with respect to a symmetric function basis and symmetric polynomials. While the degree of the sym-

metric function fixes the degree of the resulting polynomial, the number of indeterminates is arbitrary.

```
> Q := Rationals();
> S := SFASchur(Rationals());
> e := S.[2,1];
> P2<[x]> := PolynomialRing(Q, 2);
> P2 ! e;
x[1]^2*x[2] + x[1]*x[2]^2
> P3<[y]> := PolynomialRing(Q, 3);
> P3 ! e;
y[1]^2*y[2] + y[1]^2*y[3] + y[1]*y[2]^2 + 2*y[1]*y[2]*y[3] + y[1]*y[3]^2 +
    y[2]^2*y[3] + y[2]*y[3]^2
> P4<[z]> := PolynomialRing(Q, 4);
> P4 ! e;
z[1]^2*z[2] + z[1]^2*z[3] + z[1]^2*z[4] + z[1]*z[2]^2 + 2*z[1]*z[2]*z[3] +
    2*z[1]*z[2]*z[4] + z[1]*z[3]^2 + 2*z[1]*z[3]*z[4] + z[1]*z[4]^2 +
    z[2]^2*z[3] + z[2]^2*z[4] + z[2]*z[3]^2 + 2*z[2]*z[3]*z[4] +
    z[2]*z[4]^2 + z[3]^2*z[4] + z[3]*z[4]^2
>
> P5<[w]> := PolynomialRing(Q, 5);
> P5 ! e;
w[1]^2*w[2] + w[1]^2*w[3] + w[1]^2*w[4] + w[1]^2*w[5] + w[1]*w[2]^2 +
    2*w[1]*w[2]*w[3] + 2*w[1]*w[2]*w[4] + 2*w[1]*w[2]*w[5] + w[1]*w[3]^2 +
    2*w[1]*w[3]*w[4] + 2*w[1]*w[3]*w[5] + w[1]*w[4]^2 + 2*w[1]*w[4]*w[5] +
    w[1]*w[5]^2 + w[2]^2*w[3] + w[2]^2*w[4] + w[2]^2*w[5] + w[2]*w[3]^2 +
    2*w[2]*w[3]*w[4] + 2*w[2]*w[3]*w[5] + w[2]*w[4]^2 + 2*w[2]*w[4]*w[5] +
    w[2]*w[5]^2 + w[3]^2*w[4] + w[3]^2*w[5] + w[3]*w[4]^2 +
    2*w[3]*w[4]*w[5] + w[3]*w[5]^2 + w[4]^2*w[5] + w[4]*w[5]^2
```

146.2 Creation

146.2.1 Creation of Symmetric Function Algebras

Symmetric functions are symmetric polynomials over some coefficient ring, hence the algebra of symmetric functions is defined by specifying this ring. There are five standard bases that can be used to express symmetric functions. In MAGMA there are separate constructions for creating an algebra using each distinct basis.

`SymmetricFunctionAlgebra(R)`

`SFA(R)`

`Basis` MonStgElt *Default :* "*Schur*"

Given a ring R, return the algebra of symmetric functions over R. By default this algebra will use the basis of `"Schur"` functions, though the parameter `Basis` allows the user to specify that the basis be one of the `"Homogeneous"`, `"PowerSum"`, `"Elementary"` or `"Monomial"` functions.

`SymmetricFunctionAlgebraSchur(R)`

`SFASchur(R)`

Given a commutative ring with unity R, create the algebra of symmetric functions (polynomials) with coefficients from R. Its elements are expressed in terms of the basis of *Schur* symmetric functions, which are indexed by partitions.

`SymmetricFunctionAlgebraHomogeneous`

`SFAHomogeneous(R)`

Given a commutative ring with unity R, create the algebra of symmetric functions (polynomials) with coefficients from R. Its elements are expressed in terms of the basis of *Homogeneous* symmetric functions, which are indexed by partitions.

`SymmetricFunctionAlgebraPower(R)`

`SFAPower(R)`

Given a commutative ring with unity R, create the algebra of symmetric functions (polynomials) with coefficients from R. Its elements are expressed in terms of the basis of *Power Sum* symmetric functions, which are indexed by partitions.

`SymmetricFunctionAlgebraElementary(R)`

`SFAElementary(R)`

Given a commutative ring with unity R, create the algebra of symmetric functions (polynomials) with coefficients from R. Its elements are expressed in terms of the basis of *Elementary* symmetric functions, which are indexed by partitions.

`SymmetricFunctionAlgebraMonomial(R)`

`SFAMonomial(R)`

Given a commutative ring with unity R, create the algebra of symmetric functions (polynomials) with coefficients from R. Its elements are expressed in terms of the basis of *Monomial* symmetric functions, which are indexed by partitions.

Example H146E2

A symmetric polynomial can be expressed in terms of any of the 5 standard bases.

```
> R := Rationals();
> S := SymmetricFunctionAlgebraSchur(R);
Symmetric Algebra over Rational Field, Schur symmetric functions as basis
> E := SymmetricFunctionAlgebra(R : Basis := "Elementary");
Symmetric Algebra over Rational Field, Elementary symmetric functions as basis
> f1 := S.[2,1];
> f1;
S.[2,1]
>
> f2 := E ! f1;
> f2;
E.[2,1] - E.[3]
> f1 eq f2;
true
>
> P<x,y,z> := PolynomialRing(R, 3);
> P ! f1;
x^2*y + x^2*z + x*y^2 + 2*x*y*z + x*z^2 + y^2*z + y*z^2
> P ! f2;
x^2*y + x^2*z + x*y^2 + 2*x*y*z + x*z^2 + y^2*z + y*z^2
```

146.2.2 Creation of Symmetric Functions

For each of the 5 different standard basis for symmetric functions, basis elements are indexed via partitions (weakly decreasing positive sequences). The *weight* of a partition is the sum of its entries, and gives the degree of the element.

For example, $[3, 1]$ is a partition of weight 4, hence a symmetric function basis element corresponding to $[3, 1]$ will be a symmetric polynomial of degree 4.

General symmetric functions are linear combinations of basis elements and can be created by taking such linear combinations or via coercion from either another basis or directly from a polynomial.

`A . P`

Given a partition P, which is a weakly decreasing positive sequence of integers, return the basis element of the algebra of symmetric functions A corresponding to P.

`A . i`

Given a positive integer i, return the basis element of the algebra of symmetric functions A corresponding to the partition $[i]$.

Example H146E3

We can create elements via linear combinations of basis elements.

```
> R := Rationals();
> M := SFAMonomial(R);
> M.[3,1];
M.[3,1]
>  M.4;
M.[4]
> 3 * M.[3,1] - 1/2 * M.4;
3*M.[3,1] - 1/2*M.[4]
```

`IsCoercible(A, f)`

`A ! f`

Given a multivariate polynomial f which is symmetric in all of its indeterminates (and hence is a symmetric function), return f as an element of the algebra of symmetric functions A. This element returned will be expressed in terms of the symmetric function basis of A.

Example H146E4

Symmetric polynomials are symmetric functions. These can be coerced into algebras of symmetric functions and hence expressed in terms of the relevant basis. Polynomials which are not symmetric cannot be coerced.

```
> R := Rationals();
> M := SFAMonomial(R);
> P<[x]> := PolynomialRing(R, 3);
> f := -3*x[1]^3 + x[1]^2*x[2] + x[1]^2*x[3] + x[1]*x[2]^2 + x[1]*x[3]^2 -
>          3*x[2]^3 + x[2]^2*x[3] + x[2]*x[3]^2 - 3*x[3]^3;
> M!f;
M.[2,1] - 3*M.[3]
>  M ! (x[1] + x[2]*x[3]);
>> M ! (x[1] + x[2]*x[3]);
     ^
Runtime error in '!': Polynomial is not symmetric
```

`A ! r`

Create the scalar element r in the symmetric function algebra A.

Example H146E5

```
> R := Rationals();
> P := SFAPower(R);
> m := P!3;
> m;
3
> Parent(m);
Symmetric Algebra over Rational Field, Power sum symmetric functions as basis
> m + P.[3,2];
3 + P.[3,2]
```

`A ! m`

Given a symmetric function algebra A and a symmetric function m (possibly with a different basis), return the element m expressed in terms of the basis of A.

Example H146E6

A symmetric function can easily be expressed in terms of any of the symmetric function bases, or as a polynomial.

```
> R := Rationals();
> S := SFASchur(R);
> H := SFAHomogeneous(R);
> P := SFAPower(R);
> E := SFAElementary(R);
> M := SFAMonomial(R);
>
> m := S.[3,1];
> S!m;
S.[3,1]
> H!m;
H.[3,1] - H.[4]
> P!m;
1/8*P.[1,1,1,1] + 1/4*P.[2,1,1] - 1/8*P.[2,2] - 1/4*P.[4]
> E!m;
E.[2,1,1] - E.[3,1] - E.[2,2] + E.[4]
> M!m;
3*M.[1,1,1,1] + 2*M.[2,1,1] + M.[3,1] + M.[2,2]
>
> PP<[x]> := PolynomialRing(R, 4);
> PP ! m;
x[1]^3*x[2] + x[1]^3*x[3] + x[1]^3*x[4] + x[1]^2*x[2]^2 + 2*x[1]^2*x[2]*x[3] +
    2*x[1]^2*x[2]*x[4] + x[1]^2*x[3]^2 + 2*x[1]^2*x[3]*x[4] + x[1]^2*x[4]^2 +
    x[1]*x[2]^3 + 2*x[1]*x[2]^2*x[3] + 2*x[1]*x[2]^2*x[4] + 2*x[1]*x[2]*x[3]^2 +
    3*x[1]*x[2]*x[3]*x[4] + 2*x[1]*x[2]*x[4]^2 + x[1]*x[3]^3 +
    2*x[1]*x[3]^2*x[4] + 2*x[1]*x[3]*x[4]^2 + x[1]*x[4]^3 + x[2]^3*x[3] +
```

```
x[2]^3*x[4] + x[2]^2*x[3]^2 + 2*x[2]^2*x[3]*x[4] + x[2]^2*x[4]^2 +
x[2]*x[3]^3 + 2*x[2]*x[3]^2*x[4] + 2*x[2]*x[3]*x[4]^2 + x[2]*x[4]^3 +
x[3]^3*x[4] + x[3]^2*x[4]^2 + x[3]*x[4]^3
```

Example H146E7

We show that the k-th homogeneous symmetric function is defined as the sum over all monomial symmetric functions indexed by partitions of weight k.

```
> R := Rationals();
> M := SFA(R : Basis := "Monomial");
> H := SFA(R : Basis := "Homogeneous");
>
> H ! (M.[1]);
H.[1]
> H ! (M.[2] + M.[1,1]);
H.[2]
> H ! (M.[3] + M.[2,1] + M.[1,1,1]);
H.[3]
> H ! (M.[4] + M.[3,1] + M.[2,2] + M.[2,1,1] + M.[1,1,1,1]);
H.[4]
>
> k := 5;
> H ! &+ [ M.P : P in Partitions(k)];
H.[5]
> k := 10;
> H ! &+ [ M.P : P in Partitions(k)];
H.[10]
```

146.3 Structure Operations

146.3.1 Related Structures

The main structure related to an algebra of symmetric functions is its coefficient ring. An algebra of symmetric functions belongs to the MAGMA category `AlgSym`.

`BaseRing(L)`

`CoefficientRing(L)`

Return the coefficient ring of an algebra of symmetric functions L.

`Category(L)` `Parent(L)` `PrimeRing(L)`

146.3.2 Ring Predicates and Booleans

The usual ring functions returning boolean values are available on algebras of symmetric functions.

`IsCommutative(L)` `IsUnitary(L)` `IsFinite(L)` `IsOrdered(L)`
`IsField(L)` `IsEuclideanDomain(L)` `IsPID(L)` `IsUFD(L)`
`IsDivisionRing(L)` `IsEuclideanRing(L)` `IsDomain(L)`
`IsPrincipalIdealRing(L)`

`L eq M`
`L ne M`

Return `true` if L and M are equal (respectively, not equal). MAGMA considers two algebras to be equal if they are over the same ring.

146.3.3 Predicates on Basis Types

`HasSchurBasis(A)`

Returns `true` if A is an algebra with a Schur basis.

`HasHomogeneousBasis(A)`
`HasElementaryBasis(A)`
`HasPowerSumBasis(A)`
`HasMonomialBasis(A)`

Returns `true` if A is an algebra with a homogeneous, elementary, power sum or monomial basis respectively.

146.4 Element Operations

146.4.1 Parent and Category

The category for elements in algebras of symmetric functions is `AlgSymElt`.

`Parent(f)` `Category(f)`

146.4.2 Print Styles

By default, elements are printed using a lexicographical ordering on the partitions indexing the basis elements. For partitions of the same weight w this ordering is the reverse of that in `Partitions(w)`. More generally, basis elements indexed by partitions with smaller entries print first (see 10.5.2). It is possible to rearrange the linear combination of basis elements so that the basis elements indexed by the longest partition print first and also so that the basis elements indexed by the partition with greatest maximal part (first entry) print first.

`A ‘ PrintStyle`

Retrieve or set the style in which elements of the algebra A will print. The default is the lexicographical ordering described above, `"Lex"`. Other options are `"Length"` and `"MaximalPart"`.

Example H146E8

We demonstrate the setting of the `PrintStyle` and the corresponding printing of elements.

```
> M := SFAMonomial(Rationals());
> M‘PrintStyle;
Lex
> P := Partitions(3);
> P;
[
    [ 3 ],
    [ 2, 1 ],
    [ 1, 1, 1 ]
]
> f := &+[M.p : p in P];
> f;
M.[1,1,1] + M.[2,1] + M.[3]
> M‘PrintStyle := "Length";
> f;
M.[3] + M.[2,1] + M.[1,1,1]
> M‘PrintStyle := "MaximalPart";
> f;
M.[1,1,1] + M.[2,1] + M.[3]
```

146.4.3 Additive Arithmetic Operators

The usual unary and binary ring element operations are available for symmetric functions. It is possible to combine elements of different algebras (so long as the coefficient rings are compatible) in these operations. Where the elements are written with respect to different bases, the result will be written with respect to the basis of the second operand.

`+ a` `- a`

`a + b` `a - b`

`a +:= b` `a -:= b`

146.4.4 Multiplication

Where the elements being multiplied are expressed with respect to different bases, the result will again be expressed with respect to the basis of the second operand. The algorithm used for multiplication is dependent on the bases with respect to which the elements are expressed.

`a * b`

`a *:= b`

The product of the symmetric functions a and b.

If b is expressed with respect to a Schur basis and a is expressed with respect to a power sum, elementary or monomial basis then the algorithm based on Muirs rule [Mui60] is used. If a is expressed with respect to a homogeneous basis the algorithm based on the Pieri rule [Mac95] is used and if a is also expressed with respect to a Schur basis then the method of Schubert polynomials [LS85] is used.

Special algorithms are also used if b is expressed with respect to a monomial basis and a is expressed with respect to a homogeneous, elementary or monomial basis.

When both a and b have a homogeneous, elementary or power sum basis, the multiplication of basis elements involves the merging of the parts of the partitions. This follows from the definition of the basis elements $f_\lambda = \prod_i f_{\lambda_i}$ where f_λ is a homogeneous, elementary or power sum basis element.

Otherwise a is coerced into the parent of b before the elements are multiplied.

The degree of the result is the sum of the degrees of both the operands.

`a ^ k`

Example H146E9

```
> Q := Rationals();
> s := SFASchur(Q);
> m := SFAMonomial(Q);
> m.[3]*s.[2,1];
s.[2,1,1,1,1] + s.[5,1] - s.[2,2,2] - s.[3,3]
```

To illustrate the merging of the partitions :

```
> E := SFAElementary(Q);
> E.4*E.3*E.1;
E.[4,3,1]
```

This is the definition of $e_{[4,3,1]}$.

146.4.5 Plethysm

Plethysm is also referred to as composition of symmetric functions.

`a ~ b`

This operator computes the plethysm or composition of the symmetric functions a and b. The result is given with respect to the basis of the second operand.

The degree of the result is the product of the degrees of operands which may be very large.

Example H146E10

```
> Q := Rationals();
> s := SFASchur(Q);
> m := SFAMonomial(Q);
> m.[3]~s.[2,1];
s.[4,1,1,1,1,1] - s.[3,2,1,1,1,1] - s.[5,1,1,1,1] + s.[2,2,2,1,1,1] +
s.[3,3,1,1,1] + s.[6,1,1,1] - s.[2,2,2,2,1] - s.[3,3,2,1] - s.[6,2,1] +
s.[4,4,1] + s.[3,2,2,2] + s.[5,2,2] - s.[4,3,2] + 2*s.[3,3,3] + s.[6,3] -
s.[5,4]
```

146.4.6 Boolean Operators

`IsHomogeneous(s)`

Returns `true` if the partitions indexing the basis elements present in the symmetric function s are all of the same weight. This implies that each term has the same degree so is the same as the polynomial expansion of s being a homogeneous polynomial.

`IsZero(s)` `IsOne(s)` `IsMinusOne(s)`

`s eq t`

`s ne t`

Return `true` if the symmetric functions s and t are (not) the same.

146.4.7 Accessing Elements

`Coefficient(s, p)`

Given a symmetric function s return the coefficient of the basis element A_p, where A is the parent of s and p is a sequence defining a partition. The coefficient may be zero.

`Support(s)`

Return two parallel sequences of the partitions indexing the basis elements and the coefficients of those basis elements in the symmetric function s, which is a linear combination of basis elements.

`Length(s)`

Given a symmetric function s, return the length of s, i.e., the number of basis elements having non zero coefficients in s, with respect to the current basis.

Example H146E11

We pull apart an element and show that we can put it back together again.

```
> H := SFAHomogeneous(Rationals());
> P := Partitions(4);
> f := &+[Random(1, 5)*H.p : p in P];
> f;
H.[1,1,1,1] + 4*H.[2,1,1] + 4*H.[2,2] + 5*H.[3,1] + 5*H.[4]
> s, e := Support(f);
> s, e;
[
    [ 1, 1, 1, 1 ],
    [ 2, 1, 1 ],
    [ 2, 2 ],
    [ 3, 1 ],
    [ 4 ]
]
[ 1, 4, 4, 5, 5 ]
> f eq &+[e[i]*H.s[i] : i in [1 .. Length(f)]];
true
```

`Degree(s)`

Given a symmetric function s, return the degree of s, i.e., the maximal degree of the basis elements having non zero coefficients in s, which is the maximal weight of the partitions indexing those basis elements.

146.4.8 Multivariate Polynomials

A symmetric function may be seen as a polynomial in any number of variables.

`P ! s`

Return the polynomial expansion of the symmetric function s in the polynomial ring P.

Example H146E12

```
> S := SFASchur(GF(7));
> s := S.[3,1];
```

Now we compute the multivariate polynomial we get by restricting to 5 variables.

```
> G<e1, e2, e3, e4, e5> := PolynomialRing(GF(7), 5);
> p := G!s;
> p;
e1^3*e2 + e1^3*e3 + e1^3*e4 + e1^3*e5 + e1^2*e2^2 + 2*e1^2*e2*e3 + 2*e1^2*e2*e4
    + 2*e1^2*e2*e5 + e1^2*e3^2 + 2*e1^2*e3*e4 + 2*e1^2*e3*e5 + e1^2*e4^2 +
    2*e1^2*e4*e5 + e1^2*e5^2 + e1*e2^3 + 2*e1*e2^2*e3 + 2*e1*e2^2*e4 +
    2*e1*e2^2*e5 + 2*e1*e2*e3^2 + 3*e1*e2*e3*e4 + 3*e1*e2*e3*e5 + 2*e1*e2*e4^2 +
    3*e1*e2*e4*e5 + 2*e1*e2*e5^2 + e1*e3^3 + 2*e1*e3^2*e4 + 2*e1*e3^2*e5 +
    2*e1*e3*e4^2 + 3*e1*e3*e4*e5 + 2*e1*e3*e5^2 + e1*e4^3 + 2*e1*e4^2*e5 +
    2*e1*e4*e5^2 + e1*e5^3 + e2^3*e3 + e2^3*e4 + e2^3*e5 + e2^2*e3^2 +
    2*e2^2*e3*e4 + 2*e2^2*e3*e5 + e2^2*e4^2 + 2*e2^2*e4*e5 + e2^2*e5^2 + e2*e3^3
    + 2*e2*e3^2*e4 + 2*e2*e3^2*e5 + 2*e2*e3*e4^2 + 3*e2*e3*e4*e5 + 2*e2*e3*e5^2
    + e2*e4^3 + 2*e2*e4^2*e5 + 2*e2*e4*e5^2 + e2*e5^3 + e3^3*e4 + e3^3*e5 +
    e3^2*e4^2 + 2*e3^2*e4*e5 + e3^2*e5^2 + e3*e4^3 + 2*e3*e4^2*e5 + 2*e3*e4*e5^2
    + e3*e5^3 + e4^3*e5 + e4^2*e5^2 + e4*e5^3
```

To check the polynomial is actually symmetric, we can use the MAGMA intrinsic `IsSymmetric`, which also computes an expansion as a sum of elementary symmetric polynomials.

```
> IsSymmetric(p,G);
true e1^2*e2 + 6*e1*e3 + 6*e2^2 + e4
```

Which is identical to the result of

```
> E := SFAElementary(GF(7));
> E!s;
E.[2,1,1] + 6*E.[2,2] + 6*E.[3,1] + E.[4]
```

Example H146E13

These conversions may be used to change the alphabet of a symmetric function. For example, if we substitute the variable x_i by $x_i + 1$, the result is again a symmetric function, however we use polynomials to do the evaluation.

```
> S := SFASchur(Rationals());
> R<a, b, c, d, e> := PolynomialRing(Rationals(), 5);
```

```
> p := Polynomial(S.[3,2], R);
> q := Evaluate(p, [a+1, b+1, c+1, d+1, e+1]);
> x, y := IsCoercible(S, q);
> y;
175 + 175*S.[1] + 70*S.[1,1] + 70*S.[2] + 35*S.[2,1] + 7*S.[2,2] + 10*S.[3] +
5*S.[3,1] + S.[3,2]
```

146.4.9 Frobenius Homomorphism

There is an automorphism which maps the elementary symmetric function to the homogeneous symmetric function.

`Frobenius(s)`

Given any symmetric function s, compute the image of s under the Frobenius automorphism. The image will have the same parent as s. When the power sum symmetric functions are involved, it may be necessary to work with a coefficient ring which allows division by an integer.

Example H146E14

It is known that the Frobenius automorphism on the Schur functions acts just by conjugating the indexing partitions.

```
> S := SFASchur(Integers());
> E := SFAElementary(Integers());
> h := S!E.[3,3,3];
> h;
S.[1,1,1,1,1,1,1,1,1] + 2*S.[2,1,1,1,1,1,1,1] + S.[3,1,1,1,1,1,1] +
3*S.[2,2,1,1,1,1,1] + 2*S.[3,2,1,1,1,1] + 4*S.[2,2,2,1,1,1] + S.[3,3,1,1,1] +
3*S.[3,2,2,1,1] + 2*S.[2,2,2,2,1] + 2*S.[3,3,2,1] + S.[3,2,2,2] + S.[3,3,3]
```

Now apply the Frobenius automorphism.

```
> f:=Frobenius(h);
> f;
S.[3,3,3] + 2*S.[4,3,2] + S.[4,4,1] + S.[5,2,2] + 3*S.[5,3,1] + 2*S.[5,4] +
2*S.[6,2,1] + 4*S.[6,3] + S.[7,1,1] + 3*S.[7,2] + 2*S.[8,1] + S.[9]
```

To check whether the coefficient of the basis element indexed by a partition in one element is the same as the coefficient of the basis element indexed by the conjugate partition in the other :

```
> p:=Partitions(f);
> for pp in p do
>    if Coefficient(h, ConjugatePartition(pp)) ne Coefficient(f, pp) then
>       print pp;
>    end if;
> end for;
```

146.4.10 Inner Product

An inner product on Λ is defined by

$$\langle m_\lambda, h_{\lambda'} \rangle = \delta_{\lambda,\lambda'}.$$

This definition ensures that the bases m_λ and h_λ are dual to each other. This is the inner product used by MAGMA.

`InnerProduct(a,b)`

Computes the inner product of the symmetric functions a and b.

Example H146E15

The inner product of a elementary symmetric function indexed by a partition and the homogeneous symmetric function indexed by the conjugate partition is 1. (This allows the computation of irreducible representations of the symmetric group.) To check this with MAGMA, we do the following:

```
> E := SFAElementary(Rationals());
> H := SFAHomogeneous(Rationals());
> p:=RandomPartition(45);
> pc:=ConjugatePartition(p);
> InnerProduct(E.p,H.pc);
1
```

As it should be the result is 1.

146.4.11 Combinatorial Objects

The Schur function is the generating function of standard tableaux. Therefore, it is possible to get the corresponding tableaux.

`Tableaux(sf, m)`

Given a Schur function sf over the integers with positive coefficients, return the multiset of the tableaux, with maximal entry m, for which sf is the generating function.

146.4.12 Symmetric Group Character

A Schur function indexed by a single partition, i.e. a basis element, corresponds to an irreducible character of the symmetric group.

`SymmetricCharacter(sf)`

Given an element sf of an algebra of symmetric functions return a linear combination of irreducible characters of the symmetric group, whose coefficients are the coefficients of sf with respect to the Schur function basis.

Example H146E16

We look at a result in the representation theory of the symmetric group. There is exactly one irreducible character contained in both the induced character from the identity character of a Young subgroup indexed by the partition I and the induced character from the alternating character of a Young subgroup indexed by the partition J, conjugate to I. As the induced character of the identity character of a Young subgroup corresponds to the homogeneous symmetric function h_I and the induced character of the alternating character corresponds to the elementary symmetric function e_J, we can verify this using the following routine:

```
> H := SFAHomogeneous(Rationals());
> E := SFAElementary(Rationals());
> p := Partitions(7);
> for I in p do
>     a := SymmetricCharacter(H.I);
>     J := ConjugatePartition(I);
>     b := SymmetricCharacter(E.J);
>     i := InnerProduct(a,b);
>     if i ne 1 then print i; end if;
> end for;
```

And there should be no output.

146.4.13 Restrictions

It is possible to form symmetric functions whose support is a subset of the support of a given symmetric function, subject to some restrictions.

`RestrictDegree(a, n)`

`Exact` BoolElt *Default :* `true`

Return the symmetric function which is a linear combination of those basis elements of the symmetric function a with degree n. This is the restriction of a into the submodule Λ^n. If `Exact` is `false` then the basis elements included will have degree $\leq n$. This is the restriction of a into $\bigcup_{k \leq n} \Lambda^k$.

`RestrictPartitionLength(a, n)`

`Exact` BoolElt *Default :* `true`

Return the symmetric function which is a linear combination of those basis elements of the symmetric function a whose indexing partitions are of length n. If `Exact` is `false`, then the indexing partitions will be of length $\leq n$.

`RestrictParts(a, n)`

`Exact` BoolElt *Default :* `true`

Return the symmetric function which is a linear combination of those basis elements of the symmetric function a whose indexing partitions have maximal part n. If `Exact` is `false`, then the indexing partitions will have maximal part $\leq n$.

146.5 Transition Matrices

One area of interest in the theory of symmetric functions is the study of the change of bases between the five different bases. The matrices of change of base between the s_λ, h_λ, m_λ and the e_λ are all integer matrices. Only when changing from one of these four bases to the p_λ, is the matrix over the rationals. For a discussion of their computation and interactions see [Mac95, pages 54–58].

In MAGMA there are routines available to obtain all these matrices. These routines are described below. Some interactions of these matrices are verified in examples.

146.5.1 Transition Matrices from Schur Basis

`SchurToMonomialMatrix(n)`

Computes the matrix for the expansion of a Schur function indexed by a partition of weight n as a sum of monomial symmetric functions. This matrix is also known as the table of *Kostka* numbers. These are the numbers of tableaux of each shape and content. The content of a tableau prescribes its entries, so for example a tableau with content $[2, 1, 4, 1]$ has two 1's, one 2, four 3's and one 4. The entries of the matrix are non negative integers. The matrix is upper triangular.

Example H146E17

Compute the base change matrix from the Schur functions to the monomial symmetric functions for degree 5. The entries in this matrix are what are known as the *Kostka* numbers. They count the number of young tableaux on a given shape Look on the order of the labelling partitions, and check whether the entry 3 in the upper right corner is right by generating the corresponding tableaux.

```
> M := SchurToMonomialMatrix(5);
> M;
[1 1 1 1 1 1 1]
[0 1 1 2 2 3 4]
[0 0 1 1 2 3 5]
[0 0 0 1 1 3 6]
[0 0 0 0 1 2 5]
[0 0 0 0 0 1 4]
[0 0 0 0 0 0 1]
> Parts := Partitions(5);
> Parts;
[
    [ 5 ],
    [ 4, 1 ],
    [ 3, 2 ],
    [ 3, 1, 1 ],
    [ 2, 2, 1 ],
    [ 2, 1, 1, 1 ],
    [ 1, 1, 1, 1, 1 ]
]
```

```
> #TableauxOnShapeWithContent(Parts[2], Parts[6]);
3
> M[2,6];
3
```

`SchurToHomogeneousMatrix(n)`

Computes the matrix for the expansion of a Schur function indexed by a partition of weight n as a sum of homogeneous symmetric functions. The entries of the matrix are positive and negative integers. The matrix is lower triangular. It is the transpose of the matrix returned by `MonomialToSchurMatrix(n)`.

`SchurToPowerSumMatrix(n)`

Computes the matrix for the expansion of a Schur function indexed by a partition of weight n as a sum of power sum symmetric functions. The entries of the matrix are rationals.

`SchurToElementaryMatrix(n)`

Computes the matrix for the expansion of a Schur function indexed by a partition of weight n as a sum of elementary symmetric functions. The entries of the matrix are positive and negative integers. The matrix is upper left triangular.

Example H146E18

We verify by hand that the action of base change matrix is the same as coercion.

```
> S := SFASchur(Rationals());
> P := SFAPower(Rationals());
> NumberOfPartitions(4);
5
> m := SchurToPowerSumMatrix(4);
> Partitions(4);
[
    [ 4 ],
    [ 3, 1 ],
    [ 2, 2 ],
    [ 2, 1, 1 ],
    [ 1, 1, 1, 1 ]
]
> s := S.[3, 1] + 5*S.[1, 1, 1, 1] - S.[4];
> s;
5*S.[1,1,1,1] + S.[3,1] - S.[4]
> p, c := Support(s);
> c;
[ 5, 1, -1 ]
> p;
[
```

```
    [ 1, 1, 1, 1 ],
    [ 3, 1 ],
    [ 4 ]
]
> cm := Matrix(Rationals(), 1, 5, [-1, 1, 0, 0, 5]);
> cm*m;
[-7/4  4/3  3/8 -5/4 7/24]
> P!s;
7/24*P.[1,1,1,1] - 5/4*P.[2,1,1] + 3/8*P.[2,2] + 4/3*P.[3,1] - 7/4*P.[4]
```

The coefficients of the coerced element are the reverse of the matrix product, consistent with the partition in the coerced element being in reverse order to those in `Partitions(4)`.

146.5.2 Transition Matrices from Monomial Basis

`MonomialToSchurMatrix(n)`

Computes the matrix for the expansion of a monomial symmetric function indexed by a partition of weight n as a sum of Schur symmetric functions. The entries of the matrix are positive and negative integers. The matrix is upper triangular. It is the transpose of the matrix returned by `SchurToHomogeneousMatrix(n)`.

`MonomialToHomogeneousMatrix(n)`

Computes the matrix for the expansion of a monomial symmetric function indexed by a partition of weight n as a sum of homogeneous symmetric functions. The entries are positive and negative integers.

`MonomialToPowerSumMatrix(n)`

Computes the matrix for the expansion of a monomial symmetric function indexed by a partition of weight n as a sum of power sum symmetric functions. The entries are rationals. The matrix is lower triangular.

`MonomialToElementaryMatrix(n)`

Computes the matrix for the expansion of a monomial symmetric function indexed by a partition of weight n as a sum of elementary symmetric functions. The entries of the matrix are positive and negative integers. The matrix is upper left triangular.

146.5.3 Transition Matrices from Homogeneous Basis

`HomogeneousToSchurMatrix(n)`

Computes the matrix for the expansion of a homogeneous symmetric function indexed by a partition of weight n as a sum of Schur symmetric functions. The entries of the matrix are positive integers. The matrix is lower triangular.

Example H146E19

It is known that the matrix computed by `HomogeneousToSchurMatrix` is the transpose of the matrix computed by `SchurToMonomialMatrix`.

```
> SchurToMonomialMatrix(7) eq Transpose(HomogeneousToSchurMatrix(7));
true
```

`HomogeneousToMonomialMatrix(n)`

Computes the matrix M for the expansion of a homogeneous symmetric function indexed by a partition of weight n as a sum of monomial symmetric functions. The entries of the matrix are positive integers. The matrix has no zero entries.

The coefficient $M_{\mu,\lambda}$ in the expansion $h_\lambda = \sum_\mu M_{\mu,\lambda} m_\mu$ is the number of non negative integer matrices with row sums λ_i and column sums μ_j, see [Mac95, page 57].

Example H146E20

The matrix converting from homogeneous basis to monomial basis is symmetric.

```
> IsSymmetric(HomogeneousToMonomialMatrix(7));
true
```

`HomogeneousToPowerSumMatrix(n)`

Computes the matrix for the expansion of a homogeneous symmetric function indexed by a partition of weight n as a sum of power sum symmetric functions. The entries of the matrix are positive rationals. The matrix is upper triangular.

`HomogeneousToElementaryMatrix(n)`

Computes the matrix for the expansion of a homogeneous symmetric function indexed by a partition of weight n as a sum of elementary symmetric functions. The entries of the matrix are integers. The matrix is upper triangular.

Example H146E21

It is known that the matrix compute by `HomogeneousToElementaryMatrix` is the same as the matrix computed by `ElementaryToHomogeneousMatrix`.

```
> HomogeneousToElementaryMatrix(7) eq ElementaryToHomogeneousMatrix(7);
true
```

146.5.4 Transition Matrices from Power Sum Basis

`PowerSumToSchurMatrix(n)`

Computes the matrix for the expansion of a power sum symmetric function indexed by a partition of weight n as a sum of Schur symmetric functions. The entries of the matrix are positive and negative integers. This matrix is the character table of the symmetric group.

Example H146E22

The matrix returned by `PowerSumToSchurMatrix` is compared to the character table of the appropriate symmetric group.

```
> PowerSumToSchurMatrix(5);
[ 1 -1  0  1  0 -1  1]
[ 1  0 -1  0  1  0 -1]
[ 1 -1  1  0 -1  1 -1]
[ 1  1 -1  0 -1  1  1]
[ 1  0  1 -2  1  0  1]
[ 1  2  1  0 -1 -2 -1]
[ 1  4  5  6  5  4  1]
> CharacterTable(Sym(5));

Character Table
---------------

-----------------------------
Class |   1  2  3  4  5  6  7
Size  |   1 10 15 20 30 24 20
Order |   1  2  2  3  4  5  6
-----------------------------
p  =  2   1  1  1  4  3  6  4
p  =  3   1  2  3  1  5  6  2
p  =  5   1  2  3  4  5  1  7
-----------------------------
X.1   +   1  1  1  1  1  1  1
X.2   +   1 -1  1  1 -1  1 -1
```

```
X.3   +   4  2  0  1  0 -1 -1
X.4   +   4 -2  0  1  0 -1  1
X.5   +   5  1  1 -1 -1  0  1
X.6   +   5 -1  1 -1  1  0 -1
X.7   +   6  0 -2  0  0  1  0
```

In the character table the first row is the unity character, which corresponds to the first column of the transition matrix. The second row of the character table is the alternating character which corresponds to the last column of the transition matrix. The first column of the character table contains the dimensions of the irreducible characters, this is the last row of the transition matrix.

`PowerSumToMonomialMatrix(n)`

Computes the matrix for the expansion of a power sum symmetric function indexed by a partition of weight n as a sum of monomial symmetric functions. The entries of the matrix are positive integers. The matrix is lower triangular.

`PowerSumToHomogeneousMatrix(n)`

Computes the matrix for the expansion of a power sum symmetric function indexed by a partition of weight n as a sum of homogeneous symmetric functions. The entries of the matrix are integers. The matrix is upper triangular.

`PowerSumToElementaryMatrix(n)`

Computes the matrix for the expansion of a power sum symmetric function indexed by a partition of weight n as a sum of elementary symmetric functions. The entries of the matrix are integers. The matrix is upper triangular.

146.5.5 Transition Matrices from Elementary Basis

`ElementaryToSchurMatrix(n)`

Computes the matrix for the expansion of an elementary symmetric function indexed by a partition of weight n as a sum of Schur symmetric functions. The entries of the matrix are positive integers.

`ElementaryToMonomialMatrix(n)`

Computes the matrix M for the expansion of an elementary symmetric function indexed by a partition of weight n as a sum of monomial symmetric functions. The entries of the matrix are positive integers.

The coefficient $M_{\mu,\lambda}$ in the expansion $e_\lambda = \sum_\mu M_{\mu,\lambda} m_\mu$ is the number of 0-1 integer matrices with row sum λ_i and column sum μ_j, see [Mac95, page 57].

Example H146E23

The matrix converting from elementary basis to monomial basis is symmetric.

```
> IsSymmetric(ElementaryToMonomialMatrix(7));
true
```

`ElementaryToHomogeneousMatrix(n)`

Computes the matrix for the expansion of a elementary symmetric function indexed by a partition of weight n as a sum of homogeneous symmetric functions.

`ElementaryToPowerSumMatrix(n)`

Computes the matrix for the expansion of a elementary symmetric function indexed by a partition of weight n as a sum of power sum symmetric functions.

147 INCIDENCE STRUCTURES AND DESIGNS

Chapter 147
INCIDENCE STRUCTURES AND DESIGNS

147.1 Introduction

Since there is some variation between authors of the terminology employed in design theory, we begin with some definitions. An *incidence structure* is a triple $D = (P, B, I)$, where:

(a) P is a set, the elements of which are called *points*;

(b) B is a set, the elements of which are called *blocks*;

(c) I is an incidence relation between P and B, so that $I \subset P \times B$. The elements of I are called *flags*.

Usually, blocks will be subsets of P, so that instead of writing $(p, b) \in I$, we write $p \in b$. In general, repeated blocks are allowed so that different blocks may correspond to the same subset of P. If D has no repeated blocks, then we say that D is *simple*.

An incidence structure D is said to be *uniform* with *blocksize* k if D has at least one block and all blocks contain exactly k points. A uniform incidence structure is called *trivial* if each k-subset of the point set appears as a block (at least once).

Let $t \geq 0$ be an integer. Then an incidence structure D is said to be *t–balanced* if there exists an integer $\lambda \geq 1$ such that each t–subset of the point set is contained in exactly λ blocks of D.

A *near–linear space* is an incidence structure in which every block contains at least two points and any two points lie in at most one block. A *linear space* is a near–linear space in which any two points lie in *exactly* one block. It is usual, when discussing near–linear spaces, to use the term *line* in place of the term *block*.

Let v, k, t and λ be integers with $v \geq k \geq t \geq 0$ and $\lambda \geq 1$. A *t–design* with v points and *blocksize* k is an incidence structure $D = (P, B, I)$ where:

(a) The cardinality of P is v;

(b) D is uniform with blocksize k;

(c) D is simple;

(d) For each t–subset T of P there are exactly λ blocks of B incident with all the points of T (so D is t–balanced).

Such a design is usually referred to as a t–(v, k, λ) design. The parameter λ is called the *index* of the design. If b denotes the cardinality of B, a t–design with $v = b$ and $t \geq 2$ is called a *symmetric design*. A t–design with $\lambda = 1$ is called a *Steiner design*. A design which is trivial is also called a *complete design*. Note that a design D must contain at least one block (i.e $b > 0$).

The category names for the different families of incidence structures are as follows:

- Incidence structure : `Inc`
- Near-linear space : `IncNsp`
- Linear space : `IncLsp`
- t–design : `Dsgn`

147.2 Construction of Incidence Structures and Designs

`IncidenceStructure< v | X >`

`IncidenceStructure< P | X >`

Construct the incidence structure D having point set $P = \{@p_1, p_2, \ldots, p_v@\}$ (where $p_i = i$ for each i if the first form of the constructor is used), and block set $B = \{B_1, B_2, \ldots, B_b\}$ given by X. The value of X must be either:

(a) A list of subsets of the set P.

(b) A sequence, set or indexed set of subsets of P.

(c) A list of blocks of an existing incidence structure.

(d) A sequence, set or indexed set of blocks of an existing incidence structure.

(e) A combination of the above.

(f) A $v \times b$ $(0,1)$-matrix A, where A may be defined over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the incidence structure D.

(g) A set of codewords of a linear code with length v. The block set of D is taken to be the set of supports of the codewords.

The incidence structure D produced by this constructor will have P as its point set and B as its set of blocks. The function returns three values:

(i) The incidence structure D;

(ii) The point-set P for D; and

(iii) The block-set B for D.

`NearLinearSpace< v | X : parameters >`

`NearLinearSpace< P | X : parameters >`

`Check` BoolElt *Default :* `true`

Construct the near–linear space S on the set of points $P = \{@p_1, p_2, \ldots, p_v@\}$ (where $p_i = i$ for each i if the first form of the constructor is used), with lines $L = \{L_1, L_2, \ldots, L_b\}$ given by X. The value of X must be either:

(a) A list of subsets of the set P.

(b) A sequence, set or indexed set of subsets of P.

(c) A list of blocks of an existing incidence structure.

(d) A sequence, set or indexed set of blocks of an existing incidence structure.

(e) A combination of the above.

(f) A $v \times b$ $(0,1)$-matrix A, where A may be over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the near–linear space S.

(g) A set of codewords of a linear code with length v. The line set of S is taken to be the set of supports of the codewords.

The set of lines L defined by X must satisfy two properties:

(a) Each line of L must contain at least two points;

(b) Any two points of P may lie on at most one line.
The optional boolean argument `Check` indicates whether or not to check that these two properties are satisfied.

The near–linear space S produced by this constructor will have P as its point set and L as its set of lines. The function returns three values:

(i) The near–linear space S;

(ii) The point-set P for S; and

(iii) The line-set L for S.

`LinearSpace< v | X :` *parameters* `>`

`LinearSpace< P | X :` *parameters* `>`

`Check` BoolElt *Default :* `true`

Construct the linear space S on the set of points $P = \{@p_1, p_2, \ldots, p_v@\}$ (where $p_i = i$ for each i if the first form of the constructor is used), with lines $L = \{L_1, L_2, \ldots, L_b\}$ given by X. The value of X must be either:

(a) A list of subsets of the set P.

(b) A sequence, set or indexed set of subsets of P.

(c) A list of blocks of an existing incidence structure.

(d) A sequence, set or indexed set of blocks of an existing incidence structure.

(e) A combination of the above.

(f) A $v \times b$ $(0,1)$-matrix A, where A may be defined over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the linear space S.

(g) A set of codewords of a linear code with length v. The line set of S is taken to be the set of supports of the codewords.

The set of lines L defined by X must satisfy two properties:

(a) Each line of L must contain at least two points;

(b) Any two points of P must lie on precisely one line.
The optional boolean argument `Check` indicates whether or not to check that these two properties are satisfied.

The linear space S produced by this constructor will have P as its point set and L as its set of lines. The function returns three values:

(i) The linear space S;

(ii) The point-set P for S; and

(iii) The line-set L for S.

```
Design< t, v | X : parameters >
```

```
Design< t, P | X : parameters >
```

`Check`	BoolElt	*Default :* `true`
`Al`	MonStg	*Default :* "*NoOrbits*"

Construct the t–design D on the set of points $P = \{@p_1, p_2, \ldots, p_v@\}$ (where $p_i = i$ for each i if the first form of the constructor is used), with blocks $B = \{B_1, B_2, \ldots, B_b\}$ given by X. The value of X must be either:

(a) A list of subsets of the set P.

(b) A sequence, set or indexed set of subsets of P.

(c) A list of blocks of an existing incidence structure.

(d) A sequence, set or indexed set of blocks of an existing incidence structure.

(e) A combination of the above.

(f) A $v \times b$ $(0, 1)$-matrix A, where A may be over any coefficient ring. The matrix A will be interpreted as the incidence matrix for the t–(v, k, λ) design D.

(g) A set of codewords of a linear code with length v. The block set of D is taken to be the set of supports of the codewords.

The set of blocks B defined by X must satisfy three properties:

(a) Each block must contain the same number, k say, of points.

(b) Every t–subset of P must lie in the same number, λ say (where $\lambda > 0$), of blocks.

(c) There must be no repeated blocks.

The optional boolean argument `Check` indicates whether or not to check that these three properties are satisfied. The optional parameter `Al` can be used to specify the algorithm used for balance testing, see the introduction to Section 147.8 for a full description of its usage.

The t–(v, k, λ) design D produced by this constructor will have P as its point set and B as its set of blocks. The function returns three values:

(i) The design D;

(ii) The point-set P for D; and

(iii) The block-set B for D.

Example H147E1

The Fano plane, considered as a 2-$(7, 3, 1)$ design, may be constructed by the following statement:

```
> F := Design< 2, 7 | {1,2,3}, {1,4,5}, {1,6,7}, {2,4,7},
>                                {2,5,6}, {3,5,7}, {3,4,6} >;
> F: Maximal;
2-(7, 3, 1) Design with 7 blocks
Points: {@ 1, 2, 3, 4, 5, 6, 7 @}
Blocks:
    {1, 2, 3},
    {1, 4, 5},
    {1, 6, 7},
    {2, 4, 7},
    {2, 5, 6},
    {3, 5, 7},
    {3, 4, 6}
```

General incidence structures are allowed repeated blocks, as in the following:

```
> S := IncidenceStructure< {@ 4, 5, 7, 9 @} | [{4, 5, 7}, {7, 9},
>                                              {5, 7, 9} , {7, 9}] >;
> S: Maximal;
Incidence Structure on 4 points with 4 blocks
Points: {@ 4, 5, 7, 9 @}
Blocks:
    {4, 5, 7},
    {7, 9},
    {5, 7, 9},
    {7, 9}
```

We now construct a linear space by giving its incidence matrix:

```
> R := RMatrixSpace(Integers(), 5, 6);
> I := R![ 1, 0, 1, 1, 0, 0,
>          1, 0, 0, 0, 1, 1,
>          1, 1, 0, 0, 0, 0,
>          0, 1, 1, 0, 1, 0,
>          0, 1, 0, 1, 0, 1];
> L := LinearSpace< 5 | I >;
> L: Maximal;
Linear Space on 5 points with 6 lines
Points: {@ 1, 2, 3, 4, 5 @}
Lines:
    {1, 2, 3},
    {3, 4, 5},
    {1, 4},
    {1, 5},
    {2, 4},
```

```
    {2, 5}
```

Finally, we use the minimum weight codewords of the unextended binary Golay code to construct a 4-(23, 7, 1) design. Since we know that this is indeed a 4-design, we set the checking parameter to `false`.

```
> C := GolayCode(GF(2), false);
> C;
[23, 12, 7] Unextended Golay Code over GF(2)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 1 0 1 0 1 1 1 0 0 0 1]
[0 1 0 0 0 0 0 0 0 0 0 0 1 1 1 1 1 0 0 1 0 0 1]
[0 0 1 0 0 0 0 0 0 0 0 0 1 1 0 1 0 0 1 0 1 0 1]
[0 0 0 1 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 1]
[0 0 0 0 1 0 0 0 0 0 0 0 1 1 0 0 1 1 0 1 1 0 0]
[0 0 0 0 0 1 0 0 0 0 0 0 0 1 1 0 0 1 1 0 1 1 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 0 1 1 0 0 1 1 0 1 1]
[0 0 0 0 0 0 0 1 0 0 0 0 1 0 1 1 0 1 1 1 1 0 0]
[0 0 0 0 0 0 0 0 1 0 0 0 0 1 0 1 1 0 1 1 1 1 0]
[0 0 0 0 0 0 0 0 0 1 0 0 0 0 1 0 1 1 0 1 1 1 1]
[0 0 0 0 0 0 0 0 0 0 1 0 1 0 1 1 1 0 0 0 1 1 0]
[0 0 0 0 0 0 0 0 0 0 0 1 0 1 0 1 1 1 0 0 0 1 1]
> minwt := MinimumWeight(C);
> minwt;
7
> wds := Words(C, minwt);
> D := Design< 4, Length(C) | wds : Check := false >;
> D;
4-(23, 7, 1) Design with 253 blocks
```

147.3 The Point-Set and Block-Set of an Incidence Structure

147.3.1 Introduction

An incidence structure created by Magma consists of three objects: the *point-set* P, the *block-set* B and the incidence structure D itself.

Although called the point-set and block-set, P and B are not actual MAGMA sets. They simply act as the parent structures for the points and blocks (respectively) of the incidence structure D, enabling easy creation of these objects via the `!` and `.` operators.

The point-set P belongs to the MAGMA category `IncPtSet`, and the block-set B to the category `IncBlkSet`.

In this section, the functions used to create point-sets, block-sets and the points and blocks themselves are described.

147.3.2 Creating Point-Sets and Block-Sets

As mentioned above, the point-set and block-set are returned as the second and third arguments of any function which creates an incidence structure. They can also be created via the following two functions.

`PointSet(D)`

Given an incidence structure D, return the point-set P of D.

`BlockSet(D)`

Given an incidence structure D, return the block-set B of D.

147.3.3 Creating Points and Blocks

For efficiency and clarity, the points and blocks of an incidence structure are given special types in MAGMA. The category names for points and blocks are `IncPt` and `IncBlk`, respectively. They can be created in the following ways.

`Point(D, i)`

The i-th point of the incidence structure D.

`P . i`

Given the point-set P of an incidence structure D and an integer i, return the i-th point of D.

`Representative(P)`
`Rep(P)`

Given the point-set P of an incidence structure D, return a representative point of D.

`Random(P)`

Given the point-set P of an incidence structure D, return a random point of D.

`P ! x`

Given the point-set P of an incidence structure D, return the point of D corresponding to the element x of the indexed set used to create D.

`Block(D, i)`

The i-th block of the incidence structure D.

`B . i`

Given the block-set B of an incidence structure D and an integer i, return the i-th block of D.

`Representative(B)`

`Rep(B)`

Given the block-set B of an incidence structure D, return a representative block of D.

`Random(B)`

Given the block-set B of an incidence structure D, return a random block of D.

`B ! S`

Given the block-set B of an incidence structure D, and a set S, tries to coerce S into B.

`Representative(b)`

`Rep(b)`

Given a block b of an incidence structure D, return a representative point of D which is incident with b.

`Random(b)`

Given a block b of an incidence structure D, return a random point incident with b.

Example H147E2

The following example shows how points and blocks of an incidence structure can be created.

```
> V := {@ 2, 4, 6, 8, 10 @};
> D, P, B := IncidenceStructure< V | {2, 4, 6}, {2, 8, 10}, {4, 6, 8} >;
> D;
Incidence Structure on 5 points with 3 blocks
> P;
Point-set of Incidence Structure on 5 points with 3 blocks
> B;
Block-set of Incidence Structure on 5 points with 3 blocks
> B.2;
{2, 8, 10}
> P.4;
8
> P!4;
4
> P.5 eq Point(D, 5);
true
> b := Random(B);
> b;
{2, 4, 6}
> Parent(b);
Block-set of Incidence Structure on 5 points with 3 blocks
> p := Rep(b);
> p;
```

```
2
> Parent(p);
Point-set of Incidence Structure on 5 points with 3 blocks
> B!{2, 8, 10};
{2, 8, 10}
```

147.4 General Design Constructions

Each of these functions returns three values:

(i) The incidence structure D;

(ii) The point-set P of D;

(iii) The block-set B of D.

147.4.1 The Construction of Related Structures

All operations defined for incidence structures apply also to near–linear spaces, linear spaces and designs.

`Complement(D)`

The complement of the incidence structure D.

`Dual(D)`

The dual of the incidence structure D.

`Contraction(D, p)`

Given an incidence structure $D = (P, B)$, and a point $p \in P$, form the incidence structure

$$E = (P - \{p\}, \{b - \{p\} : b \in B | p \in b\}).$$

Thus, E is constructed from D by deleting p and retaining only those blocks incident with it.

`Contraction(D, b)`

Given an incidence structure $D = (P, B)$, and a block $b \in B$, form the incidence structure

$$E = (b, \{b \cap c : c \in B | c \neq b\}).$$

Thus, E has point set b and its blocks are the non–empty intersections of b with the blocks of D other than b itself.

`Residual(D, b)`

Given an incidence structure $D = (P, B)$, and a block $b \in B$, form the incidence structure

$$E = (P - b, B - \{b\}).$$

Thus, E has point set $P - b$ and its blocks are the non–empty intersections of $P - b$ with the blocks of D.

`Residual(D, p)`

Given an incidence structure $D = (P, B)$, and a point $p \in P$, form the incidence structure

$$E = (P - \{p\}, \{x : x \in B | p \notin x\}).$$

Thus, E has point set $P - \{p\}$ and its blocks are the blocks of D which do not contain p.

`Simplify(D)`

Simplify the incidence structure D; i.e., remove repeated blocks from D.

`Sum(Q)`

Given a sequence $Q = [D_1, \ldots, D_l]$ of incidence structures, each of which is defined over the same set P of points, form the incidence structure obtained by taking the union of the block sets of $D_1, \ldots, D_l$. Thus, if $D_i = (P, B_i)$ then $D = (P, B_1 \cup \ldots \cup B_l)$.

`Union(D, E)`

The union of incidence structures D and E. That is, if $D = (P, B)$ and $E = (Q, C)$, then return $U = (P \cup Q, B \cup C)$. The point sets P and Q must be disjoint.

`Restriction(D, S)`

The restriction of the (near–)linear space D to the set of points S.

Example H147E3

We illustrate some of the above functions with an example.

```
> K := Design< 3, 8 | {1,3,7,8}, {1,2,4,8}, {2,3,5,8}, {3,4,6,8}, {4,5,7,8},
> {1,5,6,8}, {2,6,7,8}, {1,2,3,6}, {1,2,5,7}, {1,3,4,5}, {1,4,6,7}, {2,3,4,7},
> {2,4,5,6}, {3,5,6,7} >;
> CK := Contraction(K, Point(K, 8));
> RK := Residual(K, Block(K, 1));
> K: Maximal;

{2, 4, 5, 6}
```

147.4.2 The Witt Designs

The 5–(12, 6, 1) and 5–(24, 8, 1) designs constructed by Witt, also known as the small and large Mathieu designs, respectively, can be constructed in Magma with the following function.

`WittDesign(n)`

The Witt 5–design on n points, where $n = 12$ or 24.

Example H147E4

We construct the Witt 5–(24, 8, 1) design and take its contraction at a point. This contraction is in fact isomorphic to the design constructed above from the unextended binary Golay code.

```
> D, P, B := WittDesign(24);
> D;
5-(24, 8, 1) Design with 759 blocks
> p := P.1;
> Cp := Contraction(D, p);
> Cp;
4-(23, 7, 1) Design with 253 blocks
```

147.4.3 Difference Sets and their Development

Let G be a group of order v and let k and λ be positive integers such that $1 < k < v$. A (v, k, λ) *difference set* for G is a set D of k group elements such that the set

$$\{gh^{-1} : g, h \in D | g \neq h\}$$

contains every non–identity element of G exactly λ times.

`DifferenceSet(p, t)`

The difference set of type given by t (which must be one of `"Q"`, `"H6"`, `"T"`, `"B"`, `"B0"`, `"O"`, `"O0"`, or `"W4"`) corresponding to the prime p. The types have the same interpretation as given by Marshall Hall in [Hal86], pp. 141–142.

`SingerDifferenceSet(n, q)`

The Singer difference set corresponding to a hyperplane of $\mathrm{PG}(n, q)$.

`IsDifferenceSet(B)`

Returns `true` iff B is a difference set over an integer residue class ring or a finite group (with an iterator). If `true`, the value of the parameter λ (i.e., the number of times each non–identity group/ring element appears as a "difference" of elements of B) is also returned.

`Development(B)`

Let B be a subset of a magma A which is a difference set relative to A, where A is either the ring Z/mZ, a finite abelian group or an arbitrary finite group (with an iterator). This function constructs the symmetric design having point set A and whose blocks consist of the sets obtained by translating B by each element of A in turn.

`Development(T)`

Let $T = \{B_1, \ldots, B_l\}$ be a difference family consisting of subsets of a magma A which is either the ring $\mathbf{Z}/m\mathbf{Z}$, a finite abelian group or an arbitrary finite group (with an iterator). This function constructs the incidence structure with point set A and whose i-th block is the set $\{B_1 \cup \ldots \cup B_l\}$ translated by the i-th element of A.

Example H147E5

The set $\{1, 3, 4, 5, 9\}$, where the elements are residues modulo 11, forms an $(11, 5, 2)$ difference set. We develop this set and construct a 2-$(11, 5, 2)$ design.

```
> Z11 := IntegerRing(11);
> B := { Z11 | 1, 3, 4, 5, 9};
> IsDifferenceSet(B);
true 2
> D := Development(B);
> D: Maximal;
2-(11, 5, 2) Design with 11 blocks
Points: {@ 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 @}
Blocks:
    {1, 3, 4, 5, 9},
    {2, 4, 5, 6, 10},
    {0, 3, 5, 6, 7},
    {1, 4, 6, 7, 8},
    {2, 5, 7, 8, 9},
    {3, 6, 8, 9, 10},
    {0, 4, 7, 9, 10},
    {0, 1, 5, 8, 10},
    {0, 1, 2, 6, 9},
    {1, 2, 3, 7, 10},
```

```
    {0, 2, 3, 4, 8}
```

We now construct the twin primes (type "T") difference set modulo 323 (= 17 × 19), and its development.

```
> B := DifferenceSet(17, "T");
> D := Development(B);
> D;
2-(323, 161, 80) Design with 323 blocks
```

147.5 Elementary Invariants of an Incidence Structure

All operations defined for incidence structures apply also to near–linear spaces, linear spaces and designs.

`NumberOfPoints(D)`
`#P`

The cardinality v of the point set P of the incidence structure D.

`Points(D)`

An indexed set E whose elements are the points of the incidence structure D. Note that this creates a standard set and not the point-set of D, in contrast to the function `PointSet`.

`Support(D)`

An indexed set E which is the underlying point set of the incidence structure D (i.e., the elements of the set have their "real" types; they are no longer from the category IncPt).

`PointDegrees(D)`

A sequence whose i-th term gives the number of blocks containing the i-th point of the design D.

`NumberOfBlocks(D)`
`#B`

The number of blocks b of the incidence structure D with block-set B.

`Blocks(D)`

An indexed set containing the blocks of the incidence structure D. In contrast to the function `BlockSet`, this function returns the collection of blocks of D in the form of a standard set.

`BlockDegrees(D)`

`BlockSizes(D)`

A sequence whose i-th term gives the number of points in the i-th block of the incidence structure D.

`Covalence(D, S)`

Given a subset S of the point set of an incidence structure D, return the number of blocks of D that contain S.

`IncidenceMatrix(D)`

The incidence matrix of the incidence structure D.

`pRank(D, p)`

The p-rank of the incidence structure D.

147.6 Elementary Invariants of a Design

The following functions can be applied only to designs.

`Parameters(D)`

The parameters t–(v, b, r, k, λ) of the design D returned as a record.

`ReplicationNumber(D)`

The number of blocks r containing any point of the t–(v, k, λ) design D, where $t > 0$.

`BlockDegree(D)`

`BlockSize(D)`

The number of points in a block of the design D.

`Covalence(D, s)`

Given a t–(v, k, λ) design D and an integer s such that $0 \leq s \leq t$, return the value of λ_s; i.e., the number of blocks that contain an arbitrary s-subset of the points of D.

`Order(D)`

The order of the t–(v, k, λ) design D. This is defined only for designs with $t \geq 2$.

`IntersectionNumber(D, i, j)`

The block intersection number λ_i^j; i.e., the number of blocks of the design D containing an i-set and disjoint from a j-set. The arguments i and j must satisfy $i + j \leq t$.

`PascalTriangle(D)`

The "Pascal triangle" of the design D, returned as a sequence; the i-th element of the sequence is a sequence representing the i-th row of the triangle. That is, the i-th element of the sequence is

$$[\lambda_0^{i-1}, \lambda_1^{i-2}, \ldots, \lambda_{i-1}^0].$$

If D is a Steiner t–design, then the triangle returned has $k+1$ rows (where k is the size of a block of D); otherwise the triangle has $t+1$ rows.

Example H147E6

We illustrate some of the functions of the previous two sections with an example.

```
> F := Design< 2, 7 | {1,2,4}, {1,3,7}, {2,3,5}, {1,5,6}, {3,4,6}, {4,5,7},
>   {2,6,7} >;
> G := IncidenceStructure< 7 | Blocks(F), {1, 3, 7}, {1, 2, 4},
>   {3, 4, 5}, {2, 3, 6}, {2, 5, 7}, {1, 5, 6}, {4, 6, 7} >;
> F;
2-(7, 3, 1) Design with 7 blocks
> G;
Incidence Structure on 7 points with 14 blocks
> Points(G);
{@ 1, 2, 3, 4, 5, 6, 7 @}
> Blocks(F);
{@
    {1, 2, 4},
    {1, 3, 7},
    {2, 3, 5},

147.7 Operations on Points and Blocks

In incidence structures, particularly simple ones, blocks are basically sets. For this reason, the elementary set operations such as `join, meet` and `subset` have been made to work on blocks. However, blocks are not true MAGMA enumerated sets, and so the functions `Set` and `Support` below have been provided to convert a block to an enumerated set of points for other uses.

`p in B`

Returns `true` if point p lies in block B, otherwise `false`.

`p notin B`

Returns `true` if point p does not lie in block B, otherwise `false`.

`S subset B`

Given a subset S of the point set of the incidence structure D and a block B of D, return `true` if the subset S of points lies in B, otherwise `false`.

`S notsubset B`

Given a subset S of the point set of the incidence structure D and a block B of D, return `true` if the subset S of points does not lie in B, otherwise `false`.

`PointDegree(D, p)`

The number of blocks of the incidence structure D that contain the point p.

`BlockDegree(D, B)`

`BlockSize(D, B)`

`#B`

The number of points contained in the block B of the incidence structure D.

`Set(B)`

The set of points contained in the block B.

`Support(B)`

The set of underlying points contained in the block B (i.e., the elements of the set have their "real" types; they are no longer from the category IncPt).

`IsBlock(D, S)`

Returns `true` iff the set (or block) S represents a block of the incidence structure D. If `true`, also returns one such block.

`Line(D, p, q)`

`Block(D, p, q)`

A block of the incidence structure D containing the points p and q (if one exists). In linear spaces, such a block exists and is unique (assuming p and q are different).

`ConnectionNumber(D, p, B)`

The connection number $c(p, B)$; i.e., the number of blocks joining p to B in the incidence structure D.

Example H147E7

The following examples uses some of the functions of the previous section.

```
> D, P, B := Design< 2, 7 | {3, 5, 6, 7}, {2, 4, 5, 6}, {1, 4, 6, 7},
>   {2, 3, 4, 7}, {1, 2, 5, 7}, {1, 2, 3, 6}, {1, 3, 4, 5} >;
> D: Maximal;
2-(7, 4, 2) Design with 7 blocks
Points: {@ 1, 2, 3, 4, 5, 6, 7 @}
Blocks:
    {3, 5, 6, 7},
    {2, 4, 5, 6},
    {1, 4, 6, 7},
    {2, 3, 4, 7},
    {1, 2, 5, 7},
    {1, 2, 3, 6},
    {1, 3, 4, 5}
> P.1 in B.1;
false
> P.1 in B.3;
true
> {P| 1, 2} subset B.5;
true
> Block(D, P.1, P.2);
{1, 2, 5, 7}
> b := B.4;
```

```
> b;
{2, 3, 4, 7}
> b meet {2, 8};
{ 2 }
> S := Set(b);
> S, Universe(S);
{ 2, 3, 4, 7 }
Point-set of 2-(7, 4, 2) Design with 7 blocks
> Supp := Support(b);
> Supp, Universe(Supp);

Integer Ring
```

147.8 Elementary Properties of Incidence Structures and Designs

Testing the t-balance: A general Note on Parameter `Al`

A parameter `Al` is provided to allow users to specify the algorithm to be used for balance testing. The default value is `"NoOrbits"`, which applies a "brute force" test. One alternative is `"Orbits"`, which uses the orbits of t-sets under the automorphism group of the incidence structure under consideration. This is much faster than `"NoOrbits"` for some cases, but slower for others.

The other alternative for checking if an object is t-balanced is `"FastBalanceTest"`: It is also a "brute force" test but whose implementation allows for a dramatic improvement in efficiency, especially for larger t ($t \geq 4$). This implementation has a drawback however as it may necessitate more memory space than is available, thus resulting in an out-of-memory error. It is for this reason that `"FastBalanceTest"` is not the default setting for `Al`, but as a general rule we strongly recommend its usage as we surmise that execution should successfully complete in most cases.

`IsSimple(D)`

Returns `true` if and only if the incidence structure D has no repeated blocks.

`IsTrivial(D)`

Returns `true` if and only if the incidence structure D is a trivial incidence structure.

`IsSelfDual(D)`

Returns `true` if and only if the incidence structure D is self-dual, that is, if D is isomorphic to its dual.

`IsUniform(D)`

Returns `true` if and only if the incidence structure D is uniform; that is, each block contains the same number of points. If `true`, also returns the blocksize.

`IsNearLinearSpace(D)`

Returns `true` if and only if the incidence structure D is a near–linear space.

`IsLinearSpace(D)`

Returns `true` if and only if the incidence structure D is a linear space.

`IsDesign(D, t:` *parameters*`)`

`Al` MonStgElt *Default :* "*NoOrbits*"

Returns `true` if and only if the incidence structure D is a t–design. If `true`, then the number of blocks of D containing a general t-set is also returned. The optional parameter `Al` can be used to specify the algorithm used for balance testing, see the introduction to Section 147.8 for a full description of its usage.

`IsBalanced(D, t:` *parameters*`)`

`Al` MonStgElt *Default :* "*NoOrbits*"

Returns `true` if and only if the incidence structure D is balanced (with respect to t). If `true`, then the number of blocks of D containing a general t-set is also returned. The optional parameter `Al` can be used to specify the algorithm used for balance testing, see the introduction to Section 147.8 for a full description of its usage.

`IsComplete(D)`

Return `true` if and only if D is the complete design.

`IsSymmetric(D)`

Return `true` if and only if the design D is symmetric.

`IsSteiner(D, t)`

`Al` MonStg *Default :* "*NoOrbits*"

Return `true` if and only if the design D is a Steiner t–design. The optional parameter `Al` can be used to specify the algorithm used for balance testing, see the introduction to Section 147.8 for a full description of its usage.

`IsPointRegular(D)`

Return `true` if and only if the (near–)linear space D is point regular. If `true`, the point regularity is also returned.

`IsLineRegular(D)`

Return `true` if and only if the (near–)linear space D is line regular. If `true`, the line regularity is also returned.

147.9 Resolutions, Parallelisms and Parallel Classes

Let D be an incidence structure with v points. A *resolution* of D is a partition of the blocks of D into classes C_i such that each class is a 1-design with v points and index λ. The positive integer λ is called the *index* of the resolution. A resolution with $\lambda = 1$ is called a *parallelism*. In this case the classes C_i are called *parallel classes*.

All the functions which deal with resolutions apply to general incidence structures. The functions `HasParallelism`, `AllParallelisms`, `HasParallelClass`, `IsParallelClass` and `AllParallelClasses` require that the incidence structure be uniform. The function `IsParallelism` however applies to a general incidence structure.

`HasResolution(D)`

Return `true` if and only if the incidence structure D has a resolution. If `true`, one resolution is returned as the second value of the function and the index of the resolution is returned as the third value.

`HasResolution(D, λ)`

Return `true` if and only if the incidence structure D has a resolution with index λ. If `true`, one such resolution is returned as the second value of the function.

`AllResolutions(D)`

Returns all resolutions of the incidence structure D.

`AllResolutions(D, λ)`

Returns all resolutions of the incidence structure D having index λ. When the problem is to find all parallelisms ($\lambda = 1$) in a uniform design D, it is best to use the function `AllParallelisms` described below.

`IsResolution(D, P)`

Returns `true` if and only if the set P of blocks (or sets) is a resolution of the incidence structure D. If `true`, also returns the index of the resolution as the second value of the function.

`HasParallelism(D: parameters)`

`Al` MonStg *Default :* "*Backtrack*"

Returns `true` if and only if the uniform incidence structure D has a parallelism. If `true`, a parallelism is returned as the second value of the function. The parameter `Al` allows the user to specify the algorithm used.

`Al := "Backtrack"`: A backtrack search is employed. This is in general very efficient when the design D is parallelizable, irrespective of the number of blocks. In particular, it compares very favourably with the algorithm `Clique`, described below. The later algorithm is recommended when the design appears to have no parallelism. Backtrack is the default.

`Al := "Clique"`: This algorithm proceeds in two stages. Assume that D has v points and b blocks of size k. Define the graph G_1 of D to be the graph whose vertices are the blocks of D and where two blocks are adjacent if and only if they

are disjoint. The first stage of the Clique algorithm involves constructing the graph G_1 and finding all cliques of size v/k in G_1. Any such clique is a parallel class of D. The second stage involved building a graph G_2 of D where the vertices are the parallel classes of D and two parallel classes are adjacent if and only if they are disjoint. The second stage of the Clique algorithm involves searching for cliques of size $b/(v/k)$ in G_2. If such a clique exists then it yields a parallelism of D. (This algorithm was communicated by Vladimir Tonchev).

The clique algorithm is recommended when the design is suspected of having no parallelism. As an example, in the case of a non–parallelizable design with 272 blocks, Clique took around 0.1 second to complete as compared to 2 seconds for the backtrack algorithm. For a non–parallelizable design having 6642 blocks, Clique took around four hours to complete as compared to Backtrack which did not complete in 15 hours. Apart from performing very poorly when D has a parallelism, Clique may require a considerable amount of memory. It is recommended that Backtrack be tried first, and if it does not complete in a reasonable amount of time, then Clique should be used.

`AllParallelisms(D)`

Returns all parallelisms of the uniform incidence structure D. This function is to be preferred to the function `AllResolutions(D, 1)` when D is uniform. This is the case since the implementation of `AllParallelClasses` implies finding cliques in graphs (see the algorithm Clique described in the function `HasParallelism`), while `AllResolutions` performs a full backtrack search.

`IsParallelism(D, P)`

Returns `true` if and only if the set P of blocks (or sets) is a parallelism of the incidence structure D.

`HasParallelClass(D)`

Returns `true` if and only if the uniform incidence structure D has a parallel class.

`IsParallelClass(D, B, C)`

Returns `true` if and only if the uniform incidence structure D has a parallel class containing the blocks B and C. If such a parallel class does exist, one is returned as the second value of the function.

`AllParallelClasses(D)`

Returns all parallel classes of the uniform incidence structure D.

Example H147E8

Some of the above functions are illustrated here.

```
> D := IncidenceStructure< 6 | {1,2,3}, {4,5,6}, {1,3,4}, {2,5,6}>;
> bool, R, lambda := HasResolution(D);
> bool;
true
> R;
{
  {
    {1, 2, 3},
    {4, 5, 6},
    {1, 3, 4},
    {2, 5, 6}
  }
}
> lambda;
2
> HasResolution(D,2);
true {
  {
    {1, 2, 3},
    {4, 5, 6},
    {1, 3, 4},
    {2, 5, 6}
  }
}
> AllResolutions(D);
[
  {
    {
      {1, 2, 3},
      {4, 5, 6},
      {1, 3, 4},
      {2, 5, 6}
    }
  },
  {
    {
      {1, 2, 3},
      {4, 5, 6}
    },
    {
      {1, 3, 4},
      {2, 5, 6}
    }
  }
]
```

```
> HasParallelism(D);
true {
  {
    {1, 2, 3},
    {4, 5, 6}
  },
  {
    {1, 3, 4},
    {2, 5, 6}
  }
}
> V := PointSet(D);
> S := { PowerSet(PowerSet(V)) |
>        { {1, 2, 3}, {4, 5, 6} }, { {1, 3, 4}, {2, 5, 6} } };
> IsParallelism(D, S);
true
> B := BlockSet(D);
> S := { { B.1, B.2 }, {B.3, B.4 }};
> IsParallelism(D, S);
true
> AllParallelClasses(D);
{
  {
    {1, 2, 3},
    {4, 5, 6}
  },
  {
    {1, 3, 4},
    {2, 5, 6}
  }
}
```

147.10 Conversion Functions

`IncidenceStructure(I)`

Given an incidence structure I (of any type), return the same structure as a "true" incidence structure (i.e., belonging to the category Inc).

`NearLinearSpace(I)`

Given an incidence structure I (of any type), return the same structure as a near–linear space (i.e., belonging to the category `IncNsp`), if possible.

`LinearSpace(I)`

Given an incidence structure I (of any type), return the same structure as a linear space (i.e., belonging to the category `IncLsp`), if possible.

`Design(I, t)`

Given an incidence structure I (of any type), return the same structure as a t–design (i.e., belonging to the category `Dsgn`), if possible.

Example H147E9

The following example illustrates some of the functions of the previous two sections.

```
> I := IncidenceStructure< 8 | {1, 2, 3, 4}, {1, 3, 5, 6}, {1, 4, 7, 8},
>   {2, 5, 6, 7}, {2, 5, 7, 8}, {3, 4, 6, 8} >;
> IsDesign(I, 1);
true 3
> IsDesign(I, 2);
false
> D := Design(I, 1);
> D;
1-(8, 4, 3) Design with 6 blocks
> IsSteiner(D, 1);
false
> IsNearLinearSpace(I);
false
```

147.11 Identity and Isomorphism

Incidence structures $D_1 = (P_1, B_1, I_1)$ and $D_2 = (P_2, B_2, I_2)$ are *identical* if $P_1 = P_2$, $B_1 = B_2$ and $I_1 = I_2$.

`D eq E`

Return `true` if the incidence structures D and E are identical, otherwise `false`.

`D ne E`

Return `true` if the incidence structures D and E are not identical, otherwise `false`.

`IsIsomorphic(D, E: parameters)`

`AutomorphismGroups` MonStgElt *Default : "None"*

Return `true` if the incidence structures D and E are isomorphic, otherwise `false`. If they are isomorphic, then an isomorphism is returned as the second value. The function first computes none, one, or both of the automorphism groups of the left and right incidence structures. In difficult examples, this may significantly speed up testing for isomorphism. The parameter `AutomorphismGroups`, with valid string values `"Both"`, `"Left"`, `"Right"`, `"None"`, may be used to specify which of the automorphism groups should be constructed if not already known. The default is `"None"`.

147.12 The Automorphism Group of an Incidence Structure

The automorphism group A of an incidence structure D is always presented as a permutation group G acting on the standard support. The reasons for this include the fact that the support chosen when computing the automorphism group is often quite complicated. Further, if the group is represented as acting on a set of objects relating to the incidence structure, printed permutations are often unreadable. The support used when constructing the automorphism group of an incidence structure D is either the point set of D (when D is simple), or the disjoint union of the point set with the block set (when D has repeated blocks).

The automorphism group G of D does not act directly on D. Instead, G-sets are used to transfer the action of G to various sets associated with D. The two most important G-sets, corresponding to action of G on the point set and on the block set, are returned by each of the functions provided for constructing automorphism group or some specified subgroup of it.

In some circumstances, rather than viewing automorphisms as group elements, it is desirable to view them is as mappings of D into itself. Associated with each incidence structure is a mapping structure, Aut(D), which denotes the set of automorphisms of D. Note that Aut(D) is the *parent* of the automorphisms of G so that the function `Aut(D)` simply creates a shell structure rather than the actual automorphism group of D. A transfer map is provided to convert a permutation of the automorphism group G into a mapping belonging to $Aut(D)$.

147.12.1 Construction of Automorphism Groups

`AutomorphismGroup(D)`

Construct the automorphism group G of the incidence structure D. The set on which G acts depends upon whether or not the design is simple. Suppose D has v points and b blocks. If the incidence structure D is simple, the automorphism group is constructed in its action on the points of D. It is returned acting on the standard support $\{1,\ldots,\text{v}\}$, where i corresponds to the i-th point of D. If D is not simple, it is constructed in its action of the disjoint union of the point set and block set of D.

Again, it is returned acting on the standard support {1,...,v+b}, where $1 \leq i \leq v$ corresponds to the i-th point of D and $v+1 \leq i \leq v+b$ corresponds to the $(i-v)$-th point of D. The function returns:

(i) The automorphism group G of D as described above;

(ii) A G-set Y corresponding to the action of G on the point set of D.

(iii) A G-set W corresponding to the action of G on the block set of D.

(iv) The *Aut* structure S for D; and

(v) A transfer map $t : G \to S$.

Given a permutation g of G, $t(g)$ is the *mapping* of D into itself that corresponds to the automorphism group element g. The G-sets Y and W should be used whenever it is necessary to have G act on the points or lines of D.

`AutomorphismSubgroup(D)`

A cyclic subgroup H of the automorphism group G of the incidence structure D. The purpose of this function is to terminate the search for automorphisms of D as soon as a non–trivial automorphism is found. The function returns:

(i) The automorphism group H of D as described above;

(ii) The *Aut* structure S for D; and

(iii) A transfer map $t : G \to S$.

Given a permutation g of H, $t(g)$ is the *mapping* of D into itself that corresponds to the automorphism group element g.

`AutomorphismGroupStabilizer(D, k)`

The subgroup H of the automorphism group G of the incidence structure D, which stabilizes the first k base points of G. This function is provided so as to return a subgroup of G that is sometimes easier to compute than all of G. The function returns:

(i) The automorphism group H of D as described above;

(ii) The *Aut* structure S for D; and

(iii) A transfer map $t : G \to S$.

Given a permutation g of H, $t(g)$ is the *mapping* of D into itself that corresponds to the automorphism group element g.

`PointGroup(D)`

The automorphism group of the incidence structure D given in its action on the point set of D, together with the points G-set.

`BlockGroup(D)`

The automorphism group of the incidence structure D given in its action on the block set of D.

`Aut(D)`

The power structure A of all automorphisms of the incidence structure D, together with the transfer map $t : Sym(n) \to A$, where the points of $Sym(n)$ are assumed to be in one–to–one correspondence with the natural support for the automorphism group of D.

Example H147E10

We construct a $3-(16,8,3)$ Hadamard design and investigate its automorphism group. The first step is to construct a Hadamard matrix of order 16.

```
> R := MatrixRing(Integers(), 4);
> H := R ! [1,1,1,-1, 1,1,-1,1, 1,-1,1,1, -1,1,1,1];
> L := TensorProduct(H, -H);
> D, P, B := HadamardRowDesign(L, 1);
> D;
3-(16, 8, 3) Design with 30 blocks
> G, pg, bg, A, t := AutomorphismGroup(D);
> G;
Permutation group G acting on a set of cardinality 16
Order = 322560 = 2^10 * 3^2 * 5 * 7
    (9, 15)(10, 16)(11, 13)(12, 14)
    (5, 11, 7, 9)(6, 12, 8, 10)(13, 15)(14, 16)
    (5, 9, 14)(6, 10, 13)(7, 11, 16)(8, 12, 15)
    (1, 2)(7, 8)(9, 13, 10, 14)(11, 16, 12, 15)
    (2, 5)(4, 7)(10, 13)(12, 15)
    (3, 9)(4, 10)(7, 13)(8, 14)
    (3, 8, 15, 12)(4, 7, 16, 11)(5, 9)(6, 10)
    (5, 6)(7, 8)(13, 14)(15, 16)
    (3, 12, 4, 11)(7, 16, 8, 15)(9, 10)(13, 14)
    (3, 7)(4, 8)(11, 15)(12, 16)
    (3, 8)(4, 7)(9, 10)(11, 15)(12, 16)(13, 14)
    (9, 10)(11, 12)(13, 14)(15, 16)
    (9, 13)(10, 14)(11, 15)(12, 16)
> CompositionFactors(G);
    G
    |  Alternating(8)

    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
```

147.12.2 Action of Automorphisms

As noted at the beginning of the section, the automorphism group G of an incidence structure D is given in its action on the standard support and it does not act directly on D. The action of G on D is obtained using the G-set mechanism. The two basic G-sets associated with D correspond to the action of G on the set of points P and the set of blocks B of D. These two G-sets are given as return values of the function `AutomorphismGroup` or may be constructed directly. Additional G-sets associated with D may be built using the G-set constructors. Given a G-set Y for G, the action of G on Y may be studied using the permutation group functions that allow a G-set as an argument. In this section, only a few of the available functions are described: see the section on G-sets for a complete list.

`Image(g, Y, y)`

Let G be a subgroup of the automorphism group for the incidence structure D and let Y be a G-set for G. Given an element y belonging either to Y or to a G-set derived from Y, find the image of y under G.

`Orbit(G, Y, y)`

Let G be a subgroup of the automorphism group for the incidence structure D and let Y be a G-set for G. Given an element y belonging either to Y or to a G-set derived from Y, construct the orbit of y under G.

`Orbits(G, Y)`

Let G be a subgroup of the automorphism group for the incidence structure D and let Y be a G-set for G. This function constructs the orbits of the action of G on Y.

`Stabilizer(G, Y, y)`

Let G be a subgroup of the automorphism group for the incidence structure D and let Y be a G-set for G. Given an element y belonging either to Y or to a G-set derived from Y, construct the stabilizer of y in G.

`Action(G, Y)`

Given a subgroup G of the automorphism group of the incidence structure D, and a G-set Y for G, construct the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the set Y. The function returns:

(a) The natural homomorphism $\phi : G \to L$;

(b) The induced group L;

(c) The kernel of the action (a subgroup of G).

`ActionImage(G, Y)`

Given a subgroup G of the automorphism group of the incidence structure D, and a G-set Y for G, construct the permutation group L giving the action of G on the set Y.

`ActionKernel(G, Y)`

Given a subgroup G of the automorphism group of the incidence structure D, and a G-set Y for G, construct the kernel of the action of G on the set Y.

`IsPointTransitive(D)`

Returns `true` iff the automorphism group of the incidence structure D acts transitively on the point set of D.

`IsBlockTransitive(D)`

Returns `true` iff the automorphism group of the incidence structure D acts transitively on the block set of D.

Example H147E11

In the following example, the automorphism group of the Witt design on 12 points is constructed.

```
> D, P, B := WittDesign(12);
> A, PY, BY := AutomorphismGroup(D);
> A;
Permutation group Aut acting on a set of cardinality 12
Order = 95040 = 2^6 * 3^3 * 5 * 11
    (1, 2)(5, 8)(6, 11)(10, 12)
    (2, 3)(5, 12)(6, 8)(10, 11)
    (3, 4)(5, 10)(6, 11)(8, 12)
    (4, 7)(5, 8)(6, 12)(10, 11)
    (5, 11, 12, 6)(7, 8, 9, 10)
    (5, 9, 12, 7)(6, 10, 11, 8)
    (5, 12)(6, 11)(7, 9)(8, 10)
> a := A!(1, 2, 3, 4)(5, 6, 12, 11);
> 4^a;
1
> {1, 2, 3}^a;
{ 2, 3, 4 }
> Image(a, BY, Block(D, 3));
{1, 2, 3, 8, 11, 12}
> S2 := SylowSubgroup(A, 2);
> S2;
Permutation group S2 acting on a set of cardinality 12
Order = 64 = 2^6
   (1, 11, 9, 4)(6, 10, 12, 7)
   (1, 9)(2, 12)(3, 7)(4, 11)(5, 10)(6, 8)
   (1, 4)(3, 5)(7, 10)(9, 11)
> Stabilizer(S2, BY, Block(D, 4));
Permutation group acting on a set of cardinality 12
Order = 2
    (1, 9)(3, 5)(6, 7)(10, 12)
> Stabilizer(S2, 6);
Permutation group acting on a set of cardinality 12
```

```
Order = 8 = 2^3
    (1, 4)(3, 5)(7, 10)(9, 11)
    (1, 4, 9, 11)(2, 5, 8, 3)
> 3^S2;
GSet{ 2, 3, 5, 6, 7, 8, 10, 12 }
> IsPointTransitive(D);
true
> IsBlockTransitive(D);
true
```

We calculate the action of the automorphism group of the design on its blocks.

```
> H := ActionImage(A, BY);
> #H;
95040
> H;
Permutation group H acting on a set of cardinality 132
Order = 95040 = 2^6 * 3^3 * 5 * 11
```

147.13 Incidence Structures, Graphs and Codes

`IncidenceStructure(G)`

Construct the incidence structure D corresponding to the graph G, where the blocks of D correspond to the edges of G.

`PointGraph(D)`

The point graph G of the incidence structure D. The graph G has the same point set as D and two vertices u and v of G are adjacent whenever there is a block of D containing both u and v.

`BlockGraph(D)`

The block graph of the incidence structure D, i.e., the point graph of the dual of D.

`IncidenceGraph(D)`

The incidence graph of the incidence structure D. This bipartite graph has as vertex set the union of the point set P and block set B of D. A vertex $p \in P$ is adjacent to a vertex $b \in B$ whenever $p \in b$.

`LinearCode(D, K)`

Given an incidence structure D with v points and a finite field K, this function returns the linear code C of length v generated by the characteristic functions of the blocks of D considered as vectors of the K-space $K^{(v)}$.

Example H147E12

The linear code of the Witt 5-(24, 8, 1) design over GF(2) is the extended Golay code over GF(2).

```
> D := WittDesign(24);
> C := LinearCode(D, GF(2));
> C eq GolayCode(GF(2), true);
true
```

147.14 Automorphisms of Matrices

Matrices may be regarded as defining a design with the entry of a matrix in a particular row and column defining the incidence of the row and column. The automorphism group of a matrix is the set of permutations of the rows and columns of the matrix that leave the matrix unchanged.

`M ^ x`

The action of a permutation on a matrix by permuting rows and columns. If M has r rows and c columns then x must have degree $r + c$ and fix the set $R = \{1..r\}$. The action of x on R gives the permutation of the rows of the matrix. The remainder of x gives the action on columns.

`AutomorphismGroup(M)`

Computes the group of all permutations x such that $M^x = M$. Currently this is done by constructing a graph from M, and applying the `AutomorphismGroup` function to the graph.

`IsIsomorphic(M, N)`

Finds a permutation x such that $M^x = N$, if such exists. If a permutation is found return values are true and the permutation, otherwise returns false. Currently this is done by constructing graphs from M and N, and applying the `IsIsomorphic` function to the graphs.

Example H147E13

We construct a matrix from a Fano polytope and compute its automorphism group.

```
> M := VertexFacetHeightMatrix(PolytopeSmoothFanoDim3(10)); M;
[1 0 0 0 2 1 2 2]
[0 0 0 1 1 2 2 2]
[0 0 1 2 0 2 2 1]
[2 0 1 0 2 0 2 1]
[0 2 0 1 1 2 0 2]
[1 2 0 0 2 1 0 2]
[0 2 1 2 0 2 0 1]
[2 2 1 0 2 0 0 1]
```

```
[2 2 2 1 1 0 0 0]
[1 2 2 2 0 1 0 0]
[1 0 2 2 0 1 2 0]
[2 0 2 1 1 0 2 0]
> A := AutomorphismGroup(M); A;
Permutation group A acting on a set of cardinality 20
Order = 24 = 2^3 * 3
  (2, 4)(3, 12)(5, 8)(7, 9)(13, 18)(15, 16)(17, 20)
  (1, 5)(2, 6)(3, 8)(4, 7)(9, 11)(10, 12)(13, 16)(14, 19)(17, 18)
  (1, 2)(3, 4)(5, 6)(7, 8)(9, 10)(11, 12)(13, 16)(17, 18)
> Nrows(M), Ncols(M);
12, 8
> Orbits(A);
[
  GSet{@ 14, 19 @},
  GSet{@ 13, 18, 16, 17, 15, 20 @},
  GSet{@ 1, 5, 2, 8, 6, 4, 3, 7, 12, 9, 10, 11 @}
]
```

The automorphism group is transitive on the rows of the matrix. Now dualize the matrix and test for isomorphism.

```
> D := Matrix(12, 8, [2-x:x in Eltseq(M)]);
> f, x := IsIsomorphic(M, D); f, x;
true (2, 4)(3, 12)(5, 8)(7, 9)(14, 19)(15, 17)(16, 20)
> M^x eq D;
true
```

148 HADAMARD MATRICES

Chapter 148
HADAMARD MATRICES

148.1 Introduction

A *Hadamard matrix* is an $n \times n$ matrix, all of whose entries are ± 1, such that every pair of rows and every pair of columns differ in exactly $\frac{n}{2}$ places. Two such matrices are considered equivalent if one can be transformed into the other by performing row swaps, column swaps, row negations or column negations. The problem of deciding whether two Hadamard matrices are equivalent is hard.

MAGMA contains several specialised routines for working with Hadamard matrices; of special note is the introduction of a canonical form for such matrices (based on Brendan McKay's `nauty` program). This leads to a much faster equivalence algorithm than previously available.

148.2 Equivalence Testing

`IsHadamard(H)`

Returns `true` if and only if the matrix H is a Hadamard matrix.

`HadamardNormalize(H)`

Given a Hadamard matrix H, returns a normalized matrix equivalent to H. This matrix is created by negating rows and columns to ensure that the first row and column consist entirely of ones.

`HadamardCanonicalForm(H)`

Given a Hadamard matrix H, returns a Hadamard-equivalent matrix H' and transformation matrices X and Y such that $H' = XHY$. The matrix H' is canonical in the sense that all matrices that are Hadamard-equivalent to H (and no others) will produce the same matrix H'.

`HadamardInvariant(H)`

Returns a sequence S of integers giving the 4-profile of the Hadamard matrix H. All Hadamard-equivalent matrices have the same 4-profile, but so may some inequivalent ones. Thus this test may determine inequivalence of two matrices more cheaply than performing a full equivalence test, but cannot establish equivalence.

`IsHadamardEquivalent(H, J : parameters)`

`Al` MONSTGELT *Default : "nauty"*

Returns `true` if and only if the Hadamard matrices H and J are Hadamard equivalent. The parameter `Al` may be set to either `"Leon"` or `"nauty"` (the default). If the `"nauty"` option is chosen and the matrices are equivalent then transformation matrices X and Y are also returned, such that $J = XHY$.

`HadamardMatrixToInteger(H)`

Returns an integer that encodes the entries in the given Hadamard matrix in more compact form. The intended use is to save time when testing for equality against the same set of matrices many times.

`HadamardMatrixFromInteger(x, n)`

Returns a Hadamard matrix of degree n whose encoded form is the integer x. This function is the inverse of `HadamardMatrixToInteger()`.

Example H148E1

We demonstrate the use of some of these functions on certain degree 16 Hadamard matrices. For convenience, we create them from the more compact integer form.

```
> S := [
>   47758915483058652629300889924143904114798786457834842901517979108472281628672,
>   52517743516350345514775635367035460577743730272737765852723792818755052170805,
>   69809270372633075610047556428719374057869882804054059134346034969950931648512,
>   72098012275487127961355071358205554032515600906148326841367820166804453457 92
> ];
> T := [ HadamardMatrixFromInteger(x, 16) : x in S ];
> &and [ IsHadamard(m) : m in T ];
true
```

Now we can test them for equivalence; we start by checking the 4-profiles.

```
> [ HadamardInvariant(m) : m in T ];
[
    [ 1680, 0, 140 ],
    [ 1680, 0, 140 ],
    [ 1344, 448, 28 ],
    [ 1344, 448, 28 ]
]
```

We see that the only possible equivalencies are between the first two and the last two, since equivalent matrices must have the same 4-profile.

```
> equiv,X,Y := IsHadamardEquivalent(T[1], T[2]);
> equiv;
true
> T[2] eq X*T[1]*Y;
true
> equiv,X,Y := IsHadamardEquivalent(T[3], T[4]);
> equiv;
false
```

So we have three inequivalent matrices. An alternative way to determine the inequivalent matrices would have been to use the canonical forms.

```
> #{ HadamardCanonicalForm(m) : m in T };
```

3

148.3 Associated 3–Designs

`HadamardRowDesign(H, i)`

Given an $n \times n$ Hadamard matrix H (with $n \geq 4$) and an integer i with $1 \leq i \leq n$, returns the Hadamard 3–design corresponding to the ith row of H.

`HadamardColumnDesign(H, i)`

Given an $n \times n$ Hadamard matrix H (with $n \geq 4$) and an integer i with $1 \leq i \leq n$, returns the Hadamard 3–design corresponding to the ith column of H.

Example H148E2

There is only one Hadamard equivalence class of 8×8 Hadamard matrices. We construct one matrix, and two of its designs.

```
> R := MatrixRing(Integers(), 8);
> H := R![1,  1,  1,  1,  1,  1,  1,  1,
>         1,  1,  1,  1, -1, -1, -1, -1,
>         1,  1, -1, -1,  1,  1, -1, -1,
>         1,  1, -1, -1, -1, -1,  1,  1,
>         1, -1,  1, -1,  1, -1, -1,  1,
>         1, -1,  1, -1, -1,  1,  1, -1,
>         1, -1, -1,  1, -1,  1, -1,  1,
>         1, -1, -1,  1,  1, -1,  1, -1];
> IsHadamard(H);
true
> DR := HadamardRowDesign(H, 3);
> DR: Maximal;
3-(8, 4, 1) Design with 14 blocks
Points: {@ 1, 2, 3, 4, 5, 6, 7, 8 @}
Blocks:
    {1, 2, 5, 6},
    {1, 2, 7, 8},
    {1, 2, 3, 4},
    {1, 4, 5, 7},
    {1, 4, 6, 8},
    {1, 3, 6, 7},
    {1, 3, 5, 8},
    {3, 4, 7, 8},
    {3, 4, 5, 6},
    {5, 6, 7, 8},
    {2, 3, 6, 8},
    {2, 3, 5, 7},
```

```
    {2, 4, 5, 8},
    {2, 4, 6, 7}
> HadamardColumnDesign(H, 8);
3-(8, 4, 1) Design with 14 blocks
```

148.4 Automorphism Group

`HadamardAutomorphismGroup(H : parameters)`

`Al`	MonStgElt	*Default : "nauty"*

Given a Hadamard matrix H of degree n, returns the automorphism group of H as a permutation group of degree $4n$. The parameter `Al` may be set to either `"Leon"` or `"nauty"` (the default).

148.5 Databases

Magma contains two databases of Hadamard matrices; the first database includes all inequivalent matrices of degree at most 28, and examples of matrices of all degrees up to 256. The representatives used are the canonical forms (as output by `HadamardCanonicalForm`), and matrices of a given degree are ordered lexicographically (with 1 considered to be less than -1 for the purposes of this ordering).

A database of skew-symmetric Hadamard matrices also exists; in this case the matrices are not stored in canonical form, since the canonical forms are not skew-symmetric. With the exception of the creation routines, the intrinsics below apply to both databases.

`HadamardDatabase()`

Returns the database of Hadamard matrices.

`SkewHadamardDatabase()`

Returns the database of skew-symmetric Hadamard matrices.

`Matrix(D, n, k)`

Returns the kth matrix of degree n in the database D.

`Matrices(D, n)`

Returns the sequence of all matrices of degree n that are stored in the database D.

`DegreeRange(D)`

Returns the smallest and largest degrees of matrices in the database D.

`Degrees(D)`

Returns the sequence of degrees for which there is at least one matrix of that degree in the database D.

`NumberOfMatrices(D, n)`

Return the number of matrices of degree n in the database D.

Example H148E3

```
> D := HadamardDatabase();
> Matrix(D, 16, 3);
[ 1  1  1  1  1  1  1  1  1  1  1  1  1  1  1  1]
[ 1  1  1  1  1  1  1  1 -1 -1 -1 -1 -1 -1 -1 -1]
[ 1  1  1  1 -1 -1 -1 -1  1  1  1  1 -1 -1 -1 -1]
[ 1  1 -1 -1  1  1 -1 -1  1  1 -1 -1  1  1 -1 -1]
[ 1  1 -1 -1 -1  1  1 -1  1 -1 -1  1 -1 -1  1  1]
[ 1  1 -1 -1  1 -1 -1  1 -1  1  1 -1 -1 -1  1  1]
[ 1  1 -1 -1 -1 -1  1  1 -1 -1  1  1  1  1 -1 -1]
[ 1 -1 -1  1 -1 -1  1  1  1  1 -1 -1  1 -1 -1  1]
[ 1 -1 -1  1  1  1 -1 -1 -1 -1  1  1  1 -1 -1  1]
[ 1 -1  1 -1  1 -1  1 -1  1 -1  1 -1  1 -1  1 -1]
[ 1 -1  1 -1  1 -1 -1  1  1 -1 -1  1 -1  1 -1  1]
[ 1 -1  1 -1 -1  1  1 -1 -1  1  1 -1 -1  1 -1  1]
[ 1 -1  1 -1 -1  1 -1  1 -1  1 -1  1  1 -1  1 -1]
[ 1 -1 -1  1  1 -1  1 -1 -1  1 -1  1 -1  1  1 -1]
[ 1 -1 -1  1 -1  1 -1  1  1 -1  1 -1 -1  1  1 -1]
[ 1  1  1  1 -1 -1 -1 -1 -1 -1 -1 -1  1  1  1  1]

```

148.5.1 Updating the Databases

The databases are noticeably incomplete (for example, it is known that more than 60 000 Hadamard matrices exist for degree 32 whereas only 23 are in the database; also, only matrices of degrees 36, 44, or 52 are present in the skew database). The MAGMA group welcomes contributions of matrices not equivalent to ones already present and will add them to future versions of the databases.

The functions in this section can be used to create new versions of the databases. This allows users to include matrices not already present without having to wait for new official versions of the databases. These functions use a record whose format is not described, as this record should only be manipulated by these functions.

`HadamardDatabaseInformation(D : parameters)`

`Canonical` BoolElt *Default :* `true`

This takes an existing Hadamard database and extracts the information in it to an internal form which will be used by the other intrinsics. This internal form is returned. The parameter `Canonical` indicates whether the entries in the database are known to be the canonical forms or not. It defaults to `true`, which is correct for the standard database; it should be set to `false` if working with the skew database or a user-created database where the entries are not canonical.

Note that the value of the `Canonical` parameter also controls whether the database created from this data should store the canonical forms or the original ones. If you want to extract the matrices from a canonical database but store them in a non-canonical one, you should create the non-canonical database first — using either this intrinsic or `HadamardDatabaseInformationEmpty` — with `Canonical` set to `false` and then add the matrices from the database with `UpdateHadamardDatabase` and `Canonical` set to `true`.

`HadamardDatabaseInformationEmpty(: parameters)`

`Canonical` BoolElt *Default :* `true`

Returns the internal data that would correspond to an empty database. The parameter `Canonical` is used to indicate whether the entries in the database should be written out in canonical form or not.

This allows the creation of a new database, or a slice of an existing one, without including the entirety of a previous one.

`UpdateHadamardDatabase(~R, S : parameters)`

`Canonical` BoolElt *Default :* `false`

This augments the record R containing the database information with the matrices in the sequence S. The matrices are only added if they are inequivalent with matrices already there. Note that this requires finding the canonical forms, which can be expensive. If the matrices in S are known to be in canonical form already then the parameter `Canonical` should be set to `true`.

If the matrices of matching degree already in R are not known to be canonical then their canonical forms must also be computed. Again, this can take significant time. This is particularly troublesome for the skew database, where the canonical forms are not stored. For one way to deal with this, see the description of `WriteRawHadamardData` below.

`WriteHadamardDatabase(S, ~R)`

This creates the database files *name*`.dat` and *name*`.ind` from the database data R, where *name* is taken from the string S. Since canonical forms may need to be computed during this process, the data is passed with a variable reference so that this computation is not lost. (For instance, if one writes out the database, then adds some more matrices and writes it out again.)

`WriteRawHadamardData(S, R)`

This saves the data in R to the file whose name is given by the string S. When loaded, this file will define a single variable `data` which will behave identically to R. This is desirable for the non-canonical databases since the canonical forms will not have to be recomputed.

This routine destroys the original contents, if any, of the file.

`SetVerbose("HadamardDB", v)`

This procedure changes the verbose printing level for the Hadamard database update routines. The verbose value v should be an integer in the range 0 to 3. This can provide reassuring indications of progress when a long update process is underway.

Example H148E4

Here are some examples of how one might use these routines. We assume that the file `matrixfile` contains code that will define a sequence S of Hadamard matrices when loaded.

```
> D := HadamardDatabase();
> #D;
2004
> data := HadamardDatabaseInformation(D);
> SetVerboseLevel("HadamardDB", 1);
> load "matrixfile";
> UpdateHadamardDatabase(~data, S);
3 new matrices added
> WriteHadamardDatabase("~/data/hadamard", ~data);
Sorting matrices by canonical forms
Sorting by degrees
Computing size information
Writing data file
Data file written (2007 matrices total)

Writing index file
Index file written
```

This has created the files `hadamard.dat` and `hadamard.ind` (in the directory `~/data`) containing the updated data for the Hadamard database. The file stems should be `hadamard` for the standard database, or `hadamard_skew` for the database of skew-symmetric matrices; in this case we wanted the former. In order to use these files instead of the standard database, the library root must be changed. Database files are looked for in the `data` subdirectory of the library root, so in this example the library root should be changed to `~` in order to get the newly created database.

```
> SetLibraryRoot("~");
> D := HadamardDatabase();
> #D;
```

```
2007
```

Of course, the library root is used by other databases, so it would be a good idea to set it back to its original value after creating the modified database. A better approach would be to encapsulate this process in a function (which could be put into the user startup file).

```
> function MyHadamardDatabase()
>     oldlibroot := GetLibraryRoot();
>     SetLibraryRoot("~");
>     D := HadamardDatabase();
>     SetLibraryRoot(oldlibroot);
>     return D;
> end function;
>
> D := MyHadamardDatabase();
> #D;
2007
```

If working with the database of skew-symmetric Hadamard matrices, it will probably be desirable to use the raw data instead, since the computation of the canonical forms takes a lot of time (about 23 minutes on a 750MHz machine). This does have to be done, but by using the raw forms it will only have to be done once, rather than each time.

```
> D := SkewHadamardDatabase();
> #D;
638
> data := HadamardDatabaseInformationEmpty(: Canonical := false);
> for n in Degrees(D) do
>     UpdateHadamardDatabase(~data, Matrices(D, n));
> end for;
> WriteRawHadamardData("skewraw.m", data);
```

Now that the raw data has been created, it can be used in other sessions to update the database (or the same session, of course).

```
> load "skewraw.m";
> load "matrixfile";
> UpdateHadamardDatabase(~data, S);
> WriteHadamardDatabase("~/data/hadamard_skew", ~data);
> WriteRawHadamardData("skewraw.m", data);
```

Note that the updated raw form is saved as well as the database. Now the new data can be accessed in the same way as the previous database was.

```
> SetLibraryRoot("~");
> D := SkewHadamardDatabase();
> #D;
641
```

As before, for maximum convenience access to the new database should also be put into a function in the startup file.

149 GRAPHS

Chapter 149
GRAPHS

149.1 Introduction

A *simple graph* is a graph in which each edge joins two distinct vertices and two distinct vertices are joined by at most one edge. A *simple digraph*, whose edges are directed, is defined in an analogous manner. Thus, loops and multiple edges are not permitted in simple graphs and simple digraphs. A graph (digraph) with loops and/or multiple edges joining a fixed pair of vertices is called a *multigraph* (resp. *multidigraph*). A multidigraph whose edges are assigned a capacity is more commonly called a *network*.

In this chapter the term "graph" is used when referring to a simple undirected graph, while the term "digraph" is used when referring to a simple directed graph. Sometimes the term "graph" is used as the generic term for the incidence structure on vertices and edges. Such uses should be clear from the context in which they occur.

There are five MAGMA graph objects: the undirected simple graph of type `GrphUnd`, the directed simple graph of type `GrphDir`, the undirected multigraph of type `GrphMultUnd`, the directed multigraph of type `GrphMultDir`, and the network of type `GrphNet`. The simple graphs are all of type `Grph`, while the multigraphs (including the network) are of type `GrphMult`. There is a caveat here with respect to simple digraphs and loops: for historical reasons, MAGMA allows loops in digraphs.

Simple graphs and digraphs are covered in this chapter, while multigraphs, multidigraphs and networks are covered in Chapter 150. All types of graphs may have vertex labellings and/or edge labellings. In addition, assigning weights and/or capacities to graph edges is also possible, thus allowing to run shortest-paths and flow-based algorithms over the graphs.

Importantly, from the present version (V2.11) onwards, all the standard graph construction functions (see Subsections 149.6.1 and 149.6.2) respect the graph's support set and vertex and edge decorations. That is, the resulting graph will have a support set and vertex and edge decorations compatible with the original graph and the operation performed on that graph.

MAGMA employs two distinct data structures for representing graphs. A graph may be represented in the form of an adjacency matrix (the dense representation) or in the form of an adjacency list (the sparse representation). The latter is better suited for sparse graphs and for algorithms which have been designed with the adjacency list representation in mind. An advantage of the sparse representation is the possibility of creating much larger (sparse) graphs than would be possible using the dense representation, since memory requirements for the adjacency list representation is linear in the number of edges, while memory requirements for the adjacency matrix representation is quadratic in the number of vertices (order) of the graph. This is covered in detail in Section 149.2.1.

Further, multigraphs and multidigraphs (and networks) may only be represented by an adjacency list since they may contain multiple edges. Users have control over the choice of representation when creating simple graphs or digraphs. If no indication is given, simple graphs and digraphs are *always* created with the dense representation. At the time of the present release (V2.11), a significant part of MAGMA functions are able to work directly with either of the representations. However, wherever necessary, a graph will be converted internally to whichever representation is required by a given function. We emphasize that this process is completely transparent to users and *requires no intervention on their part.*

For a concise and comprehensive overview on graph theory and algorithms, the reader is referred to [Eve79]; in [TCR90] they'll find a clear exposure of some graph algorithms, and [RAO93] is the recommended reference for flow problems in graphs.

149.2 Construction of Graphs and Digraphs

Any enumerated or indexed set S may be given as the vertex-set of a graph. The graph constructor will take a copy V of S, convert V into an indexed set if necessary, and flag its type as `GrphVertSet`. A graph may be specifically created as a sparse graph. If no indication is given then the graph is *always* created with the dense representation, that is, as an adjacency matrix.

149.2.1 Bounds on the Graph Order

Memory allocation for any elementary object (that is, accessed via a single pointer) cannot exceed 2^{32} bytes. For this reason there is a bound on the graph order. This bound is dependent upon the (internal) graph representation chosen at creation: the dense representation (as a packed adjacency matrix), or the sparse representation (as an adjacency list). The former is quadratic in the number of vertices of the graph, the latter is linear in the number of the edges. Thus a large graph with a low edge density will require less memory space than the same graph with a dense representation.

The bounds on the graph order n are as follows:

- for the dense representation, $n \leq 65535$,
- for the sparse representation, $n \leq 134217722$.

These bounds are maximal, that is, they assume — for the sparse representation — that the number of edges is zero. To help users determine the likely size of the graph they want to construct, we provide the following function.

`GraphSizeInBytes(n, m : parameters)`

`IsDigraph`	BOOL	*Default :* `false`
`SparseRep`	BOOL	*Default :* `false`

Computes the memory requirement in bytes of a graph of order n and size m. By default it is assumed that the graph is undirected and has a dense representation.

Example H149E1

One may verify that the dense representation cannot be used for a value of n (graph order) larger than 65535.

```
> n := 65536;
> m := 0;
> assert GraphSizeInBytes(n, m) gt 2^32;
```

It is possible to construct such a graph with a sparse representation:

```
> GraphSizeInBytes(n, m : SparseRep := true);
2097580
```

However, assuming that the graph of order $n = 65535$ has a size of $m = 33538101$ we see that such a graph cannot be constructed as its total memory requirement is again larger than 2^{32}:

```
> m := 33538101;
> assert GraphSizeInBytes(n, m : SparseRep := true) gt 2^32;
```

149.2.2 Construction of a General Graph

`Graph< n | edges :` *parameters* `>`

`Graph< S | edges :` *parameters* `>`

`SparseRep` BOOL *Default :* `false`

Construct the graph G with vertex-set $V = \{@v_1, v_2, \ldots, v_n@\}$ (where $v_i = i$ for each i if the first form of the constructor is used, or the ith element of the enumerated or indexed set S otherwise), and edge-set $E = \{e_1, e_2, \ldots, e_q\}$. This function returns three values: The graph G, the vertex-set V of G; and the edge-set E of G. If SparseRep is `true` then the resulting graph will have a sparse representation.

The elements of E are specified by the list `edges`, where the items of `edges` may be objects of the following types:

(a) A pair $\{v_i, v_j\}$ of vertices in V. The edge from v_i to v_j will be added to the edge-set for G.

(b) A tuple of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i. The elements of the sets N_i must be elements of V. If $N_i = \{u_1, u_2, \ldots, u_r\}$, the edges $\{v_i, u_1\}, \ldots, \{v_i, u_r\}$ will be added to G.

(c) A sequence $[N_1, N_2, \ldots, N_n]$ of n sets, where N_i will be interpreted as a set of neighbours for the vertex v_i. The edges $\{v_i, u_i\}$, $1 \leq i \leq n$, $u_i \in N_i$, are added to G.

In addition to these three basic ways of specifying the *edges* list, the items in *edges* may also be:

(d) An edge e of a graph or digraph or multigraph or multidigraph or network of order n. If e is an edge from u to v in a directed graph H, then the undirected edge $\{u, v\}$ will be added to G.

(e) An edge-set E of a graph or digraph or multigraph or multidigraph or network of order n. Every edge e in E will be added to G.

(f) A graph or a digraph or a multigraph or a multidigraph or a network H of order n. Every edge e in H's edge-set is added to G.

(g) A $n \times n$ symmetric (0, 1)-matrix A. The matrix A will be interpreted as the adjacency matrix for a graph H on n vertices and the edges of H will be added will be added to G.

(h) A set of

(i) Pairs of the form $\{v_i, v_j\}$ of vertices in V.

(ii) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i.

(iii) Edges of a graph or digraph or multigraph or multidigraph or network of order n.

(iv) Graphs or digraphs or multigraphs or multidigraphs or networks of order n.

(j) A sequence of

(i) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i.

`IncidenceGraph(A)`

Let A be a $n \times m$ $(0, 1)$ matrix having exactly two $1s$ in each column. Then a graph G of order n and size m having A as its incidence matrix will be constructed. The rows of A will correspond to the vertices of G while the columns will correspond to the edges.

Example H149E2

The Petersen graph will be constructed in various different ways to illustrate the use of the constructor. Firstly, it will be constructed by listing the edges:

```
> P := Graph< 10 | { 1, 2 }, { 1, 5 }, { 1, 6 }, { 2, 3 }, { 2, 7 },
>            { 3, 4 }, { 3, 8 }, { 4, 5 }, { 4, 9 }, { 5, 10 },
>            { 6, 8 }, { 6, 9 }, { 7, 9 }, { 7, 10 }, { 8, 10 } >;
```

We next construct the Petersen graph by listing the neighbours of each vertex:

```
> P := Graph< 10 | [ { 2, 5, 6 }, { 1, 3, 7 }, { 2, 4, 8 }, { 3, 5, 9 },
>              { 1, 4, 10 }, { 1, 8, 9 }, { 2, 9, 10 }, { 3, 6, 10 },
>              { 4, 6, 7 }, { 5, 7, 8 } ] >;
```

We repeat the above construction but now the graph is created as a sparse graph:

```
> PS := Graph< 10 | [ { 2, 5, 6 }, { 1, 3, 7 }, { 2, 4, 8 }, { 3, 5, 9 },
```

```
>              { 1, 4, 10 }, { 1, 8, 9 }, { 2, 9, 10 }, { 3, 6, 10 },
>              { 4, 6, 7 }, { 5, 7, 8 } ] : SparseRep := true >;
> assert PS eq P;
```

Here is yet another way of constructing the sparse graph, from the dense graph:

```
> PS := Graph< 10 | P : SparseRep := true >;
> assert PS eq P;
```

We finally construct the graph in terms of an adjacency matrix:

```
> M := MatrixRing( Integers(), 10 );
> P := Graph< 10 | M![ 0,1,0,0,1,1,0,0,0,0,
>                      1,0,1,0,0,0,1,0,0,0,
>                      0,1,0,1,0,0,0,1,0,0,
>                      0,0,1,0,1,0,0,0,1,0,
>                      1,0,0,1,0,0,0,0,0,1,
>                      1,0,0,0,0,0,0,1,1,0,
>                      0,1,0,0,0,0,0,0,1,1,
>                      0,0,1,0,0,1,0,0,0,1,
>                      0,0,0,1,0,1,1,0,0,0,
>                      0,0,0,0,1,0,1,1,0,0] >;
> P;
        Graph
    Vertex  Neighbours

       1     2 5 6 ;
       2     1 3 7 ;
       3     2 4 8 ;
       4     3 5 9 ;
       5     1 4 10 ;
       6     1 8 9 ;
       7     2 9 10 ;
       8     3 6 10 ;
       9     4 6 7 ;
      10     5 7 8 ;
```

Example H149E3

A more sophisticated example is the construction of Tutte's 8-cage using the technique described in P. Lorimer [Lor89]. The graph is constructed so that it has $G = P\Gamma L(2, 9)$ in its representation of degree 30 as its automorphism group. The vertices of the graph correspond to the points on which G acts. The neighbours of vertex 1 are the points lying in the unique orbit N_1 of length 3 of the stabilizer of 1. The edges for vertex i are precisely the points N_1^g where g is an element of G such that $1^g = i$.

```
> G := PermutationGroup< 30 |
>     (1, 2)(3, 4)(5, 7)(6, 8)(9, 13)(10, 12)(11, 15)(14, 19) (16, 23)
>         (17, 22)(18, 21)(20, 27)(24, 29)(25, 28)(26, 30),
>     (1, 24, 28, 8)(2, 9, 17, 22)(3, 29, 19, 15)(4, 5, 21, 25)
```

```
>         (6, 18, 7, 16)(10, 13, 30, 11)(12, 14)(20, 23)(26, 27) >;
> N1 := rep{ o : o in Orbits(Stabilizer(G, 1)) | #o eq 3 };
> tutte := Graph< 30 | <1, N1>^G >;
```

149.2.3 Construction of a General Digraph

`Digraph< n | edges :` *parameters* `>`
`Digraph< S | edges :` *parameters* `>`

`SparseRep` BOOL *Default :* `false`

Construct the digraph G with vertex-set $V = \{@v_1, v_2, \ldots, v_n@\}$ (where $v_i = i$ for each i if the first form of the constructor is used, or the ith element of the enumerated or indexed set S otherwise), and edge-set $E = \{e_1, e_2, \ldots, e_q\}$. This function returns three values: The graph G, the vertex-set V of G; and the edge-set E of G. If SparseRep is `true` then the resulting graph will have a sparse representation.

The elements of E are specified by the list `edges`, where the items of `edges` may be objects of the following types:

(a) A pair $[v_i, v_j]$ of vertices in V. The directed edge from v_i to v_j will be added to the edge-set for G.

(b) A tuple of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i. The elements of the sets N_i must be elements of V. If $N_i = \{u_1, u_2, \ldots, u_r\}$, the directed edges $[v_i, u_1], \ldots, [v_i, u_r]$ will be added to G.

(c) A sequence $[N_1, N_2, \ldots, N_n]$ of n sets, where N_i will be interpreted as a set of neighbours for the vertex v_i. The directed edges $[v_i, u_i]$, $1 \leq i \leq n$, $u_i \in N_i$, are added to G.

In addition to these three basic ways of specifying the *edges* list, the items in *edges* may also be:

(d) An edge e of a graph or digraph or multigraph or multidigraph or network of order n. If e is an edge $\{u, v\}$ in an undirected graph then both directed edges $[u, v]$ and $[v, u]$ are added to G.

(e) An edge-set E of a graph or digraph or multigraph or multidigraph or network of order n. Every edge e in E will be added to G according to the rule set out for a single edge.

(f) A graph or a digraph or a multigraph or a multidigraph or a network H of order n. Every edge e in H's edge-set is added to G according to the rule set out for a single edge.

(g) A $n \times n$ (0, 1)-matrix A. The matrix A will be interpreted as the adjacency matrix for a digraph H on n vertices and the edges of H will be added will be added to G.

(h) A set of

(i) Pairs of the form $[v_i, v_j]$ of vertices in V.

(ii) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

(iii) Edges of a graph or digraph or multigraph or multidigraph or network of order n.

(iv) Graphs or digraphs or multigraphs or multidigraphs or networks of order n.

(j) A sequence of
(i) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

`IncidenceDigraph(A)`

Let A be a $n \times m$ matrix such that each column contains at most one entry equal to $+1$ and at most one entry equal to -1 (all others being zero). Then a digraph G of order n and size m having A as its incidence matrix will be constructed. The rows of A will correspond to the vertices of G while the columns will correspond to the edges. If column k of A contains $+1$ in row i and -1 in row j, the directed edge $v_i v_j$ will be included in G. If only row i has a non-zero entry (either 1 or -1), then the loop $v_i v_i$ will be included in G.

Example H149E4

The digraph D with vertices $\{v_1, v_2, v_3, v_4, v_5\}$ and edges $(v_1, v_2), (v_1, v_3), (v_1, v_4), (v_3, v_2)$, and (v_4, v_3) will be constructed, firstly by listing its edges and secondly by giving its adjacency matrix.

```
> D1 := Digraph< 5 | [1, 2], [1, 3], [1, 4],
>                   [3, 2], [4, 3] >;
> D1;
Digraph
Vertex  Neighbours
1       2 3 4 ;
2       ;
3       2 ;
4       3 ;
5       ;
```

The same digraph with a sparse representation:

```
> D1 := Digraph< 5 | [1, 2], [1, 3], [1, 4],
>                   [3, 2], [4, 3] : SparseRep := true>;
```

We next construct the digraph by giving its adjacency matrix:

```
> M := MatrixRing(Integers(), 5);
> D2 := Digraph< 5 |
>           M![ 0,1,1,1,0,
>               0,0,0,0,0,
>               0,1,0,0,0,
```

```
>               0,0,1,0,0,
>               0,0,0,0,0 ] >;
> IsIsomorphic(D1, D2);
true
```

149.2.4 Operations on the Support

Let S be the set over which the graph G is defined. The set S is referred to as the *support* of G.

`Support(G)`

`Support(V)`

The indexed set used in the construction of G (or the graph for which V is the vertex-set), or the standard set $\{@1, \ldots, n@\}$ if it was not given.

`ChangeSupport(G, S)`

If G is a graph having n vertices and S is an indexed set of cardinality n, return a new graph H equal to G but whose support is S. That is, H is structurally equal to G and its vertex and edge decorations are the *same* as those for G.

`ChangeSupport(~G, S)`

The procedural version of the above function.

`StandardGraph(G)`

The graph H equal to G but defined on the standard support. That is, H is structurally equal to G and its vertex and edge decorations are the same as those for G.

Example H149E5

The Odd Graph, O_n, has as vertices all n-subsets of a $2n-1$ set with two vertices adjacent if and only if they are disjoint. We construct O_3 and then form its standard graph.

```
> V := Subsets({1..5}, 2);
> O3 := Graph< V | { {u,v} : u,v in V | IsDisjoint(u, v) } >;
> O3;
Graph
Vertex  Neighbours

{ 1, 5 }        { 2, 4 } { 2, 3 } { 3, 4 } ;
{ 2, 5 }        { 1, 3 } { 1, 4 } { 3, 4 } ;
{ 1, 3 }        { 2, 5 } { 2, 4 } { 4, 5 } ;
{ 1, 4 }        { 2, 5 } { 3, 5 } { 2, 3 } ;
{ 2, 4 }        { 1, 5 } { 1, 3 } { 3, 5 } ;
{ 3, 5 }        { 1, 4 } { 2, 4 } { 1, 2 } ;
```

```
{ 2, 3 }        { 1, 5 } { 1, 4 } { 4, 5 } ;
{ 1, 2 }        { 3, 5 } { 3, 4 } { 4, 5 } ;
{ 3, 4 }        { 1, 5 } { 2, 5 } { 1, 2 } ;
{ 4, 5 }        { 1, 3 } { 2, 3 } { 1, 2 } ;

> Support(O3);
{@
    { 1, 5 },
    { 2, 5 },
    { 1, 3 },
    { 1, 4 },
    { 2, 4 },
    { 3, 5 },
    { 2, 3 },
    { 1, 2 },
    { 3, 4 },
    { 4, 5 }
@}
> SO3 := StandardGraph(O3);
> SO3;
Graph
Vertex  Neighbours

1       5 7 9 ;
2       3 4 9 ;
3       2 5 10 ;

```

149.2.5 Construction of a Standard Graph

Some of the construction functions listed below can also be used to create a graph with a sparse representation. Are concerned only those functions creating relatively sparse graphs.

`BipartiteGraph(m, n)`

The complete bipartite graph, $K_{m,n}$, with partite sets of cardinality m and n.

`CompleteGraph(n)`

The complete graph K_n on n vertices.

`KCubeGraph(n : parameters)`

`SparseRep` BOOL *Default :* `false`

The graph of the n-dimensional cube, Q_n. The graph can be created as a sparse graph if so requested.

`MultipartiteGraph(Q)`

Given a sequence Q of positive integers $m_1, \ldots, m_r$, construct the complete multipartite graph $K_{m_1,\ldots,m_r}$.

`EmptyGraph(n : parameters)`

`SparseRep` BOOL *Default :* `false`

The graph on n vertices with no edges. It can be created as a sparse graph if so requested.

`NullGraph( : parameters)`

`SparseRep` BOOL *Default :* `false`

The graph with no vertices and no edges. It can be created as a sparse graph if so requested.

`PathGraph(n : parameters)`

`SparseRep` BOOL *Default :* `false`

The path graph on n vertices, i.e. the graph on vertices $v_1, \ldots, v_n$, with v_i and v_j $(1 \leq i < j \leq n)$ adjacent if and only if $j = i + 1$. The graph can be created as a sparse graph if so requested.

`PolygonGraph(n : parameters)`

`SparseRep` BOOL *Default :* `false`

Given an integer $n \geq 3$, define the polygon graph on n vertices, i.e. the graph on vertices $v_1, \ldots, v_n$, with v_i and v_j $(1 \leq i < j \leq n)$ adjacent if and only if $j = i + 1$, or $i = 1$ and $j = n$. The graph can be created as a sparse graph if so requested.

`RandomGraph(n, r : parameters)`

`SparseRep` BOOL *Default :* `false`

A random graph on n vertices such that the probability that an arbitrary pair of vertices is adjacent is given by the real number r, where r lies in the interval $[0, 1]$. The graph can be created as a sparse graph if so requested.

`RandomTree(n : parameters)`

`SparseRep` BOOL *Default :* `false`

A random tree on n vertices. It can be created as a sparse graph if so requested.

149.2.6 Construction of a Standard Digraph

As for standard graphs (Subsection 149.2.5) some of the construction functions listed below can be used to create digraphs with a sparse representation.

`CompleteDigraph(n)`

The complete symmetric digraph on n vertices.

`EmptyDigraph(n : parameters)`

`SparseRep` BOOL *Default :* `false`

The null digraph on n vertices. It can be created as sparse if so requested.

`RandomDigraph(n, r : parameters)`

`SparseRep` BOOL *Default :* `false`

A random digraph on n vertices such that the probability that there exists an edge directed from vertex u to vertex v, where u and v arbitrary vertices, is given by the real number r, where r lies in the interval $[0, 1]$. The digraph can be created as sparse if so requested.

Example H149E6

The complete symmetric digraph on 5 vertices is created as follows:

```
> kd5 := CompleteDigraph(5);
> kd5;
Digraph
Vertex  Neighbours

1       2 3 4 5 ;
2       1 3 4 5 ;
3       1 2 4 5 ;
4       1 2 3 5 ;
5       1 2 3 4 ;
```

We next construct a random digraph on 5 vertices such that the probability that there is an edge directed from an arbitrary vertex to any other arbitrary vertex is 0.75.

```
> rd5 := RandomDigraph(5, 0.75);
> rd5;
Digraph
Vertex  Neighbours

1       2 5 ;
2       2 3 4 5 ;
3       2 3 4 5 ;
4       1 2 3 5 ;
5       2 3 4 ;
```

149.3 Graphs with a Sparse Representation

As mentioned in the Introduction 149.1 of this chapter it is possible to construct graphs having a sparse representation. That is, graphs which are represented by means of an adjacency list. This has an obvious advantage for graphs with a low edge density, in that it allows to construct much larger graphs than if they were represented by means of an adjacency matrix (the dense representation). See Section 149.2.1 for more details on this issue.

Another advantage of the sparse representation is for graph algorithms which are linear in the number of edges (the planarity tester and the triconnectivity tester), and more generally, for those algorithms based on the adjacency list representation (the flow-based algorithms and the shortest-paths algorithms). Further, the sparse representation is required when creating multigraphs (see Chapter 150) since they may have multiple edges.

A significant number, but not all, of the existing MAGMA functions have been written for both representations. Should a function designed for a matrix representation of the graph be applied to a graph with a sparse representation, then the graph is automatically converted *without any user intervention*. This is also true when the reverse conversion is required.

Without being exhaustive, we will list here the functions which can deal with both graph representations without having to perform an (internal) conversion.

- Nearly all construction functions (149.2),
- All functions in 149.4, 149.6.1, 149.6.2,
- Some functions in 149.6.3 and 149.7,
- All functions in 149.8,
- The basic invariants and predicates in 149.10 and 149.11,
- Almost all functions in 149.12,
- All functions in 149.13.1 and all but the last in 149.13.2,
- The functions in 149.14.1,
- All functions in 149.17.

The functions in 149.5, 149.13.3, 149.13.4, 149.13.5, and 149.21, and all the functions listed in Chapter 150, deal with a graph as an adjacency list.

The functions in 149.9, 149.14.2, 149.16, 149.18, 149.19, 149.20, 149.22, and 149.23 deal with a graph as an adjacency matrix.

We emphasize again that should a conversion of the graph's representation take place due to internal specifications, the conversion takes place *automatically*, that is, *without user intervention*.

The only problem that may occur is when such a conversion concerns a (very) large graph and thus may possibly result in a lack of memory to create the required representation. This is where users might require control over which internal representation is used so as to minimise the likelihood of both representations coexisting. This is achieved by tuning the creation functions (as described in Section 149.2), and the following functions which determine the nature of a graph's representation.

When conversion of the graph's representation into the alternative one occurs the original representation is not deleted.

`HasSparseRep(G)`

`HasDenseRep(G)`

`HasSparseRepOnly(G)`

`HasDenseRepOnly(G)`

`HasDenseAndSparseRep(G)`

This set of functions determine the nature of a graph's representation.

Example H149E7

We give four examples, each illustrating one of the four possible cases that may arise. First, when the graph's dense representation remains unchanged:

```
> G := Graph<5 | { {1,2}, {2,3}, {3,4}, {4,5}, {5,1} }>;
> HasDenseRepOnly(G);
true
> A := AutomorphismGroup(G);
> HasDenseRepOnly(G);
true
```

The same example using a sparse graph representation:

```
> G := Graph<5 | { {1,2}, {2,3}, {3,4}, {4,5}, {5,1} } : SparseRep := true>;
> HasSparseRepOnly(G);
true
> A := AutomorphismGroup(G);
> HasDenseAndSparseRep(G);
true
```

Next the case when the graph's sparse representation remains unchanged:

```
> G := Graph<5 | { {1,2}, {2,3}, {3,4}, {4,5}, {5,1} } : SparseRep := true>;
> HasSparseRepOnly(G);
true
> IsPlanar(G);
true
> HasSparseRepOnly(G);
true
```

Finally the same example using a dense graph representation:

```
> G := Graph<5 | { {1,2}, {2,3}, {3,4}, {4,5}, {5,1} }>;
> HasDenseRepOnly(G);
true
> IsPlanar(G);
true
> HasDenseAndSparseRep(G);
```

```
true
```

149.4 The Vertex–Set and Edge–Set of a Graph

149.4.1 Introduction

Let G be a graph on n vertices and m edges whose vertex-set is $V = \{v_1, \ldots, v_m\}$ and edge-set is $E = \{e_1, \ldots, e_m\}$. A graph created by MAGMA consists of three objects: the *vertex-set* V, the *edge-set* E and the graph G itself. The vertex-set and edge-set of a graph are *enriched* sets and consequently constitute types. The vertex-set and edge-set are returned as the second and third arguments, respectively, by all functions which create graphs. Alternatively, a pair of functions are provided to extract the vertex-set and edge-set of a graph G. The main purpose of having vertex-sets and edge-sets as types is to provide a convenient mechanism for referring to vertices and edges of a graph. Here, the functions applicable to vertex-sets and edge-sets are described.

149.4.2 Creating Edges and Vertices

`EdgeSet(G)`

Given a graph G, return the edge-set of G.

`Edges(G)`

A set E whose elements are the edges of the graph G. Note that this creates an indexed set and not the edge-set of G, in contrast to the function `EdgeSet`.

`VertexSet(G)`

Given a graph G, return the vertex-set of G.

`Vertices(G)`

A set V whose elements are the vertices of the graph G. In contrast to the function `VertexSet`, this function returns the collection of vertices of G in the form of an indexed set.

`V ! v`

Given the vertex-set V of the graph G and an element v of the support of V, create the corresponding vertex of G.

`V . i`

Given a vertex-set V and an integer i such that $1 \leq i \leq \#V$, create the vertex v_i of V.

`Index(v)`

Given a vertex v of some graph G, return the index of v in the (indexed) vertex-set of G.

`E ! {u, v}`

Given the edge-set E of the graph G and objects u, v belonging to the support of G, which correspond to adjacent vertices, create the edge uv of G.

`E ! [u, v]`

Given the edge-set E of the digraph G and objects u, v belonging to the support of G, which correspond to adjacent vertices, create the edge uv of G.

`E . i`

Given an edge-set E and an integer i such that $1 \leq i \leq \#E$, create the i-th edge of E.

Example H149E8

The construction of vertices and edges is illustrated using the Odd Graph, O_3. and then form its standard graph.

```
> S := Subsets({1..5}, 2);
> O3, V, E := Graph< S | { {u,v} : u,v in S | IsDisjoint(u, v) } >;
> VertexSet(O3);
Vertex-set of O3
> Vertices(O3);
{@ { 1, 5 }, { 2, 5 }, { 1, 3 }, { 1, 4 }, { 2, 4 }, { 3, 5 },
{ 2, 3 }, { 1, 2 }, { 3, 4 }, { 4, 5 } @}
> EdgeSet(O3);
Edge-set of O3
> Edges(O3);
{@ {{ 1, 5 }, { 2, 4 }}, {{ 1, 5 }, { 2, 3 }}, {{ 1, 5 }, { 3, 4 }},
{{ 2, 5 }, { 1, 3 }}, {{ 2, 5 }, { 1, 4 }}, {{ 2, 5 }, { 3, 4 }},
{{ 1, 3 }, { 2, 4 }}, {{ 1, 3 }, { 4, 5 }}, {{ 1, 4 }, { 3, 5 }},
{{ 1, 4 }, { 2, 3 }}, {{ 2, 4 }, { 3, 5 }}, {{ 3, 5 }, { 1, 2 }},
{{ 2, 3 }, { 4, 5 }}, {{ 1, 2 }, { 3, 4 }}, {{ 1, 2 }, { 4, 5 }} @}
> u := V!{1, 2};
> u, Type(u);
{1, 2} GrphVert
> Index(u);
8
> x := E!{ {1,2}, {3,4}};
> x, Type(x);
{{ 1, 2 }, { 3, 4 }} GrphEdge
```

149.4.3 Operations on Vertex-Sets and Edge-Sets

For each of the following operations, S and T may be interpreted as either the vertex-set or the edge-set of the graph G. The variable s may be interpreted as either a vertex or an edge. The edge-set and vertex-set support all the standard set operations.

`#S`

The cardinality of the set S.

`s in S`

Return `true` if the vertex (edge) s lies in the vertex-set (edge-set) S, otherwise `false`.

`s notin S`

Return `true` if the vertex (edge) s does not lie in the vertex-set (edge-set) S, otherwise `false`.

`S subset T`

Return `true` if the vertex-set (edge-set) S is contained in the vertex-set (edge-set) T, otherwise `false`.

`S notsubset T`

Return `true` if the vertex-set (edge-set) S is not contained in the vertex-set (edge-set) T, otherwise `false`.

`S eq T`

Return `true`if the vertex-set (edge-set) S is equal to the vertex-set (edge-set) T.

`s eq t`

Returns `true` if the vertex (edge) s is equal to the vertex (edge) t.

`S ne T`

Returns `true` if the vertex-set (edge-set) S is not equal to the vertex-set (edge-set) T.

`s ne t`

Returns `true` if the vertex (edge) s is not equal to the vertex (edge) t.

`ParentGraph(S)`

Return the graph G for which S is the vertex-set (edge-set).

`ParentGraph(s)`

Return the graph G for which s is a vertex (edge).

`Random(S)`

Choose a random element from the vertex-set (edge-set) S.

`Representative(S)`

`Rep(S)`

Choose some element from the vertex-set (edge-set) S.

```
for x in S do ...  end for;
```

The vertex-set (edge-set) S may appear as the range in the `for`-statement.

```
for random x in S do ... end for;
```

The vertex-set (edge-set) S may appear as the range in the `for random` - statement.

149.4.4 Operations on Edges and Vertices

`EndVertices(e)`

Given an edge e belonging to the graph G, return a set containing the two end-vertices of e. If G is a digraph return the two end-vertices in a sequence.

`InitialVertex(e)`

Given an undirected or directed edge e from vertex u to vertex v, return vertex u. This is useful in the undirected case since it indicates, where relevant, the direction in which the edge has been traversed.

`TerminalVertex(e)`

Given an undirected or directed edge e from vertex u to vertex v, return vertex v. This is useful in the undirected case since it indicates, where relevant, the direction in which the edge has been traversed.

`IncidentEdges(u)`

Given a vertex u of a graph G, return the set of all edges incident with the vertex u. If G is directed, then the set consists of all the edges incident into u and from v.

149.5 Labelled, Capacitated and Weighted Graphs

A vertex labelling of a graph G is a partial map f from the vertex-set V of G into a set L. An edge labelling of a graph G is a partial map f from the edge-set E of G into a set L. A labelled graph is built by assigning labels successively to vertices or edges after the (unlabelled) graph has been constructed.

Similarly, a capacitated graph G is a partial map from its edge-set into Z^+, and a weighted graph G is a partial map from its edge-set into R, R any ring with a total order. Those two last features are particularly convenient when running shortest-paths and flow algorithms. Edge capacities and edge weights are assigned to edges once the graph has been constructed. Any graph edge may carry a label, together with a capacity and/or a weight.

All the functions for decorating graph vertices and edges are fully documented in Section 150.4 in Chapter 150. A few examples are also given there.

149.6 Standard Constructions for Graphs

The two main ways in which to construct a new graph from an old one are either by taking a subgraph of or by modifying the original graph. Another method is to take the quotient graph. When the first two methods are employed, the support set and vertex and edge decorations are retained in the resulting graph.

149.6.1 Subgraphs and Quotient Graphs

`sub< G | list >`

Construct the graph H as a subgraph of G. The function returns three values: The graph H, the vertex-set V of H; and the edge-set E of H. If G has a support set and/or if G has vertex/edge decorations, then these attributes are transferred to the subgraph H.

The elements of V and of E are specified by the list *list* whose items can be objects of the following types:

(a) A vertex of G. The resulting subgraph will be the subgraph induced on the subset of `VertexSet(`G`)` defined by the vertices in *list*.

(b) An edge of G. The resulting subgraph will be the subgraph with vertex-set `VertexSet(`G`)` whose edge-set consists of the edges in *list*.

(c) A set of
   (i) Vertices of G.
   (ii) Edges of G.

It is easy to recover the map that maps the vertices of the subgraph to the vertices of the supergraph and vice-versa. We give an example below.

`quo< G | P >`

Given a graph G and a partition P of the vertex-set $V(G)$ of G, construct the quotient graph Q of G defined by P. The partition is given as a set of subsets of $V(G)$. Suppose the cells of the partition P are $P_1, \ldots, P_r$. The vertices of Q correspond to the cells P_i. Vertices v_i and v_j of Q are adjacent if and only if there is an edge in G joining a vertex in P_i with a vertex in P_j.

Example H149E9

We start with a simple example which demonstrates how to map the vertices of a subgraph onto the vertices of the supergraph and vice-versa: This is achieved by simple coercion into the appropriate vertex-set.

```
> K5, V := CompleteGraph(5);
> K3, V1 := sub< K5 | { V | 3, 4, 5 } >;
> IsSubgraph(K5, K3);
true
>
> V!V1!1;
3
>
> V1!V!4;
2
>
>  V1!V!1;
>> V1!V!1;
     ^
Runtime error in '!': Illegal coercion
LHS: GrphVertSet
RHS: GrphVert
```

A 1-factor of a graph G is a set of disjoint edges which form a spanning forest for G. In the following example, we construct the graph that corresponds to K_6 with a 1-factor removed.

```
> K6, V, E := CompleteGraph(6);
> K6;
Graph
Vertex  Neighbours

1       2 3 4 5 6 ;
2       1 3 4 5 6 ;
3       1 2 4 5 6 ;
4       1 2 3 5 6 ;
5       1 2 3 4 6 ;
6       1 2 3 4 5 ;
> F1 := { E | {1,2}, {3, 4}, {5, 6} };
> G1, V1, E1 := K6 - F1;
> G1;
Graph
```

```
Vertex  Neighbours

1       3 4 5 6 ;
2       3 4 5 6 ;
3       1 2 5 6 ;
4       1 2 5 6 ;
5       1 2 3 4 ;
6       1 2 3 4 ;
```

Example H149E10

Taking the complete graph K_9, we form its quotient with respect to the partition of the vertex-set into three 3-sets.

```
> K9, V, E := CompleteGraph(9);
> P := { { V | 1, 2, 3}, { V | 4, 5, 6}, { V | 7, 8, 9} };
> Q := quo< K9 | P >;
> Q;
Graph
Vertex  Neighbours

1       2 3 ;
2       1 3 ;
3       1 2 ;
```

149.6.2 Incremental Construction of Graphs

Unless otherwise specified, each of the functions described in this section returns three values:

(i) The graph G;

(ii) The vertex-set V of G;

(iii) The edge-set E of G.

149.6.2.1 Adding Vertices

`G + n`

Given a graph G and a non-negative integer n, adds n new vertices to G. The existing vertex and edge decorations are retained, but the support will become the standard support.

`G +:= n`
`AddVertex(~G)`
`AddVertices(~G, n)`

The procedural version of the previous function. `AddVertex` adds one vertex only to G.

`AddVertex(~G, l)`

Given a graph G and a label l, adds a new vertex with label l to G. The existing vertex and edge decorations are retained, but the support will become the standard support.

`AddVertices(~G, n, L)`

Given a graph G and a non-negative integer n, and a sequence of n labels, adds n new vertices to G with labels from L. The existing vertex and edge decorations are retained, but the support will become the standard support.

149.6.2.2 Removing Vertices

`G - v`
`G - U`

Given a graph G and a vertex v or a set of vertices U of G, removes v or the vertices in U from G. The support and vertex and edge decorations are retained.

`G -:= v`
`G -:= U`
`RemoveVertex(~G, v)`
`RemoveVertices(~G, U)`

The procedural versions of the previous functions.

149.6.2.3 Adding Edges

`G + { u, v }`
`G + [ u, v ]`

Given a graph G and a pair of vertices of G, add the edge to G described by this pair. If G is undirected then the edge must be given as a set of (two) vertices, if G is directed the edge is given as a sequence of (two) vertices. The support and existing vertex and edge decorations are retained. This set of functions has two return values: The first is the modified graph and the second is the newly created edge.

```
G + { { u, v } }
```
```
G + { [ u, v ] }
```

Given a graph G and a set of pairs of vertices of G, add the edges to G described by these pairs. If G is undirected then edges must be given as a set of (two) vertices, if G is directed edges are given as a sequence of (two) vertices. The support and existing vertex and edge decorations are retained.

```
G +:= { u, v }
```
```
G +:= [ u, v ]
```
```
G +:= { { u, v } }
```
```
G +:= { [ u, v ] }
```

The procedural versions of the previous four functions.

```
AddEdge(G, u, v)
```

Given a graph G, two vertices of G u and v, returns a new edge between u and v. The support and existing vertex and edge decorations are retained. This function has two return values: The first is the modified graph and the second is the newly created edge.

```
AddEdge(G, u, v, l)
```

Given a graph G, two vertices of G u and v, and a label l, adds a new edge with label l between u and v. The support and existing vertex and edge decorations are retained. This function has two return values: The first is the modified graph and the second is the newly created edge.

```
AddEdge(~G, u, v)
```
```
AddEdge(~G, u, v, l)
```

Procedural versions of previous functions adding edges to a graph.

```
AddEdges(G, S)
```

Given a graph G, a set S of pairs of vertices of G, adds the edges specified in S. The elements of S must be sets or sequences of two vertices of G, depending on whether G is undirected or directed respectively. The support and existing vertex and edge decorations are retained.

```
AddEdges(G, S, L)
```

Given a graph G, a sequence S of pairs of vertices of G, and a sequence L of labels of same length, adds the edges specified in S with its corresponding label in L. The elements of S must be sets or sequences of two vertices of G, depending on whether G is undirected or directed respectively. The support and existing vertex and edge decorations are retained.

`AddEdges(~G, S)`

`AddEdges(~G, S, L)`

Procedural versions of previous functions adding edges to a graph.

149.6.2.4 Removing Edges

`G - e`

`G - { e }`

Given a graph G and an edge e or a set S of edges of G, removes e or the edges in S from G. The resulting graph will have vertex-set $V(G)$ and edge-set $E(G) \setminus \{e\}$ or $E(G) \setminus S$. The support and existing vertex and edge decorations are retained.

`G - { { u, v } }`

`G - { [u, v] }`

Given a graph G and a set S of pairs $\{u, v\}$ or $[u, v]$, u, v vertices of G, form the graph having vertex-set $V(G)$ and edge-set $E(G)$ minus the edges from u to v for all pairs in S. An edge is represented as a set if G is undirected, as a set otherwise. The support and existing vertex and edge decorations are retained.

`G -:= e`

`G -:= { e }`

`G -:= { { u, v } }`

`G -:= { [u, v] }`

`RemoveEdge(~G, e)`

`RemoveEdges(~G, S)`

`RemoveEdge(~G, u, v)`

The procedural versions of the previous functions.

149.6.3 Constructing Complements, Line Graphs; Contraction, Switching

Unless otherwise stated, each of the functions described here apply to both graphs and digraphs. Further, each of the functions returns three values:

(i) The graph G;

(ii) The vertex-set V of G;

(iii) The edge-set E of G.

`Complement(G)`

The complement of the graph G.

`Contract(e)`

Given an edge $e = \{u, v\}$ of the graph G, form the graph obtained by identifying the vertices u and v, and removing any multiple edges (and loops if the graph is undirected) from the resulting graph. The graph's support and vertex/edges decorations are retained.

`Contract(u, v)`

Given vertices u and v belonging to the graph G, return the graph obtained by identifying the vertices u and v, and removing any multiple edges (and loops if the graph is undirected) from the resulting graph. The graph's support and vertex/edges decorations are retained.

`Contract(S)`

Given a set S of vertices belonging to the graph G, return the graph obtained by identifying all of the vertices in S, and removing any multiple edges (and loops if the graph is undirected) from the resulting graph. The graph's support and vertex/edges decorations are retained.

`InsertVertex(e)`

Given an edge e in the graph G, insert a new vertex of degree 2 in e. If applicable, the two new edges thus created that replace e will have the same capacity and weight as e. They will be unlabelled. The vertex labels and the edge decorations of G are retained, but the resulting graph will have standard support.

`InsertVertex(T)`

Given an a set T of edges belonging to the graph G, insert a vertex of degree 2 in each edge belonging to the set T. Vertex and edge decorations are handled as in the single edge case.

`LineGraph(G)`

The line graph of the non-empty graph G.

`Switch(u)`

Given a vertex u in an undirected graph G, construct an undirected graph H from G, where H has the same vertex-set as G and the same edge-set, except that the vertices that were the neighbours of u in G become the non-neighbours of u in H, and the vertices that were non-neighbours of u in G become the neighbours of u in H. The support and vertex labels are *not* retained in the resulting graph.

`Switch(S)`

Given a set S of vertices belonging to the undirected graph G, apply the function `Switch(u)`, to each vertex of S in turn. The support and vertex labels are *not* retained in the resulting graph.

Example H149E11

We illustrate the use of some of these operations by using them to construct the Grötzch graph. This graph may be built by taking the complete graph $K5$, choosing a cycle of length 5 (say, 1-3-5-2-4), inserting a vertex of degree two on each edge of this cycle and finally connecting each of these vertices to a new vertex.

```
> G := CompleteGraph(5);
> E := EdgeSet(G);
> H := InsertVertex({ E | { 1, 3 }, { 1, 4 }, { 2, 4 }, { 2, 5 }, { 3, 5 } } );
> L := Union(H, CompleteGraph(1));
> V := VertexSet(L);
> L := L + {  { V.11, V.6 }, { V.11, V.7 }, { V.11, V.8 }, { V.11, V.9 },
>            { V.11, V.10 } };
> L;
Graph
Vertex  Neighbours

1       2 5 6 7 ;
2       1 3 8 10 ;
3       2 4 6 9 ;
4       3 5 7 8 ;
5       1 4 9 10 ;
6       1 3 11 ;
7       1 4 11 ;
8       2 4 11 ;
9       3 5 11 ;
10      2 5 11 ;
11      6 7 8 9 10 ;
```

149.7 Unions and Products of Graphs

The support and vertex/edge decorations of the original graphs are *not* retained in the graph resulting from applying any of the union functions below.

`Union(G, H)`

`G join H`

Given graphs G and H with disjoint vertex sets $V(G)$ and $V(H)$, respectively, construct their union, i.e. the graph with vertex-set $V(G) \cup V(H)$, and edge-set $E(G) \cup E(H)$.

`EdgeUnion(G, H)`

Given graphs G and H having the same number of vertices, construct their edge union K. This construction identifies the i-th vertex of G with the i-th vertex of H for all i. The edge union has the same vertex-set as G (and hence as H) and vertices u and v of K are adjacent if and only if either u and v are adjacent in G or u and v are adjacent in H.

`CompleteUnion(G, H)`

Given graphs G and H with disjoint vertex-sets $V(G)$ and $V(H)$, respectively, construct the complete union of G and H. This graph consists of the union of G and H (`Union(G, H)`), together with edges uv, for all u in $V(G)$ and all v in $V(H)$.

`CartesianProduct(G, H)`

Given graphs G and H with disjoint vertex-sets $V(G)$ and $V(H)$, respectively, form the product $K = G \times H$ of G and H. The product has vertex-set $V(G) \times V(H)$. Two vertices $u = (u_1, u_2)$ and $v = (v_1, v_2)$ of K are adjacent when either

(a) $u_1 = v_1$ and u_2 adj v_2, or

(b) $u_2 = v_2$ and u_1 adj v_1.

`LexProduct(G, H)`

Given graphs G and H with disjoint vertex-sets $V(G)$ and $V(H)$, respectively, form the lexicographic product K of G and H. The lexicographic product has vertex-set $V(G) \times V(H)$. Two vertices $u = (u_1, u_2)$ and $v = (v_1, v_2)$ of K are adjacent when either

(a) u_1 adj v_1, or

(b) $u_1 = v_1$ and u_2 adj v_2.

`TensorProduct(G, H)`

Given graphs G and H with disjoint vertex-sets $V(G)$ and $V(H)$, respectively, form the tensor product K of G and H. This graph has vertex-set $V(G) \times V(H)$. Two vertices $u = (u_1, u_2)$ and $v = (v_1, v_2)$ of K are adjacent when u_1 adj v_1 and u_2 adj v_2.

`G ^ n`

Given a graph G and a positive integer n, construct the n-th power K of G. This graph has the same vertex-set as G, and vertices u and v of K are adjacent if and only if the distance between u and v in G is less than or equal to n.

149.8 Converting between Graphs and Digraphs

Note that the two functions `UnderlyingGraph` and `UnderlyingDigraph` may also be used when one needs to get a copy of a graph G without G's support and vertex/edge decorations.

`OrientatedGraph(G)`

Given a graph G, produce a digraph D whose vertex-set is the same as that of G and whose edge-set consists of the edges of G, each given a direction. The edges of D are always directed from the lower numbered vertex to the higher numbered vertex. Thus, if G contains the edge $\{u, v\}$, then D will have the edge $[u, v]$ if $u < v$, otherwise the edge $[u, v]$. The support and vertex/edge decorations of G are not retained.

`UnderlyingGraph(D)`

The underlying graph G of the graph D; G has the same vertex-set as D. If D is undirected, then G is a copy of D without D's support and vertex/edge decorations. If D is directed, then two vertices u and v are adjacent in G if and only if, in D, there is either an edge directed from u to v or from v to u. The support and vertex/edge decorations of G are not retained.

`UnderlyingDigraph(G)`

The underlying digraph D of the graph G; D has the same vertex-set as G. If G is directed, then D is a copy of G without D's support and vertex/edge decorations. If G is undirected, then if vertices u and v are adjacent in G then, in D, there will be both an edge directed from u to v and an edge directed from v to u. The support and vertex/edge decorations of G are not retained.

149.9 Construction from Groups, Codes and Designs

149.9.1 Graphs Constructed from Groups

`CayleyGraph(A)`

`CayleyGraph(A :` *parameter*`)`

`UnlabelledCayleyGraph(A)`

`Labelled` BoolElt *Default :* `true`

Given a finite group A defined on generating set X, construct the Cayley graph C of A relative to the generating set X. This graph is defined as follows: The vertices correspond to the elements of A and two vertices u, v are adjacent if and only if there exists an element x in X such that $u * x = v$.

The optional parameter `Labelled` (`Labelled := true` by default) can be set to `false` to prevent the graph being labelled. If this is not done, then the vertices of

C will be labelled with the appropriate elements of A and the (directed) edge from u to v will be labelled with the appropriate element x as defined above.

`SchreierGraph(A, B)`

`UnlabelledSchreierGraph(A, B)`

Given a finite group A defined on the generating set X and a subgroup B of A, construct the Schreier coset graph S for A over B, relative to X. The graph S is defined as follows: The vertices correspond to the cosets of B in A, and two vertices u, v are adjacent in S if and only if there exists an element x in X such that $u*x = v$.

The graph is available in both a labelled and an unlabelled version.

`OrbitalGraph(P, u, T)`

Let P be a transitive permutation group acting on the set $\Omega = \{1, \ldots, n\}$. Let u be an element of Ω and let $T = \{t_1, \ldots, t_r\}$ be a subset of Ω. This function constructs the underlying graph G of the digraph corresponding to the union of P-orbits containing the pairs $(u, t_1), \ldots, (u, t_r)$. Thus, if T defines a self-paired orbit Δ of the stabilizer in P of the point u, this function constructs the orbital graph associated with Δ.

`ClosureGraph(P, G)`

Let P be a permutation group acting on the set $\Omega = \{1, \ldots, n\}$. Let G be a graph (digraph) with vertices $v_1, \ldots, v_n$. This function adds the minimum number of edges to G so as to produce a graph (digraph) H which is left invariant by the group P.

`PaleyGraph(q)`

The Paley graph of $\mathbf{F}_q$ where q must be a prime power equivalent to 1 mod 4. Vertices are in bijection with elements of $\mathbf{F}_q$ and distinct elements are adjacent when their difference is a square in the field.

`PaleyTournament(q)`

The Paley tournament of $\mathbf{F}_q$ where q must be a prime power equivalent to 3 mod 4. Vertices are in bijection with elements of $\mathbf{F}_q$ and there is an edge from u to v when $u \neq v$ and $v - u$ is a square in the field.

149.9.2 Graphs Constructed from Designs

`IncidenceGraph(D)`

Given an incidence structure $D = (X, \mathcal{B})$, construct the incidence graph G of D. The vertices of G is $X \cup \mathcal{B}$. The adjacency rules are as follows: No two vertices of X are adjacent; no two vertices of $\mathcal{B}$ are adjacent; a vertex $x \in X$ is adjacent to a vertex $B \in \mathcal{B}$ if and only if $x \in B$.

`PointGraph(D)`

Given an incidence structure $D = (X, \mathcal{B})$, construct the point graph G of D. The vertex-set of G is X. Vertices $x \in X$, $y \in X$ are adjacent in G if there is a block $B \in \mathcal{B}$ such that $x \in B$ and $y \in B$.

`BlockGraph(D)`

The block graph of the incidence structure D; i.e. the point graph of the dual of D.

`IncidenceGraph(P)`

Given a plane P with point-set V and line-set L, construct the incidence graph G of P. The vertex-set of G is $V \cup L$. The adjacency rules are as follows: No two vertices of V are adjacent; no two vertices of L are adjacent; a vertex $v \in V$ is adjacent to a vertex $a \in L$ if and only if v lies on a.

`PointGraph(P)`

Given a plane P with point-set V and line-set L, construct the point graph G of P. The vertex-set of G is V. Vertices $u, v \in V$ are adjacent in G iff there is a line in L that contains them both.

`LineGraph(P)`

Given a plane P with point-set V and line-set L, construct the point graph G of P. The vertex-set of G is L. Lines $a, b \in L$ are adjacent in G iff there is a vertex in V that lies on them both.

`HadamardGraph(H :` *parameters*`)`

`Labels` BoolElt *Default :* `false`

The graph of the ± 1 matrix H as described in Brendan D. McKay's note "Hadamard equivalence via graph isomorphism" (with self-loops omitted). The parameter `Labels` is set to `false` by default, but when set to `true`, the vertices associated with rows are labelled "row" and the others "col". Those labelled "row" are those given loops in McKay's paper.

149.9.3 Miscellaneous Graph Constructions

`Converse(G)`

Returns the converse H of the directed graph G: if $[u, v]$ is an edge of G then $[v, u]$ is an edge of H.

`OddGraph(n)`

The nth odd graph. Vertices are $(n-1)$–subsets of a $(2n-1)$-set with vertices adjacent if and only if the $(n-1)$–subsets are disjoint.

`TriangularGraph(n)`

The nth triangular graph. Vertices are 2-subsets of a n-set with vertices adjacent if and only if the 2-subsets are unequal and not disjoint.

`SquareLatticeGraph(n)`

The nth square lattice graph. This is the cartesian product of the nth complete graph with itself.

`ClebschGraph()`
`ShrikhandeGraph()`
`GewirtzGraph()`

Return the named graph.

`ChangGraphs()`

Return a sequence of the three Chang graphs.

149.10 Elementary Invariants of a Graph

`Order(G)`
`NumberOfVertices(G)`

The number of vertices of the graph G.

`Size(G)`
`NumberOfEdges(G)`

The number of edges of the graph G.

`CharacteristicPolynomial(G)`

The characteristic polynomial (over the integers) of the graph G; i.e. the characteristic polynomial of the adjacency matrix of G.

`Spectrum(G)`

The spectrum of the graph G; i.e. the roots of the characteristic polynomial of G. The roots are returned as a set of tuples, each containing a root and its multiplicity.

149.11 Elementary Graph Predicates

Let G and H be two graphs. For clarity, we list here the conditions under which G is equal to H and H is a subgraph of G. The conditions take into account the fact that the graphs may have a support and that their vertex and edges may be decorated.

The graphs G and H are equal if and only if:

- they are of the same type,
- they are structurally identical,
- they have the same support,
- they have identical vertex and edge labels,
- if applicable, the total capacity from u to v in G is equal to the total capacity from u to v in H.

Also, H is a subgraph of G if and only if:

- they are of the same type,
- H is a structural subgraph of G,
- any vertex `v` in H has the same support as the vertex `VertexSet(G)!v` in G,
- any vertex `v` in H has the same label as the vertex `VertexSet(G)!v` in G,
- any edge `e` in H has the same label as the edge `EdgeSet(G)!e` in G,
- if applicable, the total capacity from u to v in G is at least as large as the total capacity from u to v in H.

Note that the truth value of the above two tests is not dependent on the weights of the edges of the graphs, should these edges be weighted. One could argue that given this shortcoming, the tests should not be dependent on the capacities of the edges either. We welcome users' comments on this matter.

`u adj v`

Let u and v be two vertices of the same graph G. If G is undirected, returns `true` if and only if u and v are adjacent. If G is directed, returns `true` if and only if there is an edge directed from u to v.

`e adj f`

Let e and f be two edges of the same graph G. If G is undirected, returns `true` if and only if e and f share a common vertex. If G is directed, returns `true` if and only if the terminal vertex of e (f) is the initial vertex of f (e).

`u notadj v`

The negation of the `adj` predicate applied to vertices.

`e notadj f`

The negation of the `adj` predicate applied to edges.

`u in e`

Let u be a vertex and e an edge of a graph G. Returns `true` if and only if u is an end-vertex of e.

`u notin e`

The negation of the `in` predicate applied to a vertex with respect to an edge.

`G eq H`

Returns `true` if the graphs G and H are identical, otherwise `false`. G and H are identical if and only if:

- they are structurally identical,
- they have the same support,
- they have identical vertex and edge labels,
- if applicable, the total capacity from u to v in G is equal to the total capacity from u to v in H.

Thus, as an example, if G and H are structurally identical graphs, and the vertices of G are labelled while the vertices of H are not, then `G eq H` returns `false`.

`IsSubgraph(G, H)`

Returns `true` if H is a subgraph of G, otherwise `false`. H is a subgraph of G if and only if:

- H can be determined to be a structural subgraph of G,
- any vertex `v` in H has the same support as the vertex `VertexSet(G)!v` in G,
- any vertex `v` in H has the same label as the vertex `VertexSet(G)!v` in G,
- any edge `e` in H has the same label as the edge `EdgeSet(G)!e` in G.
- if applicable, the total capacity from u to v in G is at least as large as the total capacity from u to v in H.

`IsBipartite(G)`

Returns `true` if the graph G is a bipartite graph, otherwise `false`.

`IsComplete(G)`

Returns `true` if the graph G on n vertices is the complete graph on n vertices, otherwise `false`.

`IsEulerian(G)`

Returns `true` if the graph G is an eulerian graph, otherwise `false`. A eulerian graph is a graph whose vertices have all even degree. An eulerian digraph is a digraph whose vertices have same in and outdegree. That is, if D is a digraph, D is eulerian if and only if `OutDegree(v)` equals `InDegree(v)` for all vertices v of D.

`IsForest(G)`

Returns `true` if the graph G is a forest, i.e. does not possess any cycles, otherwise `false`.

`IsEmpty(G)`

Returns `true` if the graph G is an empty graph, otherwise `false`. A graph is empty if its edge-set E is empty.

`IsNull(G)`

Returns `true` if the graph G is a null graph, otherwise `false`. A graph is null if its vertex-set V is empty.

`IsPath(G)`

Returns `true` if the graph G is a path graph, otherwise `false`.

`IsPolygon(G)`

Returns `true` if the graph G is a polygon graph, otherwise `false`.

`IsRegular(G)`

Returns `true` if the graph G is a regular graph, otherwise `false`.

`IsTree(G)`

Returns `true` if the graph G is a tree, otherwise `false`.

149.12 Adjacency and Degree

149.12.1 Adjacency and Degree Functions for a Graph

`Degree(u)`

Given a vertex u of the graph G, return the degree of u, ie the number of edges incident to u.

`Alldeg(G, n)`

Given a graph G, and a non-negative integer n, return the set of all vertices of G that have degree equal to n.

`MaximumDegree(G)`

`Maxdeg(G)`

The maximum of the degrees of the vertices of the graph G. This function returns two values: the maximum degree, and a vertex of G having that degree.

`MinimumDegree(G)`

`Mindeg(G)`

The minimum of the degrees of the vertices of the graph G. This function returns two values: the minimum degree, and a vertex of G having that degree.

`DegreeSequence(G)`

Given a graph G such that the maximum degree of any vertex of G is r, return a sequence D of length $r+1$, such that $D[i]$, $1 \leq i \leq r+1$, is the number of vertices in G having degree $i-1$.

`Valence(G)`

Given a regular graph G, return the valence of G (the degree of any vertex).

`Neighbours(u)`

`Neighbors(u)`

Given a vertex u of the graph G, return the set of vertices of G that are adjacent to u.

`IncidentEdges(u)`

The set of all edges incident with the vertex u.

`Bipartition(G)`

Given a bipartite graph G, return its two partite sets in the form of a pair of subsets of $V(G)$.

`MinimumDominatingSet(G)`

A dominating set S of a graph G is such that the vertices of S together with the vertices adjacent to vertices in S form the vertex-set of G. A dominating set S is minimal if no proper subset of S is a dominating set. A minimum dominating set is a minimal dominating set of smallest size. The algorithm implemented is a backtrack algorithm (see [Chr75] p. 41).

149.12.2 Adjacency and Degree Functions for a Digraph

`InDegree(u)`

The number of edges directed into the vertex u belonging to the directed graph G.

`OutDegree(u)`

The number of edges of the form uv where u is a vertex belonging to the directed graph G.

`Degree(u)`

Given a vertex u belonging to the digraph G, return the total degree of u, i.e. the sum of the in–degree and out–degree for u.

`Alldeg(G, n)`

Given a digraph G, and a non–negative integer n, return the set of all vertices of G that have total degree equal to n.

`MaximumInDegree(G)`

`Maxindeg(G)`

The maximum indegree of the vertices of the digraph G. This function returns two values: the maximum indegree, and the first vertex of G having that degree.

`MaximumOutDegree(G)`

`Maxoutdeg(G)`

The maximum outdegree of the vertices of the digraph G. This function returns two values: the maximum outdegree, and the first vertex of G having that degree.

`MinimumInDegree(G)`

`Minindeg(G)`

The minimum indegree of the vertices of the digraph G. This function returns two values: the minimum indegree, and the first vertex of G having that degree.

`MinimumOutDegree(G)`

`Minoutdeg(G)`

The minimum outdegree of the vertices of the digraph G. This function returns two values: the minimum outdegree, and the first vertex of G having that degree.

`MaximumDegree(G)`

`Maxdeg(G)`

The maximum total degree of the vertices of the digraph G. This function returns two values: the maximum total degree, and the first vertex of G having that degree.

`MinimumDegree(G)`

`Mindeg(G)`

The minimum total degree of the vertices of the digraph G. This function returns two values: the minimum total degree, and the first vertex of G having that degree.

`DegreeSequence(G)`

Given a digraph G such that the maximum degree of any vertex of G is r, return a sequence D of length $r+1$, such that $D[i]$, $1 \leq i \leq r+1$, is the number of vertices in G having degree $i-1$.

`InNeighbours(u)`

`InNeighbors(u)`

Given a vertex u of the digraph G, return the set containing all vertices v such that vu is an edge in the digraph, i.e. the starting points of all edges that are directed into the vertex u.

`OutNeighbours(u)`

`OutNeighbors(u)`

Given a vertex u of the digraph G, return the set of vertices v of G such that uv is an edge in the graph G, i.e. the set of vertices v that are the end vertices of edges directed from u to v.

`IncidentEdges(u)`

The set of all edges incident with the vertex u.

149.13 Connectedness

149.13.1 Connectedness in a Graph

`IsConnected(G)`

Returns `true` if and only if the graph G is connected.

`Components(G)`

The connected components of the graph G. These are returned in the form of a sequence of subsets of the vertex-set of G.

`Component(u)`

The subgraph corresponding to the connected component of the graph G containing vertex u. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

`IsSeparable(G)`

Returns `true` if and only if the graph G is connected and has at least one cut vertex.

`IsBiconnected(G)`

Returns `true` if and only if the graph G is biconnected.

`CutVertices(G)`

The set of cut vertices for the connected graph G (a set of vertices).

`Bicomponents(G)`

The biconnected components of the graph G. These are returned in the form of a sequence of subsets of the vertex-set of G. The graph may be disconnected.

149.13.2 Connectedness in a Digraph

`IsStronglyConnected(G)`

Returns `true` if and only if the digraph G is strongly connected.

`IsWeaklyConnected(G)`

Returns `true` if and only if the digraph G is weakly connected.

`StronglyConnectedComponents(G)`

The strongly connected components of the digraph G. These are returned in the form of a sequence of subsets of the vertex-set of G.

`Component(u)`

The subgraph corresponding to the connected component of the digraph G containing vertex u. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

149.13.3 Graph Triconnectivity

The linear-time triconnectivity algorithm by Hopcroft and Tarjan [HT73] has been implemented with corrections of our own and from C. Gutwenger and P. Mutzel [GM01]. This algorithm requires that the graph has a sparse representation. The input graph may be disconnected or have cut vertices.

The algorithm completely splits the graph into components that can later be reconstructed as triconnected graphs: It is our belief that the word "tricomponents" is misused in all the papers discussing Hopcroft and Tarjan's algorithm, including [HT73] and [GM01]. Let us clarify this point.

Assume that G is a biconnected but not triconnected graph with vertex-set V and with one separation pair (a, b) which splits $V - \{a, b\}$ into V_1 and V_2. That is, for any vertices $u \in V_1$ and $v \in V_2$, every path from u to v in G contains at least one of a or b.

Now, the algorithm will correctly find the separation pair (a, b) and return the two subsets of V, $V_1 + \{a, b\}$ and $V_2 + \{a, b\}$. Let G_1 and G_2 be the subgraphs of G induced by $V_1 + \{a, b\}$ and $V_2 + \{a, b\}$ respectively. We say that the algorithm *splits* G into G_1 and G_2.

But G_1 and G_2 are triconnected if and only if there is an edge (a, b) in G. We call G_1 and G_2 the *split components* of G.

More generally, if $G_1, \ldots, G_m$ are the split components of a graph G, one can make the G_i triconnected by adding the edges (a, b) to them for all the separation pairs (a, b) of G with $a, b \in G_i$ for some i.

The algorithm finds all the cut vertices and/or the separation pairs of a graph, unless only the boolean test is applied. When this is the case the algorithm stops as soon as a cut vertex or separation pair is found.

The triconnectivity algorithm only applies to undirected graphs.

`IsTriconnected(G)`

Returns `true` if and only if the graph G is triconnected.

`Splitcomponents(G)`

The split components of the graph G. These are returned in the form of a sequence of subsets of the vertex-set of G. The graph may be disconnected. The second return value returns the cut vertices and the separation pairs.

`SeparationVertices(G)`

The cut vertices and/or the separation pairs of the graph G as a sequence of vertices or pairs of vertices of G. The graph may be disconnected. The second return value returns G's split components.

Example H149E12

```
> G := Graph< 11 |
> {1, 3}, {1, 4}, {1, 7}, {1, 11}, {1, 2},
> {2, 4}, {2, 3},
> {3, 4},
> {4, 7}, {4, 11}, {4, 7}, {4, 5},
> {5, 10}, {5, 9}, {5, 8}, {5, 6},
> {6, 8}, {6, 7},
> {7, 8},
> {9, 11}, {9, 10},
> {10, 11}: SparseRep := true >;
> TS, PS := Splitcomponents(G);
> TS;
[
  { 5, 6, 7, 8 },
  { 5, 9, 10, 11 },
  { 1, 4, 5, 7, 11 },
  { 1, 4 },
  { 1, 2, 3, 4 }
]
> PS;
[
  [ 5, 7 ],
  [ 5, 11 ],
```

```
  [ 1, 4 ]
]
```

Let `G1` be the subgraph induced by `TS[1]`. We will verify that it is not triconnected and we make it triconnected by adding the edge `[5, 7]`, since `[5, 7]` is a separation pair of `G` whose vertices belong to `G1`.

```
> G1 := sub< G | TS[1] >;
> IsTriconnected(G1);
false
> AddEdge(~G1, Index(VertexSet(G1)!VertexSet(G)!5),
>       Index(VertexSet(G1)!VertexSet(G)!7));
> IsTriconnected(G1);
true
```

149.13.4 Maximum Matching in Bipartite Graphs

The maximum matching algorithm is a flow-based algorithm. We have implemented two maximum flow algorithms, the Dinic algorithm, and a push-relabel algorithm. The latter is almost always the most efficient, it may be outperformed by Dinic only in the case of very sparse graphs. For a full discussion of these algorithms, the reader is referred to Section 151.4 in Chapter 150. Example H151E4 in this same chapter actually is an implementation in MAGMA code of the maximum matching algorithm.

`MaximumMatching(G)`

`Al` MONSTGELT *Default : "PushRelabel"*

A maximum matching in the bipartite graph G. The matching is returned as a sequence of edges of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

Example H149E13

We begin by creating a random bipartite graph. The matching algorithm is flow-based and is one of the algorithms which deals with graphs as adjacency lists. For this reason we might as well create the graph with a sparse representation (see Section 149.3).

```
> n := 5;
> m := 7;
> d := 3;
> G := EmptyGraph(n);
> H := EmptyGraph(m);
> G := G join H;
> for u in [1..n] do
>     t := Random(0, d);
>     for tt in [1..t] do
>         v := Random(n+1, n+m);
```

```
>         AddEdge(~G, u, v);
>     end for;
> end for;
> G := Graph< Order(G) | G : SparseRep := true >;
>
> IsBipartite(G);
true
> Bipartition(G);
[
  { 1, 12, 2, 3, 4, 5, 7 },
  { 11, 6, 8, 9, 10 }
]
> MaximumMatching(G);
[ {1, 11}, {4, 10}, {2, 9}, {5, 8}, {3, 6} ]
```

149.13.5 General Vertex and Edge Connectivity in Graphs and Digraphs

As for the maximum matching algorithm (Subsection 149.13.4) the vertex and edge connectivity algorithms are flow-based algorithms. We have implemented two flow algorithms, Dinic and a push relabel method. In general Dinic outperforms the push relabel method only in the case of very sparse graphs. This is particularly visible when computing the edge connectivity of a graph. For full details on those flow algorithms, refer to Section 151.4 in Chapter 150. For details on how vertex and edge connectivity are implemented, see [Eve79].

The general connectivity algorithms apply to both undirected and directed graphs.

`VertexSeparator(G)`

`Al` MonStgElt *Default :* "*PushRelabel*"

If G is an undirected graph, a *vertex separator* for G is a smallest set of vertices S such that for any u, $v \in V(G)$, every path connecting u and v passes through at least one vertex of S.

If G is a directed graph, a vertex separator for G is a smallest set of vertices S such that for any u, $v \in V(G)$, every directed path from u to v passes through at least one vertex of S.

`VertexSeparator` returns the vertex separator of G as a sequence of vertices of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`VertexConnectivity(G)`

`Al` MonStgElt *Default :* "*PushRelabel*"

Returns the vertex connectivity of the graph G, the size of a minimum vertex separator of G. Also returns a vertex separator for G as the second value. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`IsKVertexConnected(G, k)`

`Al` MonStgElt *Default :* "*PushRelabel*"

Returns `true` if the graph G's vertex connectivity is at least k, `false` otherwise. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`EdgeSeparator(G)`

`Al` MonStgElt *Default :* "*PushRelabel*"

If G is an undirected graph, an *edge separator* for G is a smallest set of edges T such that for any u, $v \in V(G)$, every path connecting u and v passes through at least one edge of T.

If G is a directed graph, an edge separator for G is a smallest set of edges T such that for any u, $v \in V(G)$, every directed path from u to v passes through at least one edge of T.

`EdgeSeparator` returns the edge separator of G as a sequence of edges of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`EdgeConnectivity(G)`

`Al` MonStgElt *Default :* "*PushRelabel*"

Returns the edge connectivity of the graph G, the size of a minimum edge separator of G. Also returns as the second value an edge separator for G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`IsKEdgeConnected(G, k)`

`Al` MonStgElt *Default :* "*PushRelabel*"

Returns `true` if the graph G's edge connectivity is at least k, `false` otherwise. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

Example H149E14

We compute the vertex and edge connectivity for a small undirected graph and we perform a few checks. The connectivity algorithm is one of the algorithms which deals with graphs as adjacency lists. For this reason we might as well create the graph with a sparse representation (see Section 149.3).

```
> G := Graph< 4 | {1, 2}, {1, 3}, {2, 3}, {2, 4}, {3, 4}
> : SparseRep := true >;
> IsConnected(G);
true
>
> vc := VertexConnectivity(G);
> S := VertexSeparator(G);
```

```
> vc;
2
> S;
[ 3, 2 ]
>
> H := G;
> vs := [ Integers() | Index(x) : x in S ];
> RemoveVertices(~H, vs);
> IsConnected(H);
false
> for k in [0..vc] do
>     IsKVertexConnected(G, k);
> end for;
true
true
true
> for k in [vc+1..Order(G)-1] do
>     IsKVertexConnected(G, k);
> end for;
false
>
>
>
> ec := EdgeConnectivity(G);
> T :=  EdgeSeparator(G);
> ec;
2
> T;
[ {1, 2}, {1, 3} ]
>
> H := G;
> M := [ { Index(e[1]), Index(e[2]) }
> where e := SetToSequence(EndVertices(e)) : e in T ];
> RemoveEdges(~H, M);
> IsConnected(H);
false
> for k in [0..ec] do
>     IsKEdgeConnected(G, k);
> end for;
true
true
true
> for k in [ec+1..Order(G)-1] do
>     IsKEdgeConnected(G, k);
> end for;
false
```

149.14 Distances, Paths and Circuits in a Graph

The distance functions apply to graphs as well as to digraphs.

149.14.1 Distances, Paths and Circuits in a Possibly Weighted Graph

There are a few distance and path functions that take into account the fact that the edges of the graph under consideration may be weighted. If the graph is not weighted, then the distance between two vertices is taken to be the length of the shortest path between the vertices. For more details on distance and paths functions in weighted graphs, refer to Section 150.12 in Chapter 150.

`Reachable(u, v)`

Return `true` if and only if vertices u and v of a graph G are in the same component of G.

`Distance(u, v)`

Given two vertices u and v belonging to a graph G, return the length of a shortest path from u to v. If the graph is weighted, the function returns the total weight of the path from u to v. Results in an error if there is no path in G from u to v.

`Geodesic(u, v)`

Given vertices u and v belonging to the graph G, return a sequence of vertices $u = v_1, v_2, \ldots, v_n = v$ such that the sequence of edges $v_1v_2, v_2v_3, \ldots v_{n-1}v_n$ forms a shortest path joining u and v. Results in an error if there is no path in G from u to v.

149.14.2 Distances, Paths and Circuits in a Non-Weighted Graph

All the distance and path functions listed below do not take account of the fact that the graph edges may be weighted. *The distance between two vertices is understood in its usual meaning of being the length of the shortest path between the vertices.*

`Diameter(G)`

The length of the longest path in the graph G. If G is not connected, the value -1 is returned. To see how the automorphism group of G is computed see Subsection 149.22.3.

`DiameterPath(G)`

A sequence of vertices defining a longest path if the graph G is connected, or the empty sequence if G is not connected. To see how the automorphism group of G is computed see Subsection 149.22.3.

`Ball(u, n)`

Given a vertex u belonging to a graph G, and a non-negative integer n, return the set of vertices of G that are at distance n or less from u.

`Sphere(u, n)`

Given a vertex u belonging to the graph G, and a non-negative integer n, return the set of vertices of G that are at distance n from u.

`DistancePartition(u)`

Given a vertex u belonging to the graph G, return the partition $P_0 \cup P_1 \cup \ldots \cup P_d$ of the vertex-set of G, where P_i is the set of vertices lying at distance i from vertex u. The partition is returned as a sequence of sets. Any vertices not connected to u are treated as being at infinite distance from u and are returned as the last set of the partition.

`IsEquitable(G, P)`

Given a partition P of the vertex-set $V(G)$ of the graph G, return the value `true` if P is an equitable partition.

`EquitablePartition(P, G)`

Given a partition P of the vertex-set $V(G)$ of the graph G, return the coarsest partition of $V(G)$ that refines P and which is equitable.

`Girth(G)`

The girth of graph G, i.e. the length of a shortest cycle. To see how the automorphism group of G is computed see Subsection 149.22.3.

`GirthCycle(G)`

A cycle of shortest length in the graph G. To see how the automorphism group of G is computed see Subsection 149.22.3.

149.15 Maximum Flow, Minimum Cut, and Shortest Paths

Whenever the edges of a graph are assigned a capacity it is possible to compute the maximum flow and the minimum cut of the graph. Whenever the edges of a graph are assigned a weight it is possible to find shortest paths in the graph. If one wants to perform these computations on a graph where none of its edges have been assigned a capacity or a weight, then the edges are taken to have a capacity or weight of one, and the computations are carried out accordingly.

The flow-based and shortest-paths algorithms and the resulting functionalities are fully documented in Chapter 150, Sections 151.4 and 150.12 respectively.

149.16 Matrices and Vector Spaces Associated with a Graph or Digraph

`AdjacencyMatrix(G)`

Returns the adjacency matrix for the (p, q) graph G as an element of the matrix ring $M_p(Z)$.

`DistanceMatrix(G)`

Returns the distance matrix A for the (p, q) graph G as an element of the matrix ring $M_p(Z)$. The (i, j)-th entry of A gives the distance between vertices v_i and v_j of G.

`IncidenceMatrix(G)`

Returns the incidence matrix M for the (p, q) graph G as an element of the matrix bimodule $M^{p\times q}(Z)$.

If G is a graph, then entry (i, j) of M is 1 if the vertex v_i of G lies on the edge e_j of G. Otherwise entry (i, j) is zero.

If G is a digraph, entry (i, j) of M is 1 if vertex v_i is the initial vertex of the edge e_j, and -1 if v_i is the final vertex of the edge e_j. Otherwise entry (i, j) is zero. If e_j is a loop, then entry (i, j) may be either 1 or -1.

`IntersectionMatrix(G, P)`

Given an ordered equitable partition $P = P_1 \cup P_2 \cup \ldots \cup P_r$ of the vertex-set of the graph G, return the intersection matrix T for the partition. Thus, entry $T[i, j]$ is the number of vertices of the set P_j that are adjacent to a vertex of the set P_i.

149.17 Spanning Trees of a Graph or Digraph

`SpanningTree(G)`

Given a connected (undirected) graph G, construct a spanning tree for G rooted at an arbitrary vertex of G. The spanning tree is returned as a subgraph of G. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

`SpanningForest(G)`

Given a graph G, construct a spanning forest for G. The forest is returned as a subgraph of G. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

`BreadthFirstSearchTree(u)`

`BFSTree(u)`

Given a vertex u belonging to the graph G, return a breadth-first search for G rooted at the vertex u. The tree is returned as a subgraph of G. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph. Note that G may be disconnected.

`DepthFirstSearchTree(u)`

`DFSTree(u)`

Given a vertex u belonging to the graph G, return a depth-first search tree T for G rooted at the vertex u. The tree T is returned as a subgraph of G. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph. Note that G may be disconnected.

The fourth return argument returns, for each vertex u of G, the tree order of u, that is, the order in which the vertex u has been visited while performing the depth-first search. If T does not span G then the vertices of G not in T are given tree order from `Order(T) + 1` to `Order(G)`.

149.18 Directed Trees

In the following functions, the graph is assumed to be a directed tree. This means it is a tree containing a root vertex and all edges are directed away from that vertex.

`IsRootedTree(G)`

Returns `true` exactly when the directed graph G is a tree having a vertex v such that all edges are directed away from v. In this case, the root vertex v is returned as a second value.

`Root(G)`

The root vertex of a rooted tree.

`IsRoot(v)`

Returns `true` if and only if the graph containing the vertex v is directed as a rooted tree with v as root.

`RootSide(v)`

When the graph containing the vertex v is directed as a rooted tree, this returns the unique neighbouring vertex to v which is closer to the root vertex. If v is the root vertex, it is returned itself.

`VertexPath(u,v)`

A sequence of vertices comprising a path in a directed graph from the vertex u to the vertex v. The path does not necessarily respect the edge directions. Indeed it will first trace back to a common ancestor of u and v and then follow edge directions to v.

`BranchVertexPath(u,v)`

The sequence of vertices on the vertex path from the vertex u to the vertex v having valency at least 3.

149.19 Colourings

The functions given here are not applicable to digraphs.

`ChromaticNumber(G)`

The chromatic number of the graph G, that is, the minimum number of colours required to colour the vertices of G such that no two adjacent vertices share the same colour.

`OptimalVertexColouring(G)`

An optimal vertex colouring of the graph G as a sequence of sets of vertices of G. Each set in the sequence contains the vertices which are given the same colour. Some optimal vertex colouring is returned, others may exist.

`ChromaticIndex(G)`

The chromatic index of the graph G, that is, the minimum number of colours required to colour the edges of G such that no two adjacent edges share the same colour.

`OptimalEdgeColouring(G)`

An optimal edge colouring of the graph G as a sequence of sets of edges of G. Each set in the sequence contains the edges which are given the same colour. Some optimal edge colouring is returned, others may exist.

`ChromaticPolynomial(G)`

The chromatic polynomial of the graph G. For a given natural number x, the chromatic polynomial $p_G(x)$ gives the number of colourings of G with colours $1, 2, \ldots, x$.

Example H149E15

We illustrate the use of these functions with the following graph:

```
> G:=Graph< 5 | [{2,5}, {1,3,5}, {2,4,5}, {3,5}, {1,2,3,4} ]>;
> ChromaticNumber(G);
3
> OptimalVertexColouring(G);
[
  { 1, 3 },
  { 2, 4 },
  { 5 }
]
> ChromaticIndex(G);
4
> OptimalEdgeColouring(G);
[
  { {1, 2}, {3, 5} },
  { {2, 3}, {1, 5} },
  { {3, 4}, {2, 5} },
  { {4, 5} }
]
> ChromaticPolynomial(G);
$.1^5 - 7*$.1^4 + 18*$.1^3 - 20*$.1^2 + 8*$.1
```

149.20 Cliques, Independent Sets

The functions given here are not applicable to digraphs.

A *clique* of a graph G is a complete subgraph of G. A *maximal clique* is a clique which is not contained in any other clique. A *maximum clique* is a maximal clique of largest size.

An *independent set* of G is an empty subgraph of G. A *maximal* (*maximum*) *independent set* is defined is the same way as a maximal (maximum) clique. Note that an independent set of size k in the graph G is a clique of size k in the complement graph of G.

The clique and independent set functions presented below are implemented using one of two algorithms, called here *BranchAndBound* and *Dynamic*. The algorithms *BranchAndBound* and *Dynamic* are briefly described here.

BranchAndBound : The algorithm is an implementation of the branch and bound algorithm by Bron and Kerbosch [BK73].

The algorithm is designed to find maximal cliques and it has been adapted here to also find cliques of specific size which may not be maximal. It attempts to build a maximal clique by trying to expend the current maximal clique. Some heuristics are built into the algorithm which enable to prune the search tree.

Dynamic : The algorithm finds a clique of size exactly k, not necessarily maximal, in the graph G by using recursion and dynamic programming. If a clique of size k exists in G,

then, for a given vertex v of G, there is either a clique of size $k-1$ in the subgraph induced by the neighbours of v, or there is a clique of size k in the graph $G-v$. This is the recursive step. The *Dynamic* algorithm applies a different strategy (sorting of vertices and selection of vertices to consider) according to the order and density of the subgraph considered at the current level of recursion. This is achieved by dynamic programming, hence the name. This algorithm is due to Wendy Myrvold [WM].

Comment: When comparing both algorithms in the situation where the problem is to find a maximum clique one observes that in general *BranchAndBound* does better. However *Dynamic* outperforms *BranchAndBound* when the graphs under consideration are large (more then 400 vertices) random graphs with high density (larger than 0.5%). So far, it can only be said that the comparative behaviour of both algorithms is highly dependent on the structure of the graphs.

`HasClique(G, k)`

Returns `true` if and only if the graph G has a maximal clique of size k. If `true`, returns such a clique as the second argument.

`HasClique(G, k, m` : *parameters*`)`

`Al` MonStgElt *Default :* "*BranchAndBound*"

If m is `true`, the function is `true` if and only if the graph G has a maximal clique of size k. If m is `false`, the function is `true` if and only if the graph G has a — not necessarily maximal — clique of size k. If the function is `true`, an appropriate clique is returned as the second argument. When m is `false`, the parameter `Al` enables the user to select the algorithm which is to be used. When m is `true`, the parameter `Al` is ignored.

The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "BranchAndBound"` or `Al := "Dynamic"`. See the description given at the beginning of this section.

The default is `"BranchAndBound"`.

`HasClique(G, k, m, f` : *parameters*`)`

`Al` MonStgElt *Default :* "*BranchAndBound*"

If m is `true` and $f = 0$, the function is `true` if and only if the graph G has a maximal clique of size k. If m is `true` and $f = 1$, the function is `true` if and only if the graph G has a maximal clique of size larger than or equal to k. If m is `true` and $f = -1$, the function is `true` if and only if the graph G has a maximal clique of size smaller than or equal to k. If m is `false`, the function is `true` if and only if the graph G has a — not necessarily maximal — clique of size k. If the function is `true`, an appropriate clique is returned as the second argument. When m is `false`, the parameter `Al` enables the user to select the algorithm which is to be used. When m is `true` the parameter `Al` is ignored, and when m is `false`, the flag f is ignored.

The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "BranchAndBound"` or `Al := "Dynamic"`. See the description given at the beginning of this section.

The default is "BranchAndBound".

`MaximumClique(G : parameters)`

`Al` MonStgElt *Default :* "*BranchAndBound*"

Finds a maximum clique in the graph G. The clique is returned as a set of vertices.

The parameter `Al` enables the user to select the algorithm which is to be used.

`Al := "BranchAndBound"`: See the description at the beginning of this section.

`Al := "Dynamic"`: Two steps are required here.

Step 1 Finding a lowerbound on the size of a maximum clique. This is achieved by using the *dsatur* colouring (*dsatur* stands for saturation degree) due to Brélaz [Bre79]. The *dsatur* colouring gives a reasonably good approximation to the size of a maximum clique, usually with a penalty of 2 to 3.

Step 2 Assume that the lowerbound found in Step 1 if l. Then a maximum clique is found by finding the largest possible clique of size $k \geq l$ using the Dynamic algorithm.

The default is "BranchAndBound".

`CliqueNumber(G : parameters)`

`Al` MonStgElt *Default :* "*BranchAndBound*"

Finds the size of a maximum clique in the graph G. The parameter `Al` enables the user to select the algorithm which is to be used. `Al := "BranchAndBound"`: See the description given at the beginning of this section.

`Al := "Dynamic"`: See the function `MaximumClique`.

The default is "BranchAndBound".

`AllCliques(G : parameters)`

`Limit` RngIntElt *Default :* 0

Returns all maximal cliques of the graph G as a sequence of sets of vertices. If `Limit` is set to a positive integer, returns `Limit` maximal cliques of G.

`AllCliques(G, k : parameters)`

`Limit` RngIntElt *Default :* 0

Returns all maximal cliques of size k of the graph G as a sequence of sets of vertices. If `Limit` is set to a positive integer, returns `Limit` maximal cliques of size k of G.

`AllCliques(G, k, m : parameters)`

`Limit`	RngIntElt	*Default :* 0
`Al`	MonStgElt	*Default :* "*BranchAndBound*"

If m is `true`, returns all maximal cliques of size k in the graph G. If m is `false`, returns all — not necessarily maximal — cliques of size k. When m is `false`, the parameter `Al` enables the user to select the algorithm which is to be used. When m is `true`, the parameter `Al` is ignored.

The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "BranchAndBound"` or `Al := "Dynamic"`. See the description given at the beginning of this section. The default is `"BranchAndBound"`.

Except in the case where m is `false` and `Al` is `"Dynamic"`, the parameter `Limit`, if set to a positive integer, limits the number of cliques returned.

Maximal independent sets or independent sets of a given size k in a graph G can be easily found by finding maximal cliques or cliques of size k in the complement of G. Only two functions which are concerned with independent sets are provided: one finds a maximum independent set and the other returns the independence number of a graph.

`MaximumIndependentSet(G: parameters)`

`Al`	MonStgElt	*Default :* "*BranchAndBound*"

Finds a maximum independent set in the graph G. The maximum independent set is returned as a set of vertices.

The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "BranchAndBound"` or `Al := "Dynamic"`. See the function `MaximumClique`.

The default is `"BranchAndBound"`.

`IndependenceNumber(G: parameters)`

`Al`	MonStgElt	*Default :* "*BranchAndBound*"

Finds the size of a maximum independent set in the graph G.

The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "BranchAndBound"` or `Al := "Dynamic"`. See the function `CliqueNumber`.

The default is `"BranchAndBound"`.

Example H149E16

We illustrate the use of the clique functions with the following graph:

```
> G := Graph< 9 | [ {4,5,6,7,8,9}, {4,5,6,7,8,9}, {4,5,6,7,8,9},
>                   {1,2,3,7,8,9}, {1,2,3,7,8,9}, {1,2,3,7,8,9},
>                   {1,2,3,4,5,6}, {1,2,3,4,5,6}, {1,2,3,4,5,6} ]>;
> HasClique(G, 2);
false
> HasClique(G, 2, true);
false
> HasClique(G, 2, false);
```

```
true { 1, 4 }
> HasClique(G, 2, true: Al := "Dynamic");
false
> HasClique(G, 2, false: Al := "Dynamic");
true { 1, 9 }
> HasClique(G, 2, true, 1);
true { 1, 4, 7 }
> MaximumClique(G);
{ 1, 4, 7 }
> AC := AllCliques(G);
> #AC;
27
> AC3 := AllCliques(G,3);
> #AC3;
27
> AC eq AC3;
true
> AllCliques(G, 2, true);
[]
> AllCliques(G, 2, false);
[
  { 1, 4 },
  { 1, 5 },
  { 1, 6 },
  { 1, 7 },
  { 1, 8 },
  { 1, 9 },
  { 2, 4 },
  { 2, 5 },
  { 2, 6 },
  { 2, 7 },
  { 2, 8 },
  { 2, 9 },
  { 3, 4 },
  { 3, 5 },
  { 3, 6 },
  { 3, 7 },
  { 3, 8 },
  { 3, 9 },
  { 4, 7 },
  { 4, 8 },
  { 4, 9 },
  { 5, 7 },
  { 5, 8 },
  { 5, 9 },
  { 6, 7 },
  { 6, 8 },
  { 6, 9 }
```

]

149.21 Planar Graphs

A linear-time algorithm due to Boyer and Myrvold [BM01] has been implemented to test if a graph is planar, and to identify a Kuratowski subgraph if the graph is non-planar. This algorithm requires that the graph has a sparse representation.

The interest of this new algorithm is that it is very easy to implement when compared to previous linear-time planarity testers. In addition, the algorithm also isolates a Kuratowski subgraph, if any, in linear-time.

The concept underlying the tester is deceptively simple: the idea is to perform a depth first search of the graph and then to try to embed (by post-order traversal of the tree) the back edges from a vertex v to its descendants in such a way that they do not cross and such that vertices with connections to ancestors of v remain along the external face.

To decide the order in which to embed back edges from v to its descendants, the external faces of components rooted by children of v are explored top-down, avoiding paths containing vertices with ancestor connections. To decide whether a vertex u has ancestor connections and must therefore be kept on the external face, one only needs the least ancestor directly adjacent to u and the lowpoint information for the children of u that are separable from the parent of u in the partial embedding.

Each back edge $[w, v]$ is added as soon as the descendant endpoint w is encountered. If w is not in the same biconnected component as v, then the biconnected components encountered during the traversal are merged at their respective cut vertices since the new edge $[w, v]$ biconnects them. The merge is performed such that vertices with ancestor connections remain on the external face of the newly formed biconnected component.

Traversal is terminated when all back edges from v to its descendants are added or when the external face traversal is prevented from reaching the descendant endpoint of a back edge. This occurs when both external face paths extending from the least numbered vertex in a biconnected component contain vertices with ancestor connections that block further traversal to a vertex that is the descendant endpoint w of a back edge $[w, v]$. In this case, a Kuratowski subgraph is isolated based primarily on ancestor connections, external face paths and depth first search tree paths.

MAGMA is deeply grateful for the valuable help and collaboration from the authors of [BM01], in particular John Boyer.

`IsPlanar(G)`

Tests whether the (undirected) graph G is planar. The graph may be disconnected. If the graph is non-planar then a Kuratowski subgraph of G is returned: That is, a subgraph of G homeomorphic to K_5 or $K_{3,3}$. The support and vertex/edge decorations of G are *not* retained in this (structural) subgraph.

`Obstruction(G)`

Returns a Kuratoswki obstruction if the graph is non-planar, or the empty graph if the graph is planar. The Kuratoswki is a (structural) subgraph of G; the support and vertex/edge decorations of G are not transferred to it.

`IsHomeomorphic(G : parameters)`

`Graph` MonStgElt *Default :*

Tests if a graph is homeomorphic to either K_5 or $K_{3,3}$. The parameter `Graph` must be set to either "K5" or "K33"; it has no default setting.

`Faces(G)`

Returns the faces of the planar graph G as sequences of the edges bordering the faces of G. If G is disconnected, then the face defined by an isolated vertex v is given as $[v]$.

`Face(u, v)`

Returns the face of the planar graph G bordered by the directed edge $[u, v]$ as an ordered list of edges of G.

Note that a directed edge and an orientation determine a face uniquely: We can assume without loss of generality that the plane is given a clockwise orientation. Then given a directed edge $e = [u_1, v_1]$, the face defined by e is the ordered set of edges $[u_1, v_1], [u_2, v_2], \ldots, [u_m, v_m]$ such that $v_i = u_{i+1}$ for all i, $1 \leq i < m$, $v_m = u_1$, and for each $v_i = u_{i+1}$, the neighbours of v_i, u_i and v_{i+1}, are *consecutive* vertices in v_i's adjacency list whose order is *anti-clockwise*.

`Face(e)`

Let e be the edge u, v of the planar graph G (recall that G is undirected). Then `Face`(u, v) returns the face bordered by the directed edge $[u, v]$ as a sequence of edges of G.

`NFaces(G)`

`NumberOfFaces(G)`

Returns the number of faces of the planar graph G. In the case of a disconnected graph, an isolated vertex counts for one face.

`Embedding(G)`

Returns the graph G's planar embedding as a sequence S where $S[i]$ is a sequence of edges incident from vertex i.

`Embedding(v)`

Returns the ordered list of edges (in clockwise order say) incident from vertex v.

`PlanarDual(G)`

Constructs the dual G' of a planar graph G. The numbering of the vertices of G' corresponds to the order of the faces as returned by `Faces(G)`.

Example H149E17

We start with a small disconnected planar graph G: Notice how one of the faces of G is defined by the isolated vertex 4.

```
> G := Graph< 5 | [ {2, 3, 5}, {1, 5}, {1}, {}, {1, 2} ] >;
> G;
Graph
Vertex  Neighbours
1       2 3 5 ;
2       1 5 ;
3       1 ;
4       ;
5       1 2 ;
> IsConnected(G);
false
> IsPlanar(G);
true
> Faces(G);
[
  [ {1, 2}, {2, 5}, {5, 1} ],
  [ {1, 5}, {5, 2}, {2, 1}, {1, 3}, {3, 1} ],
  [ 4 ]
]
> Embedding(G);
[
  [ {1, 2}, {1, 5}, {1, 3} ],
  [ {2, 5}, {2, 1} ],
  [ {3, 1} ],
  [],
  [ {5, 1}, {5, 2} ]
]
> Embedding(VertexSet(G)!1);
[ {1, 2}, {1, 5}, {1, 3} ]
```

Now let's turn to a simple non-planar graph whose obstruction is $K_{3,3}$:

```
> G := Graph< 6 | [ {3, 4, 5}, {3, 4, 5, 6}, {1, 2, 5, 6},
> {1, 2, 5, 6}, {1, 2, 3, 4, 6}, {2, 3, 4, 5} ] >;
> G;
Graph
Vertex  Neighbours
1       3 4 5 ;
2       3 4 5 6 ;
3       1 2 5 6 ;
4       1 2 5 6 ;
5       1 2 3 4 6 ;
6       2 3 4 5 ;
> IsPlanar(G);
false
```

```
> b, O := IsPlanar(G);
> IsSubgraph(G, O);
true
> O;
Graph
Vertex  Neighbours
1       4 5 3 ;
2       3 5 4 ;
3       1 6 2 ;
4       2 6 1 ;
5       6 1 2 ;
6       5 4 3 ;
> IsHomeomorphic(O : Graph := "K33");
true
```

149.22 Automorphism Group of a Graph or Digraph

The automorphism group functionality is an interface to B. McKay's `nauty` V 2.2 programme. For a paper describing `nauty` see [McK81]. There also exists a user's manual [McK] describing `nauty`'s essential features.

149.22.1 The Automorphism Group Function

`AutomorphismGroup(G : parameters)`

Compute the automorphism group of the graph G. This returns the group A, the vertex and edge G-sets (in that order), the power structure $\mathcal{A}$ of all automorphisms of G, and the transfer map from A to $\mathcal{A}$. Note that G may be directed or undirected. For small graphs (i.e. having less than 500 vertices) the canonically labelled graph is also returned.

The automorphism group computation may be driven by several user parameters. There are four principal parameters: `Canonical`, `Stabilizer`, `Invariant` and `Print`. Some of these parameters have associated parameters.

`Canonical` BoolElt *Default :* `false`

If the parameter `Canonical` is set to `true`, then the canonically labelled graph will be returned. If the graph has fewer than 500 vertices then the default value for this parameter is `true`, while if the graph has 500 or more vertices, the default value is `false`. It is important to note that the canonically labelled graph is *dependent* upon all the parameters used to compute the automorphism group.

`Stabilizer` [{ GrphVert }] *Default :*

If the parameter `Stabilizer` is assigned a partition P of the vertex-set of G as its value, then the subgroup of the automorphism group of G that preserves the

partition P will be computed. The partition given as `Stabilizer` need not be a partition of the full vertex-set of G. Any vertices not covered by the sets in `Stabilizer` are assumed to belong to an extra partition cell.

`Invariant` MonStgElt *Default :*

Use the named invariant to assist the auto group computation. The invariant is specified by a string which is the name of a C function computing an invariant, as on pages 16–17 of the tt nauty manual [McK]. The default value for `Invariant` is `"Null"` when G is an undirected graph, or `"adjacencies"` when G is a digraph. For a more detailed discussion on invariants see Subsection 149.22.2.

There are three optional associated parameters to `Invariant`:

`Minlevel` RngIntElt *Default :* 0

`Maxlevel` RngIntElt *Default :*

`Arg` RngIntElt *Default :*

An expression, depending upon the type of invariant. When G is undirected these three parameters take the values 0, 1, and 0 respectively. When G is a digraph they take the values 0, 2, and 0 respectively. When `Invariant` is one of "indsets", "cliques", "cellcliq", or "cellind", the default value for `Arg` is 3. Again, see Subsection 149.22.2 for more information.

`Print` RngIntElt *Default :* 0

The integer valued parameter `Print` is used to control informative printing according to the following table:

`Print := 0` : No output (default).
`Print := 1` : Statistics are printed.
`Print := 2` : Summary upon completion of each level.
`Print := 3` : Print the automorphisms as they are discovered.

`IgnoreLabels` BoolElt *Default :* `false`

By default, the automorphism group computation respects vertex labels (colours). That is, elements of the group will only take a vertex to an identically labelled vertex. The Boolean value `IgnoreLabels` will treat all vertices as identically labelled for the purposes of this computation.

149.22.2 `nauty` Invariants

Invariants can be used to supplement the built–in partition refinement code in `nauty`, to assist in the processing of difficult graphs. Invariants are used with three parameters:

`Minlevel`: the minimum depth in the search tree at which an invariant is to be applied (default 0)

`Maxlevel`: the maximum depth in the search tree at which an invariant is to be applied (default 1 for undirected graphs and 2 for digraphs)

`Arg`: an integer argument which has a different meaning (or no meaning) for each invariant

The root of the tree, corresponding to the partition provided by the user, has level 1. Note that the invariants use an existing partition and attempt to refine it. Thus, it can be that an invariant fails to refine the partition at the root of the search tree but succeeds further down the tree. In particular, all invariants necessarily fail at the root of the tree if the graph is vertex-transitive.

The invariants are :

`"default"`

Default — No invariant is used.

`"twopaths"`

Each vertex is classified according to the vertices reachable from along a path of length 2. This is a cheap invariant sometimes useful for regular graphs. `Arg` is not used.

`"adjtriang"`

This counts the number of common neighbours between pairs of adjacent (if `Arg` = 0) or non–adjacent (if `Arg` = 1) vertices. This is a fairly cheap invariant which can often work for strongly–regular graphs.

`"triples"`

This considers in detail the neighbourhoods of each triple of vertices. It often works for strongly–regular graphs that `"adjtriang"` fails on, but is more expensive. `Arg` is not used.

`"quadruples"`

Similar to triples but using quadruples of vertices. Much more expensive but can work on graphs with highly regular structure that `"triples"` fails on. `Arg` is not used.

`"celltrips"`

Like `"triples"`, but only triples inside one cell are used. One to try for the bipartite incidence graphs of structures like block designs (but won't work for projective planes). `Arg` is not used.

`"cellquads"`

Like `"quadruples"`, but only quadruples inside one cell are used. Originally designed for some exceptional graphs derived from Hadamard matrices (where applying it at level 2 is best). `Arg` is not used.

`"cellquins"`

Considers 5–tuples of vertices inside a cell. Very expensive. We don't know of a good application. `Arg` is not used.

`"cellfano"`

`"cellfano2"`

These are intended for the bipartite graphs of projective planes and similar highly regular structures. `"cellfano2"` is cheaper, so try it first. `Arg` is not used. The method is similar to counting Fano subplanes.

`"distances"`

This uses the distance matrix of the graph. It is good at partitioning general regular graphs (but not strongly regular graphs). Moderately cheap. `Arg` is unused.

`"indsets"`

This uses the independent sets of size `Arg` (default 3). Can be successful for strongly regular graphs (for `Arg` ≥ 4) or regular bipartite graphs.

`"cliques"`

This uses the cliques of size `Arg` (default 3). Can be successful for strongly regular graphs (for `Arg` ≥ 4).

`"cellind"`

This uses the independent sets of size `Arg` (default 3) that lie entirely within one cell of the partition. Try applying at level 2 for difficult vertex–transitive graphs.

`"cellcliq"`

This uses the cliques of size `Arg` (default 3) that lie entirely within one cell of the partition. Try applying at level 2 for difficult vertex–transitive graphs.

`"adjacencies"`

This is a simple invariant that corrects for a deficiency in the built–in partition refinement procedure for directed graphs. It is the default in MAGMA for directed graphs. Apply at a few levels, say levels $1 - 5$. `Arg` is unused.

These invariants are further described on pages 16–17 of the `nauty` manual [McK]. Also, we provide a facility enabling users to test if a specific `Invariant` achieves a partition refinement for a graph G.

`IsPartitionRefined(G:` *parameters*`)`

Returns `true` if and only the invariant in `Invariant` could refine the graph G's vertex-set partition. If no invariant is set in `Invariant` then the refinement procedure which is tested is taken to be the default one.

Four parameters can be passed:

`Stabilizer`	[{ VERT }]	*Default :*
`Invariant`	MONSTGELT	*Default :*
`Arg`	RNGINTELT	*Default :*
`IgnoreLabels`	BOOLELT	*Default :* `false`

The parameters have the same meaning as for `AutomorphismGroup`.

149.22.3 Graph Colouring and Automorphism Group

For any calls to `nauty` via MAGMA functions the graph colouring of a graph G (as set by `AssignLabels` or a similar function) is taken as an *intrinsic* property of G. Consequently, the default automorphism group computed by `nauty` is the group for the coloured graph G. In particular this implies that, when G is coloured, this default automorphism group is *not* G's full automorphism group.

There are several MAGMA functions which make use of the automorphism group of a graph, and therefore rely on a call to `nauty`. We list them here:

1 `Diameter`, `DiameterPath`, `IsDistanceRegular`, `GirthCycle`, `Girth`

2 `IsDistanceTransitive`, `IsTransitive`, `IsPrimitive`, `IsSymmetric`, `IsIsomorphic`, `IsEdgeTransitive`, `EdgeGroup`, `OrbitsPartition`, `CanonicalGraph`

The functions in Group 1 make use of the automorphism group of the graph only as a means to improve efficiency. If some group has already been computed for the graph under consideration then this group will be used. Otherwise the graph's default group is computed.

The functions in Group 2 all use the graph's default group. If a group A of the graph G has already been computed but is not G's default group (for example if a stabilizer of G was given when computing A) then the graph's default group will be computed. Consequently, as an example, if G is coloured, `IsTransitive(`G`)` will (always) return `false`.

For all these functions it is possible to drive the group computation by setting an appropriate `Invariant` parameter. This is particularly useful when it is known that some invariant will speed up the group computation. This is achieved by first computing the group using `AutomorphismGroup` while setting `Invariant`. This parameter is then remembered for any further (re)computation of the default automorphism group, unless reset by a subsequent call to `AutomorphismGroup`. For convenience, the function `IsIsomorphic` accepts a parameter suite very similar to that of the `AutomorphismGroup` function: It is particularly useful when stabilizers need to be set.

149.22.4 Variants of Automorphism Group

`CanonicalGraph(G)`

Given a graph G, return the canonically labelled graph isomorphic to G. To see which automorphism group is computed see Subsection 149.22.3. Users should be aware that the canonical graph is *dependent* upon the invariant used when computing the automorphism group. Thus, the computation of the automorphism group of G using different invariants will produce *different* canonical labellings.

`EdgeGroup(G)`

Returns the automorphism group of the graph G in its action on the edges of G, and the G-set of edges of G. To see which automorphism group is computed see Subsection 149.22.3.

`IsIsomorphic(G, H :` *parameters*`)`

This function returns `true` if the graphs G and H are isomorphic. If G and H are isomorphic, a second value is returned, namely a mapping between the vertices of G and the vertices of H giving the isomorphism.

The parameters accepted by `IsIsomorphic` are almost the same as for `AutomorphismGroup`. The exceptions are:

`Stabilizer` [{ VERT }] *Default :*

This sets the stabilizer set for *both* graphs G and H. If one wishes to set two distinct stabilizers then one would also use:

`Stabilizer2` [{ VERT }] *Default :*

This sets the stabilizer set for the second graph H only.

`IgnoreLabels` BOOLELT *Default :* `false`

This indicates whether or not to ignore the graph labelling for *both* graphs G and H.

Graph isomorphism is understood as mapping colours to colours and stabilizers to stabilizers. Consequently comparing two graphs for isomorphism will always return `false`if one graph is coloured while the other one is not. Similarly two graphs can't be isomorphic if each is coloured using a different set of colours. Moreover, it is a `nauty` requirement that in order to achieve mapping of stabilizers they must be compatible: that is, they *must* have same-sized cells in the same order.

In general, to see which and how the graphs' automorphism groups are computed see Subsection 149.22.3.

Example H149E18

We provide a very simple example of the use of `AutomorphismGroup` which shows how the automorphism group and the corresponding canonical graph differ depending on the labelling of the graph and of the stabilizer given, if any.

```
> G := Graph<5 | { {1,2}, {2,3}, {3,4}, {4,5}, {5,1} }>;
>
> AssignLabels(VertexSet(G), ["a", "b", "a", "b", "b"]);
> A, _, _, _, _, C1 := AutomorphismGroup(G);
> A;
Permutation group A acting on a set of cardinality 5
Order = 2
  (1, 3)(4, 5)
> C1;
Graph
Vertex  Neighbours
1       3 5 ;
2       4 5 ;
3       1 4 ;
4       2 3 ;
5       1 2 ;
> B, _, _, _, _, C2 := AutomorphismGroup(G : IgnoreLabels := true);
> B;
Permutation group B acting on a set of cardinality 5
Order = 10 = 2 * 5
  (2, 5)(3, 4)
  (1, 2)(3, 5)
> C2;
```

```
Graph
Vertex  Neighbours
1       2 3 ;
2       1 4 ;
3       1 5 ;
4       2 5 ;
5       3 4 ;
> C, _, _, _, _, C3 := AutomorphismGroup(G : Stabilizer :=
> [ { VertexSet(G) | 1, 2 } ]);
> C;
Permutation group C acting on a set of cardinality 5
> #C;
1
> C3;
Graph
Vertex  Neighbours
1       3 4 ;
2       3 5 ;
3       1 2 ;
4       1 5 ;
5       2 4 ;
```

We now check that the graph returned by `CanonicalGraph` is identical to C_1:

```
> C4 := CanonicalGraph(G);
> C4 eq C1;
true
```

Example H149E19

These two examples should help clarify how `IsIsomorphic` behaves for graphs for which a colouring is defined. The first example shows that two graphs cannot be isomorphic if one is coloured while the other is not. This example also demonstrates the use of stabilizers.

```
> G1 := CompleteGraph(5);
> AssignLabels(VertexSet(G1), ["a", "a", "b", "b", "b"]);
> G2 := CompleteGraph(5);
> IsIsomorphic(G1, G2);
false
> IsIsomorphic(G1, G2 : IgnoreLabels := true);
true
>
> V1 := Vertices(G1);
> V2 := Vertices(G2);
> S1 := { V1 | 1, 2, 3};
> S2 := { V2 | 3, 4, 5};
>
> IsIsomorphic(G1, G2 : Stabilizer := [S1],
>       Stabilizer2 := [S2]);
```

```
false
> IsIsomorphic(G1, G2 : Stabilizer := [S1],
>       Stabilizer2 := [S2], IgnoreLabels := true);
true
> IsIsomorphic(G1, G2 : Stabilizer := [S1],
> IgnoreLabels := true);
true
>
> SS1 := [ { V1 | 1}, {V1 | 2, 3} ];
> SS2 := [ { V2 | 3, 4}, { V2 | 1} ];
> IsIsomorphic(G1, G2 : Stabilizer := SS1, Stabilizer2 := SS2,
> IgnoreLabels := true);
false
>
> SS1 := [ {V1 | 2, 3}, { V1 | 1} ];
> IsIsomorphic(G1, G2 : Stabilizer := SS1, Stabilizer2 := SS2,
> IgnoreLabels := true);
true
```

The second example shows that two graphs are isomorphic if and only if colours map to the *same* colours.

```
> G1 := CompleteGraph(5);
> AssignLabels(VertexSet(G1), ["b", "b", "b", "a", "a"]);
> G2 := CompleteGraph(5);
> AssignLabels(VertexSet(G2), ["a", "a", "b", "b", "b"]);
> IsIsomorphic(G1, G2);
true
>
> G1 := CompleteGraph(5);
> AssignLabels(VertexSet(G1), ["a", "b", "b", "c", "c"]);
> G2 := CompleteGraph(5);
> AssignLabels(VertexSet(G2), ["a", "c", "b", "b", "c"]);
> IsIsomorphic(G1, G2);
true
>
> G1 := CompleteGraph(5);
> G2 := CompleteGraph(5);
> AssignLabels(VertexSet(G1), ["a", "a", "b", "b", "b"]);
> AssignLabels(VertexSet(G2), ["b", "b", "a", "a", "a"]);
> IsIsomorphic(G1, G2);
false
> IsIsomorphic(G1, G2 : IgnoreLabels := true);
true
>
> G1 := CompleteGraph(5);
> AssignLabels(VertexSet(G1), ["b", "b", "b", "a", "a"]);
> G2 := CompleteGraph(5);
> AssignLabels(VertexSet(G2), ["b", "b", "c", "c", "c"]);
```

```
> IsIsomorphic(G1, G2);
false
> IsIsomorphic(G1, G2 : IgnoreLabels := true);
true
```

149.22.5 Action of Automorphisms

The automorphism group A of a graph G is given in its action on the standard support and it does not act directly on G. The action of A on G is obtained using the G-set mechanism. The two basic G-sets associated with the graph correspond to the action of A on the set of vertices V and the set of edges V of G. These two G-sets are given as return values of the function `AutomorphismGroup` or may be constructed directly. Additional G-sets associated with a graph may be built using the G-set constructors. Given a G-set Y for A, the action of A on Y may be studied using the permutation group functions that allow a G-set as an argument In this section, only a few of the available functions are described: see the section on G-sets for a complete list.

`Image(a, Y, y)`

Let a be an element of the automorphism group A for the graph G and let Y be a G-set for A. Given an element y belonging either to Y or to a G-set derived from Y, find the image of y under a.

`Orbit(A, Y, y)`

Let A be a subgroup of the automorphism group for the graph G and let Y be a G-set for A. Given an element y belonging either to Y or to a G-set derived from Y, construct the orbit of y under A.

`Orbits(A, Y)`

Let A be a subgroup of the automorphism group for the graph G and let Y be a G-set for G. This function constructs the orbits of the action of A on Y.

`Stabilizer(A, Y, y)`

Let A be a subgroup of the automorphism group for the graph G and let Y be a G-set for A. Given an element y belonging either to Y or to a G-set derived from Y, construct the stabilizer of y in A.

`Action(A, Y)`

Given a subgroup A of the automorphism group of the graph G, and a G-set Y for A, construct the homomorphism $\phi : A \to L$, where the permutation group L gives the action of A on the set Y. The function returns:

(a) The natural homomorphism $\phi : A \to L$;

(b) The induced group L;

(c) The kernel of the action (a subgroup of A).

`ActionImage(A, Y)`

Given a subgroup A of the automorphism group of the graph structure G, and a G-set Y for A, construct the permutation group L giving the action of A on the set Y.

`ActionKernel(A, Y)`

Given a subgroup A of the automorphism group of the graph G, and a G-set Y for A, construct the kernel of the action of A on the set Y.

Example H149E20

We construct the Clebsch graph (a strongly regular graph) and investigate the action of its automorphism group.

```
> S := { 1 .. 5 };
> V := &join[ Subsets({1..5}, 2*k) : k in [0..#S div 2]];
> E := { {u,v} : u,v in V | #(u sdiff v) eq 4 };
> G, V, E := StandardGraph( Graph< V | E >);
> G;
Graph
Vertex  Neighbours
1       4 6 8 10 12 ;
2       5 6 9 12 14 ;
3       9 10 12 13 16 ;
4       1 7 9 14 16 ;
5       2 7 8 10 16 ;
6       1 2 13 15 16 ;
7       4 5 12 13 15 ;
8       1 5 9 11 13 ;
9       2 3 4 8 15 ;
10      1 3 5 14 15 ;
11      8 12 14 15 16 ;
12      1 2 3 7 11 ;
13      3 6 7 8 14 ;
14      2 4 10 11 13 ;
15      6 7 9 10 11 ;
16      3 4 5 6 11 ;
> A, AV, AE := AutomorphismGroup(G);
> A;
Permutation group aut acting on a set of cardinality 16
Order = 1920 = 2^7 * 3 * 5
    (2, 15)(5, 11)(7, 14)(10, 12)
    (3, 11)(8, 10)(9, 14)(13, 15)
    (2, 11)(5, 15)(6, 8)(9, 16)
    (2, 7)(4, 6)(9, 13)(14, 15)
    (1, 2, 13, 15)(3, 11, 4, 5)(7, 10, 12, 14)(8, 9)
> CompositionFactors(A);
    G
```

```
    |  Cyclic(2)
    *
    |  Alternating(5)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
> IsPrimitive(A);
true
```

From the composition factors we guess that the group is $Sym(5)$ extended by the elementary abelian group of order 16. Let us verify this and relate it to the graph. We begin by trying to get at the group of order 16. We ask for the Fitting subgroup.

```
> F := FittingSubgroup(A);
> F;
Permutation group F acting on a set of cardinality 16
Order = 16 = 2^4
    (1, 13)(2, 11)(3, 4)(5, 15)(6, 8)(7, 10)(9, 16)(12, 14)
    (1, 10)(2, 9)(3, 12)(4, 14)(5, 8)(6, 15)(7, 13)(11, 16)
    (1, 11)(2, 13)(3, 5)(4, 15)(6, 14)(7, 9)(8, 12)(10, 16)
    (1, 12)(2, 6)(3, 10)(4, 7)(5, 16)(8, 11)(9, 15)(13, 14)
```

Since A is primitive, this looks as if it is an elementary abelian regular normal subgroup:

```
> EARNS(A) eq F;
true
```

Thus, A has a regular normal subgroup of order 16. Further, it acts transitively on the vertices. The complement of N is the stabilizer of a point.

```
> S1 := Stabilizer(A, AV, V!1);
> #S1;
120
> IsTransitive(S1);
false
> O := Orbits(S1);
> O;
[
    GSet{ 1 },
    GSet{ 2, 3, 5, 7, 9, 11, 13, 14, 15, 16 },
    GSet{ 4, 6, 8, 10, 12 }
]
> IsSymmetric(ActionImage(S1, O[3]));
```

```
true
```

So the stabilizer of the vertex 1 is Sym(5). Note that it acts faithfully on the 5 neighbours of 1.

149.23 Symmetry and Regularity Properties of Graphs

`IsTransitive(G)`
`IsVertexTransitive(G)`

Returns `true` if the automorphism group of the graph G is transitive, otherwise `false`. To see which automorphism group is computed see Subsection 149.22.3.

`IsEdgeTransitive(G)`

Returns `true` if the automorphism group of the graph G is transitive on the edges of G (i.e. if the edge group of G is transitive). To see which automorphism group is computed see Subsection 149.22.3.

`OrbitsPartition(G)`

Given a graph G, return the partition of its vertex-set corresponding to the orbits of its automorphism group in the form of a set system. To see which automorphism group is computed see Subsection 149.22.3.

`IsPrimitive(G)`

Returns `true` if the graph G is primitive, i.e. if its automorphism group is primitive. To see which automorphism group is computed see Subsection 149.22.3.

`IsSymmetric(G)`

Returns `true` if the graph G is symmetric, i.e. if for all pairs of vertices u, v and w, t such that u adj v and w adj t, there exists an automorphism a such $u^a = w$ and $v^a = t$. To see which automorphism group is computed see Subsection 149.22.3.

`IsDistanceTransitive(G)`

Returns `true` if the connected graph G is distance transitive i.e. if for all vertices u, v, w, t of G such that $d(u, v) = d(w, t)$, there is an automorphism a in A such that $u^a = w$ and $v^a = t$. To see which automorphism group is computed see Subsection 149.22.3.

`IsDistanceRegular(G)`

Returns `true` if the graph G is distance regular, otherwise `false`. To see how the automorphism group of G is computed see Subsection 149.22.3.

`IntersectionArray(G)`

The intersection array of the distance regular graph G. This is returned as a sequence $[k, b(1), \ldots, b(d-1), 1, c(2), \ldots, c(d)]$ where k is the valency of the graph, d is the diameter of the graph, and the numbers $b(i)$ and $c(i)$ are defined as follows: Let $N_j(u)$ denote the set of vertices of G that lie at distance j from vertex u. Let u and v be a pair of vertices satisfying $d(u, v) = j$.

Then $c(j)$ = number of vertices in $N_{j-1}(v)$ that are adjacent to u, $(1 \leq j \leq d)$, and $b(j)$ = number of vertices in $N_{j+1}(v)$ that are adjacent to u $(0 \leq j \leq d-1)$.

Example H149E21

We illustrate the use of some of the symmetry functions by applying then to the graph of the 8-dimensional cube.

```
> g := KCubeGraph(8);
> IsVertexTransitive(g);
true
> IsEdgeTransitive(g);
true
> IsSymmetric(g);
true
> IsDistanceTransitive(g);
true
> IntersectionArray(g);
[ 8, 7, 6, 5, 4, 3, 2, 1, 1, 2, 3, 4, 5, 6, 7, 8 ]
```

We also see that the functions using the graph's automorphism group are dependent upon the graph being coloured or not:

```
> q := 9;
> P := FiniteProjectivePlane(q);
> X := IncidenceGraph(P);
>
> Order(X);
182
> Valence(X);
10
> Diameter(X);
3
> Girth(X);
6
> O1 := OrbitsPartition(X);
> IsSymmetric(X);
true
>
> Labels := [ "a" : i in [1..96] ];
> #Labels;
96
```

```
> AssignLabels(VertexSet(X), Labels);
> O2 := OrbitsPartition(X);
> O2 eq O1;
false
> IsSymmetric(X);
false
```

149.24 Graph Databases and Graph Generation

MAGMA provides interfaces to some databases of certain graphs of interest. These databases are not provided by default with MAGMA, but may be downloaded from the optional databases section of the MAGMA website.

149.24.1 Strongly Regular Graphs

A catalogue of strongly regular graphs is available. This catalogue has been put together from various sources by B. McKay and can be found at

`http://cs.anu.edu.au/~bdm/data/`

Graphs in the database are indexed by a sequence of four parameters. They are, in order: the order of the graph, its degree, the number of common neighbours to each pair of adjacent vertices, and the number of common neighbours to each pair of non-adjacent vertices.

`StronglyRegularGraphsDatabase()`

Opens the database of strongly regular graphs.

`Classes(D)`

Returns all the parameter sequences used to index the graphs in the database D.

`NumberOfClasses(D)`

Returns the number of "classes" of graphs in the database D.

`NumberOfGraphs(D)`

Returns the number of graphs in the database D.

`NumberOfGraphs(D, S)`

Returns the number of graphs in the database D with parameter sequence S.

`Graphs(D, S)`

Returns (in a sequence) all the graphs in the database D with parameter sequence S.

`Graph(D, S, i)`

Returns the ith graph in the database D with parameter sequence S.

`RandomGraph(D)`

Returns a random graph in the database D.

`RandomGraph(D, S)`

Returns a random graph in the database D with parameter sequence S.

`for G in D do ... end for;`

The database of strongly regular graphs may appear as the range in the `for`-statement.

Example H149E22

The following few statements illustrate the basic access functions to the database of strongly regular graphs.

```
> D := StronglyRegularGraphsDatabase();
> Cs := Classes(D);
> Cs;
[
  [ 25, 8, 3, 2 ],
  [ 25, 12, 5, 6 ],
  [ 26, 10, 3, 4 ],
  [ 27, 10, 1, 5 ],
  [ 28, 12, 6, 4 ],
  [ 29, 14, 6, 7 ],
  [ 35, 16, 6, 8 ],
  [ 35, 14, 4, 6 ],
  [ 36, 15, 6, 6 ],
  [ 37, 18, 8, 9 ],
  [ 40, 12, 2, 4 ]
]
> assert NumberOfClasses(D) eq #Cs;
>
> NumberOfGraphs(D);
43442
>
> for i in [1..#Cs] do
>     NumberOfGraphs(D, Cs[i]);
> end for;
1
15
10
1
4
41
```

```
3854
180
32548
6760
28
>
>  gs := Graphs(D, Cs[2]);
>
>  g :=  Graph(D, Cs[2], Random(1, NumberOfGraphs(D, Cs[2])));
```

149.24.2 Small Graphs

An enumeration of small graphs with various properties has been created by B. McKay and may be found at

`http://cs.anu.edu.au/~bdm/data/graphs.html`

Certain of these databases are available from within MAGMA: Simple graphs, Eulerian graphs, planar connected graphs, and self-complementary graphs.

149.24.2.1 Creation of Small Graph Databases

`SmallGraphDatabase(n : parameters)`

`IncludeDisconnected` BOOL *Default :* `false`

Opens the database of simple graphs with n vertices, $2 \leq n \leq 10$. If the optional parameter `IncludeDisconnected` is set to true then the database will also include non-connected graphs.

`EulerianGraphDatabase(n : parameters)`

`IncludeDisconnected` BOOL *Default :* `false`

Opens the database of Eulerian graphs with n vertices, $3 \leq n \leq 11$. If the optional parameter `IncludeDisconnected` is set to true then the database will also include non-connected graphs. The allowed range of n for non-connected graphs is $2 \leq n \leq 12$.

`PlanarGraphDatabase(n)`

Opens the database of planar connected graphs with n vertices, $2 \leq n \leq 11$.

`SelfComplementaryGraphDatabase(n)`

Opens the database of self-complementary graphs with n vertices, $n \in \{4, 5, 8, 9, 12, 13, 16, 17, 20\}$. For $n = 20$ this is not a complete enumeration.

149.24.2.2 Access functions

`#D`

Returns the number of graphs in the database D.

`Graph(D, i)`

Returns the ith graph in the database D.

`Random(D)`

Returns a random graph from the database D.

```
for G in D do ...  end for;
```

A database of small graphs may appear as the range in the `for`-statement.

149.24.3 Generating Graphs

We provide an interface to a graph generation programme, also due to B. McKay (see [McK98]). For the time being, users wanting to benefit from this facility must download the generation programme themselves directly from

`http://cs.anu.edu.au/~bdm/nauty/`

Important restriction: Since this program runs within a Unix pipe it is only available to users running MAGMA on a Unix platform.

And a note of caution: When the graph generation programme is used to generate reasonably large graphs ($n > 17$) it can be observed that the procedure of closing down the pipe (ie. closing the stream) may take some time. This will happen when the closing down attempt is made before the programme has completed the generation of all the graphs.

`GenerateGraphs(n : parameters)`

Opens a pipe to the graph generation programme to generate all graphs of order n. Only available on Unix platforms.

The `GenerateGraphs` function allows the user to drive the generation programme via a set of parameters. These parameters are described below.

Once the generation programme has been downloaded from

`http://cs.anu.edu.au/~bdm/nauty/`

and compiled (using `make geng`), the resulting executable (named `geng` – it is *compulsory* that the resulting executable's name be `geng`) can be placed anywhere in the user's directory tree. The environment variable `MAGMA_NAUTY` *must* then be set to the path where the executable/command `geng` is to be found.

`FirstGraph` RNGINTELT *Default :* 1

Reading of the generated graphs starts at the `FirstGraph`-th graph.

`MinEdges` RNGINTELT *Default :*

Generate graphs with minimum number of edges `MinEdges`.

`MaxEdges` RngIntElt *Default :*

Generate graphs with maximum number of edges `MaxEdges`.

`Classes` RngIntElt *Default :* 1

Divide the generated graphs into disjoint `Classes` classes of very approximately equal size.

`Class` RngIntElt *Default :* 1

When generated graphs are divided into disjoint `Classes` classes, write only the `Class`th class.

`Connected` BoolElt *Default :* `false`

Only generate connected graphs.

`Biconnected` BoolElt *Default :* `false`

Only generate biconnected graphs.

`TriangleFree` BoolElt *Default :* `false`

Only generate triangle–free graphs.

`FourCycleFree` BoolElt *Default :* `false`

Only generate 4–cycle–free graphs.

`Bipartite` BoolElt *Default :* `false`

Only generate bipartite graphs.

`MinDeg` RngIntElt *Default :*

Specify a lower bound for the minimum degree.

`MaxDeg` RngIntElt *Default :*

Specify an upper bound for the maximum degree.

`Canonical` BoolElt *Default :* `false`

Canonically label output graphs.

`SparseRep` BoolElt *Default :* `false`

If `true`, generate the graphs in Sparse6 format (see below).

`NextGraph(F: parameters)`

`SparseRep` Bool *Default :* `false`

Returns `true` if and only if file F is not at the end. In this case the next graph is returned as well.

Since `NextGraph` can in principle take as an argument any Magma object of type `File`, the following restriction applies to the `File` F: The graphs in F *must* be in either of the output formats Graph6 or Sparse6. Details on the Graph6 and Sparse6 format can be found at

`http://cs.anu.edu.au/~bdm/data/formats.html`

If SparseRep is `true` then the resulting graph will have a sparse representation. This of course is of special interest if the graphs read from F are also in Sparse6 format.

Example H149E23

The following statements should help clarify the usage of the graph generation programme.

```
> F := GenerateGraphs (12:
>     FirstGraph:= 10,
>     Connected:= true,
>     Biconnected:= true,
>     TriangleFree:= true,
>     FourCycleFree:= true,
>     Bipartite:= true,
>     MinDeg:= 1,
>     MaxDeg:= 9
> );
```

We'll read all the graphs from the 10th graph onwards (one can check that 28 graphs have been generated):

```
> count := 0;
> while true do
>     more := NextGraph(F);
>     if more then
>       count +:= 1;
>     else
>       break;
>     end if;
> end while;
> count;
19
```

If one wants to work with sparse graphs, it is recommended to proceed as follows:

```
> F := GenerateGraphs (6: SparseRep := true);
> count := 0;
> while true do
>     more := NextGraph(F: SparseRep := true);
>     if more then
>       count +:= 1;
>     else
>       break;
>     end if;
> end while;
> count;
156
```

149.24.4 A General Facility

In order to give users more flexibility in dealing with certain graph files the MAGMA function `OpenGraphFile` is provided. It allows one to open either a graph file or a pipe to a graph generation programme. Since in both cases (file or Unix pipe) the outcome is the access to a stream of graphs, we henceforth refer to the graphs to be read as a *graph stream*.

The usual restriction: The `OpenGraphFile` which opens a pipe is only available to users running MAGMA on a Unix platform.

Accessing and reading the graph stream: Reading the graph stream is achieved by the above described access function `NextGraph`. As mentioned there, the graphs in the graph stream *must* be in either of the output formats Graph6 or Sparse6. This is why `OpenGraphFile` is restricted to streams of graphs in format Graph6 or Sparse6.

Details on the Graph6 and Sparse6 format can be found at

`http://cs.anu.edu.au/~bdm/data/formats.html`.

`OpenGraphFile(s, f, p)`

Opens a graph file/pipe at position p. If the stream to be opened is a Unix pipe then the string s *must* have the format "cmd command" where command stands for the command to run including necessary parameters. If the stream to be opened is a file the string s has format "filename".

The integer f indicates that the record length is fixed, which is true for streams in Graph6 format with every graph having the same order. This permits rapid positioning to position p in that case. If in doubt, use $f = 0$. Also, positioning to 0 or positioning to 1 has the same effect of positioning to the start of the stream.

Opening a pipe is only available on Unix platforms. The file/pipe F *must* contain graphs in Graph6 and Sparse6 format.

Example H149E24

As an example one could download one of the files found at

`http://cs.anu.edu.au/~bdm/data/`

Assuming this has been done, one can then proceed to read the graphs in the file:

```
> F := OpenGraphFile("/home/paule/graph/bdm_data/sr251256.g6", 0, 0);
>
> count := 0;
> more, g := NextGraph(F);
> while more do
>    count +:= 1;
>    more, g := NextGraph(F);
> end while;
> count;
15
```

Alternatively one could also drive the graph generation programme (or any other suitable programme for that matter) described in 149.24.3 using the `OpenGraphFile` access function.

The graph generation programme's name is `geng` (which can be found at `http://cs.anu.edu.au/~bdm/nauty/`) and has a help facility:

```
>  F := OpenGraphFile("cmd /home/paule/graph/bdm_pgr/nauty/geng -help", 0, 0);
Usage: geng [-cCmtfbd#D#] [-uygsnh] [-lvq] [-x#X#] n [mine[:maxe]] [res/mod]
[file]
 Generate all graphs of a specified class.
      n    : the number of vertices (1..32)
 mine:maxe : a range for the number of edges
              #:0 means '# or more' except in the case 0:0
   res/mod : only generate subset res out of subsets 0..mod-1
     -c    : only write connected graphs
     -C    : only write biconnected graphs
     -t    : only generate triangle-free graphs
     -f    : only generate 4-cycle-free graphs
     -b    : only generate bipartite graphs
                (-t, -f and -b can be used in any combination)
     -m    : save memory at the expense of time (only makes a
                difference in the absence of -b, -t, -f and n <= 30).
     -d#   : a lower bound for the minimum degree
     -D#   : a upper bound for the maximum degree
     -v    : display counts by number of edges
     -l    : canonically label output graphs
     -u    : do not output any graphs, just generate and count them
     -g    : use graph6 output (default)
     -s    : use sparse6 output
     -y    : use the obsolete y-format instead of graph6 format
     -h    : for graph6 or sparse6 format, write a header too
     -q    : suppress auxiliary output (except from -v)
  See program text for much more information.
```

Finally, here is a typical run of this graph generation programme:

```
>  F := OpenGraphFile(
>  "cmd /home/paule/graph/bdm_pgr/nauty/geng 15 -cCtfb -v", 0, 0);
>A geng -Ctfbd2D14 n=15 e=15-22
>C 4 graphs with 16 edges
>C 45 graphs with 17 edges
>C 235 graphs with 18 edges
>C 294 graphs with 19 edges
>C 120 graphs with 20 edges
>C 13 graphs with 21 edges
>C 1 graphs with 22 edges
>Z 712 graphs generated in 1.38 sec
```

150 MULTIGRAPHS

Chapter 150
MULTIGRAPHS

150.1 Introduction

Multigraphs and *multidigraphs* are graphs and digraphs which may have multiple (i.e., parallel) edges and loops. This is in contrast to simple graphs (see Section 149.1 in the chapter on graphs). In the context of this chapter we use the term "graph" as a generic term for the general vertex-edge incident structure, and the term "multigraph" as a generic term whenever we want to emphasize the possible existence of multiple edges and loops. Thus, graphs and multigraphs may be directed or undirected. The meaning of the terms "graph" and "multigraph" should be made clear from the context in which they occur.

Multigraphs are represented in the form of an adjacency list; for more information on this topic we refer the reader to Section 149.3. As is the case for simple graphs, the vertices and edges of a multigraph may be given "decorations". More precisely, they may be labelled; in addition the edges may also be assigned a capacity (if one is interested in flow problems) and/or a weight (for investigation of shortest path problems).

For convenience, MAGMA provides users with *networks*: in the MAGMA context, a network is understood as being a multidigraph whose edges are *always* given a capacity. Any MAGMA function that takes a network as an argument will usually take any graph whose edges have a capacity as an argument. Networks are covered in Chapter 151; a few functionalities specific to networks will, however, be discussed in the general multigraph context whenever there is a need to highlight some differences between networks and general multi(di)graphs.

In particular, almost all the standard graph construction functions (see Section 150.5) preserve the graph's support set and vertex and edge decorations. That is, the resulting graph will have a support and vertex and edge decorations compatible with the original graph and the operation performed on that graph.

A MAGMA multigraph object has type `GrphMultUnd`, a multidigraph has type `GrphMultDir`, and a network has type `GrphNet`. All three objects are of type `GrphMult`.

The multigraph facilities represent a significant subset of the (simple) graph functionality. Consequently, some sections of this chapter are very similar to their counterparts in Chapter 149. For the sake of clarity, this chapter describes the complete multigraph functionality.

150.2 Construction of Multigraphs

In this implementation, the order n of a multigraph or multidigraph is bounded by 134217722. See Section 149.2.1 in Chapter 149 for more details.

150.2.1 Construction of a General Multigraph

Undirected multigraphs are constructed in a similar way to graphs (Subsection 149.2.2).

```
MultiGraph< n | edges  >
```

```
MultiGraph< S | edges  >
```

Construct the multigraph G with vertex-set $V = \{@v_1, v_2, \ldots, v_n@\}$ (where $v_i = i$ for each i if the first form of the constructor is used, or the ith element of the enumerated or indexed set S otherwise), and edge-set $E = \{e_1, e_2, \ldots, e_q\}$. This function returns three values: The multigraph G, the vertex-set V of G; and the edge-set E of G.

The elements of E are specified by the list *edges*, where the items of *edges* may be objects of the following types:

(a) A pair $\{v_i, v_j\}$ of vertices in V. The undirected edge $\{v_i, v_j\}$ from v_i to v_j will be added to the edge-set for G.

(b) A tuple of the form $\langle v_i, N_i\rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i. The elements of the sets N_i must be elements of V. If $N_i = \{u_1, u_2, \ldots, u_r\}$, the edges $\{v_i, u_1\}, \ldots, \{v_i, u_r\}$ will be added to G.

(c) A sequence $[N_1, N_2, \ldots, N_n]$ of n sets, where N_i will be interpreted as a set of neighbours for the vertex v_i. The edges $\{v_i, u_i\}$, $u_i \in N_i$, are added to G.

In addition to these three basic ways of specifying the *edges* list, the items in *edges* may also be:

(d) An edge e of a graph or digraph or multigraph or multidigraph or network of order n. If e is an edge from u to v, then the edge $\{u, v\}$ is added to G.

(e) An edge-set E of a graph or digraph or multigraph or multidigraph or network of order n. Every edge e in E will be added to G according to the rule set out for a single edge.

(f) A graph or a digraph or a multigraph or a multidigraph or a network H of order n. Every edge e in H's edge-set is added to G according to the rule set out for a single edge.

(g) A set of

- (i) Pairs of the form $\{v_i, v_j\}$ of vertices in V.
- (ii) Tuples of the form $\langle v_i, N_i\rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i.
- (iii) Edges of a graph or digraph or multigraph or multidigraph or network of order n.

(iv) Graphs or digraphs or multigraphs or multidigraphs or networks of order n.

(h) A sequence of

(i) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of neighbours for the vertex v_i.

Example H150E1

```
> G := MultiGraph< 3 | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> G;
Multigraph
Vertex  Neighbours
1       2 3 2 ;
2       3 2 2 1 1 ;
3       2 1 ;
```

150.2.2 Construction of a General Multidigraph

Multidigraphs are constructed in the same way as digraphs (Subsection 149.2.3).

```
MultiDigraph< n | edges  >
```

```
MultiDigraph< S | edges  >
```

Construct the multidigraph G with vertex-set $V = \{@v_1, v_2, \ldots, v_n@\}$ (where $v_i = i$ for each i if the first form of the constructor is used, or the ith element of the enumerated or indexed set S otherwise), and edge-set $E = \{e_1, e_2, \ldots, e_q\}$. This function returns three values: The multidigraph G, the vertex-set V of G; and the edge-set E of G.

The elements of E are specified by the list *edges*, where the items of *edges* may be objects of the following types:

(a) A pair $[v_i, v_j]$ of vertices in V. The directed edge $[v_i, v_j]$ from v_i to v_j will be added to the edge-set for G.

(b) A tuple of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i. The elements of the sets N_i must be elements of V. If $N_i = \{u_1, u_2, \ldots, u_r\}$, the edges $[v_i, u_1], \ldots, [v_i, u_r]$ will be added to G.

(c) A sequence $[N_1, N_2, \ldots, N_n]$ of n sets, where N_i will be interpreted as a set of out-neighbours for the vertex v_i. All the edges $[v_i, u_i]$, $u_i \in N_i$, are added to G.

In addition to these four basic ways of specifying the *edges* list, the items in *edges* may also be:

(d) An edge e of a graph or digraph or multigraph or multidigraph or network of order n. If e is an edge from u to v, then the edge $[u, v]$ is added to G. Thus, if e is an undirected edge from u to v, both edges $[u, v]$ and $[v, u]$ are added to G.

(e) An edge-set E of a graph or digraph or multigraph or multidigraph or network of order n. Every edge e in E will be added to G according to the rule set out for a single edge.

(f) A graph or a digraph or a multigraph or a multidigraph or a network H of order n. Every edge e in H's edge-set is added to G according to the rule set out for a single edge.

(g) A set of

(i) Pairs of the form $[v_i, v_j]$ of vertices in V.

(ii) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

(iii) Edges of a graph or digraph or multigraph or multidigraph or network of order n.

(iv) Graphs or digraphs or multigraphs or multidigraphs or networks of order n.

(h) A sequence of

(i) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

Example H150E2

```
> G := MultiDigraph< 3 | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> G;
Multidigraph
Vertex  Neighbours
1       2 3 2 ;
2       3 2 ;
3       ;
```

150.2.3 Printing of a Multi(di)graph

A multi(di)graph is displayed by listing, for each vertex, all of its adjacent vertices. If the multigraph has multiple edges from u to v, then the adjacency list of u contains as many copies of the vertex v as there are edges from u to v.

The vertices in the adjacency list are not ordered, they appear in the order in which they were created. See the previous examples H150E1 and H150E2.

150.2.4 Operations on the Support

The support of a multi(di)graph is subject to exactly the same operations as simple graphs (see Subsection 149.2.4).

`Support(G)`

`Support(V)`

The indexed set used in the construction of G (or the graph for which V is the vertex-set), or the standard set $\{@1, \ldots, n@\}$ if it was not given.

`ChangeSupport(G, S)`

If G is a graph having n vertices and S is an indexed set of cardinality n, return a new graph H equal to G but whose support is S. That is, H is structurally equal to G and its vertex and edge decorations are the *same* as those for G (see Sections 150.4.1 and 150.4.2).

`ChangeSupport(~G, S)`

The procedural version of the above function.

`StandardGraph(G)`

Returns a graph H that is isomorphic to G but defined on the standard support. That is, H is structurally equal to G and its vertex and edge decorations are the same as those for G.

Example H150E3

```
> S := {@ "a", "b", "c" @};
> G := MultiGraph< S | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> G;
Multigraph
Vertex  Neighbours
c       b a b ;
b       a b b c c ;
a       b c ;
> StandardGraph(G);
Multigraph
Vertex  Neighbours
1       2 3 2 ;
2       3 2 2 1 1 ;
3       2 1 ;
```

150.3 The Vertex–Set and Edge–Set of Multigraphs

Much of the functionality for simple graphs (see Section 149.4) also applies to multigraphs. We will not repeat here the functions pertaining to the vertex-set and edge-set of a graph, but concentrate instead on the edges. Indeed, there is a difference in the manner in which multigraph edges are created and accessed when compared to simple graph edges.

Since multigraphs may have multiple edges from u to v, it is necessary to know how many of these edges there are, and how each can be accessed. More importantly a scheme is required to uniquely identify an edge.

Recall that a multigraph is represented by means of an adjacency list, so any edge from u to v can be identified by its index in this list. If there is more than one edge from u to v, then a list of indices will identify each edge from u to v. Thus, the index of the edge in the adjacency list will be the means by which this edge can be *uniquely* identified.

This has a bearing on how an edge can be coerced into a multigraph: Successful coercion will require two vertices u and v so that v is a neighbour of u, and a valid index i in the multigraph's adjacency list. That is, the position i in the list is the index of an edge from u to v.

`EdgeIndices(u, v)`

`Indices(u, v)`

Given vertices u and v of a multigraph G, returns the indices of the possibly multiple edge from u to v.

`EdgeMultiplicity(u, v)`

`Multiplicity(u, v)`

Given vertices u and v of a multigraph G, returns the multiplicity of the possibly multiple edge from u to v. Returns 0 if u is not adjacent to v.

`Edges(u, v)`

Given vertices u and v of a multigraph G, returns all the edges from u to v as a sequence of elements of the edge-set of G.

`IncidentEdges(u)`

Given a vertex u of an undirected multigraph G, returns all the edges incident to u as a set of elements of the edge-set of G. If G is a multidigraph, the function returns all the edges incident to *and* from u as a set of elements of the edge-set of G.

`E ! < { u, v }, i >`

Given the edge-set E of the undirected multigraph G and objects u, v belonging to the support of G corresponding to adjacent vertices, returns the edge from u to v which corresponds to the edge with index i in the adjacency list of G. This requires that the edge at i in the adjacency list of G is an edge from u to v.

`E ! < [ u, v ], i >`

Given the edge-set E of the multidigraph G and objects u, v belonging to the support of G corresponding to adjacent vertices, returns the edge from u to v which corresponds to the edge with index i in the adjacency list of G. This requires that the edge at i in the adjacency list of G is an edge from u to v.

`E . i`

Let E be the edge-set of G. If G is a simple graph (digraph) then this function is as described in Subsection 149.4.2.

If G is a multigraph or multidigraph, then this function returns the edge at index i in the adjacency list of G, provided i is a valid index.

`EndVertices(e)`

Given an edge e in an undirected multigraph G, returns the end vertices of e as a set of vertices $\{u, v\}$. If G is a multidigraph, returns e's end vertices as a sequence of vertices $[u, v]$.

`InitialVertex(e)`

Given an edge $e = \{u, v\}$ or $e = [u, v]$, returns vertex u. This is useful in the undirected case since it indicates, where relevant, the direction in which the edge has been traversed.

`TerminalVertex(e)`

Given an edge $e = \{u, v\}$ or $e = [u, v]$, returns vertex v. This is useful in the undirected case since it indicates, where relevant, the direction in which the edge has been traversed.

`Index(e)`

Given an edge e in a multi(di)graph G, returns the index of e in the adjacency list of G.

`s eq t`

Returns `true` if the edge s is equal to the edge t. It s and t are edges in a multi(di)graph G, returns `true` if and only if s and t have the same index in the adjacency list of G.

Example H150E4

```
> G := MultiGraph< 3 | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
```

The graph G has a loop at vertex 2:

```
> Edges(G);
{@ < {1, 2}, 1 >, < {1, 2}, 5 >, < {1, 3}, 3 >, < {2, 2}, 7 >, < {2,
3}, 9 > @}
> E := EdgeSet(G);
> E.7;
< {2, 2}, 7 >
> assert InitialVertex(E.7) eq TerminalVertex(E.7);
```

The graph G has a multiple edge from vertex 1 to vertex 2:

```
> u := VertexSet(G)!1;
> v := VertexSet(G)!2;
> I := EdgeIndices(u, v);
> I;
[ 5, 1 ]
> assert #I eq Multiplicity(u, v);
>
> E := EdgeSet(G);
> e1 := E!< { 1, 2 }, I[1] >;
> e2 := E!< { 1, 2 }, I[2] >;
> e1, e2;
< {1, 2}, 5 > < {1, 2}, 1 >
> EndVertices(e1);
{ 1, 2 }
> EndVertices(e2);
{ 1, 2 }
> assert Index(e1) eq I[1];
> assert Index(e2) eq I[2];
>
> assert e1 eq E.I[1];
> assert not e2 eq E.I[1];
> assert e2 eq E.I[2];
> assert not e1 eq E.I[2];
```

We have seen that these two edges can be accessed directly:

```
> Edges(u, v);
[ < {1, 2}, 5 >, < {1, 2}, 1 > ]
```

150.4 Vertex and Edge Decorations

150.4.1 Vertex Decorations: Labels

In this implementation, it is only possible to assign labels as vertex decorations.

A vertex labelling of a graph G is a partial map from the vertex-set of G into a set L of labels.

`AssignLabel(~G, u, l)`

Assigns the label l to the vertex u in the graph G.

`AssignLabels(~G, S, L)`

Assigns the labels in L to the corresponding vertices in G in the sequence or indexed set S. If for vertex u the corresponding entry in L is not defined then any existing label of u is removed.

`AssignVertexLabels(~G, L)`

Assigns the labels in L to the corresponding vertices in the graph G.

`IsLabelled(u)`

Returns `true` if and only if the vertex u has a label.

`IsLabelled(V)`

Returns `true` if and only if the vertex-set V is labelled.

`IsVertexLabelled(G)`

Returns `true` if and only if vertices of the graph G are labelled.

`Label(u)`

The label of the vertex u. An error is raised if u is not labelled.

`Labels(S)`

The sequence L of labels of the vertices in the sequence S. If an element of S has no label, then the corresponding entry in L is undefined.

`Labels(V)`

The sequence L of labels of the vertices in the vertex-set V. If an element of V has no label, then the corresponding entry in L is undefined.

`VertexLabels(G)`

The sequence L of labels of the vertices of G. If a vertex of G has no label, then the corresponding entry in L is undefined.

`DeleteLabel(~G, u)`

Removes the label of the vertex u.

Remove the labels of the vertices in S.

```
DeleteVertexLabels(~G)
```

Remove the labels of the vertices in the graph G.

150.4.2 Edge Decorations

Simple graph or multigraph edges can be assigned three different types of decorations:

- a label,
- a capacity,
- a weight.

Edge labels can be objects of any MAGMA type. Edge capacities must be non-negative integers (and loops must be assigned a zero capacity). Edge weights must be elements of a totally ordered ring. Not all edges need to be assigned labels when labelling edges, nor do all edges need to be assigned capacities or weights when assigning either decoration. In the latter case, if some edges have been assigned a capacity or a weight, then the capacity or weight of any remaining unassigned edge is always taken to be zero.

One may want to assign capacities to edges in order to apply a network-flow algorithm to the graph (Section 151.4). By assigning weights to edges one may also be able to run a shortest-path algorithm (Section 150.12).

150.4.2.1 Assigning Edge Decorations

```
AssignLabel(~G, e, l)
```

```
AssignCapacity(~G, e, c)
```

```
AssignWeight(~G, e, w)
```

Assigns the label l or the capacity c or the weight w to the edge e in the graph G. The capacity of any edge must be a non-negative integer except in the case of a loop when it must be zero. The weight w must be an element from a totally ordered ring.

```
AssignLabels(~G, S, D)
```

```
AssignCapacities(~G, S, D)
```

```
AssignWeights(~G, S, D)
```

Assigns the labels or capacities or weights in the sequence D to the corresponding edges in the sequence or indexed set S. If for some edge e the corresponding entry in D is not defined then any existing label or capacity or weight of e is removed. The same constraints regarding capacity and weight apply as in the single edge assignment case.

`AssignEdgeLabels(~G, D)`

`AssignCapacities(~G, D)`

`AssignWeights(~G, D)`

Assigns the labels or capacities or weights in the sequence D to the corresponding edges in graph G. Let E be the edge-set of G and let d be the decoration at position i in D, that is, $d = D[i]$. Then the corresponding edge e in E which will be decorated is $E.i$ (see `E.i`).

If for some edge e the corresponding entry in D is not defined then any existing label or capacity or weight of e is removed. The same constraints regarding capacity and weight apply as in the single edge assignment case.

150.4.2.2 Testing for Edge Decorations

While it is the case that an edge is considered to be labelled if and only if it has been assigned a label, an edge may have a default capacity (weight) of zero. Let e be an edge of a graph G and assume that e has not been assigned a capacity (weight).

If any other edge of G has been assigned a capacity (weight), then the edge-set of G is considered to be capacitated (weighted). In which case the capacity (weight) of e has a default value of zero.

If no other edge of G has been assigned a capacity (weight), then the edge-set of G is considered to be uncapacitated (unweighted). In which case asking for the capacity (weight) of e results in an error.

This is in contrast to the labelling situation where there is no concept of a "default" label. The edge-set of G is considered to be labelled if and only if at least one edge of G has been labelled, while any edge of G is considered to be labelled if and only if e has been labelled.

`IsLabelled(e)`

Returns `true` if and only if the edge e has a label.

`IsLabelled(E)`

Returns `true` if and only if the edge-set is labelled; that is, if and only if at least one edge of E has been assigned a label.

`IsEdgeLabelled(G)`

Returns `true` if and only if the edge-set of G is labelled.

`IsCapacitated(E)`

Returns `true` if and only if the edge-set is capacitated; that is, if and only if at least one edge of E has been assigned a capacity.

`IsEdgeCapacitated(G)`

Returns `true` if and only if the edge-set of G is capacitated.

`IsWeighted(E)`

Returns `true` if and only if the edge-set is weighted; that is, if and only if at least one edge of E has been assigned a weight.

`IsEdgeWeighted(G)`

Returns `true` if and only if the edge-set of G is weighted.

150.4.2.3 Reading Edge Decorations

An edge may have a default capacity and weight of zero, see Subsubsection 150.4.2.2 for more details.

`Label(e)`

The label of the edge e. An error is raised if e has not been assigned a capacity.

`Capacity(e)`

The capacity of the edge e. Let G be the parent graph of e. An error is raised if the edge-set of G is uncapacitated. If the edge-set of G is capacitated but e has not been assigned a capacity, then `Capacity(e)` returns zero as the default value.

`Weight(e)`

The weight of the edge e. Let G be the parent graph of e. An error is raised if the edge-set of G is unweighted. If the edge-set of G is weighted but e has not been assigned a weight, then `Weight(e)` returns zero as the default value.

`Labels(S)`
`Capacities(S)`
`Weights(S)`

The sequence D of labels or capacities or weights of the edges in the sequence S. Let E be the edge-set of the parent graph of the edges. If E is unlabelled or uncapacitated or unweighted then D is the null sequence. If an element of S has no label then the corresponding entry in D is undefined. If an element of S has no capacity or weight while E is capacitated or weighted then the corresponding entry in D has the default value of zero.

`Labels(E)`
`Capacities(E)`
`Weights(E)`

The sequence D of labels or capacities or weights of the edges in the edge-set E. If E is unlabelled or uncapacitated or unweighted then D is the null sequence. If an element of E has no label then the corresponding entry in D is undefined. If an element of E has no capacity or weight while E is capacitated or weighted then the corresponding entry in D has the default value of zero. The corresponding entry i in D of any edge e is such that $e = E.i$ (see `E.i`).

`EdgeLabels(G)`

`EdgeCapacities(G)`

`EdgeWeights(G)`

The sequence D of labels or capacities or weights of the edges in edge-set E of the graph G. If E is unlabelled or uncapacitated or unweighted then D is the null sequence. If an element of E has no label then the corresponding entry in D is undefined. If an element of E has no capacity or weight while E is capacitated or weighted then the corresponding entry in D has the default value of zero. The corresponding entry i in D of any edge e is such that $e = E.i$ (see `E.i`).

150.4.2.4 Deleting Edge Decorations

`DeleteLabel(~G, e)`

`DeleteCapacity(~G, e)`

`DeleteWeight(~G, e)`

Removes the label or capacity or weight of the edge e in the graph G.

`DeleteLabels(~G, S)`

`DeleteCapacities(~G, S)`

`DeleteWeights(~G, S)`

Remove the labels or capacities or weights of the edges (of the graph G) in S.

`DeleteEdgeLabels(~G)`

`DeleteCapacities(~G)`

`DeleteWeights(~G)`

Remove the labels or capacities or weights of the edges in the edge set of the graph G.

150.4.3 Unlabelled, or Uncapacitated, or Unweighted Graphs

Starting with a graph G, the functions below return a graph that is isomorphic as a simple graph to G, but without the vertex and edge labels of G, (or without the edge capacities or weights of G in the case of a network). Should one require a copy of a graph without the support of G, see Subsection 149.2.4. Should one require a copy of a graph without the support of G *and* without the vertex/edge decorations of G, see Subsection 150.6.3.

`UnlabelledGraph(G)`

Return the (vertex and edge) unlabelled graph structurally identical to G, whose edges have the same capacities and weights as those in G. The support of G is also retained in the resulting graph.

`UncapacitatedGraph(G)`

Return the uncapacitated graph structurally identical to G, whose vertices and edges have the same labels, and whose edges have the same weights as those in G. The support of G is also retained in the resulting graph.

`UnweightedGraph(G)`

Return the unweighted graph structurally identical to G, whose vertices and edges have the same labels, and whose edges have the same capacities as those in G. The support of G is also retained in the resulting graph.

Example H150E5

The labelling operations are illustrated by constructing a 2-colouring of the complete bipartite graph $K_{3,4}$. Use is made of the function `Distance`(u, v) which returns the distance between vertices u and v.

```
> K34, V, E := BipartiteGraph(3, 4);
> L := [ IsEven(Distance(V!1, v)) select "red" else "blue" : v in Vertices(K34) ];
> AssignLabels(Vertices(K34), L);
> VertexLabels(K34);
[ red, red, red, blue, blue, blue, blue ]
```

Example H150E6

Another illustration is the creation of the Cayley graph of a group. In this example Sym(4) is used.

```
> G<a,b> := FPGroup(Sym(4));
> I, m := Transversal(G, sub<G | 1>);
> S := Setseq(Generators(G));
> N := [ {m(a*b) : b in S} : a in I ];
> graph := StandardGraph(Digraph< I | N >);
> AssignLabels(VertexSet(graph), IndexedSetToSequence(I));
> V := VertexSet(graph);
> E := EdgeSet(graph);
> for i in [1..#I] do
>     AssignLabels([ E![V | i, Index(I, m(I[i]*s))] : s in S], S);
> end for;
```

In this graph, [1,2,5,4] is a cycle. So the corresponding edge labels should multiply to the identity.

```
> &*Labels([ EdgeSet(graph) | [1,2], [2,5], [5,4], [4,1] ]);
a^4
> G;
Finitely presented group G on 2 generators
Relations
    b^2 = Id(G)
    a^4 = Id(G)
    (a^-1 * b)^3 = Id(G)
```

Example H150E7

We turn to multigraphs to illustrate a point with respect to the listing of the edge decorations. We assign random labels, capacities and weights to a multigraph.

```
> G := MultiGraph< 3 | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> E := EdgeSet(G);
> I := Indices(G);
>
> for i in I do
>     AssignLabel(~G, E.i, Random([ "a", "b", "c", "d" ]));
>     if not InitialVertex(E.i) eq TerminalVertex(E.i) then
>         AssignCapacity(~G, E.i, Random(1, 3));
>     end if;
>     AssignWeight(~G, E.i, Random(1, 3));
> end for;
>
> EdgeLabels(G);
[ c, undef, c, undef, d, undef, c, undef, c ]
> EdgeCapacities(G);
[ 2, undef, 3, undef, 2, undef, 0, undef, 3 ]
> EdgeWeights(G);
[ 3, undef, 2, undef, 1, undef, 2, undef, 1 ]
```

Since G is undirected, the edge $\{v, u\}$ and the edge $\{v, u\}$ are the same object, and thus they have the same index:

```
> V := VertexSet(G);
> u := V!1;
> v := V!3;
> Indices(u, v);
[ 3 ]
> Indices(v, u);
[ 3 ]
```

However, since G is represented by means of an adjacency list, the undirected edge $\{u, v\}$ is stored twice in the list, and so there are two positions in the list associated with the edge. By convention, these positions are contiguous, but, more importantly from the user's perspective, the function `Index` that returns the index of the edge $\{u, v\}$ *always* returns the odd index associated with the edge.
This explains why, for an undirected multigraph, the sequence returned by a function like `EdgeLabels` will always have undefined elements.
Finally note that the loop $\{2, 2\}$, which was assigned no capacity, is shown to have capacity zero:

```
> E := EdgeSet(G);
> E.7;
< {2, 2}, 7 >
> Capacity(E.7);
0
```

This is in accordance with the definition of the default value for edge capacity and weight (see Subsubsection 150.4.2.2).

150.5 Standard Construction for Multigraphs

As noted in the Introduction 150.1, most of the functions listed in this section correctly handle a graph's support and vertex/edge decorations. That is, these attributes are inherited by the graph created as a result of applying such a function.

150.5.1 Subgraphs

The construction of subgraphs from multigraphs or multidigraphs is similar to the construction of subgraphs from simple graphs or digraphs (see Subsection 149.6.1).

Note that the support set, vertex labels and edge decorations are transferred from the supergraph to the subgraph.

`sub< G | list >`

Construct the multigraph H as a subgraph of G. The function returns three values: The multigraph H, the vertex-set V of H; and the edge-set E of H. If G has a support set and/or if G has vertex/edge labels, and/or edge capacities or edge weights then *all* these attributes are transferred to the subgraph H.

The elements of V and of E are specified by the list *list* whose items can be objects of the following types:

(a) A vertex of G. The resulting subgraph will be the subgraph induced on the subset of `VertexSet(`G`)` defined by the vertices in *list*.

(b) An edge of G. The resulting subgraph will be the subgraph with vertex-set `VertexSet(`G`)` whose edge-set consists of the edges in *list*.

(c) A set of

(i) Vertices of G.

(ii) Edges of G.

If the list of vertices and edges happens to contain duplicate elements, they will be ignored by the subgraph constructor. It is easy to recover the map that sends the vertices of the subgraph to the vertices of the supergraph and vice-versa: Simply coerce the vertex of the subgraph into the supergraph's vertex-set, and, if applicable, coerce the vertex of the supergraph into the subgraph's vertex-set.

Example H150E8

We create a multidigraph G with a support set; we assign labels to its vertices, and labels, capacities and weights to its edges. This demonstrates the fact that any subgraph of G retains the support set, as well as the vertex and edge decorations.

```
> S := {@ "a", "b", "c" @};
> G := MultiDigraph< S | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> G;
Multidigraph
Vertex  Neighbours
a       b c b ;
b       c b ;
c       ;
>
> V := VertexSet(G);
> for u in V do
>     AssignLabel(~G, u, Random([ "X", "Y", "Z" ]));
> end for;
>
> E := EdgeSet(G);
> I := Indices(G);
> for i in I do
>     AssignLabel(~G, E.i, Random([ "D", "E", "F" ]));
>     if not InitialVertex(E.i) eq TerminalVertex(E.i) then
>         AssignCapacity(~G, E.i, Random(1, 3));
>     end if;
>     AssignWeight(~G, E.i, Random(1, 3));
> end for;
>
> VertexLabels(G);
[ Z, Y, Z ]
> EdgeLabels(G);
[ E, F, D, E, E ]
> EdgeCapacities(G);
[ 2, 1, 3, 0, 2 ]
> EdgeWeights(G);
[ 2, 1, 3, 1, 1 ]
>
> V := VertexSet(G);
> H := sub< G | V!1, V!2 >;
> H;
Multidigraph
Vertex  Neighbours
a       b b ;
b       b ;
>
> for u in VertexSet(H) do
>     assert Label(u) eq Label(V!u);
```

```
> end for;
>
> for e in EdgeSet(H) do
>     u := InitialVertex(e);
>     v := TerminalVertex(e);
>
>     assert SequenceToSet(Labels(Edges(u, v)))
>     eq SequenceToSet(Labels(Edges(V!u, V!v)));
>     assert SequenceToSet(Capacities(Edges(u, v)))
>     eq SequenceToSet(Capacities(Edges(V!u, V!v)));
>     assert SequenceToSet(Weights(Edges(u, v)))
>     eq SequenceToSet(Weights(Edges(V!u, V!v)));
> end for;
```

Note that since G is a multidigraph it is not possible to coerce an edge of H into the edge-set of G. This is because edge coercion for multi(di)graphs involves the coercion of both the end-vertices *and* the index of the edge.
A correspondence is established between the edges of H and the edges of G by retrieving *all* the edges in H and G having same end-vertices.

150.5.2 Incremental Construction of Multigraphs

The complete functionality for adding and removing vertices or edges in simple graphs (see Subsection 149.6.2) is also available for multigraphs.

Note that some functions adding an edge to a multigraph also return the newly created edge. This feature is useful when there is a need to determine the index of this edge in the adjacency list of the modified multigraph. Also, there is the possibility of removing *all* the edges from u to v for given vertices u and v of the multigraphs.

Further, whenever a vertex or an edge is added or removed from a graph, the existing vertex labels and the edge labels or capacities or weights are retained. The support of the graph is retained in all cases except when adding a new vertex.

Unless otherwise specified, each of the functions described in this section returns three values:

(i) The multigraph G;

(ii) The vertex-set V of G;

(iii) The edge-set E of G.

150.5.2.1 Adding Vertices

`G + n`

Given a non-negative integer n, adds n new vertices to the multigraph G. The existing vertex labels and edge labels or capacities or weights are retained, but the support will become the standard support.

`G +:= n`

`AddVertex(~G)`

`AddVertices(~G, n)`

The procedural version of the previous function. `AddVertex` adds one vertex only to G.

`AddVertex(~G, l)`

Given a graph G and a label l, adds a new vertex with label l to G. The existing vertex labels and edge labels or capacities or weights are retained, but the support will become the standard support.

`AddVertices(~G, n, L)`

Given a graph G and a non-negative integer n, and a sequence L of n labels, adds n new vertices to G with labels from L. The existing vertex labels and edge labels or capacities or weights are retained, but the support will become the standard support.

150.5.2.2 Removing Vertices

`G - v`

`G - U`

Given a vertex v of G, or a set U of vertices of G, removes v (or the vertices in U) from G. The support, vertex labels, and edge labels or capacities or weights are retained.

`G -:= v`

`G -:= U`

`RemoveVertex(~G, v)`

`RemoveVertices(~G, U)`

The procedural versions of the previous functions.

150.5.2.3 Adding Edges

`G + { u, v }`

`G + [ u, v ]`

Given a graph G and a pair of vertices of G, add the edge to G described by this pairs. If G is undirected then the edge must be given as a set of (two) vertices, if G is directed the edge is given as a sequence of (two) vertices. If G is a network, then the edge is added with a capacity of 1 (0 if a loop). The support, vertex labels, and edge labels or capacities or weights are retained. This set of functions has two return values: The first is the modified graph and the second is the newly created edge. This feature is especially useful when adding parallel edges.

```
G + { { u, v } }
G + [ { u, v } ]
G + { [ u, v ] }
G + [ [ u, v ] ]
```

Given a graph G and a set or a sequence of pairs of vertices of G, add the edges to G described by these pairs. If G is undirected then the edges must be given as a set of (two) vertices, if G is directed the edges are given as a sequence of (two) vertices. If G is a network, then the edges are added with a capacity of 1 (0 if a loop). The support, vertex labels, and edge labels or capacities or weights are retained.

```
G +:= { u, v }
G +:= [ u, v ]
G +:= [ u, v ]
G +:= { { u, v } }
G +:= [ { u, v } ]
G +:= { [ u, v ] }
G +:= [ [ u, v ] ]
```

The procedural versions of the previous four functions.

```
AddEdge(G, u, v)
```

Given a graph G, two vertices of G u and v, returns a new edge between u and v. If G is a network, the edge is added with a capacity of 1 (0 if loop). The support, vertex labels, and edge labels or capacities or weights are retained. This function has two return values: The first is the modified graph and the second is the newly created edge. This feature is especially useful when adding parallel edges.

```
AddEdge(G, u, v, l)
```

Given a graph G which is not a network, two vertices of G u and v, and a label l, adds a new edge with label l between u and v. The support, vertex labels, and edge labels or capacities or weights are retained. This function has two return values: The first is the modified graph and the second is the newly created edge.

```
AddEdge(G, u, v, c)
```

Given a network G, two vertices of G u and v, and a non-negative integer c, adds a new edge from u to v with capacity c. The support, vertex labels, and edge labels or capacities or weights are retained. This function has two return values: The first is the modified graph and the second is the newly created edge.

`AddEdge(G, u, v, c, l)`

Given a network G, two vertices of G u and v, a non-negative integer c, and a label l, adds a new edge from u to v with capacity c and label l. If G is a network, then add a new edge with label l and capacity c between u and v. The support, vertex labels, and edge labels or capacities or weights are retained. This function has two return values: The first is the modified graph and the second is the newly created edge.

`AddEdge(~G, u, v)`

`AddEdge(~G, u, v, l)`

`AddEdge(~G, u, v, c)`

`AddEdge(~G, u, v, c, l)`

Procedural versions of the previous functions for adding edges to a graph.

`AddEdges(G, S)`

Given a graph G, and a sequence or set S of pairs of vertices of G, the edges specified in S are added to G. The elements of S must be sets or sequences of two vertices of G, depending upon whether G is undirected or directed respectively.

If G is a network, the edges are added with a capacity of 1 (0 if a loop). The support, vertex labels, and edge labels or capacities or weights are retained.

`AddEdges(G, S, L)`

Given a graph G, a sequence S of pairs of vertices of G, and a sequence L of labels of the same length, the edges specified in S are added to G with its corresponding label as given in L. The elements of S must be sets or sequences of two vertices of G, depending upon whether G is undirected or directed respectively. If G is a network, the edges are added with a capacity of 1 (0 if loop). The support, vertex labels, and edge labels or capacities or weights are retained.

`AddEdges(~G, S)`

`AddEdges(~G, S, L)`

These are procedural versions of the previous functions for adding edges to a graph.

150.5.2.4 Removing Edges

`G - e`

`G - { e }`

Given an edge e or a set S of edges of a multigraph G, this function creates a graph that corresponds to G with the edge e (respectively, set of edges S) removed. The resulting multigraph will have vertex-set $V(G)$ and edge-set $E(G) \setminus \{e\}$ (respectively, $E(G) \setminus S$). The support, vertex labels and edge labels are retained on the remaining edges.

```
G - { { u, v } }
```

```
G - { [u, v] }
```

Given a graph G and a set S of pairs $\{ u, v\}$ or $[u, v]$, u, v vertices of G, this function forms the graph having vertex-set $V(G)$ and edge-set $E(G) - S$. That is, the graph returned is the same as G except that *all* the edges specified by pairs in S have been removed. An edge is represented as a set if G is undirected, and as a sequence otherwise. The support, vertex labels and edge labels are retained on the remaining edges.

```
G -:= e
```

```
G -:= { e }
```

```
G -:= { { u, v } }
```

```
G -:= { [u, v] }
```

```
RemoveEdge(~G, e)
```

```
RemoveEdges(~G, S)
```

```
RemoveEdge(~G, u, v)
```

These operations represent procedural versions of the previous functions. Whenever an edge is represented as a pair $\{u, v\}$ or $[u, v]$ of vertices of G, it is assumed that *all* the edges from u to v are to be removed from G.

150.5.3 Vertex Insertion, Contraction

As in the case of simple graphs (see Subsection 149.6.3) it is possible to insert a vertex in a multigraph edge. The new edges thus created will be unlabelled with their capacities and weights set as follows: (These rules apply regardless as to whether the edge-set is capacitated and/or weighted).

Let e be an edge from u to v with capacity c and weight w in a multigraph G. After the insertion of a new vertex x in e, the edge e will be replaced by two edges, one from u to x and the other from x to v, *both* having capacity c and weight w.

These rules apply regardless as to whether the edge-set is capacitated and/or weighted.

The contraction operation can only be applied to a pair of vertices, since contracting a single multigraph edge which might have parallel edges is meaningless. The graph's support and vertex/edges decorations are retained when contracting its edges.

Each of the functions described below returns three values:

(i) The multigraph G;

(ii) The vertex-set V of G;

(iii) The edge-set E of G.

`InsertVertex(e)`

Given an edge e of the multigraph G, this function inserts a new vertex of degree 2 in e. If appropriate, the two new edges that replace e will have the same capacity and weight as e. They will be unlabelled. The vertex labels and the edge decorations of G are retained, but the resulting graph will have standard support.

`InsertVertex(T)`

Given a set T of edges belonging to the multigraph G, this function inserts a vertex of degree 2 in each edge belonging to the set T.

`Contract(e)`

Given an edge $e = \{u, v\}$ of the graph G, form the graph obtained by removing the edge e and then identifying the vertices u and v. New parallel edges and new loops may result from this operation but any new loop will be assigned zero capacity. With the above exception, the edge decorations are retained, as are the support and the vertex labels of G.

`Contract(u, v)`

Given vertices u and v belonging to the multigraph G, this function returns the multigraph obtained by identifying the vertices u and v. New parallel edges and new loops may result from this operation but any new loop will be assigned zero capacity. With the above exception, the edge decorations are retained, as are the support and the vertex labels of G.

`Contract(S)`

Given a set S of vertices belonging to the multigraph G, this function returns the multigraph obtained by identifying all of the vertices in S.

150.5.4 Unions of Multigraphs

Of the union operations available for simple graphs (see Section 149.7) only `Union` and `EdgeUnion` have been implemented for multigraphs. It is straightforward to write MAGMA code for other union functions with multigraphs.

In contrast with the other standard graph constructions, the support, vertex labels and edge decorations are generally *not* handled by the functions listed below. Thus, the resulting graph will always have standard support and no vertex labels nor edge decorations. The one exception occurs in the case of networks, where edge capacities are properly handled.

`Union(G, H)`

`G join H`

Given multi(di)graphs G and H with disjoint vertex sets $V(G)$ and $V(H)$ respectively, this function constructs their union, i.e. the multi(di)graph with vertex-set $V(G) \cup V(H)$, and edge-set $E(G) \cup E(H)$. The resulting multi(di)graph has standard support and no vertex labels nor edge decorations.

`Union(N, H)`

`N join H`

Given networks N and H with disjoint vertex sets $V(N)$ and (H) respectively, construct their union, i.e. the network with vertex-set $V(N) \cup V(H)$, and edge-set $E(N) \cup E(H)$. The resulting network has standard support and capacities but neither vertex labels, edge labels nor weights retained.

`& join S`

The union of the multigraphs or networks in the sequence or the set S.

`EdgeUnion(G, H)`

Given multi(di)graphs G and H having the same number of vertices, construct their edge union K. This construction identifies the i-th vertex of G with the i-th vertex of H for all i. The edge union has the same vertex-set as G (and hence as H) and there is an edge from u to v in K if and only if there is an edge from u to v in either G or H. The resulting multi(di)graph has standard support but neither vertex labels nor edge decorations.

`EdgeUnion(N, H)`

Given networks N and H having the same number of vertices, construct their edge union K. This construction identifies the i-th vertex of N with the i-th vertex of H for all i. The edge union has the same vertex-set as N (and hence as H) and there is an edge $[u, v]$ with capacity c in K if and only if either there is an edge $[u, v]$ with capacity c in N or if there is an edge $[u, v]$ with capacity c in H. The resulting network has standard support and the inherited edge capacities but neither vertex labels, edge labels nor weights.

150.6 Conversion Functions

Conversion functions do not preserve a graph's support and vertex/edge decorations. That is, the resulting graph has standard support and no vertex/edge decorations. A slight exception to this rule occurs when the resulting graph is a network (of type `GrphNet`) and is described in detail in `UnderlyingNetwork`.

150.6.1 Orientated Graphs

The rules followed in building an orientated graph from an undirected graph are the same as those described for simple graphs (see Section 149.8).

`OrientatedGraph(G)`

Given a multigraph G, produce a multidigraph D whose vertex-set is the same as that of G and whose edge-set consists of the edges of G, each given a direction. The edges of D are always directed from the lower numbered vertex to the higher numbered vertex. Thus, if G contains the edge $\{u, v\}$, then D will have the edge $[u, v]$ if $u < v$, otherwise the edge $[u, v]$. If G has a loop at u, then D will have a directed loop at u.

150.6.2 Converse

`Converse(G)`

Given a multidigraph G with edge-set E, produce a multidigraph D whose vertex-set is the same as that of G and whose edge-set is $\{[u, v] : [v, u] \in E\}$.

150.6.3 Converting between Simple Graphs and Multigraphs

Any simple (di)graph can be converted into a multi(di)graph and any multi(di)graph can be converted into a simple (di)graph. The resulting graph has standard support and neither vertex labels nor edge decorations, unless it is a network, in which case all the edges in the resulting graph are assigned a capacity of 1 (0 if loops).

Let G be a graph and e an edge of G from u to v and let H be the graph resulting from the conversion. If G and H are both undirected or both directed then e is also an edge of H. If G is undirected while H is undirected then both edges $[u, v]$ and $[v, u]$ are edges of H. If G is directed while H is directed then the edge $\{u, v\}$ is an edge of H.

Since these conversion functions do not retain the original graph's support and vertex/edge decorations, they may also be used when requiring a copy of a graph G without G's support and vertex/edge decorations.

`UnderlyingGraph(G)`

The underlying simple graph of the graph G. The support and vertex/edge decorations of G are not retained.

`UnderlyingDigraph(G)`

The underlying simple digraph of the graph G. The support and vertex/edge decorations of G are not retained.

`UnderlyingMultiGraph(G)`

The underlying multigraph of the graph G. The support and vertex/edge decorations of G are not retained.

`UnderlyingMultiDigraph(G)`

The underlying multidigraph of the graph G. The support and vertex/edge decorations of G are not retained.

`UnderlyingNetwork(G)`

The underlying network of the graph G. The support and vertex/edge decorations of G are not retained except when G is a network in which case only the edge capacities are retained. If G is not a network, then all the edge capacities are set to 1 (0 for loops).

150.7 Elementary Invariants and Predicates for Multigraphs

Most but not all of the invariants and predicates that apply to simple graphs (see Sections 149.10 and 149.11) also apply to multigraphs. We list them below.

Let G and H be two graphs. For clarity, we list here once again the conditions under which G is equal to H and H is a subgraph of G.

The graphs G and H are equal if and only if:

- they are of the same type,
- they are structurally identical,
- they have the same support,
- they have identical vertex and edge labels,
- if applicable, the total capacity from u to v in G is equal to the total capacity from u to v in H.

Also, H is a subgraph of G if and only if:

- they are of the same type,
- H is a structural subgraph of G,
- any vertex `v` in H has the same support as the vertex `VertexSet(G)!v` in G,
- any vertex `v` in H has the same label as the vertex `VertexSet(G)!v` in G,
- any edge `e` in H has the same label as the edge `EdgeSet(G)!e` in G,
- if applicable, the total capacity from u to v in G is at least as large as the total capacity from u to v in H.

Note that the truth value of the above two tests is not dependent on the weights of the edges of the graphs, should these edges be weighted.

Finally, we have introduced a few predicates to help users determine if a general graph is simple or not, undirected or not.

`Order(G)`

`NumberOfVertices(G)`

The number of vertices of the graph G.

`Size(G)`

`NumberOfEdges(G)`

The number of edges of the graph G.

`u adj v`

Let u and v be two vertices of the same graph G. If G is undirected, returns `true` if and only if u and v are adjacent. If G is directed, returns `true` if and only if there is an edge directed from u to v.

`e adj f`

Let e and f be two edges of the same graph G. If G is undirected, returns `true` if and only if e and f share a common vertex. If G is directed, returns `true` if and only if the terminal vertex of e (f) is the initial vertex of f (e).

`u notadj v`

The negation of the `adj` predicate applied to vertices.

`e notadj f`

The negation of the `adj` predicate applied to edges.

`u in e`

Let u be a vertex and e an edge of a graph G. Returns `true` if and only if u is an end-vertex of e.

`u notin e`

The negation of the `in` predicate applied to a vertex with respect to an edge.

`G eq H`

Returns `true` if and only if the graphs G and H are equal, that is if and only if they are structurally equal and are compatible with respect to their support, vertex and edge labels, and edge capacities (see the introduction to this section).

`IsSubgraph(G, H)`

Returns `true` if and only if H is a subgraph of G, that is, if and only if H is a structural subgraph of G and the graphs are compatible with respect to their support, vertex and edge labels, and edge capacities (see the introduction to this section).

`IsBipartite(G)`

Returns `true` if and only if the graph G is bipartite.

`Bipartition(G)`

Given a bipartite graph G, return its two partite sets in the form of a pair of subsets of $V(G)$.

`IsRegular(G)`

Returns `true` if and only if G is a regular graph.

`IsComplete(G)`

Returns `true` if and only if the graph G, on n vertices, is the complete graph on n vertices.

`IsEmpty(G)`

Returns `true` if and only if the edge-set of the graph is empty.

`IsNull(G)`

Returns `true` if and only if the vertex-set of the graph is empty.

`IsSimple(G)`

Returns `true` if and only if G is a simple graph.

`IsUndirected(G)`

Returns `true` if and only if G is a undirected graph.

`IsDirected(G)`

Returns `true` if and only if G is a directed graph.

150.8 Adjacency and Degree

The adjacency and degree functionalities that apply to simple graphs (see 149.12) similarly apply to multigraphs.

150.8.1 Adjacency and Degree Functions for Multigraphs

`Degree(u)`

Given a vertex u of a graph G, return the degree of u, ie the number of edges incident to u.

`Alldeg(G, n)`

Given a multigraph G, and a non-negative integer n, return the set of all vertices of G that have degree equal to n.

`MaximumDegree(G)`

`Maxdeg(G)`

The maximum of the degrees of the vertices of the multigraph G. This function returns two values: the maximum degree, and a vertex of G having that degree.

`MinimumDegree(G)`

`Mindeg(G)`

The minimum of the degrees of the vertices of the multigraph G. This function returns two values: the minimum degree, and a vertex of G having that degree.

`DegreeSequence(G)`

Given a multigraph G such that the maximum degree of any vertex of G is r, return a sequence D of length $r+1$, such that $D[i]$, $1 \leq i \leq r+1$, is the number of vertices in G having degree $i-1$.

`Neighbours(u)`

`Neighbors(u)`

Given a vertex u of a graph G, return the set of vertices of G that are adjacent to u.

`IncidentEdges(u)`

Given a vertex u of a graph G, return the set of all edges incident with the vertex u.

150.8.2 Adjacency and Degree Functions for Multidigraphs

`InDegree(u)`

The number of edges directed into the vertex u belonging to a multidigraph.

`OutDegree(u)`

The number of edges of the form $[u, v]$ where u is a vertex belonging to a multidigraph.

`MaximumInDegree(G)`

`Maxindeg(G)`

The maximum indegree of the vertices of the multidigraph G. This function returns two values: the maximum indegree, and the first vertex of G having that degree.

`MinimumInDegree(G)`

`Minindeg(G)`

The minimum indegree of the vertices of the multidigraph G. This function returns two values: the minimum indegree, and the first vertex of G having that degree.

`MaximumOutDegree(G)`

`Maxoutdeg(G)`

The maximum outdegree of the vertices of the multidigraph G. This function returns two values: the maximum outdegree, and the first vertex of G having that degree.

`MinimumOutDegree(G)`

`Minoutdeg(G)`

The minimum outdegree of the vertices of the multidigraph G. This function returns two values: the minimum outdegree, and the first vertex of G having that degree.

`Degree(u)`

Given a vertex u belonging to the multidigraph G, return the total degree of u, i.e. the sum of the in–degree and out–degree for u.

`MaximumDegree(G)`

`Maxdeg(G)`

The maximum total degree of the vertices of the multidigraph G. This function returns two values: the maximum total degree, and the first vertex of G having that degree.

`MinimumDegree(G)`

`Mindeg(G)`

The minimum total degree of the vertices of the multidigraph G. This function returns two values: the minimum total degree, and the first vertex of G having that degree.

`Alldeg(G, n)`

Given a multidigraph G, and a non–negative integer n, return the set of all vertices of G that have total degree equal to n.

`DegreeSequence(G)`

Given a multidigraph G such that the maximum degree of any vertex of G is r, return a sequence D of length $r + 1$, such that $D[i]$, $1 \leq i \leq r + 1$, is the number of vertices in G having degree $i - 1$.

`InNeighbours(u)`

`InNeighbors(u)`

Given a vertex u of a multidigraph G, return the set containing all vertices v such that $[v, u]$ is an edge in G, i.e. the initial vertex of all edges that are directed into the vertex u.

`OutNeighbours(u)`

`OutNeighbors(u)`

Given a vertex u of the multidigraph G, return the set of vertices v of G such that $[u, v]$ is an edge in G, i.e. the set of vertices v that are terminal vertices of edges directed from u to v.

`IncidentEdges(u)`

Given a vertex u of a graph G, return the set of all edges incident with the vertex u, that is, the set of all edges incident into u and incident from u.

150.9 Connectedness

All the functions relating to connectivity issues are the same for simple graphs and multigraphs. See Section 149.13.1 and its subsections for specific details about the algorithms underlying these functions.

150.9.1 Connectedness in a Multigraph

`IsConnected(G)`

Returns `true` if and only if the undirected graph G is a connected graph.

`Components(G)`

The connected components of the undirected graph G. These are returned in the form of a sequence of subsets of the vertex-set of G.

`Component(u)`

The subgraph corresponding to the connected component of the multigraph G containing vertex u. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

`IsSeparable(G)`

Returns `true` if and only if the graph G is connected and has at least one cut vertex.

`IsBiconnected(G)`

Returns `true` if and only if the graph G is biconnected. The graph G must be undirected.

`CutVertices(G)`

The set of cut vertices for the connected undirected graph G (as a set of vertices).

`Bicomponents(G)`

The biconnected components of the undirected graph G. These are returned in the form of a sequence of subsets of the vertex-set of G. The graph may be disconnected.

150.9.2 Connectedness in a Multidigraph

`IsStronglyConnected(G)`

Returns `true` if and only if the multidigraph G is strongly connected.

`IsWeaklyConnected(G)`

Returns `true` if and only if the multidigraph G is weakly connected.

`StronglyConnectedComponents(G)`

The strongly connected components of the multidigraph G. These are returned in the form of a sequence of subsets of the vertex-set of G.

`Component(u)`

The subgraph corresponding to the connected component of the multidigraph G containing vertex u. The support and vertex/edge decorations are *not* retained in the resulting (structural) subgraph.

150.9.3 Triconnectivity for Multigraphs

We refer the reader to Subsection 149.13.3 of the graphs chapter for details about the triconnectivity algorithm implemented here, and especially about the meaning of the `Splitcomponents` function. The triconnectivity algorithm applies to undirected graphs only.

`IsTriconnected(G)`

Returns `true` if and only if G is triconnected. The graph G must be undirected.

`Splitcomponents(G)`

The split components of the undirected graph G. These are returned in the form of a sequence of subsets of the vertex-set of G. The graph may be disconnected. The second return value returns the cut vertices and the separation pairs as sequences of one or two vertices respectively.

`SeparationVertices(G)`

The cut vertices and/or the separation pairs of the undirected graph G as a sequence of sequences of one and/or two vertices respectively. The graph may be disconnected. The second return value returns the split components of G .

150.9.4 Maximum Matching in Bipartite Multigraphs

We refer the reader to Subsection 149.13.4 for information about the maximum matching algorithm.

`MaximumMatching(G : parameters)`

`Al` MonStg *Default : "PushRelabel"*

A maximum matching in the bipartite graph G. The matching is returned as a sequence of edges of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

150.9.5 General Vertex and Edge Connectivity in Multigraphs and Multidigraphs

See Subsection 149.13.5 for details about the algorithms underlying the functions listed below. These functions apply to both undirected and directed graphs.

`VertexSeparator(G : parameters)`

`Al` MonStg *Default : "PushRelabel"*

If G is an undirected graph, a *vertex separator* for G is a smallest set of vertices S such that for any u, $v \in V(G)$, every path connecting u and v passes through at least one vertex of S.

If G is a directed graph, a vertex separator for G is a smallest set of vertices S such that for any u, $v \in V(G)$, every directed path from u to v passes through at least one vertex of S.

`VertexSeparator` returns the vertex separator of G as a sequence of vertices of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`VertexConnectivity(G :` *parameters*`)`

`Al` MonStg *Default :* "*PushRelabel*"

Returns the vertex connectivity of the graph G, the size of a minimum vertex separator of G. Also returns a vertex separator for G as the second value. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`IsKVertexConnected(G, k :` *parameters*`)`

`Al` MonStg *Default :* "*PushRelabel*"

Returns `true` if the vertex connectivity of the graph G is at least k, `false` otherwise. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`EdgeSeparator(G :` *parameters*`)`

`Al` MonStg *Default :* "*PushRelabel*"

If G is an undirected graph, an *edge separator* for G is a smallest set of edges T such that for any u, $v \in V(G)$, every path connecting u and v passes through at least one edge of T.

If G is a directed graph, an edge separator for G is a smallest set of edges T such that for any u, $v \in V(G)$, every directed path from u to v passes through at least one edge of T.

`EdgeSeparator` returns the edge separator of G as a sequence of edges of G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`EdgeConnectivity(G :` *parameters*`)`

`Al` MonStg *Default :* "*PushRelabel*"

Returns the edge connectivity of the graph G, the size of a minimum edge separator of G. Also returns as the second value an edge separator for G. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`IsKEdgeConnected(G, k :` *parameters*`)`

`Al` MonStg *Default :* "*PushRelabel*"

Returns `true` if the edge connectivity of the graph G is at least k, `false` otherwise. The parameter `Al` enables the user to select the algorithm which is to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

Example H150E9

We demonstrate that the connectivity functions deal properly with multiple edges.

```
> G := MultiGraph< 3 | < 1, {2, 3} >, < 1, {2, 3} >, < 2, {2, 3} > >;
> G;
Multigraph
Vertex  Neighbours
1       3 2 3 2 ;
2       3 2 2 1 1 ;
3       2 1 1 ;
> EdgeConnectivity(G);
3
> EdgeSeparator(G);
[ < {3, 2}, 11 >, < {1, 2}, 5 >, < {1, 2}, 1 > ]
```

150.10 Spanning Trees

All the trees returned by the functions described below are returned as structural subgraphs of the original graph whose support and vertex and edge decorations are not retained in the resulting tree.

`SpanningTree(G)`

Given a connected undirected graph G, construct a spanning tree for G rooted at an arbitrary vertex of G. The spanning tree is returned as a structural subgraph of G, without the support, vertex or edge decorations of G.

`SpanningForest(G)`

Given a graph G, construct a spanning forest for G. The forest is returned as a structural subgraph of G, without the support, vertex or edge decorations of G.

`BreadthFirstSearchTree(u)`

`BFSTree(u)`

Given a vertex u belonging to the graph G, return a breadth-first search for G rooted at the vertex u. The tree is returned as a structural subgraph of G, without the support, vertex or edge decorations of G. Note that G may be disconnected.

`DepthFirstSearchTree(u)`

`DFSTree(u)`

Given a vertex u belonging to the graph G, return a depth-first search tree T for G rooted at the vertex u. The tree T is returned as a structural subgraph of G, without the support, vertex or edge decorations of G. Note that G may be disconnected.

The fourth return argument returns, for each vertex u of G, the tree order of u, that is, the order in which the vertex u has been visited while performing the depth-first search. If T does not span G then the vertices of G not in T are given tree order from `Order(T) + 1` to `Order(G)`.

150.11 Planar Graphs

The planarity algorithm implemented in MAGMA tests whether an undirected graph or multigraph is planar. If the graph is planar, then an embedding of the graph is produced, otherwise a Kuratowski subgraph is identified. For a thorough discussion of this algorithm, its implementation and complexity, the reader is referred to Section 149.21.

`IsPlanar(G)`

Tests whether the (undirected) graph G is planar. The graph may be disconnected. If the graph is non-planar then a Kuratowski subgraph of G is returned: That is, a subgraph of G homeomorphic to K_5 or $K_{3,3}$. The support and vertex/edge decorations of G are *not* retained in this (structural) subgraph.

`Obstruction(G)`

Returns a Kuratoswki obstruction if the graph is non-planar, or the empty graph if the graph is planar. The Kuratoswki graph is returned as a (structural) subgraph of G; the support and vertex/edge decorations are not retained.

`IsHomeomorphic(G:` *parameters*`)`

`Graph`	MONSTG	*Default :*

Tests if a graph is homeomorphic to either K_5 or $K_{3,3}$. The parameter `Graph` must be set to either "K5" or "K33"; it has no default setting.

`Faces(G)`

Returns the faces of the planar graph G as sequences of the edges bordering the faces of G. If G is disconnected, then the face defined by an isolated vertex v is given as $[v]$.

`Face(u, v)`

Returns the face of the planar graph G bordered by the directed edge $[u, v]$ as an ordered list of edges of G.

Note that a directed edge and an orientation determine a face uniquely: We can assume without loss of generality that the plane is given a clockwise orientation. Then given a directed edge $e = [u_1, v_1]$, the face defined by e is the ordered set of edges $[u_1, v_1], [u_2, v_2], \ldots, [u_m, v_m]$ such that $v_i = u_{i+1}$ for all i, $1 \leq i < m$, $v_m = u_1$, and for each $v_i = u_{i+1}$, the neighbours of v_i, u_i and v_{i+1}, are *consecutive* vertices in v_i's adjacency list whose order is *anti-clockwise*.

`Face(e)`

Let e be the edge u, v of the planar graph G (recall that G is undirected). Then `Face(`u, v`)` returns the face bordered by the directed edge $[u, v]$ as a sequence of edges of G.

`NFaces(G)`

`NumberOfFaces(G)`

Returns the number of faces of the planar graph G. In the case of a disconnected graph, an isolated vertex counts for one face.

`Embedding(G)`

Returns the planar embedding of the graph G as a sequence S where $S[i]$ is a sequence of edges incident from vertex i.

`Embedding(v)`

Returns the ordered list of edges (in clockwise order say) incident from vertex v.

Example H150E10

The purpose of the example is to show the embedding and faces of a graph with multiples edges and loops.

```
> G := MultiGraph< 3 | < 1, {2, 3} >, < 1, {2} >, < 2, {2, 3} > >;
> G;
Multigraph
Vertex  Neighbours
1       2 3 2 ;
2       3 2 2 1 1 ;
3       2 1 ;
> IsPlanar(G);
true
> Faces(G);
[
  [ < {1, 2}, 5 >, < {2, 1}, 1 > ],
  [ < {1, 2}, 1 >, < {2, 2}, 7 >, < {2, 3}, 9 >, < {3, 1}, 3 > ],
  [ < {1, 3}, 3 >, < {3, 2}, 9 >, < {2, 1}, 5 > ],
```

```
  [ < {2, 2}, 7 > ]
]
> Embedding(G);
[
  [ < {1, 2}, 5 >, < {1, 2}, 1 >, < {1, 3}, 3 > ],
  [ < {2, 3}, 9 >, < {2, 2}, 7 >, < {2, 1}, 1 >, < {2, 1}, 5 > ],
  [ < {3, 1}, 3 >, < {3, 2}, 9 > ]
]
```

Example H150E11

We show how to construct the dual graph D of a planar graph G and how to find all its minimal cuts. The vertex set of the dual is the set of faces F of G where face f_i is adjacent to face f_2 if and only if f_1 and f_2 share a common edge in G. For the purpose of this example a cut of a graph G is defined as a set of edges which disconnects G.
Let us construct a small planar graph G and its dual D. For clarity, the support of D will be the standard support (we could have chosen it to be the set of faces of G).

```
> G := MultiGraph< 4 | {1, 2}, {1, 2}, {1, 3}, {2, 3}, {2, 4}, {3, 4}>;
> IsPlanar(G);
true
> Faces(G);
[
  [ < {1, 3}, 5 >, < {3, 2}, 7 >, < {2, 1}, 3 > ],
  [ < {1, 2}, 3 >, < {2, 1}, 1 > ],
  [ < {1, 2}, 1 >, < {2, 4}, 9 >, < {4, 3}, 11 >, < {3, 1}, 5 > ],
  [ < {3, 4}, 11 >, < {4, 2}, 9 >, < {2, 3}, 7 > ]
]
> F := {@ SequenceToSet(f) : f in Faces(G) @};
> D := MultiGraph< #F | >;
> mapG2D := [ 0 : i in [1..Max(Indices(G))] ];
> mapD2G := [ 0 : i in [1..Max(Indices(G))] ];
> for u in VertexSet(D) do
>     for v in VertexSet(D) do
>        if Index(v) le Index(u) then
>           continue;
>        end if;
>        M := F[ Index(u) ] meet F[ Index(v) ];
>        for e in M do
>           D, edge :=
>           AddEdge(D, VertexSet(D)!u, VertexSet(D)!v);
>
>           mapG2D[Index(e)] := Index(edge);
>           mapD2G[Index(edge)] := Index(e);
>        end for;
>     end for;
> end for;
>
```

```
> e_star := map< EdgeSet(G) -> EdgeSet(D) |
> x :-> EdgeSet(D).mapG2D[Index(x)],
> y :-> EdgeSet(G).mapD2G[Index(y)] >;
```

The map `e-star` is the bijection from G's edge-set into D's edge-set:

```
> for e in EdgeSet(G) do
>     e, "   ", e @ e_star;
> end for;
< {1, 3}, 5 >     < {1, 3}, 3 >
< {1, 2}, 3 >     < {1, 2}, 1 >
< {1, 2}, 1 >     < {2, 3}, 7 >
< {2, 4}, 9 >     < {3, 4}, 11 >
< {2, 3}, 7 >     < {1, 4}, 5 >
< {3, 4}, 11 >     < {3, 4}, 9 >
>
> for e in EdgeSet(D) do
>     e, "   ", e @@ e_star;
> end for;
< {1, 4}, 5 >     < {2, 3}, 7 >
< {1, 3}, 3 >     < {1, 3}, 5 >
< {1, 2}, 1 >     < {1, 2}, 3 >
< {2, 3}, 7 >     < {1, 2}, 1 >
< {3, 4}, 11 >     < {2, 4}, 9 >
< {3, 4}, 9 >     < {3, 4}, 11 >
```

If G is biconnected, then any of its faces is bounded by a cycle. From Euler's formula giving the number of faces in a graph, we deduce that the boundaries of the internal faces of G, which form a chordless cycle, form a basis for the cycle space of G.
It is a well-known fact that, if G is connected and planar, a set of edges E is the set of edges of a cycle in G if and only if $E^* = \{e^* : e \in E\}$ is a minimal cut in D. For more details, see [Die00, $ 4].
From this we conclude that we can compute the minimal cuts generating the cut space of the dual graph D. We verify that G is biconnected, we compute the cut corresponding to each face of G, and verify that it is a minimal cut. All the cuts together form a generating set of the cut space of D. Had we not included the cut corresponding to the external face of G, we would have a basis of the cut space.

```
> IsBiconnected(G);
true
> for f in F do
>     Cut := { e @ e_star : e in f };
>     H := D;
>     RemoveEdges(~H, Cut);
>     assert not IsConnected(H);
>
>     for e in Cut do
>        C := Exclude(Cut, e);
>        H := D;
>        RemoveEdges(~H, C);
```

```
>         assert IsConnected(H);
>     end for;
> end for;
```

150.12 Distances, Shortest Paths and Minimum Weight Trees

Two standard algorithms have been implemented for finding single-source shortest paths in weighted graphs. One is Dijsktra's algorithm for graphs without negative weight cycles, the second is Bellman-Ford's for those graphs with negative weight cycles. Dijsktra's algorithm is implemented either by a priority queue (binary heap) or a Fibonacci heap. The Fibonacci heap is asymptotically faster for sparse graphs. But for most practical purposes (graphs of small order) the binary heap outperforms the Fibonacci heap and is therefore chosen as the default data structure wherever relevant.

Johnson's algorithm has been chosen for the all-pairs shortest paths computation. Indeed, it outperforms the simpler Floyd's algorithm, especially as the graphs get larger.

Finally, Prim's algorithm is used to implement the minimum weight tree computation for undirected graphs. (The tree is a spanning tree if and only if the graph is connected.)

All the functions described below apply to general graphs whose edges are assigned a weight. If the graph under consideration is not weighted, then all its edges are assumed to have weight one. To assign weights to the edges of a graph, see Subsection 150.4.2. Note that all the functions described below accept negatively weighted edges.

`Reachable(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Return `true` if and only there is a path from vertex u to vertex v. If true, also returns the distance between u and v.

`Distance(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given vertices u and v in a graph G, computes the distance from u to v. Results in an error if there is no path in G from u to v.

`Distances(u : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given a vertex u in a graph G, computes the sequence D of distances from u to v, v any vertex in G. Given any vertex v in G, let i be `Index(v)`. Then $D[i]$, if defined, is the distance from u to v. If there is no path from u to v, then the sequence element $D[i]$ is undefined.

`PathExists(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Return `true` if and only there is a path from vertex u to vertex v in the parent graph G. If so, also returns a shortest path from u to v as a sequence of edges of G.

`Path(u, v : parameters)`

`ShortestPath(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given vertices u and v in a graph G, computes a shortest path from u to v as a sequence of edges of G. Results in an error if there is no path in G from u to v.

`Paths(u : parameters)`

`ShortestPaths(u : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given a vertex u in a graph G, computes the sequence P of shortest paths from u to v, for every vertex v in G. Given any vertex v in G, let i be `Index(v)`. If there exists a path from u to v then $P[i]$ is a sequence of edges giving a shortest path from u to v. If there is no path from u to v, then the sequence element $P[i]$ is undefined.

`GeodesicExists(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Return `true` if and only there is a path from vertex u to vertex v in the parent graph G. If true, also returns a shortest path from u to v as a sequence of vertices of G.

`Geodesic(u, v : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given vertices u and v in a graph G, this function computes a shortest path from u to v as a sequence of vertices of G. An error results if there is no path in G from u to v.

`Geodesics(u : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Given a vertex u in a graph G, this function computes the sequence P of shortest paths from u to v, for every vertex v in G. Given any vertex v in G, let i be `Index(v)`. If there exists a path from u to v then $P[i]$ is a sequence of vertices specifying a shortest path from u to v. If there is no path from u to v, then the sequence element $P[i]$ is undefined.

`HasNegativeWeightCycle(u : parameters)`

Return `true` if and only if there is a negative-weight cycle reachable from vertex u.

`HasNegativeWeightCycle(G)`

Return `true` if and only if the graph G has negative-weight cycles.

`AllPairsShortestPaths(G : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Computes the all-pairs shortest paths. Let u and v be two vertices of a graph G and let $i = Index(u)$ and $j = Index(v)$. Let S_1 and S_2 be the two sequences returned by `AllPairsShortestPaths`, and let $s_1 = S_1[i]$ and $s_2 = S_2[i]$. Then $s_1[j]$, if defined, gives the distance from u to v and $s_2[j]$, if defined, gives the vertex preceding v in the shortest path from u to v. An error results if the graph G has a negative-weight cycle.

`MinimumWeightTree(u : parameters)`

`UseFibonacciHeap` BOOL *Default :* `false`

Returns a minimum weight tree rooted at vertex u, u any vertex of an *undirected* graph G, as a subgraph of G. The tree spans G if and only if G is connected. The support of G as well as the vertex and edge decorations in G *are* transferred to the tree.

Example H150E12

We create a weighted multidigraph.

```
> G := MultiDigraph< 5 | [1, 2], [1, 2], [1, 3], [2, 4], [3, 5], [3, 4], [4, 5] >;
> E := EdgeSet(G);
> AssignWeight(~G, E.1, 1);
> AssignWeight(~G, E.2, 5);
> AssignWeight(~G, E.3, 10);
> AssignWeight(~G, E.4, 1);
> AssignWeight(~G, E.5, -5);
> AssignWeight(~G, E.6, 1);
> AssignWeight(~G, E.7, 2);
>
>
> V := VertexSet(G);
> E := EdgeSet(G);
> for e in E do
>     e, "  ", Weight(e);
> end for;
< [1, 3], 3 >    10
< [1, 2], 2 >    5
< [1, 2], 1 >    1
< [2, 4], 4 >    1
< [3, 4], 6 >    1
< [3, 5], 5 >    -5
```

```
< [4, 5], 7 >    2
```

We verify that it has no negative weight cycle reachable from vertex 1, and that there is a path from vertex 1 to vertex 5.

```
> HasNegativeWeightCycle(V!1);
false
> b, d := Reachable(V!1, V!5);
> assert b;
> P := Path(V!1, V!5);
> G := Geodesic(V!1, V!5);
>
> d;
4
> P;
[ < [1, 2], 1 >, < [2, 4], 4 >, < [4, 5], 7 > ]
> G;
[ 1, 2, 4, 5 ]
```

Finally, we verify that the shortest path found has length 4.

```
> dP := 0;
> for e in P do
>     dP +:= Weight(e);
> end for;
> assert dP eq d;
```

Note that had we taken instead an undirected graph, we would have had to assign only positive weights to the edges of the graph: any undirected edge $\{u, v\}$ with negative weight results in the negative weight cycles $\{u, u\}$ and $\{v, v\}$.

Example H150E13

We create a weighted multigraph with one edge assigned a negative weight.

```
> G := MultiGraph< 5 | {1, 2}, {1, 2}, {1, 3}, {2, 4}, {3, 5}, {3, 4}, {4, 5} >;
> E := EdgeSet(G);
> AssignWeight(~G, E.1, 1);
> AssignWeight(~G, E.3, 5);
> AssignWeight(~G, E.5, 10);
> AssignWeight(~G, E.7, 1);
> AssignWeight(~G, E.9, -5);
> AssignWeight(~G, E.11, 1);
> AssignWeight(~G, E.13, 2);
>
> V := VertexSet(G);
> E := EdgeSet(G);
> for e in E do
>     e, "  ", Weight(e);
> end for;
< {1, 3}, 5 >    10
```

```
< {1, 2}, 3 >    5
< {1, 2}, 1 >    1
< {2, 4}, 7 >    1
< {3, 4}, 11 >    1
< {3, 5}, 9 >    -5
< {4, 5}, 13 >    2
```

We compute a minimum weight spanning tree rooted at vertex 1.

```
> T := MinimumWeightTree(V!1);
> ET := EdgeSet(T);
> for e in ET do
>     e, "  ", Weight(e);
> end for;
< {1, 2}, 1 >    1
< {2, 4}, 5 >    1
< {3, 5}, 7 >    -5
< {3, 4}, 3 >    1
```

We compute any other spanning tree rooted at vertex 1 (say a depth first tree using DFSTree), and verify that the weights of the edges in G corresponding to the edges of the tree sum up to a total weight which is no smaller than the weight of the minimum weight spanning tree.

```
> DFST := DFSTree(V!1);
> EDT := EdgeSet(DFST);
> for e in EDT do
>     u := InitialVertex(e);
>     v := TerminalVertex(e);
>     w := Min([ Weight(edge) : edge in Edges(V!u, V!v) ]);
>     e, "  ", w;
> end for;
< {1, 3}, 1 >    10
< {2, 4}, 7 >    1
< {3, 4}, 3 >    1
< {4, 5}, 5 >    2
```

151 NETWORKS

Chapter 151
NETWORKS

151.1 Introduction

Networks are an essential tool in modelling communication systems and dependence problems. A network is generally defined as a directed graph whose arcs are associated with a cost and a capacity; it may have multiple (i.e., parallel) edges.

The fundamental network flow problem is the minimum cost flow problem, that is, determining a maximum flow at minimum cost from a specified source to a specified sink. Specializations of this problem are the shortest path problem (where there is no capacity constraint) and the maximum flow problem (where there is no cost constraint). Some of the related problems are the minimum spanning tree problem (finding a spanning tree whose sum of the costs of its arcs is minimum), the matching problem (a pairing of the edges of the graph according to some criteria), and the multicommodity flow problem (where arcs may carry several flows of different nature). For a comprehensive monograph on networks, their implementation and applications, see [RAO93].

For convenience we provide users with the MAGMA network object with type `GrphNet`. It differs from the MAGMA multidigraph object having type `GrphMultDir` in one respect only: its edges are always assumed to be capacitated. The edges of a network have a capacity of one by default, unless they are specifically assigned a capacity. The loops in a network always have capacity zero. Since networks are a specialisation of multidigraphs, all the functions applying to multidigraphs also apply to networks. Below we outline those few functions that specifically concern networks, namely, their construction.

151.2 Construction of Networks

Networks are constructed in a similar way to multidigraphs (Subsection 150.2.2). In this implementation the order n of a network is bounded by 134217722. See Section 149.2.1 for more details on this.

Let N be the network to be constructed. In all cases, whenever an edge $[u, v]$, $u \neq v$, is to be added to N, its capacity will be set to 1 (0 if a loop) unless either its capacity is explicitly given at construction time, or it is the edge of a network, in which case the capacity of the edge remains as it was in the original network.

As an example, if D is a digraph, then the edges of the network N constructed as `N := Network< Order(D) | D >;` will be all the edges of D whose capacity is set as 1 (or 0 if they are loops).

`Network< n | edges >`

`Network< S | edges >`

Construct the network N with vertex-set $V = \{@v_1, v_2, \ldots, v_n@\}$ (where $v_i = i$ for each i if the first form of the constructor is used, or the ith element of the enumerated or indexed set S otherwise), and edge-set $E = \{e_1, e_2, \ldots, e_q\}$. This function returns three values: The network N, the vertex-set V of N; and the edge-set E of N.

The elements of E are specified by the list *edges*, where the items of *edges* may be objects of the following types:

(a) A pair $[v_i, v_j]$ of vertices in V. The directed edge $[v_i, v_j]$ from v_i to v_j with capacity 1 (or 0 if it is a loop) will be added to the edge-set for N.

(b) A tuple of the form $\langle v_i, N_i\rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i. The elements of the sets N_i must be elements of V. If $N_i = \{u_1, u_2, \ldots, u_r\}$, the edges $[v_i, u_1], \ldots, [v_i, u_r]$ will be added to N, all with capacity 1 (or 0 if they are loops).

(c) A tuple of the form $\langle [v_i, v_j], c\rangle$ where v_i, v_j are vertices in V and c the non-negative capacity of the directed edge $[v_i, v_j]$ added to N.

(d) A sequence $[N_1, N_2, \ldots, N_n]$ of n sets, where N_i will be interpreted as a set of out-neighbours for the vertex v_i. All the edges $[v_i, u_i]$, $u_i \in N_i$, are added to N with capacity 1 (or 0 if they are loops).

In addition to these four basic ways of specifying the *edges* list, the items in *edges* may also be:

(e) An edge e of a graph (or di/multi/multidigraph) or network of order n. If e is an edge of a network H, then it will be added to N with the capacity it has in H. If e is not a network edge, then it will be added to N with capacity 1, or 0 if it is a loop.

(f) An edge-set E of a graph (or di/multi/multidigraph) or network of order n. Every edge e in E will be added to N according to the rule set out for a single edge.

(g) A graph (or di/multi/multidigraph) or network H of order n. Every edge e in H's edge-set is added to N according to the rule set out for a single edge.

(h) A $n \times n$ (0, 1)-matrix A. The matrix A will be interpreted as the adjacency matrix for a digraph H on n vertices and the edges of H will be included among the edges of N with capacity 1 (0 if loops).

(i) A set of

  (i) Pairs of the form $[v_i, v_j]$ of vertices in V.

  (ii) Tuples of the form $\langle v_i, N_i\rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

  (iii) A tuple of the form $\langle [v_i, v_j], c\rangle$ where v_i, v_j are vertices in V and c a non-negative capacity.

(iv) Edges of a graph (or di/multi/multidigraph) or network of order n.

(v) Graphs (or di/multi/multidigraphs) or networks of order n.

(j) A sequence of

(i) Tuples of the form $\langle v_i, N_i \rangle$ where N_i will be interpreted as a set of out-neighbours for the vertex v_i.

(ii) A tuple of the form $\langle [v_i, v_j], c \rangle$ where v_i, v_j are vertices in V and c a non-negative capacity.

Example H151E1

We construct a network from a digraph, and observe that the edges that are not loops have a capacity of 1:

```
> SetSeed(1, 0);
> n := 5;
> d := 0.2;
> D := RandomDigraph(n, d : SparseRep := true);
> N := Network< n | D >;
> D;
Digraph
Vertex  Neighbours
1       2 1 ;
2       3 2 ;
3       ;
4       5 ;
5       2 ;
> N;
Network
Vertex  Neighbours
1       1 [ 0 ] 2 [ 1 ] ;
2       2 [ 0 ] 3 [ 1 ] ;
3       ;
4       5 [ 1 ] ;
5       2 [ 1 ] ;
```

151.2.1 Magma Output: Printing of a Network

MAGMA displays a network N in the form of a list of vertices, each accompanied by a list of its outgoing capacitated edges (each followed by the capacity of the edge in brackets). Thus, in the previous example H151E1, it can be verified that all edges have capacity 1 (since the network was constructed from a digraph) except those edges that are loops.

If the network has multiple edges from u to v, then *each* edge from u to v, or rather its end-point v, is printed followed by the capacity of that edge. Also, the end-points in the adjacency list are not ordered and appear in the order in which they were created. The next example illustrates these two points.

Example H151E2

We construct a network from a set of tuples $< [vertex, vertex], capacity >$ and we exhibit a multiple edge.

```
> n := 5;
> C := 5;
> M := 3;
> T := [];
> for i in [1..12] do
>     u := Random(1, n);
>     v := Random(1, n);
>     m := Random(1, M);
>     for j in [1..m] do
>        c := Random(0, C);
>        if u eq v then
>            Append(~T, < [u, u], 0 >);
>        else
>            Append(~T, < [u, v], c >);
>        end if;
>     end for;
> end for;
> T;

151.3 Standard Construction for Networks

151.3.1 Subgraphs

The construction of a sub-network is very similar to the construction of a sub-multidigraph (see Subsection 150.5.1). Additional flexibility is available for setting edge capacities in the subgraph.

There are two constraints when building a subgraph (see the introduction to Section 150.7). Let N be a network, and H a subgraph of N. Then, given any vertices u, v of H, the edge multiplicity from u to v is no greater in H than it is in N, and the total capacity from u to v in H is no greater than the total capacity from u to v in N. Failure to satisfy these constraints will result in a run-time error when constructing a sub-network.

Assume that we intend to add an edge from u to v in H. Assume also that the total capacity from u to v in N is C_N, that the total capacity from u to v in H is C_H before adding the edge from u to v in H, and that the total capacity from u to v in H is C'_H after adding the edge from u to v in H. In order to satisfy the "capacity constraint" it is enough that $C'_H \leq C_N$, i.e. that $C_H + c \leq C_N$ where c is the capacity of the edge one wants to add in H.

There are two methods for adding an edge from u to v. Firstly, adding the edge $[u, v]$ to H without specifying its capacity in H assumes that the edge $[u, v]$ will be added with capacity C_N. This implies that C_H is zero, since we require that $C_H + C_G \leq C_N$. Secondly, adding the edge $[u, v]$ to H when specifying its capacity as c assumes that the edge $[u, v]$ will be added with capacity c such that $C_H + c \leq C_N$.

Note that the support set, vertex labels and edge labels and weights, if applicable, are transferred from the network to the sub-network.

`sub< N | list >`

Construct the network H as a subgraph (sub-network) of N. The function returns three values: The network H, the vertex-set V of H; and the edge-set E of H. If N has a support set and/or if N has vertex/edge labels, and/or edge weights then *all* these attributes are transferred to the subgraph H. Edge capacities are also transferred to H unless they are specifically set as explained below.

The elements of V and of E are specified by the list *list* whose items can be objects of the following types:

(a) A vertex of N. The resulting subgraph will be the subgraph induced on the subset of `VertexSet(`N`)` defined by the vertices in *list*.

(b) An edge of N. The resulting subgraph will be the subgraph with vertex-set `VertexSet(`N`)` whose edge-set consists of the edges in *list* subject to the multiplicity and capacity constraints being satisfied.

(c) A pair of $[v_i, v_j]$ of vertices of N. The resulting subgraph will be the subgraph with vertex-set `VertexSet(`N`)` whose edge-set consists of the edges $[v_i, v_j]$ in *list* whose capacity is assumed to be the total capacity from v_i to v_j in N. The multiplicity and capacity constraints must be satisfied.

(d) A tuple of the form $< [v_i, v_j], c >$ where v_i, v_j are vertices of N and c the non-negative capacity of the edge $[v_i, v_j]$ to be added to H. The resulting subgraph will be the subgraph with vertex-set `VertexSet(`N`)` whose edge-set consists of the edges as they are given in *list*, subject to the multiplicity and capacity constraints being satisfied.

(e) A set of

(i) Vertices of N.

(ii) Edges of N.

(iii) Pairs of vertices of N.

(iv) Tuples of the form $< [v_i, v_j], c >$ where v_i, v_j are vertices of N and c the non-negative capacity of the edge $[v_i, v_j]$ to be added to H.

Example H151E3

We start by constructing a network with some multiple edges.

```
> N := Network< 4 |
> < [1, 2], 2 >, < [1, 2], 3 >, < [1, 4], 5 >,
> < [2, 3], 1 >, < [2, 3], 3 >, < [3, 4], 1 >, < [3, 4], 6 > >;
> N;
Network
Vertex  Neighbours
1       4 [ 5 ] 2 [ 3 ] 2 [ 2 ] ;
2       3 [ 3 ] 3 [ 1 ] ;
3       4 [ 6 ] 4 [ 1 ] ;
4       ;
> V := VertexSet(N);
> E := EdgeSet(N);
```

We construct a subgraph H of N induced by some of N's vertices and we obtain the mapping from the vertices of N to the vertices of H and vice-versa.

```
> H := sub< N | V!1, V!3, V!4 >;
> assert IsSubgraph(N, H);
> H;
Network
Vertex  Neighbours
1       3 [ 5 ] ;
2       3 [ 1 ] 3 [ 6 ] ;
3       ;
> V!VertexSet(H)!1, VertexSet(H)!V!1;
1 1
> V!VertexSet(H)!2, VertexSet(H)!V!3;
```

```
3 2
> V!VertexSet(H)!3, VertexSet(H)!V!4;
4 3
```

The next statements illustrate the "capacity constraint": That is, given any pair $[u, v]$ of vertices of H, H a subgraph of N, the total capacity from u to v in H can not be greater than the total capacity from u to v in N. The subgraph constructor will fail whenever this rule cannot be satisfied. We give a few examples below.

```
> Edges(N);
{@ < [1, 2], 1 >, < [1, 2], 2 >, < [1, 4], 3 >, < [2, 3], 4 >, < [2, 3], 5 >,
< [3, 4], 6 >, < [3, 4], 7 > @}
> E.1, E.2;
< [1, 2], 1 > < [1, 2], 2 >
> Capacity(E.1);
2
> Capacity(E.2);
3
> Capacity(V!1, V!2);
5
>
> H := sub< N | E.1, E.1 >;
> H;
Network
Vertex  Neighbours
1       2 [ 2 ] 2 [ 2 ] ;
2       ;
3       ;
4       ;
```

Adding twice the edge $E.1$ to H is a valid operation since the resulting total capacity from 1 to 2 in H is 4 while it is 5 in N.

```
>  > H := sub< N | E.2, E.2 >;
>> H := sub< N | E.2, E.2 >;
           ^
Runtime error in sub< ... >: RHS argument 2 - Edge multiplicity and capacity
not compatible with subgraph constructor
>
```

Adding twice the edge $E.2$ (which has capacity 3) to H would have resulted in the total capacity from 1 to 2 in H to be 6, while it is 5 in N.

```
> H := sub< N | E!< [1, 2], 1 >, E!< [1, 2], 1 > >;
> H;
Network
Vertex  Neighbours
1       2 [ 2 ] 2 [ 2 ] ;
2       ;
3       ;
```

```
4       ;
```

This succeeded since the total capacity from 1 to 2 in H is now 4.

```
>  > H := sub< N | E!< [1, 2], 2 >, E!< [1, 2], 2 > >;
>> H := sub< N | E!< [1, 2], 2 >, E!< [1, 2], 2 > >;
           ^
Runtime error in sub< ... >: RHS argument 2 - Edge multiplicity and capacity
not compatible with subgraph constructor
>
```

Again, this operation failed as it would have resulted in the total capacity from 1 to 2 in H to be 6.

```
> H := sub< N | < [ V!1, V!2 ], 2 >, < [ V!1, V!2 ], 2 > >;
> H;
Network
Vertex  Neighbours
1       2 [ 2 ] 2 [ 2 ] ;
2       ;
3       ;
4       ;
```

This operation is valid since the total capacity from 1 to 2 in H is now 4.

```
>  > H := sub< N | < [ V!1, V!2 ], 2 >, < [ V!1, V!2 ], 4 > >;
>> H := sub< N | < [ V!1, V!2 ], 2 >, < [ V!1, V!2 ], 4 > >;
           ^
Runtime error in sub< ... >: RHS argument 2 - Tuple must be <[vertex,
vertex], capacity> with total edge multiplicity and capacity compatible with
subgraph constructor
>
```

This operation cannot succeed as the total capacity from 1 to 2 in H would be 6.

```
> H := sub< N | [ V!1, V!2 ] >;
> H;
Network
Vertex  Neighbours
1       2 [ 5 ] ;
2       ;
3       ;
4       ;
```

Adding the edge $[1, 2]$ without specifying its capacity implies that an edge from 1 to 2 is added with capacity 5 to H, which is the total capacity from 1 to 2 in N.

```
>  > H := sub< N | [ V!1, V!2 ], [ V!1, V!2 ] >;
>> H := sub< N | [ V!1, V!2 ], [ V!1, V!2 ] >;
           ^
Runtime error in sub< ... >: RHS argument 2 - Sequence must be
[vertex, vertex] with vertices of the LHS and must be unique
```

```
>
```

Adding twice the edge $[1, 2]$ without specifying its capacity would have resulted in the total capacity from 1 to 2 in H to be 10. This operation cannot succeed. Finally, let us illustrate the edge multiplicity constraint.

```
>  > H := sub< N | E.4, E.4, E.4 >;
>> H := sub< N | E.4, E.4, E.4 >;
           ^
Runtime error in sub< ... >: RHS argument 3 - Edge multiplicity and capacity
not compatible with subgraph constructor
>
```

Although the above statement satisfies the capacity constraint

```
> Capacity(E.4);
1
> Capacity(V!InitialVertex(E.4), V!TerminalVertex(E.4));
4
```

it cannot succeed since the edge multiplicity constraint is violated.

```
> EdgeMultiplicity(V!InitialVertex(E.4), V!TerminalVertex(E.4));
2
```

151.3.2 Incremental Construction: Adding Edges

Almost all the functions to add or remove either vertices or edges that are available for multidigraphs also apply to networks; they are not listed here, see Section 150.5.2 for details.

The only exception is the function `AddEdge(G, u, v, l)` which differs for multidigraphs and networks. It is replaced by the functions `AddEdge(G, u, v, c)` and `AddEdge(G, u, v, c, l)` which are specialised functions for adding capacitated edges to networks. There are a few more such specialised functions which are listed below, they all concern adding edges to a network.

Note that whenever an edge is added to a network using the general multidigraph functions, which do not allow specifying an edge capacity, the edge to be added is *always taken to have capacity 1 (or 0 if a loop).*

`N + < [ u, v ], c >`

Given two vertices u and v of a network N, and c a non-negative integer, adds an edge from u to v with capacity c. The support and edge capacities are retained. This function returns two values: The modified network, and the edge newly created (added). This feature is especially useful when adding parallel edges.

`N + { < [ u, v ], c > }`

`N + [ < [ u, v ], c > ]`

Given tuples of the form $< [u, v], c >$, u and v vertices of the network N and c a non-negative integer, adds the edges from u to v with capacity c. Tuples can be contained in a set or a sequence; the latter is useful when dealing with duplicates. The support and edge capacities are retained.

`N +:= < [ u, v ], c >`

`N +:= { < [ u, v ], c > }`

`N +:= [ < [ u, v ], c > ]`

The procedural versions of the previous three functions. Tuples can be contained in a set or a sequence; the latter is useful when dealing with duplicates.

`AddEdge(N, u, v, c)`

Given two vertices u and v of the network N, and c a non-negative integer, adds an edge from u to v with capacity c. The support and edge capacities are retained. This function returns the modified network and the newly created edge. This feature is especially useful when adding parallel edges.

`AddEdge(N, u, v, c, l)`

Given two vertices u and v of the network N, c a non-negative integer, and a label l, adds an edge from u to v with capacity c and label l. The support and edge capacities are retained. This function returns the modified network and the newly created edge. This feature is especially useful when adding parallel edges.

`AddEdges(N, S)`

Given a network N and a set or a sequence S of tuples, this function includes the edges specified in S. The tuples must be of the form $< [u, v], c >$, where u and v vertices of N and c a non-negative integer. The support and existing vertex and edge decorations are retained.

`AddEdge(~N, u, v, c)`

`AddEdge(~N, u, v, c, l)`

`AddEdges(~N, S)`

Procedural versions of previous functions adding edges to a network. Tuples can be contained in a set or a sequence; the latter is useful when dealing with duplicates.

151.3.3 Union of Networks

It is possible to construct a new network from the union of two networks. For more details, we refer the reader to Subsection 150.5.4.

151.4 Maximum Flow and Minimum Cut

All the functions described in this section apply to general graphs whose edges are given a capacity, that is, networks. If the graph under consideration is not capacitated, then all its edges are assumed to have capacity one. To assign capacities to the edges of a graph, see Subsection 150.4.2. To create a MAGMA network object (with type `GrphNet`) see Section 151.2.

The fundamental network flow problem is the minimum cost flow problem, that is, determining a maximum flow at minimum cost from a specified source to a specified sink. Specializations of this problem are the shortest path problem (where there is no capacity constraint) which is covered in Section 150.12, and the maximum flow problem (where there is no cost constraint). Some of the related problems are the minimum spanning tree problem, the matching problem (a pairing of the edges of the graph according to some criteria), and the multicommodity flow problem (where arcs may carry several flows of different nature). For a comprehensive monograph on network problems, their implementation and applications, see [RAO93].

Let G be a general graph or multigraph whose edges are capacitated. If G is undirected then consider any edge $\{u, v\}$ with capacity c as being equivalent to two directed edges $[u, v]$ and $[v, u]$, both with capacity c. We may thus assume without loss of generality that G is directed, and from now on G is called a network. Let V and E be G's vertex-set and edge-set respectively, and for every edge $[u, v]$ in G, denote its capacity by $c(u, v)$. If there is no edge $[u, v]$ in E we assume that $c(u, v) = 0$. By convention the capacity of an edge is a non-negative integer.

Distinguish two vertices of G, the *source* s and the *sink* t. A *flow* in G is an integer-valued function $f : V \times V \to \mathbf{Z}$ that satisfies the following properties:

(i) Capacity constraint: $\forall u, v \in V,\ f(u, v) \leq c(u, v)$.

(ii) Skew symmetry: $\forall u, v \in V,\ f(u, v) = -f(v, u)$.

(iii) Flow conservation: $\forall u \in V \setminus \{s, t\},\ \sum_{v \in V} f(u, v) = 0$.

Note that the flow could have been defined as a real-valued function if the edge capacity had been defined as real-valued.

The quantity $f(u, v)$, which can be positive or negative, is called the *net flow* from vertex u to vertex v. The *value* of a flow f is defined as $F = \sum_{v \in V} f(s, v)$, that is, the total net flow out of the source.

In the *maximum flow problem* we wish to find a flow of maximum value from s to t. A *cut* of the network G with source s and sink t is a partition of V into S and T such that $s \in S$ and $t \in T$. The *capacity* of the cut $c(S)$ determined by S is the sum of the capacity $c(u, v)$ of the edges $[u, v]$ such that $u \in S$ and $v \in T$. It is easy to see that $F \leq c(S)$, that is, the value of the flow from s into t cannot be larger than the capacity of any cut defined by s and t. In fact, $F = c(S)$ if and only if F is a maximum flow and S is a cut of minimum capacity.

We have implemented two algorithms for finding the maximum flow in a network G from a source s to a sink t. One is the Dinic algorithm, the other is an instance of the

generic push-relabel algorithm. We have already encountered both algorithms in Subsections 149.13.4 and 149.13.5.

The Dinic algorithm

The Dinic algorithm consists of two phases. In the first phase, one constructs a layered network which consists of all the "useful" edges of G: A useful edge $[u, v]$ has the property that $f(u, v) < c(u, v)$. The first and the last layer of this layered network always contain s and t respectively. If such a layered network cannot be constructed then the flow in G is maximum and the algorithm ends.

In the second phase of the Dinic algorithm, one finds a maximal flow by constructing paths from s to t (using a depth-first search) in the layered network. Note that a maximal flow may not be maximum: A maximal flow satisfies the condition that for every path P from s to t in the layered network, there is at least a *saturated* edge in P. A saturated edge is one for which its flow equals its capacity. For more details on the Dinic algorithm, see [Eve79].

The Dinic algorithm has a theoretical complexity of $\mathrm{O}(|V|^2|E|)$, which can be improved to $\mathrm{O}(|E|^{3/2})$ if G is a zero-one network (the capacities of the edges are either 0 or 1), or $\mathrm{O}(|V|^{2/3}|E|)$ if G is a zero-one network with no parallel edges. Prior to the advent of the push-relabel method (which we describe below), the Dinic algorithm was shown to be superior in practice to other methods. The MAGMA implementation of the Dinic algorithm only outperforms the push-relabel method for very sparse networks (a small number of edges relative to the number of vertices) whose edges have a small capacity and where the maximum flow is small. In other words, the Dinic method performs best on zero-one and very sparse networks.

The push-relabel method

The generic push-relabel algorithm does not construct a flow by constructing paths from s to v. Rather, it starts by pushing the maximum possible flow out from the source s into the neighbours of s, then pushing the excess flow at those vertices into their own neighbours. This is repeated until all vertices of G except s and t have an excess flow of zero (that is, the flow conservation property is satisfied). Of course this might mean that some flow is pushed back into s.

At initialisation all vertices are given a height of 0 except s which will have height $|V|$, and flow is pushed out of s. The maximum flow that can be pushed out of s is $\sum_{v \in V} c(s, v)$. The idea is to push flow into vertices only in a "downward" manner, that is, from a vertex with height $h + 1$ into a vertex with height h. If a vertex in $V \setminus \{s, t\}$ has height h, it will be relabelled if it has an excess flow and none of its neighbours to which some flow could be pushed has height $h - 1$. Its new label (height) will be $l + 1$ where l is the height of the lowest labelled neighbour towards which flow can be pushed. Flow may only be pushed along an edge $[u, v]$ while the capacity constraint $f(u, v) \leq c(u, v)$ is satisfied.

So the general notion is of pushing flow "downward" and "discharging" the vertices in $V \setminus \{s, t\}$ from all non-zero excess flow they may have accumulated, a process which may require "lifting" some vertices so that discharging can proceed. It is easy to show that the

height of any vertex in $V \setminus \{s, t\}$ is bounded by $2|V| - 1$, so the algorithm must terminate. When this happens, the flow is at a maximum.

The theoretical complexity of the generic push-relabel algorithm is $O(|V|^2|E|)$ which can be improved to at least $O(|V||E| \log(|V|^2/|E|)$ thanks to some heuristics.

One commonly used heuristic is the *global relabelling* procedure whereby the vertices in $V \setminus \{s, t\}$ are pre-labelled according to their distance from the sink. Global relabelling may occur at specified intervals during execution. Another very useful heuristic is *gap relabelling* which involves recognising those vertices that have become unreachable from the sink and labelling them accordingly so that they won't be chosen during later execution. Finally, another heuristic involves the order in which the vertices to be discharged are processed.

When G is a one-zero network, choosing the vertex with smallest height works best, while choosing the vertex with largest height is recommended for general networks. These heuristics are fully described and analysed by B.V. Cherkassky and A.V. Goldberg *et al.* in [CGM+98] and [CG97]. The MAGMA implementation incorporates all the above heuristics together with some new ones.

As a rule, whenever the push-relabel algorithm is applied to a zero-one network (such as occurs when computing the connectivity of a graph in 149.13.5 or finding a maximum matching in a bipartite network in 149.13.4) the vertex with smallest height is chosen as the next vertex to be processed. When the algorithm is used to compute a maximum flow in a network (as below) the vertex with largest height is chosen.

For the two functions `MinimumCut` and `MaximumFlow` described below, the `PushRelabel` algorithm is used. It is only in the case of a very sparse zero-one network that `Dinic` may outperform `PushRelabel`.

`MinimumCut(s, t` : *parameters*)

`Al` MONSTGELT *Default :* "*PushRelabel*"

Given vertices s and t of a network G, this function returns the subset S defining a minimum cut $\{S, T\}$ of V, where $s \in S$, $t \in T$, corresponding to the maximum flow F from s to t. The subset S is returned as a sequence of vertices of G. The maximum flow F is returned as a second value. The parameter `Al` enables the user to select the algorithm to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`MinimumCut(Ss, Ts` : *parameters*)

`Al` MONSTGELT *Default :* "*PushRelabel*"

Given two sequences S_s and T_s of vertices of a network G, this function returns the subset S defining a minimum cut $\{S, T\}$ of V, such that $S_s \subseteq S$ and $T_s \subseteq T$, and which corresponds to the maximum flow F from the vertices in S_s to the vertices in T_s. The subset S is returned as a sequence of vertices of G. The maximum flow F is returned as a second value. The parameter `Al` enables the user to select the algorithm to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`MaximumFlow(s, t : parameters)`

`Al` MonStgElt *Default : "PushRelabel"*

Given vertices s and t of a network G, this function returns the maximum flow F from s to t. The subset S defining a minimum cut $\{S, T\}$ of `VertexSet(N)`, $s \in S$, $t \in T$, corresponding to F is returned as the second value. The subset S is returned as a sequence of vertices of G. The parameter `Al` enables the user to select the algorithm to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`MaximumFlow(Ss, Ts : parameters)`

`Al` MonStgElt *Default : "PushRelabel"*

Given two sequences S_s and T_s of vertices of a network G, this function returns the maximum flow F from the vertices in S_s to the vertices in T_s. The subset S defining a minimum cut $\{S, T\}$ of `VertexSet(N)`, $S_s \subseteq S$ and $T_s \subseteq T$, corresponding to F is returned as the second value. The subset S is returned as a sequence of vertices of G. The parameter `Al` enables the user to select the algorithm to be used: `Al := "PushRelabel"` or `Al := "Dinic"`.

`Flow(e)`

Given an edge e in a network G, this function returns the flow of the edge e as an integer. In this instance we require that the edges of G be explicitly assigned capacities (see Subsection 150.4.2 or Section 151.2). Edges of G will carry a flow only if a flow has been constructed from a source to a sink in G. If no such flow has yet been constructed, all edges will have zero flow.

`Flow(u, v)`

Let u and v be adjacent vertices of a network G whose edges have been explicitly assigned capacities (see Subsection 150.4.2 or Section 151.2). `Flow(u, v)` returns the total net flow from u to v as an integer. The total net flow from u to v is defined as the total outgoing flow from u into v minus the total ingoing flow into u from v. Thus the flow satisfies the skew symmetry `Flow(u, v)` = - `Flow(v, u)`.

Edges of G will carry a flow only if a flow has been constructed from a source to a sink in G. If no such flow has yet been constructed, all edges will have zero flow.

Example H151E4

We illustrate the maximum flow algorithm by applying it to find a maximum matching in a bipartite graph. This example exactly replicates the implementation of the maximum matching algorithm (Section 149.13.4).
We construct a bipartite graph.

```
> G := Graph< 7 | [ {5, 7}, {6, 7}, {4, 5, 6},
> {3}, {1, 3}, {2, 3}, {1, 2} ] : SparseRep := true >;
> assert IsBipartite(G);
> P := Bipartition(G);
> P;
[
```

```
  { 1, 2, 3 },
  { 4, 5, 6, 7 }
]
```

We add two extra vertices to G, the source s and the sink t and we construct three sets of pairs of vertices. The first contains all the pairs $[s, u]$ where $u \in P[1]$, the second contains all the pairs $[u, t]$ where $u \in P[2]$, and the third contains all the pairs $[u, v]$ where $u \in P[1]$ and $v \in P[2]$. From these sets we construct a multidigraph with capacitated edges.

```
> G +:= 2;
> G;
Graph
Vertex  Neighbours
1       7 5 ;
2       7 6 ;
3       6 5 4 ;
4       3 ;
5       3 1 ;
6       3 2 ;
7       2 1 ;
8       ;
9       ;
> s := Order(G)-1;
> t := Order(G);
>
> E1 := { [s, Index(u)] : u in P[1] };
> E2 := { [Index(u), t] : u in P[2] };
> E3 := { [Index(u), Index(v)] : u in P[1], v in P[2] };
>
> N := MultiDigraph< Order(G) | E1, E2, E3 >;
> N;
Multidigraph
Vertex  Neighbours
1       7 6 5 4 ;
2       5 4 7 6 ;
3       7 6 5 4 ;
4       9 ;
5       9 ;
6       9 ;
7       9 ;
8       1 3 2 ;
9       ;
> E := EdgeSet(N);
> for e in E do
>     AssignCapacity(~N, e, 1);
```

```
> end for;
```

First note that all the edges of N have been assigned capacity 1. Also, the edges of N are those connecting s to all the vertices in $P[1]$, those connecting all the vertices of $P[2]$ to t, and those connecting all the vertices of $P[1]$ to all the vertices of $P[2]$.
We construct a maximum flow F from s to t and we check that the capacity of the cut is indeed F.

```
> V := VertexSet(N);
> F := MaximumFlow(V!s, V!t);
> S := MinimumCut(V!s, V!t);
> F;
3
> S;
[ 8 ]
>
> c := 0;
> for u in S do
>     for v in OutNeighbours(u) do
>        if not v in S then
>           c +:= Capacity(u, v);
>           assert Capacity(u, v) eq Flow(u, v);
>        end if;
>     end for;
> end for;
> assert c eq F;
```

We now exhibit a matching in G. It will be given by the edges in E_3 which are saturated, that is, whose flow is 1.

```
> M := [];
> for e in E3 do
>     u := V!e[1];
>     v := V!e[2];
>     if Flow(u, v) eq 1 then
>         E := Edges(u, v);
>         assert #E eq 1;
>         Append(~M, EndVertices(E[1]));
>     end if;
> end for;
> assert #M eq F;
> M;
[
  [ 1, 7 ],
  [ 3, 5 ],
  [ 2, 4 ]
```

```
]
```

Note that the statement

```
>         assert #E eq 1;
```

makes sense as the network N has no parallel edges.
We end the example by showing that the capacity constraint and the skew symmetry is satisfied by all edges in the network.

```
> for e in EdgeSet(N) do
>     u := EndVertices(e)[1];
>     v := EndVertices(e)[2];
>
>     assert Flow(u, v) le Capacity(u, v);
>     assert Flow(u, v) eq  -Flow(v, u);
> end for;
```

Also, flow conservation holds for all vertices in $V \setminus \{s, t\}$.

```
> s := V!s;
> t := V!t;
> for u in V do
>     if not u eq s and not u eq t then
>         f := 0;
>         for v in OutNeighbours(u) do
>             E := Edges(u, v);
>             f +:= Flow(E[1]);
>         end for;
>         for v in InNeighbours(u) do
>             E := Edges(v, u);
>             f -:= Flow(E[1]);
>         end for;
>
>         assert f eq 0;
>     end if;
> end for;
```

LINEAR CODES OVER FINITE FIELDS

152.1 Introduction

Let K be a finite field and let V be the vector space of n-tuples over K. The *Hamming-distance* between elements x and y of V, denoted $d(x, y)$, is defined by

$$d(x, y) := \#\{\ 1 \leq i \leq n \mid x_i \neq y_i\ \}.$$

The *minimum distance* d for a subset C of V is then

$$d = \min\{\ d(x, y) \mid x \in C, y \in C, x \neq y\ \}.$$

The subset C of V is called an (n, M, d) *code* if the minimum distance for the subset C is d and $|C| = M$. Then V is referred to as the *ambient space* of C.

The code C is called a $[n, k, d]$ *linear code* if C is a k-dimensional subspace of V. Currently MAGMA supports not only linear codes, but also codes over finite fields which are only linear over some subfield. These are known as *additive codes* and can be found in Chapter 156. This chapter deals only with linear codes.

In this chapter, the term "code" will refer to a linear code. MAGMA provides machinery for studying linear codes over finite fields $F_q = GF(q)$, over the integer residue classes $\mathbf{Z}_m = \mathbf{Z}/m\mathbf{Z}$, and over galois rings $GR(p^n, k)$.

This chapter describes those functions which are applicable to codes over F_q. The highlights of the facilities provided for such codes include:

- The construction of codes in terms of generator matrices, parity check matrices and generating polynomials (cyclic codes).
- A large number of constructions for particular families of codes, e.g., quadratic residue codes.
- Highly optimized algorithms for the calculation of the minimum weight.
- Various forms of weight enumerator including the Macwilliams transform.
- A database that gives the user access to every best known linear code over $GF(2)$ of length up to 256, and 98% of best known linear codes over $GF(4)$ of length up to 100.
- Machinery that allows the user to construct algebraic-geometric codes from a curve defined over F_q.
- The computation of automorphism groups for codes over small fields.

The reader is referred to [MS78] as a general reference on coding theory.

152.2 Construction of Codes

152.2.1 Construction of General Linear Codes

`LinearCode< R, n | L >`

Create a code as a subspace of $V = R^{(n)}$ which is generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) An element of V.

(b) A set or sequence of elements of V.

(c) A sequence of n elements of K, defining an element of V.

(d) A set or sequence of sequences of type (c).

(e) A subspace of V.

(f) A set or sequence of subspaces of V.

Example H152E1

We define the ternary Golay code as a six-dimensional subspace of the vector space $K^{(11)}$, where K is $\mathbf{F}_3$. The ternary Golay code could be defined in a single statement as follows:

```
> K := FiniteField(3);
> C := LinearCode<K, 11 |
>    [1, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1], [0, 1, 0, 0, 0, 0, 0, 1, 2, 2, 1],
>    [0, 0, 1, 0, 0, 0, 1, 0, 1, 2, 2], [0, 0, 0, 1, 0, 0, 2, 1, 0, 1, 2],
>    [0, 0, 0, 0, 1, 0, 2, 2, 1, 0, 1], [0, 0, 0, 0, 0, 1, 1, 2, 2, 1, 0]>;
```

Alternatively, if we want to see the code as a subspace of $K^{(11)}$, we would proceed as follows:

```
> K := FiniteField(3);
> K11 := VectorSpace(K, 11);
> C := LinearCode(sub<K11 |
>    [1, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1], [0, 1, 0, 0, 0, 0, 0, 1, 2, 2, 1],
>    [0, 0, 1, 0, 0, 0, 1, 0, 1, 2, 2], [0, 0, 0, 1, 0, 0, 2, 1, 0, 1, 2],
>    [0, 0, 0, 0, 1, 0, 2, 2, 1, 0, 1], [0, 0, 0, 0, 0, 1, 1, 2, 2, 1, 0]>);
```

`LinearCode(U)`

Let V be the R-space $R^{(n)}$ and suppose that U is a subspace of V. The effect of this function is to define the linear code C corresponding to the subspace U. Suppose the code C being constructed has dimension k. The evaluation of this constructor results in the creation of the following objects:

(a) The generator matrix G for C, created as a $k \times n$ matrix belonging to the R-matrix space, $R^{(k \times n)}$.

(b) The parity check matrix H for C, created as an $(n-k) \times n$ matrix belonging to the R-matrix space, $R^{(n-k) \times n)}$.

`LinearCode(A)`

Given a $k \times n$ matrix A over the ring R, construct the linear code generated by the rows of A. Note that it is not assumed that the rank of A is k. The effect of this constructor is otherwise identical to that described above.

Example H152E2

We define a code by constructing a matrix in a K-matrix space and using its row space to generate the code:

```
> M := KMatrixSpace(FiniteField(5), 2, 4);
> G := M ! [1,1,1,2, 3,2,1,4];
> G;
[1 1 1 2]
[3 2 1 4]
> C := LinearCode(G);
> C;
[4, 2, 2] Linear Code over GF(5)
Generator matrix:
[1 0 4 0]
[0 1 2 2]
```

`PermutationCode(u, G)`

Given a finite permutation group G of degree n, and a vector u belonging to the n-dimensional vector space V over the ring R, construct the code C corresponding to the subspace of V spanned by the set of vectors obtained by applying the permutations of G to the vector u.

Example H152E3

We define G to be a permutation group of degree 7 and construct the code C as the F_2-code generated by applying the permutations of G to a certain vector:

```
> G := PSL(3, 2);
> G;
Permutation group G of degree 7
    (1, 4)(6, 7)
    (1, 3, 2)(4, 7, 5)
> V := VectorSpace(GF(2), 7);
> u := V ! [1, 0, 0, 1, 0, 1, 1];
> C := PermutationCode(u, G);
> C;
[7, 3, 4] Linear Code over GF(2)
Generator matrix:
[1 0 0 1 0 1 1]
[0 1 0 1 1 1 0]
[0 0 1 0 1 1 1]
```

152.2.2 Some Trivial Linear Codes

`ZeroCode(R, n)`

Given a ring R and positive integer n, return the $[n, 0, n]$ code consisting of only the zero code word, (where the minimum weight is by convention equal to n).

`RepetitionCode(R, n)`

Given a ring R and positive integer n, return the $[n, 1, n]$ code over K generated by the all-ones vector.

`ZeroSumCode(R, n)`

Given a ring R and positive integer n, return the $[n, n-1, 2]$ code over R such that for all codewords $(c_1, c_2, \ldots, c_n)$ we have $\sum_i c_i = 0$.

`UniverseCode(R, n)`

Given a ring R and positive integer n, return the $[n, n, 1]$ code consisting of all possible codewords.

`EvenWeightCode(n)`

Given a positive integer n, return the $[n, n-1, 2]$ code over $\mathbf{F}_2$ such that all vectors have even weight. This is equivalent to the zero sum code over $\mathbf{F}_2$.

`EvenWeightSubcode(C)`

Given a linear code C over $\mathbf{F}_2$, return the subcode of C containing the vectors of even weight.

`RandomLinearCode(K, n, k)`

Given a finite field K and positive integers n and k, such that $0 < k \leq n$, the function returns a random linear code of length n and dimension k over the field K. The method employed is to successively choose random vectors from $K^{(n)}$ until generators for a k-dimensional subspace have been found.

`CordaroWagnerCode(n)`

Construct the Cordaro–Wagner code of length n, This is the 2-dimensional repetition code over $\mathbf{F}_2$ of length n and having the largest possible minimum weight.

Example H152E4

Over any specific finite field K, the zero code of length n is contained in every code of length n, and similarly every code of length n is contained in the universe code of length n. This is illustrated over $GF(2)$ for length 6 codes with an arbitrary code of length 6 dimension 3.

```
> K := GF(2);
> U := UniverseCode(K, 6);
> U;
[6, 6, 1] Linear Code over GF(2)
> Z := ZeroCode(K, 6);
> Z;
[6, 0, 6] Linear Code over GF(2)
> R := RandomLinearCode(K, 6, 3);
> (Z subset R) and (R subset U);
true
```

152.2.3 Some Basic Families of Codes

In this section we describe how to construct three very important families of codes: cyclic codes, Hamming codes and Reed-Muller codes. We choose to present these very important families at this stage since they are easily understood and they give us a nice collection of codes for use in examples.

Many more constructions will be described in subsequent sections. In particular, variations and generalizations of the cyclic code construction presented here will be given.

`CyclicCode(n, g)`

Let K be a finite field. Given a positive integer n and a univariate polynomial $g(x) \in K[x]$ of degree $n-k$ such that $g(x) \mid x^n - 1$, construct the $[n,k]$ cyclic code generated by $g(x)$.

Example H152E5

We construct the length 23 Golay code over $GF(2)$ as a cyclic code by factorizing the polynomial $x^{23}-1$ over $GF(2)$ and constructing the cyclic code generated by one of the factors of degree 11.

```
> P<x> := PolynomialRing(FiniteField(2));
> F := Factorization(x^23 - 1);
> F;
[
    <x + 1, 1>,
    <x^11 + x^9 + x^7 + x^6 + x^5 + x + 1, 1>,
    <x^11 + x^10 + x^6 + x^5 + x^4 + x^2 + 1, 1>
]
> CyclicCode(23, F[2][1]);
[23, 12, 7] Cyclic Code over GF(2)
Generator matrix:
```

```
[1 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 0]
[0 1 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1]
[0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1 0]
[0 0 0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1]
[0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1 0]
[0 0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1]
[0 0 0 0 0 0 0 0 1 0 0 0 1 1 0 1 1 1 0 0 0 1 1]
[0 0 0 0 0 0 0 0 0 1 0 0 1 0 1 0 1 0 0 1 0 1 1]
[0 0 0 0 0 0 0 0 0 0 1 0 1 0 0 1 0 0 1 1 1 1 1]
[0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 0 1]
```

`HammingCode(K, r)`

Given a positive integer r, and a finite field K of cardinality q, construct the r-th order Hamming code over K of cardinality q. This code has length

$$n = (q^r - 1)/(q - 1).$$

Example H152E6

We construct the third order Hamming code over GF(2) together with its parity check matrix.

```
> H := HammingCode(FiniteField(2), 3);
> H;
[7, 4, 3] Hamming code (r = 3) over GF(2)
Generator matrix:
[1 0 0 0 0 1 1]
[0 1 0 0 1 1 0]
[0 0 1 0 1 0 1]
[0 0 0 1 1 1 1]
> ParityCheckMatrix(H);
[1 0 1 0 1 1 0]
[0 1 1 0 0 1 1]
[0 0 0 1 1 1 1]
```

`SimplexCode(r)`

Given a positive integer r, construct the $[2^r - 1, r, 2^{r-1}]$ binary simplex code, which is the dual of a Hamming code.

`ReedMullerCode(r, m)`

Given positive integers r and m, where $0 \leq r \leq m$, construct the r-th order binary Reed–Muller code of length $n = 2^m$.

Example H152E7

We construct the first order Reed–Muller code of length 16 and count the number of pairs of vectors whose components are orthogonal.

```
> R := ReedMullerCode(1, 4);
> R;
[16, 5, 8] Reed-Muller Code (r = 1, m = 4) over GF(2)
Generator matrix:
[1 0 0 1 0 1 1 0 0 1 1 0 1 0 0 1]
[0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1]
[0 0 1 1 0 0 1 1 0 0 1 1 0 0 1 1]
[0 0 0 0 1 1 1 1 0 0 0 0 1 1 1 1]
[0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1]
> #{<v, w>: v, w in R | IsZero(InnerProduct(v, w))};
1024
```

152.3 Invariants of a Code

152.3.1 Basic Numerical Invariants

`Length(C)`

Given an $[n, k]$ code C, return the block length n of C.

`Dimension(C)`
`NumberOfGenerators(C)`

The dimension k of the $[n, k]$ linear code C.

`#C`

Given a code C, return the number of codewords belonging to C.

`InformationRate(C)`

The information rate of the $[n, k]$ code C. This is the ratio k/n.

152.3.2 The Ambient Space and Alphabet

`AmbientSpace(C)`

The ambient space of the code C, i.e. the generic R-space V in which C is contained.

`RSpace(C)`

`VectorSpace(C)`

Given an $[n, k]$ linear code C, defined as a subspace U of the n-dimensional space V, return U as a subspace of V with basis corresponding to the rows of the generator matrix for C.

`Generic(C)`

Given an $[n, k]$ code C, return the generic $[n, n, 1]$ code in which C is contained.

`Alphabet(C)`

`Field(C)`

The underlying ring (or alphabet) R of the code C.

152.3.3 The Code Space

`GeneratorMatrix(C)`

`BasisMatrix(C)`

The generator matrix for the linear code C, returned as an element of $\mathrm{Hom}(U, V)$ where U is the information space of C and V is the ambient space of C.

`Basis(C)`

The current vector space basis for the linear code C, returned as a sequence of elements of C.

`Generators(C)`

The current vector space basis for the linear code C, returned as a set of elements of C.

`C . i`

Given an $[n, k]$ code C and a positive integer i, $1 \leq i \leq k$, return the i-th element of the current basis of C.

152.3.4 The Dual Space

`Dual(C)`

The code that is dual to the code C.

`ParityCheckMatrix(C)`

The parity check matrix for the code C, returned as an element of $\mathrm{Hom}(V, U)$.

Example H152E8

We create a Reed–Muller code and demonstrate some simple relations.

```
> R := ReedMullerCode(1, 3);
> R;
[8, 4, 4] Reed-Muller Code (r = 1, m = 3) over GF(2)
Generator matrix:
[1 0 0 1 0 1 1 0]
[0 1 0 1 0 1 0 1]
[0 0 1 1 0 0 1 1]
[0 0 0 0 1 1 1 1]
> G := GeneratorMatrix(R);
> P := ParityCheckMatrix(R);
> P;
[1 0 0 1 0 1 1 0]
[0 1 0 1 0 1 0 1]
[0 0 1 1 0 0 1 1]
[0 0 0 0 1 1 1 1]
> G * Transpose(P);
[0 0 0 0]
[0 0 0 0]
[0 0 0 0]
[0 0 0 0]
> D := LinearCode(P);
> Dual(R) eq D;
true
```

`Hull(C)`

The Hull of a code is the intersection between itself and its dual.

152.3.5 The Information Space and Information Sets

`InformationSpace(C)`

Given an $[n, k]$ linear code C, return the k-dimensional R-space U which is the space of information vectors for the code C.

`InformationSet(C)`

Given an $[n, k]$ linear code C over a finite field, return the current information set for C. The information set for C is an ordered set of k linearly independent columns of the generator matrix, such that the generator matrix is the identity matrix when restricted to these columns. The information set is returned as a sequence of k integers, giving the numbers of the columns that correspond to the information set.

`AllInformationSets(C)`

Given an $[n, k]$ linear code C over a finite field, return all the possible information sets of C as a (sorted) sequence of sequences of column indices. Each inner sequence contains a maximal set of indices of linearly independent columns in the generator matrix of C.

`StandardForm(C)`

Given an $[n, k]$ linear code C over a finite field, return the standard form D of C. A code is in *standard form* if the first k components of the code words correspond to the information set. MAGMA returns one of the many codes in standard form which is isomorphic to C. (The same code is returned each time.) Thus, the effect of this function is to return a code D whose generators come from the generator matrix of C with its columns permuted, so that the submatrix consisting of the first k columns of the generator matrix for D is the identity matrix. Two values are returned:

(a) The standard form code D;

(b) An isomorphism from C to D.

Example H152E9

We construct a Reed–Muller code C and its standard form S and then map a codeword of C into S.

```
> C := ReedMullerCode(1, 4);
> C;
[16, 5, 8] Reed-Muller Code (r = 1, m = 4) over GF(2)
Generator matrix:
[1 0 0 1 0 1 1 0 0 1 1 0 1 0 0 1]
[0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1]
[0 0 1 1 0 0 1 1 0 0 1 1 0 0 1 1]
[0 0 0 0 1 1 1 1 0 0 0 0 1 1 1 1]
[0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1]
> InformationSet(C);
[ 1, 2, 3, 5, 9 ]
```

```
> #AllInformationSets(C);
2688
> S, f := StandardForm(C);
> S;
[16, 5, 8] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 0 1 1 1 0 1 1 0 1 0 0 1]
[0 1 0 0 0 1 1 0 1 1 0 1 0 1 0 1]
[0 0 1 0 0 1 0 1 1 0 1 1 0 0 1 1]
[0 0 0 1 0 0 1 1 1 0 0 0 1 1 1 1]
[0 0 0 0 1 0 0 0 0 1 1 1 1 1 1 1]
> u := C.1;
> u;
(1 0 0 1 0 1 1 0 0 1 1 0 1 0 0 1)
> f(u);
(1 0 0 0 0 1 1 1 0 1 1 0 1 0 0 1)
```

152.3.6 The Syndrome Space

`SyndromeSpace(C)`

Given an $[n, k]$ linear code C, return the $(n-k)$-dimensional vector space W, which is the space of syndrome vectors for the code C.

152.3.7 The Generator Polynomial

The operations in this section are restricted to cyclic codes.

`GeneratorPolynomial(C)`

Given a cyclic code C over a finite field, return the generator polynomial of C. The generator polynomial of C is a divisor of $x^n - 1$, where n is the length of C.

`CheckPolynomial(C)`

Given a cyclic code C over a finite field, return the check polynomial of C as an element of $K[x]$. If $g(x)$ is the generator polynomial of C and $h(x)$ is the check polynomial of C, then $g(x)h(x) = 0 \pmod{x^n - 1}$, where n is the length of C.

`Idempotent(C)`

Given a cyclic code C, return the (polynomial) idempotent of C. If $c(x)$ is the idempotent of C, then $c(x)^2 = 0 \pmod{x^n - 1}$, where n is the length of C.

Example H152E10

We find the generator and check polynomials for the third order Hamming code over GF(2).

```
> K<w> := GF(2);
> P<x> := PolynomialRing(K);
> H := HammingCode(K, 3);
> g := GeneratorPolynomial(H);
> g;
x^3 + x + 1
> h := CheckPolynomial(H);
> h;
x^4 + x^2 + x + 1
> g*h mod (x^7 - 1);
0
> forall{ c : c in H | h * P!Eltseq(c) mod (x^7-1) eq 0 };
true
> e := Idempotent(H);
> e;
x^4 + x^2 + x
> e^2;
x^8 + x^4 + x^2
```

152.4 Operations on Codewords

152.4.1 Construction of a Codeword

`C ! [a1, ..., an]`

`elt< C | a1, ..., an >`

Given a code C which is defined as a subset of the R-space $R^{(n)}$, and elements $a_1, \ldots, a_n$ belonging to R, construct the codeword $(a_1, \ldots, a_n)$ of C. It is checked that the vector $(a_1, \ldots, a_n)$ is an element of C.

`C ! u`

Given a code C which is defined as a subset of the R-space $V = R^{(n)}$, and an element u belonging to V, create the codeword of C corresponding to u. The function will fail if u does not belong to C.

`C ! 0`

The zero word of the code C.

`Random(C)`

A random codeword of C.

152.4.2 Arithmetic Operations on Codewords

`u + v`

Sum of the codewords u and v, where u and v belong to the same linear code C.

`-u`

Additive inverse of the codeword u belonging to the linear code C.

`u - v`

Difference of the codewords u and v, where u and v belong to the same linear code C.

`a * u`

Given an element a belonging to the field K, and a codeword u belonging to the linear code C, return the codeword $a * u$.

`Normalize(u)`

Given an element u over a field, not the zero element, belonging to the linear code C, return $\frac{1}{a} * u$, where a is the first non-zero component of u. If u is the zero vector, it is returned as the value of this function. The net effect is that `Normalize(u)` always returns a vector v in the subspace generated by u, such that the first non-zero component of v is the unit of K.

`Syndrome(w, C)`

Given an $[n, k]$ linear code C over a finite field with parent vector space V, and a vector w belonging to V, construct the syndrome of w relative to the code C. This will be an element of the *syndrome space* of C.

152.4.3 Distance and Weight

`Distance(u, v)`

The Hamming distance between the codewords u and v, where u and v belong to the same code C.

`Weight(u)`

The Hamming weight of the codeword u, i.e., the number of non-zero components of u.

`LeeWeight(u)`

The Lee weight of the codeword u.

Example H152E11

We calculate all possible distances between code words of the non-extended Golay code over GF(3), and show the correspondence with all possible code word weights.

```
> C := GolayCode(GF(3),false);
> {Distance(v,w):v,w in C};
{ 0, 5, 6, 8, 9, 11 }
> {Weight(v):v in C};
{ 0, 5, 6, 8, 9, 11 }
```

152.4.4 Vector Space and Related Operations

`(u, v)`

`InnerProduct(u, v)`

Inner product of the vectors u and v with respect to the Euclidean norm, where u and v belong to the parent vector space of the code C.

`Support(w)`

Given a word w belonging to the $[n, k]$ code C, return its support as a subset of the integer set $\{1..n\}$. The support of w consists of the coordinates at which w has non-zero entries.

`Coordinates(C, u)`

Given an $[n, k]$ linear code C and a codeword u of C return the coordinates of u with respect to C. The coordinates of u are returned as a sequence $Q = [a_1, \ldots, a_k]$ of elements from the alphabet of C so that $u = a_1 * C.1 + \ldots + a_k * C.k$.

`Parent(w)`

Given a word w belonging to the code C, return the ambient space V of C.

`Rotate(u, k)`

Given a vector u, return the vector obtained from u by cyclically shifting its components to the right by k coordinate positions.

`Rotate(~u, k)`

Given a vector u, destructively rotate u by k coordinate positions.

`Trace(u, S)`

`Trace(u)`

Given a vector u with components in K, and a subfield S of K, construct the vector with components in S obtained from u by taking the trace of each component with respect to S. If S is omitted, it is taken to be the prime field of K.

Example H152E12

We create a specific code word in the length 5 even weight code, after a failed attempt to create a code word of odd weight. We then display its support, find its coordinates with respect to the basis and then confirm it by way of re-construction.

```
> C := EvenWeightCode(5);
>  C![1,1,0,1,0];
>> C![1,1,0,1,0];
    ^

152.4.5 Predicates for Codewords

`u eq v`

The function returns `true` if and only if the codewords u and v are equal.

`u ne v`

The function returns `true` if and only if the codewords u and v are not equal.

`IsZero(u)`

The function returns `true` if and only if the codeword u is the zero vector.

152.4.6 Accessing Components of a Codeword

`u[i]`

Given a codeword u belonging to the code C defined over the ring R, return the i-th component of u (as an element of R).

`u[i] := x;`

Given an element u belonging to a subcode C of the full R-space $V = R^n$, a positive integer i, $1 \leq i \leq n$, and an element x of R, this function returns a vector in V which is u with its i-th component redefined to be x.

152.5 Coset Leaders

`CosetLeaders(C)`

Given a code C with ambient space V over a finite field, return a set of coset leaders (vectors of minimal weight in their cosets) for C in V as an indexed set of vectors from V. Note that this function is only applicable when V and C are small. This function also returns a map from the syndrome space of C into the coset leaders (mapping a syndrome into its corresponding coset leader).

Example H152E13

We construct a Hamming code C, encode an information word using C, introduce one error, and then decode by calculating the syndrome of the "received" vector and applying the CosetLeaders map to the syndrome to recover the original vector.
First we set C to be the third order Hamming Code over the finite field with two elements.

```
> C := HammingCode(GF(2), 3);
> C;
[7, 4, 3] Hamming code (r = 3) over GF(2)
Generator matrix:
[1 0 0 0 0 1 1]
[0 1 0 0 1 0 1]
[0 0 1 0 1 1 0]
[0 0 0 1 1 1 1]
```

Then we set L to be the set of coset leaders of C in its ambient space V and f to be the map which maps the syndrome of a vector in V to its coset leader in L.

```
> L, f := CosetLeaders(C);
> L;
{@
    (0 0 0 0 0 0 0),
    (1 0 0 0 0 0 0),
    (0 1 0 0 0 0 0),
    (0 0 1 0 0 0 0),
    (0 0 0 1 0 0 0),
    (0 0 0 0 1 0 0),
    (0 0 0 0 0 1 0),
    (0 0 0 0 0 0 1)
@}
```

Since C has dimension 4, the degree of the information space I of C is 4. We set i to be an "information vector" of length 4 in I, and then encode i using C by setting w to be the product of i by the generator matrix of C.

```
> I := InformationSpace(C);
> I;
Full Vector space of degree 4 over GF(2)
> i := I ! [1, 0, 1, 1];
> w := i * GeneratorMatrix(C);
```

```
> w;
(1 0 1 1 0 1 0)
```

Now we set r to be the same as w but with an error in the 7-th coordinate (so r is the "received vector").

```
> r := w;
> r[7] := 1;
> r;
(1 0 1 1 0 1 1)
```

Finally we let s be the syndrome of r with respect to C, apply f to s to get the coset leader l, and subtract l from r to get the corrected vector v. Finding the coordinates of v with respect to the basis of C (the rows of the generator matrix of C) gives the original information vector.

```
> s := Syndrome(r, C);
> s;
(1 1 1)
> l := f(s);
> l;
(0 0 0 0 0 0 1)
> v := r - l;
> v;
(1 0 1 1 0 1 0)
> res := I ! Coordinates(C, v);
> res;
(1 0 1 1)
```

152.6 Subcodes

152.6.1 The Subcode Constructor

`sub< C | L >`

Given an $[n, k]$ linear code C over R, construct the subcode of C, generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) An element of C;

(b) A set or sequence of elements of C;

(c) A sequence of n elements of R, defining an element of C;

(d) A set or sequence of sequences of type (c);

(e) A subcode of C;

`Subcode(C, k)`

Given an $[n, k]$ linear code C and an integer t, $1 \leq t < n$, return a subcode of C of dimension t.

`Subcode(C, S)`

Given an $[n, k]$ linear code C and a set S of integers, each of which lies in the range $[1, k]$, return the subcode of C generated by the basis elements whose positions appear in S.

`SubcodeBetweenCode(C1, C2, k)`

Given a linear code C_1 and a subcode C_2 of C_1, return a subcode of C_1 of dimension k containing C_2.

`SubcodeWordsOfWeight(C, S)`

Given an $[n, k]$ linear code C and a set S of integers, each of which lies in the range $[1, n]$, return the subcode of C generated by those words of C whose weights lie in S.

Example H152E14

We give an example of how `SubcodeBetweenCode` may be used to create a code nested in between a subcode pair.

```
> C1 := RepetitionCode(GF(2),6);
> C1;
[6, 1, 6] Cyclic Code over GF(2)
Generator matrix:
[1 1 1 1 1 1]
> C3 := EvenWeightCode(6);
> C3;
[6, 5, 2] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 0 1]
[0 1 0 0 0 1]
[0 0 1 0 0 1]
[0 0 0 1 0 1]
[0 0 0 0 1 1]
> C1 subset C3;
true
> C2 := SubcodeBetweenCode(C3, C1, 4);
> C2;
[6, 4, 2] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 1 0]
[0 1 0 0 0 1]
[0 0 1 0 0 1]
[0 0 0 1 0 1]
> (C1 subset C2) and (C2 subset C3);
true
```

152.6.2 Sum, Intersection and Dual

For the following operators, C and D are codes defined as subsets (or subspaces) of the same R-space V.

`C + D`

The (vector space) sum of the linear codes C and D, where C and D are contained in the same K-space V.

`C meet D`

The intersection of the linear codes C and D, where C and D are contained in the same K-space V.

`Dual(C)`

The dual D of the linear code C. The dual consists of all codewords in the K-space V which are orthogonal to all codewords of C.

Example H152E15

Verify some simple results from the sum and intersection of subcodes with known basis.

```
> C := EvenWeightCode(5);
> C;
[5, 4, 2] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 1]
[0 1 0 0 1]
[0 0 1 0 1]
[0 0 0 1 1]
> C1 := sub< C | C.1 >;
> C2 := sub< C | C.4 >;
> C3 := sub< C | { C.1 , C.4} >;
> (C1 + C2) eq C3;
true
> (C1 meet C3) eq C1;
true
```

Example H152E16

Verify the orthogonality of codewords in the dual for a `ReedSolomonCode`.

```
> K<w> := GF(8);
> R := ReedSolomonCode(K, 3);
> R;
[7, 5, 3] BCH code (d = 3, b = 1) over GF(2^3)
Generator matrix:
[  1   0   0   0   0 w^3 w^4]
[  0   1   0   0   0   1   1]
[  0   0   1   0   0 w^3 w^5]
```

```
[  0   0   0   1   0   w w^5]
[  0   0   0   0   1   w w^4]
> D := Dual(R);
> D;
[7, 2, 6] Cyclic Code over GF(2^3)
Generator matrix:
[  1   0 w^3   1 w^3   w   w]
[  0   1 w^4   1 w^5 w^5 w^4]
> {<u,v> : u in R, v in D | InnerProduct(u,v) ne 0};
{}
```

152.6.3 Membership and Equality

For the following operators, C and D are codes defined as a subset (or subspace) of the R-space V.

`u in C`

Return `true` if and only if the vector u of V belongs to the code C.

`u notin C`

Return `true` if and only if the vector u of V does not belong to the code C.

`C subset D`

Return `true` if and only if the code C is a subcode of the code D.

`C notsubset D`

Return `true` if and only if the code C is not a subcode of the code D.

`C eq D`

Return `true` if and only if the codes C and D are equal.

`C ne D`

Return `true` if and only if the codes C and D are not equal.

152.7 Properties of Codes

For the following operators, C and D are codes defined as a subset (or subspace) of the vector space V.

`IsCyclic(C)`

Return `true` if and only if the linear code C is a cyclic code.

`IsSelfDual(C)`

Return `true` if and only if the linear code C is self-dual. (i.e. C equals the dual of C).

`IsSelfOrthogonal(C)`

Return `true` if and only if the linear code C is self-orthogonal (i.e., C is contained in the dual of C).

`IsMaximumDistanceSeparable(C)`

`IsMDS(C)`

Returns `true` if and only if the linear code C is maximum-distance separable; that is, has parameters $[n, k, n - k + 1]$.

`IsEquidistant(C)`

Returns `true` if and only if the linear code C is equidistant.

`IsPerfect(C)`

Returns `true` if and only if the linear code C is perfect; that is, if and only if the cardinality of C is equal to the size of the sphere packing bound of C.

`IsNearlyPerfect(C)`

Returns `true` if and only if the binary linear code C is nearly perfect.

`IsEven(C)`

Returns `true` if and only if C is an even linear binary code, (i.e., all codewords have even weight). If `true`, then MAGMA will adjust the upper and lower minimum weight bounds of C if possible.

`IsDoublyEven(C)`

Returns `true` if and only if C is a doubly even linear binary code, (i.e., all codewords have weight divisible by 4). If `true`, then MAGMA will adjust the upper and lower minimum weight bounds of C if possible.

`IsProjective(C)`

Returns `true` if and only if the (non-quantum) code C is projective.

Example H152E17

We look at an extended quadratic residue code over $GF(2)$ which is self-dual, and then confirm it manually.

```
> C := ExtendCode( QRCode(GF(2),23) );
> C:Minimal;
[24, 12, 8] Linear Code over GF(2)
> IsSelfDual(C);
true
> D := Dual(C);
> D: Minimal;
[24, 12, 8] Linear Code over GF(2)
> C eq D;
true
```

Example H152E18

We look at the `CordaroWagnerCode` of length 6, which is self-orthogonal, and then confirm it manually.

```
> C := CordaroWagnerCode(6);
> C;
[6, 2, 4] Linear Code over GF(2)
Generator matrix:
[1 1 0 0 1 1]
[0 0 1 1 1 1]
> IsSelfOrthogonal(C);
true
> D := Dual(C);
> D;
[6, 4, 2] Linear Code over GF(2)
Generator matrix:
[1 0 0 1 0 1]
[0 1 0 1 0 1]
[0 0 1 1 0 0]
[0 0 0 0 1 1]
> C subset D;
true
```

152.8 The Weight Distribution

152.8.1 The Minimum Weight

In the case of a linear code, the minimum weight and distance are equivalent. It is clear that is substantially easier to determine the minimum weight of a (possibly non-linear) code than its minimum distance. The general principle underlying the minimum weight algorithm in MAGMA is the embedding of low-weight information vectors into the code space, in the hope that they will map onto low weight codewords.

Let C be a $[n, k]$ linear code over a finite field and G be its generator matrix. The minimum weight algorithm proceeds as follows: Starting with $r = 1$, all linear combinations of r rows of G are enumerated. By taking the minimum weight of each such combination, an upper bound, d_{upper}, on the minimum weight of C is obtained. A strictly increasing function, $d_{lower}(r)$, finds a lower bound on the minimum weight of the non-enumerated vectors for each computational step (the precise form of this function depends upon the algorithm being used). The algorithm terminates when $d_{lower}(r) \geq d_{upper}$, at which point the actual minimum weight is equal to d_{upper}.

The algorithm is used for non-cyclic codes, and is due to A.E. Brouwer and K.H. Zimmermann [BFK+98]. The key idea is to construct as many different generator matrices for the same code as possible, each having a different information set and such that the information sets are as disjoint as possible. By maximizing the number of information sets, $d_{lower}(r)$ can be made increasingly accurate. Each information set will provide a different embedding of information vectors into the code, and thus the probability of a low-weight information vector mapping onto a low-weight codeword is increased.

A well known improvement attributed to Brouwer exists for cyclic codes, requiring the enumeration fo only one information set. A generalisation of this improvement has been made by G. White to quasicyclic codes, and any codes whose known automorphisms have large cycles. Functionality is included in this section for inputting partial knowledge of the automorphism group to take advantage of this improvement.

Information sets are discarded if their ranks are too low to contribute to the lower bound calculation. The user may also specify a lower bound, `RankLowerBound`, on the rank of information sets initially created.

`MinimumWeight(C: parameters)`

`MinimumDistance(C: parameters)`

`Method`	MONSTGELT	*Default :* "*Auto*"
`RankLowerBound`	RNGINTELT	*Default :* 0
`MaximumTime`	RNGRESUBELT	*Default :* ∞
`Nthreads`	RNGINTELT	*Default :* 1

Determine the minimum weight of the words belonging to the code C, which is also the minimum distance between any two codewords. The parameter `RankLowerBound` sets a minimum rank on the informations sets used in the calculation, while the parameter `MaximumTime` sets a time limit (in seconds of "user time") after which the calculation is aborted.

If the base field is $\mathbf{F}_2$ and the parameter `Nthreads` is set to a positive integer n, then n threads will be used in the computation, if POSIX threads are enabled. One can alternatively use the procedure `SetNthreads` to set the global number of threads to a value n so that n threads are always used by default in this algorithm unless overridden by the `Nthreads` parameter.

Sometimes a brute force calculation of the entire weight distribution can be a faster way to get the minimum weight for small codes. When the parameter `Method` is set to the default `"Auto"` then the method is internally chosen. The user can specify which method they want using setting it to either `"Distribution"` or `"Zimmerman"`.

By setting the verbose flag `"Code"`, information about the progress of the computation can be printed. An example to demonstrate the interpretation of the verbose output follows:

```
> SetVerbose("Code", true);
> SetSeed(1);
> MinimumWeight(RandomLinearCode(GF(2),85,26));
Linear Code over GF(2) of length 85 with 26 generators. Is not cyclic
Lower Bound: 1, Upper Bound: 60
Constructed 4 distinct generator matrices
Relative Ranks:  26  26  26   7
Starting search for low weight codewords...
Enumerating using 1 generator at a time:
     New codeword identified of weight 32, time 0.000
     New codeword identified of weight 28, time 0.000
     New codeword identified of weight 27, time 0.000
     New codeword identified of weight 25, time 0.000
     Discarding non-contributing rank 7 matrix
     New Relative Ranks:  26  26  26
   Completed Matrix  1:  lower =  4, upper = 25. Time so far: 0.000
     New codeword identified of weight 23, time 0.000
   Completed Matrix  2:  lower =  5, upper = 23. Time so far: 0.000
   Completed Matrix  3:  lower =  6, upper = 23. Time so far: 0.000
Enumerating using 2 generators at a time:
     New codeword identified of weight 20, time 0.000
   Completed Matrix  1:  lower =  7, upper = 20. Time so far: 0.000
   Completed Matrix  2:  lower =  8, upper = 20. Time so far: 0.000
   Completed Matrix  3:  lower =  9, upper = 20. Time so far: 0.000
Enumerating using 3 generators at a time:
     New codeword identified of weight 19, time 0.000
   Completed Matrix  1:  lower = 10, upper = 19. Time so far: 0.000
   Completed Matrix  2:  lower = 11, upper = 19. Time so far: 0.000
   Completed Matrix  3:  lower = 12, upper = 19. Time so far: 0.000
Enumerating using 4 generators at a time:
```

```
    New codeword identified of weight 18, time 0.000
  Completed Matrix  1:  lower = 13, upper = 18. Time so far: 0.000
    New codeword identified of weight 17, time 0.000
  Completed Matrix  2:  lower = 14, upper = 17. Time so far: 0.010
  Completed Matrix  3:  lower = 15, upper = 17. Time so far: 0.010
Termination predicted with 5 generators at matrix 2
Enumerating using 5 generators at a time:
  Completed Matrix  1:  lower = 16, upper = 17. Time so far: 0.020
  Completed Matrix  2:  lower = 17, upper = 17. Time so far: 0.030
Final Results: lower = 17, upper = 17, Total time: 0.030
17
```

Verbose output can be invaluable on long minimum weight calculations.

The algorithm constructs different (equivalent) generator matrices, each of which have pivots in different column positions of the code, called its *information set*. A generator matrix's *relative rank* is the size of its information set independent from the previously constructed matrices.

The algorithm proceeds by enumerating all combinations derived from r generators, for each successive r. Once r exceeds the difference between the actual rank of a matrix (i.e., the dimension), and its relative rank, then the lower bound on the minimum weight will increment by 1 for that step.

The upper bound on the minimum weight is determined by the minimum weight of codewords that are enumerated. Once these bounds meet the computation is complete.

`MinimumWeightBounds(C)`

Return the currently known lower and upper bounds on the minimum weight of code C.

`ResetMinimumWeightBounds(C)`

Undefine the minimum weight of the code C if it is known, and reset any known bounds on its value.

`VerifyMinimumDistanceLowerBound(C, d)`

`RankLowerBound`	RngIntElt	*Default :* 0
`MaximumTime`	RngIntElt	*Default :* ∞

The minimum weight algorithm is executed until it determines whether or not d is a lower bound for the minimum weight of the code C. (See the description of the function `MinimumWeight` for information on the parameters `RankLowerBound` and `MaximumTime` and on the verbose output). Three values are returned. The first of these is a boolean value, taking the value `true` if and only if d is verified to be a lower bound for the minimum weight of C, (`false` if the calculation is aborted due to time restrictions). The second return value is the best available lower bound for the minimum weight of C, and the third is a boolean which is `true` if this value is the actual minimum weight of C.

`VerifyMinimumDistanceUpperBound(C, d)`

`VerifyMinimumWeightUpperBound(C, d)`

`RankLowerBound`	RngIntElt	*Default :* 0
`MaximumTime`	RngIntElt	*Default :* ∞

The minimum weight algorithm is executed until it determines whether or not d is an upper bound for the minimum weight of the code C. (See the description of the function `MinimumWeight` for information on the parameters `RankLowerBound` and `MaximumTime` and on the verbose output). Three values are returned. The first of these is a boolean value, taking the value `true` if and only if d is verified to be an upper bound for the minimum weight of C, (`false` if the calculation is aborted due to time restrictions). The second return value is the best available upper bound for the minimum weight of C, and the third is a boolean which is `true` if this value is the actual minimum weight of C.

`MinimumWord(C)`

Return one word of the code C having minimum weight.

`MinimumWords(C)`

`NumWords`	RngIntElt	*Default :*
`Method`	MonStgElt	*Default :* "*Auto*"
`RankLowerBound`	RngIntElt	*Default :* ∞
`MaximumTime`	RngReSubElt	*Default :* ∞

Given a linear code C, return the set of all words of C having minimum weight. If `NumWords` is set to a non-negative integer, then the algorithm will terminate after that total of words have been found. Similarly, if `MaximumTime` then the algorithm will abort if the specified time limit expires.

A variation of the Zimmermann minimum weight algorithm is generally used to collect the minimum words, although in some cases (such as small codes) a brute force enumeration may be used. When the parameter `Method` is set to the default `"Auto"` then the method is internally chosen. The user can specify which method they want using setting it to either `"Distribution"` or `"Zimmerman"`.

By setting the verbose flag `"Code"`, information about the progress of the computation can be printed.

Example H152E19

The function `BKLC(K, n, k)` returns the best known linear $[n, k]$-code over the field K. We use this function to construct the $[77, 34, 16]$ best known linear code and confirm a lower bound on its minimum weight (which is not as good as its actual minimum weight). We check to see whether the minimum weight of this code is at least 11 and in doing so we will actually get a slightly better bound, though it will be still less than the true minimum weight. Since the function `BLKC`

will set the true minimum weight, it is first necessary to reset the bounds so that the minimum weight data is lost.

```
> a := BKLC(GF(2),77,34);
> a:Minimal;
[77, 34, 16] Linear Code over GF(2)
> ResetMinimumWeightBounds(a);
> MinimumWeightBounds(a);
1 44
> a:Minimal;
[77, 34] Linear Code over GF(2)
> SetVerbose("Code",true);
> IsLB, d_lower, IsMinWeight := VerifyMinimumWeightLowerBound(a, 11);
Linear Code over GF(2) of length 77 with 34 generators. Is not cyclic
Lower Bound: 1, Upper Bound: 44
Using congruence d mod 4 = 0
Constructed 3 distinct generator matrices
Relative Ranks:  34  34   6
Starting search for low weight codewords...
     Discarding non-contributing rank 6 matrix
Enumerating using 1 generator at a time:
     New codeword identified of weight 20, time 0.000
     New codeword identified of weight 16, time 0.000
   Completed Matrix  1:  lower =  4, upper = 16. Time so far: 0.000
   Completed Matrix  2:  lower =  4, upper = 16. Time so far: 0.000
Enumerating using 2 generators at a time:
   Completed Matrix  1:  lower =  8, upper = 16. Time so far: 0.000
   Completed Matrix  2:  lower =  8, upper = 16. Time so far: 0.000
Enumerating using 3 generators at a time:
   Completed Matrix  1:  lower =  8, upper = 16. Time so far: 0.000
   Completed Matrix  2:  lower =  8, upper = 16. Time so far: 0.000
Enumerating using 4 generators at a time:
   Completed Matrix  1:  lower = 12, upper = 16. Time so far: 0.010
Final Results: lower = 12, upper = 16, Total time: 0.010
> IsLB;
true
> d_lower, IsMinWeight;
12 false
```

`IncludeAutomorphism(~C, p)`

`IncludeAutomorphism(~C, G)`

Given some automorphism p or group of automorphisms G of the code C, which can either be a permutation of the columns or a full monomial permutation of the code. Then include these automorphism in the known automorphisms subgroup. Automorphisms with long cycles that can aid the minimum weight calculation should be added in this way.

`KnownAutomorphismSubgroup(C)`

Return the maximally known subgroup of the full group of automorphisms of the code C.

152.8.2 The Weight Distribution

`WeightDistribution(C)`

Determine the weight distribution for the code C. The distribution is returned in the form of a sequence of tuples, where the i-th tuple contains the i-th weight, w_i say, and the number of codewords having weight w_i.

`WeightDistribution(C, u)`

Determine the weight distribution of the coset $C + u$ of the linear code C. The distribution is returned in the form of a sequence of tuples, where the i-th tuple contains the i-th weight, w_i say, and the number of codewords having weight w_i.

`DualWeightDistribution(C)`

The weight distribution of the dual code of C (see `WeightDistribution`).

Example H152E20

We construct the second order Reed–Muller code of length 64, and calculate the its weight distribution and that of its dual code.

```
> R := ReedMullerCode(2, 6);
> #R;
4194304
> WeightDistribution(R);
[ <0, 1>, <16, 2604>, <24, 291648>, <28, 888832>, <32, 1828134>, <36, 888832>,
<40, 291648>, <48, 2604>, <64, 1> ]
> D := Dual(R);
> #D;
4398046511104
> time WeightDistribution(D);
[ <0, 1>, <8, 11160>, <12, 1749888>, <14, 22855680>, <16, 232081500>, <18,
1717223424>, <20, 9366150528>, <22, 38269550592>, <24, 119637587496>, <26,
286573658112>, <28, 533982211840>, <30, 771854598144>, <32, 874731154374>,
<34, 771854598144>, <36, 533982211840>, <38, 286573658112>, <40,
```

```

<48, 232081500>, <50, 22855680>, <52, 1749888>, <56, 11160>, <64, 1> ]
```

`PartialWeightDistribution(C, ub)`

Return the weight distribution of the code C up to the specified upper bound. This function uses the minimum weight collection to collect word sets.

152.8.3 The Weight Enumerator

`WeightEnumerator(C)`

The (Hamming) weight enumerator $W_C(x, y)$ for the linear code C. The weight enumerator is defined by

$$W_C(x, y) = \sum_{u \in C} x^{n-wt(u)} y^{wt(u)}.$$

`WeightEnumerator(C, u)`

The (Hamming) weight enumerator $W_{C+u}(x, y)$ for the coset $C + u$.

`CompleteWeightEnumerator(C)`

The complete weight enumerator $\mathcal{W}_C(z_0, \ldots, z_{q-1})$ for the linear code C where q is the size of the alphabet K of C. Let the q elements of K be denoted by $\omega_0, \ldots, \omega_{q-1}$. If K is a prime field, we let ω_i be i (i.e. take the natural representation of each number). If K is a non-prime field, we let ω_0 be the zero element of K and let ω_i be α^{i-1} for $i = 1 \ldots q-1$ where α is the primitive element of K. Now for a codeword u of C, let $s_i(u)$ be the number of components of u equal to ω_i. The complete weight enumerator is defined by

$$\mathcal{W}_C(z_0, \ldots, z_{q-1}) = \sum_{u \in C} {z_0}^{s_0(u)} \ldots {z_{q-1}}^{s_{q-1}(u)}.$$

`CompleteWeightEnumerator(C, u)`

The complete weight enumerator $\mathcal{W}_{C+u}(z_0, \ldots, z_{q-1})$ for the coset $C + u$.

Example H152E21

We construct the cyclic ternary code of length 11 with generator polynomial $t^5 + t^4 + 2t^3 + t^2 + 2$ and calculate both its weight enumerator and its complete weight enumerator. To ensure the polynomials print out nicely, we assign names to the polynomial ring indeterminates in each case. These names will persist if further calls to `WeightEnumerator` and `CompleteWeightEnumerator` over the same alphabet are made.

```
> R<t> := PolynomialRing(GF(3));
> C := CyclicCode(11, t^5 + t^4 + 2*t^3 + t^2 + 2);
> W<x, y> := WeightEnumerator(C);
> W;
x^11 + 132*x^6*y^5 + 132*x^5*y^6 + 330*x^3*y^8 + 110*x^2*y^9 + 24*y^11
> CW<u, v, w> := CompleteWeightEnumerator(C);
> CW;
u^11 + 11*u^6*v^5 + 55*u^6*v^3*w^2 + 55*u^6*v^2*w^3 + 11*u^6*w^5 +
      11*u^5*v^6 + 110*u^5*v^3*w^3 + 11*u^5*w^6 + 55*u^3*v^6*w^2 +
      110*u^3*v^5*w^3 + 110*u^3*v^3*w^5 + 55*u^3*v^2*w^6 + 55*u^2*v^6*w^3 +
      55*u^2*v^3*w^6 + v^11 + 11*v^6*w^5 + 11*v^5*w^6 + w^11
```

The vector $u = (0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1)$ does not lie in the code C and can be taken as a coset leader. We determine the weight enumerator of the coset containing u.

```
> u := AmbientSpace(C)![0,0,0,0,0,0,0,0,0,0,1];
> Wu := WeightEnumerator(C, u);
> Wu;
x^10*y + 30*x^7*y^4 + 66*x^6*y^5 + 108*x^5*y^6 + 180*x^4*y^7 + 165*x^3*y^8 +
    135*x^2*y^9 + 32*x*y^10 + 12*y^11
```

152.8.4 The MacWilliams Transform

`MacWilliamsTransform(n, k, q, W)`

Let C be a hypothetical $[n, k]$ linear code over a finite field of cardinality q. Let W be the weight distribution of C (in the form as returned by the function `WeightDistribution`). This function applies the MacWilliams transform to W to obtain the weight distribution W' of the dual code of C. The transform is a combinatorial algorithm based on n, k, q and W alone. Thus C itself need not exist—the function simply works with the sequence of integer pairs supplied by the user. Furthermore, if W is not the weight distribution of an actual code, the result W' will be meaningless and even negative weights may be returned.

`MacWilliamsTransform(n, k, K, W)`

Let C be a hypothetical $[n, k]$ linear code over a finite field K. Let W be the complete weight enumerator of C (in the form as returned by the function `CompleteWeightEnumerator`). This function applies the MacWilliams transform to W to obtain the complete weight enumerator W' of the dual code of C. The transform is a combinatorial algorithm based on K, n, k, and W alone. Thus C itself need not exist—the function simply manipulates the given polynomial. Furthermore, if W is not the weight distribution of an actual code, the weight enumerator W' will be meaningless.

Example H152E22

Let us suppose there exists a $[31, 11]$ code C over F_2 that has complete weight enumerator

$$u^{31} + 186u^{20}v^{11} + 310u^{19}v^{12} + 527u^{16}v^{15} + 527u^{15}v^{16} + 310u^{12}v^{19} + 186u^{11}v^{20} + v^{31}$$

We compute the weight distribution and the complete weight enumerator of the dual of the hypothetical code C.

```
> W := [ <0, 1>, <11, 186>, <12, 310>, <15, 527>, <16, 527>,
>        <19, 310>, <20, 186>, <31, 1> ];
>  MacWilliamsTransform(31, 11, 2, W);
[ <0, 1>, <6, 806>, <8, 7905>, <10, 41602>, <12, 142600>, <14,
251100>, <16, 301971>, <18, 195300>, <20, 85560>, <22, 18910>, <24,
2635>, <26, 186> ]
> R<u, v> := PolynomialRing(Integers(), 2);
> CWE := u^31 + 186*u^20*v^11 + 310*u^19*v^12 + 527*u^16*v^15 + 527*u^15*v^16 +
>          310*u^12*v^19 + 186*u^11*v^20 + v^31;
> MacWilliamsTransform(31, 11, GF(2), CWE);
u^31 + 806*u^25*v^6 + 7905*u^23*v^8 + 41602*u^21*v^10 + 142600*u^19*v^12 +
      251100*u^17*v^14 + 301971*u^15*v^16 + 195300*u^13*v^18 + 85560*u^11*v^20 +
      18910*u^9*v^22 + 2635*u^7*v^24 + 186*u^5*v^26
```

152.8.5 Words

The functions in this section only apply to codes over finite fields.

`Words(C, w: parameters)`

`NumWords`	RngIntElt	*Default :*
`Method`	MonStgElt	*Default :* "*Auto*"
`RankLowerBound`	RngIntElt	*Default :* ∞
`MaximumTime`	RngReSubElt	*Default :* ∞

Given a linear code C, return the set of all words of C having weight w. If `NumWords` is set to a non-negative integer c, then the algorithm will terminate after that total

of words have been found. Similarly, if `MaximumTime` then the algorithm will abort if the specified time limit expires.

There are two methods for collecting words, one based on the Zimmermann minimum weight algorithm, and a brute force type calculation. When the parameter `Method` is set to the default `"Auto"` then the method is internally chosen. The user can specify which method they want using setting it to either `"Distribution"` or `"Zimmerman"`.

By setting the verbose flag `"Code"`, information about the progress of the computation can be printed.

`NumberOfWords(C, w)`

Given a linear code C, return the number of words of C having weight w.

`WordsOfBoundedWeight(C, l, u: parameters)`

`Cutoff`	RngIntElt	*Default :* ∞
`StoreWords`	BoolElt	*Default :* `true`

Given a linear code C, return the set of all words of C having weight between l and u, inclusive. If `Cutoff` is set to a non-negative integer c, then the algorithm will terminate after a total of c words have been found.

If `StoreWords` is true then any words of a *single weight* generated will be stored internally.

`ConstantWords(C, i)`

Given a linear code C, return the set of all words of C which have weight i and which consist of zeros and ones alone.

`NumberOfConstantWords(C, i)`

Given a linear code C, return the number of words of C which have weight i and which consist of zeros and ones alone.

Example H152E23

We construct the words of weight 11 and also the constant (zero-one) words of weight 11 in the length 23 cyclic code over $\mathbf{F}_3$ that is defined by the generator polynomial $x^{11} + x^{10} + x^9 + 2x^8 + 2x^7 + x^5 + x^3 + 2$.

```
> R<x> := PolynomialRing(GF(3));
> f := x^11 + x^10 + x^9 + 2*x^8 + 2*x^7 + x^5 + x^3 + 2;
> C := CyclicCode(23, f);
> C;
[23, 12, 8] BCH code (d = 5, b = 1) over GF(3)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 2 0 0 1 0 1 0 2 2 1 1]
[0 1 0 0 0 0 0 0 0 0 0 0 1 2 0 2 1 2 1 1 0 1 0]
[0 0 1 0 0 0 0 0 0 0 0 0 0 1 2 0 2 1 2 1 1 0 1]
[0 0 0 1 0 0 0 0 0 0 0 0 1 0 1 1 0 1 1 0 2 0 2]
```

```
[0 0 0 0 1 0 0 0 0 0 0 0 2 1 0 2 1 1 1 0 2 0 1]
[0 0 0 0 0 1 0 0 0 0 0 0 1 2 1 2 2 0 1 2 1 1 2]
[0 0 0 0 0 0 1 0 0 0 0 0 2 1 2 2 2 0 0 0 1 2 2]
[0 0 0 0 0 0 0 1 0 0 0 0 2 2 1 0 2 0 0 2 2 2 0]
[0 0 0 0 0 0 0 0 1 0 0 0 0 2 2 1 0 2 0 0 2 2 2]
[0 0 0 0 0 0 0 0 0 1 0 0 2 0 2 0 1 1 2 2 2 0 0]
[0 0 0 0 0 0 0 0 0 0 1 0 0 2 0 2 0 1 1 2 2 2 0]
[0 0 0 0 0 0 0 0 0 0 0 1 0 0 2 0 2 0 1 1 2 2 2]
> time WeightDistribution(C);
[ <0, 1>, <8, 1518>, <9, 2530>, <11, 30912>, <12, 30912>, <14, 151800>, <15,
91080>, <17, 148764>, <18, 49588>, <20, 21252>, <21, 3036>, <23, 48> ]
Time: 0.030
```

Note that the minimum distance is 8. We calculate all words of weight 11 and the constant words of weight 11.

```
1518
> time W11 := Words(C, 11);
Time: 0.350
> #W11;
30912
> ZOW11 := ConstantWords(C, 11);
> #ZOW11;
23
> ZOW11 subset W11;
true
```

152.8.6 Covering Radius and Diameter

`CosetDistanceDistribution(C)`

Given a linear code C, determine the coset distance distribution of C, relative to C. The distance between C and a coset D of C is the Hamming weight of a vector of minimum weight in D. The distribution is returned as a sequence of pairs comprising a distance d and the number of cosets that are distance d from C.

`CoveringRadius(C)`

The covering radius of the linear code C.

`Diameter(C)`

The diameter of the code C (the largest weight of the codewords of C).

Example H152E24

We construct the second order Reed–Muller code of length 32, and calculate its coset distance distribution.

```
> R := ReedMullerCode(2, 5);
> R:Minimal;
[32, 16, 8] Reed-Muller Code (r = 2, m = 5) over GF(2)
> CD := CosetDistanceDistribution(R);
> CD;
[ <0, 1>, <1, 32>, <2, 496>, <3, 4960>, <4, 17515>, <5, 27776>, <6, 14756> ]
```

From the dimension of the code we know C has 2^{16} cosets. The coset distance distribution tells us that there are 32 cosets at distance 1 from C, 496 cosets are distance 2, etc. We confirm that all cosets are represented in the distribution.

```
> &+ [ t[2] : t in CD ];
65536
> CoveringRadius(R);
6
> Diameter(R);
32
> WeightDistribution(R);
[ <0, 1>, <8, 620>, <12, 13888>, <16, 36518>, <20, 13888>, <24, 620>, <32, 1> ]
```

The covering radius gives the maximum distance of any coset from the code, and, from the coset distance distribution, we see that this maximum distance is indeed 6. We can confirm the value (32) for the diameter by examining the weight distribution and seeing that 32 is the largest weight of a codeword.

152.9 Families of Linear Codes

152.9.1 Cyclic and Quasicyclic Codes

`CyclicCode(u)`

Given a vector u belonging to the R-space $R^{(n)}$, construct the $[n, k]$ cyclic code generated by the right cyclic shifts of the vector u.

`CyclicCode(n, T, K)`

Given a positive integer n and a set or sequence T of primitive n-th roots of unity from a finite field L, together with a subfield K of L, construct the cyclic code C over K of length n, such that the generator polynomial for C is the polynomial of least degree having the elements of T as roots.

`QuasiCyclicCode(n, Gen)`

Constructs the quasi-cyclic code of length n with generator polynomials given by the sequence of polynomials in Gen. Created by `HorizontalJoin` of each `GeneratorMatrix` from the `CyclicCode`'s generated by the polynomials in Gen. Requires that $|Gen| \mid n$.

`QuasiCyclicCode(Gen)`

Constructs the quasi-cyclic code of length n generated by simultaneous cyclic shifts of the vectors in Gen.

`QuasiCyclicCode(n, Gen, h)`

Constructs the quasi-cyclic code of length n with generator polynomials given by the sequence of polynomials in Gen. The `GeneratorMatrix`'s are joined 2 dimensionally, with height h. Requires that $h \mid (|Gen|)$ and $(|Gen|/h) \mid n$.

`QuasiCyclicCode(Gen, h)`

Constructs the quasi cyclic code generated by simultaneous cyclic shifts of the vectors in Gen, arranging them two dimensionally with height h.

`ConstaCyclicCode(n, f, alpha)`

Return the length n code generated by consta-cyclic shifts by α of the coefficients of f.

`QuasiTwistedCyclicCode(n, Gen, alpha)`

Construct the quasi-twisted cyclic code of length n pasting together the constacyclic codes with parameter α generated by the polynomials in Gen.

`QuasiTwistedCyclicCode(Gen, alpha)`

Construct the quasi-twisted cyclic code generated by simultaneous constacyclic shifts w.r.t. α of the codewords in Gen.

Example H152E25

Let the m factors of $x^n - 1$ be $f_i(x)$,$i = 0, \ldots, m$ in any particular order. Then we can construct a chain of polynomials $g_k(x) = \prod_{i=0}^{k} f_i(x)$ such that $g_k(x) \mid g_{k+1}(x)$. This chain of polynomials will generate a nested chain of cyclic codes of length n, which is illustrated here for $n = 7$.

```
> P<x> := PolynomialRing(GF(2));
> n := 7;
> F := Factorization(x^n-1);
> F;
[
    <x + 1, 1>,
    <x^3 + x + 1, 1>,
    <x^3 + x^2 + 1, 1>
]
```

```
> Gens := [ &*[F[i][1]:i in [1..k]] : k in [1..#F] ];
> Gens;
[
    x + 1,
    x^4 + x^3 + x^2 + 1,
    x^7 + 1
]
> Codes := [ CyclicCode(n, Gens[k]) : k in [1..#Gens] ];
> Codes;
[
    [7, 6, 2] Cyclic Code over GF(2)
    Generator matrix:
    [1 0 0 0 0 0 1]
    [0 1 0 0 0 0 1]
    [0 0 1 0 0 0 1]
    [0 0 0 1 0 0 1]
    [0 0 0 0 1 0 1]
    [0 0 0 0 0 1 1],
     [7, 3, 4] Cyclic Code over GF(2)
    Generator matrix:
    [1 0 0 1 0 1 1]
    [0 1 0 1 1 1 0]
    [0 0 1 0 1 1 1],
    [7, 0, 7] Cyclic Code over GF(2)
]
> { Codes[k+1] subset Codes[k] : k in [1..#Codes-1] };
{ true }
```

152.9.2 BCH Codes and their Generalizations

`BCHCode(K, n, d, b)`

`BCHCode(K, n, d)`

Given a finite field $K = F_q$ and positive integers n, d and b such that $\gcd(n, q) = 1$, we define m to be the smallest integer such that $n \mid (q^m - 1)$, and α to be a primitive n-th root of unity in the degree m extension of K, $GF(q^m)$. This function constructs the BCH code of designated distance d as the cyclic code with generator polynomial

$$g(x) = \text{lcm}\{m_1(x), \cdots, m_{d-1}(x)\}$$

where $m_i(x)$ is the minimum polynomial of α^{b+i-1}. The BCH code is an $[n, \geq (n - m(d-1)), \geq d]$ code over K. If b is omitted its value is taken to be 1, in which case the corresponding code is a *narrow sense* BCH code.

Example H152E26

We construct a BCH code of length 13 over GF(3) and designated minimum distance 3

```
> C := BCHCode(GF(3), 13, 3);
> C;
[13, 7, 4] BCH code (d = 3, b = 1) over GF(3)
Generator matrix:
[1 0 0 0 0 0 0 1 2 1 2 2 2]
[0 1 0 0 0 0 0 1 0 0 0 1 1]
[0 0 1 0 0 0 0 2 2 2 1 1 2]
[0 0 0 1 0 0 0 1 1 0 1 0 0]
[0 0 0 0 1 0 0 0 1 1 0 1 0]
[0 0 0 0 0 1 0 0 0 1 1 0 1]
[0 0 0 0 0 0 1 2 1 2 2 2 1]
```

`GoppaCode(L, G)`

Let K be the field $GF(q)$, let $G(z) = G$ be a polynomial defined over the degree m extension field F of K (i.e. the field $GF(q^m)$) and let $L = [\alpha_1, \ldots, \alpha_n]$ be a sequence of elements of F such that $G(\alpha_i) \neq 0$ for all $\alpha_i \in L$. This function constructs the Goppa code $\Gamma(L, G)$ over K. If the degree of $G(z)$ is r, this is an $[n, k \geq n - mr, d \geq r + 1]$ code.

Example H152E27

We construct a Goppa code of length 31 over GF(2) with generator polynomial $G(z) = z^3 + z + 1$.

```
> q := 2^5;
> K<w> := FiniteField(q);
> P<z> := PolynomialRing(K);
> G := z^3 + z + 1;
> L := [w^i : i in [0 .. q - 2]];
> C := GoppaCode(L, G);
> C:Minimal;
[31, 16, 7] Goppa code (r = 3) over GF(2)
> WeightDistribution(C);
[ <0, 1>, <7, 105>, <8, 295>, <9, 570>, <10, 1333>, <11, 2626>,
 <12, 4250>, <13, 6270>, <14, 8150>, <15, 9188>, <16, 9193>,
 <17, 8090>, <18, 6240>, <19, 4270>, <20, 2590>, <21, 1418>,
 <22, 650>, <23, 195>, <24, 55>, <25, 36>, <26, 11> ]
```

`ChienChoyCode(P, G, n, S)`

Let P and G be polynomials over a finite field F, let n be an integer greater than one, and let S be a subfield of F. Suppose also that n is coprime to the cardinality of S, F is the splitting field of x^n-1 over S, P and G are both coprime to x^n-1 and both have degree less than n. This function constructs the Chien-Choy generalised BCH code with parameters P, G, n over S.

`AlternantCode(A, Y, r, S)`

`AlternantCode(A, Y, r)`

Let $A = [\alpha_1, \ldots, \alpha_n]$ be a sequence of n distinct elements taken from the degree m extension K of the finite field S, and let $Y = [y_1, \ldots, y_n]$ be a sequence of n non-zero elements from K. Let r be a positive integer. Given such A, Y, r, and S, this function constructs the alternant code $A(A, Y)$ over S. This is an $[n, k \geq n - mr, d \geq r + 1]$ code. If S is omitted, S is taken to be the prime subfield of K.

Example H152E28

We construct an alternant code over GF(2) based on sequences of elements in the extension field GF(2^4) of GF(2). The parameter r is taken to be 4, so the minimum weight 6 is greater than $r + 1$.

```
> q := 2^4;
> K<w> := GF(q);
> A := [w ^ i : i in [0 .. q - 2]];
> Y := [K ! 1 : i in [0 .. q - 2]];
> r := 4;
> C := AlternantCode(A, Y, r);
> C;
[15, 6, 6] Alternant code over GF(2)
Generator matrix:
[1 0 0 0 0 0 1 1 0 0 1 1 1 0 0]
[0 1 0 0 0 0 0 1 1 0 0 1 1 1 0]
[0 0 1 0 0 0 0 0 1 1 0 0 1 1 1]
[0 0 0 1 0 0 1 1 0 1 0 1 1 1 1]
[0 0 0 0 1 0 1 0 1 0 0 1 0 1 1]
[0 0 0 0 0 1 1 0 0 1 1 1 0 0 1]
```

`NonPrimitiveAlternantCode(n, m, r)`

Returns the $[n, k, d]$ non-primitive alternant code over $\mathbf{F}_2$, where $n - mr \leq k \leq n - r$ and $d \geq r + 1$.

`FireCode(h, s, n)`

Let K be the field $GF(q)$. Given a polynomial h in K[X], a nonnegative integer s, and a positive integer n, this function constructs a Fire code of length n with generator polynomial $h(X^s - 1)$.

`GabidulinCode(A, W, Z, t)`

Given sequences $A = [a_1, ...a_n]$, $W = [w_1, ...w_s]$, and $Z = [z_1, ...z_k]$, such that the $n+s$ elements of A and W are distinct and the elements of Z are non-zero, together with a positive integer t, construct the Gabidulin MDS code with parameters A, W, Z, t.

`SrivastavaCode(A, W, mu, S)`

Given sequences $A = [\alpha_1, ..., \alpha_n]$, $W = [w_1, ..., w_s]$ of elements from the extension field K of the finite field S, such that the elements of A are non-zero and the $n + s$ elements of A and W are distinct, together with an integer μ, construct the Srivastava code of parameters A, W, mu, over S.

`GeneralizedSrivastavaCode(A, W, Z, t, S)`

Given sequences $A = [\alpha_1, ..., \alpha_n]$, $W = [w_1, ..., w_s]$, and $Z = [z_1, ...z_k]$ of elements from the extension field K of the finite field S, such that the elements of A and Z are non-zero and the $n + s$ elements of A and W are distinct, together with a positive integer t, construct the generalized Srivastava code with parameters A, W, Z, t, over S.

152.9.3 Quadratic Residue Codes and their Generalizations

If p is an odd prime, the *quadratic residues modulo p* consist of the set of non-zero squares modulo p while the set of non-squares modulo p are termed the *quadratic nonresidues modulo p*.

`QRCode(K, n)`

Given a finite field $K = F_q$ and an odd prime n such that q is a quadratic residue modulo n, this function returns the quadratic residue code of length n over K. This corresponds to the cyclic code with generator polynomial $g_0(x) = \prod(x - \alpha^r)$, where α is a primitive n-th root of unity in some extension field of K, and the product is taken over all quadratic residues modulo p.

`GolayCode(K, ext)`

If the field K is $GF(2)$, construct the binary Golay code. If the field K is $GF(3)$, construct the ternary Golay code. If the boolean argument *ext* is `true`, construct the extended code in each case.

`DoublyCirculantQRCode(p)`

Given an odd prime p, this function returns the doubly circulant binary $[2p, p]$ code based on quadratic residues modulo p. A doubly circulant code has generator matrix of the form $[I \mid A]$, where A is a circulant matrix.

`DoublyCirculantQRCodeGF4(m, a)`

Given a prime power m that is greater than 2 and an integer a that is either 0 or 1, return a $[2m, m]$ doubly circulant linear code over GF(4). For details see [Gab02].

`BorderedDoublyCirculantQRCode(p, a, b)`

Given an odd prime p and integers a and b, this function returns the bordered doubly circulant binary $[2p + 1, p + 1]$ code based on quadratic residues modulo p. The construction is similar to that of a doubly circulant code except that the first p rows are extended by a mod 2 while the $p + 1$-th row is extended by b mod 2.

`TwistedQRCode(l, m)`

Given positive integers l and m, both coprime to 2, return a binary "twisted QR" code of length $l * m$.

`PowerResidueCode(K, n, p)`

Given a finite field $K = F_q$, a positive integer n and a prime p such that q is a p-th power residue modulo n, construct the p-th power residue code of length n.

Example H152E29

We construct a quadratic residue code of length 23 over GF(3).

```
> QRCode(GF(3), 23);
[23, 12, 8] Quadratic Residue code over GF(3)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 2 2 2 1 1 0 2 0 2 0 0]
[0 1 0 0 0 0 0 0 0 0 0 0 0 2 2 2 1 1 0 2 0 2 0]
[0 0 1 0 0 0 0 0 0 0 0 0 0 0 2 2 2 1 1 0 2 0 2]
[0 0 0 1 0 0 0 0 0 0 0 0 2 2 2 0 0 2 0 1 2 2 0]
[0 0 0 0 1 0 0 0 0 0 0 0 0 2 2 2 0 0 2 0 1 2 2]
[0 0 0 0 0 1 0 0 0 0 0 0 2 2 1 0 0 0 2 2 2 1 2]
[0 0 0 0 0 0 1 0 0 0 0 0 2 1 1 2 1 0 2 2 1 2 1]
[0 0 0 0 0 0 0 1 0 0 0 0 1 0 2 0 1 1 1 2 0 1 2]
[0 0 0 0 0 0 0 0 1 0 0 0 2 0 2 0 1 1 0 1 1 0 1]
[0 0 0 0 0 0 0 0 0 1 0 0 1 0 1 1 2 1 2 0 2 1 0]
[0 0 0 0 0 0 0 0 0 0 1 0 0 1 0 1 1 2 1 2 0 2 1]
[0 0 0 0 0 0 0 0 0 0 0 1 1 1 2 2 0 1 0 1 0 0 2]
```

152.9.4 Reed–Solomon and Justesen Codes

`ReedSolomonCode(K, d, b)`

`ReedSolomonCode(K, d)`

Given a finite field $K = F_q$ and a positive integer d, return the Reed–Solomon code of length $n = q - 1$ with design distance d. This corresponds to `BCHCode(K, q-1, d)`. For details see [MS78, p.294].

If b is given as a non-negative integer then the primitive element is first raised to the b-th power.

`ReedSolomonCode(n, d)`

`ReedSolomonCode(n, d, b)`

Given an integer n such that $q = n + 1$ is a prime power, and a positive integer d, return the Reed–Solomon code over F_q of length n and designed minimum distance d.

If b is given as a non-negative integer then the primitive element is first raised to the b-th power.

`GRSCode(A, V, k)`

Let $A = [\alpha_1, \ldots, \alpha_n]$ be a sequence of n distinct elements taken from the finite field K, and let $V = [v_1, \ldots, v_n]$ be a sequence of n non-zero elements from K. Let k be a non-negative integer. Given such A, V, and k, this function constructs the generalized Reed–Solomon code $GRS_k(A, V)$ over K. This is an $[n, k' \leq k]$ code. For details see [MS78, p.303].

`JustesenCode(N, K)`

Given an integer N such that $N = 2^m - 1$ and a positive integer K, construct the binary linear Justesen code of length $2mN$ and dimension mK. For details see [MS78, p.307].

Example H152E30

We construct a generalized Reed–Solomon code over GF(2) based on sequences of elements in the extension field GF(2^3) of GF(2). The parameter k is taken to be 3, so the dimension 3 is at most k.

```
> q := 2^3;
> K<w> := GF(q);
> A := [w ^ i : i in [0 .. q - 2]];
> V := [K ! 1 : i in [0 .. q - 2]];
> k := 3;
> C := GRSCode(A, V, k);
[7, 3, 5] GRS code over GF(2^3)
Generator matrix:
[  1   0   0 w^3   w   1 w^3]
[  0   1   0 w^6 w^6   1 w^2]
```

```
[  0   0   1 w^5 w^4   1 w^4]
```

152.9.5 Maximum Distance Separable Codes

`MDSCode(K, k)`

Given a finite field $GF(q = 2^m)$, this function constructs the $[q + 1, k, q - k + 2]$ maximum distance separable code.

152.10 New Codes from Existing

The operations described here produce a new code by modifying in some way the codewords of a given code.

152.10.1 Standard Constructions

`AugmentCode(C)`

Given an $[n, k]$ binary code C, construct a new code C' by including the all-ones vector with the words of C (provided that it is not already in C).

`CodeComplement(C, C1)`

Given a subcode $C1$ of C, return a code $C2$ such that $C = C1 + C2$.

`DirectSum(C, D)`

Given an $[n_1, k_1]$ code C and an $[n_2, k_2]$ code D, both over the same field F, construct the direct sum of C and D. The direct sum consists of all vectors $u|v$, where $u \in C$ and $v \in D$.

`DirectSum(Q)`

Given a sequence of codes $Q = [C_1, \ldots, C_r]$, all defined over the same field F, construct the direct sum of the C_i.

`DirectProduct(C, D)`

`ProductCode(C, D)`

Given an $[n_1, k_1]$ code C and an $[n_2, k_2]$ code D, both over the same ring R, construct the direct product of C and D. The direct product has length $n_1 \cdot n_2$, dimension $k_1 \cdot k_2$, and its generator matrix is the Kronecker product of the basis matrices of C and D.

`ExtendCode(C)`

Given an $[n, k, d]$ code C form a new code C' from C by adding the appropriate extra coordinate to each vector of C such that the sum of the coordinates of the extended vector is zero. (Thus if C is a binary code, the construction will add a 0 at the end of every codeword having even weight, and a 1 at the end of every codeword having odd weight.)

`ExtendCode(C, n)`

Return the code C extended n times.

`PadCode(C, n)`

Add n zeros to the end of each codeword of C.

`ExpurgateCode(C)`

Construct a new code by deleting all the code words of C having odd weight.

`ExpurgateCode(C, L)`

The sequence L consists of codewords from C. The result is obtained by deleting the words in L from C.

`ExpurgateWeightCode(C, w)`

Delete a subspace generated by a word of weight w.

`LengthenCode(C)`

Given an $[n, k]$ binary code C, construct a new code by first adding the all-ones codeword, and then extending it by adding an overall parity check.

`PlotkinSum(C1, C2)`

Given two codes over the same alphabet, return the code consisting of all vectors of the form $u|u + v$, where $u \in C1$ and $v \in C2$. Zeros are appended where needed to make up any length differences in the two codes. The result is a $[n_1 + \max\{n_1, n_2\}, k_1 + k_2, \min\{2 * d_1, d_2\}]$ code.

`PlotkinSum(C1, C2, C3:` *parameters*`)`

`a` FldFinElt *Default :* -1

Given three codes over the same alphabet, return the code consisting of all vectors of the form $u|u + a * v|u + v + w$, where $u \in C1$, $v \in C2$ and $w \in C3$. Zeros are appended where needed to make up any length differences in the three codes. The result for the default case of `a := -1` is a $[n_1 + \max\{n_1, n_2\} + \max\{n_1, n_2, n_3\}, k_1 + k_2 + k_3, \min\{3 * d_1, 2 * d_2, d_3\}]$ code.

`PunctureCode(C, i)`

Given an $[n, k]$ code C, and an integer i, $1 \leq i \leq n$, construct a new code C' by deleting the i-th coordinate from each code word of C.

`PunctureCode(C, S)`

Given an $[n, k]$ code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$ each of which lies in the range $[1, n]$, construct a new code C' by deleting the components $i_1, \cdots, i_r$ from each code word of C.

`ShortenCode(C, i)`

Given an $[n, k]$ code C and an integer i, $1 \leq i \leq n$, construct a new code from C by selecting only those codewords of C having a zero as their i-th component and deleting the i-th component from these codewords. Thus, the resulting code will have length $n - 1$.

`ShortenCode(C, S)`

Given an $[n, k]$ code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$, each of which lies in the range $[1, n]$, construct a new code from C by selecting only those codewords of C having zeros in each of the coordinate positions $i_1, \cdots, i_r$, and deleting these components. Thus, the resulting code will have length $n - r$.

Example H152E31

Using only two simple `RepetitionCode`'s and several standard constructions, we create a $[12, 4, 6]$ code. This is the best possible minimum weight for a code of this length and dimension, as is the minimum weight for all codes produced in this example.
Instead of printing each individual code out, the codes are named by convention as c_n_k_d, where n, k, d represent the `Length`,`Dimension` and `MinimumWeight` respectively.

```
> c_4_1_4 := RepetitionCode(GF(2),4);
> c_6_1_6 := RepetitionCode(GF(2),6);
> c_4_3_2 := Dual( c_4_1_4 );
> c_8_4_4 := PlotkinSum( c_4_3_2 , c_4_1_4 );
> c_7_4_3 := PunctureCode( c_8_4_4 , 8 );
> c_6_3_3 := ShortenCode(  c_7_4_3 , 7 );
> c_12_4_6 := PlotkinSum( c_6_3_3 , c_6_1_6 );
> c_12_4_6;
[12, 4, 6] Linear Code over GF(2)
Generator matrix:
[1 0 0 1 1 0 0 1 1 0 0 1]
[0 1 0 1 0 1 0 1 0 1 0 1]
[0 0 1 1 1 1 0 0 1 1 1 1]
[0 0 0 0 0 0 1 1 1 1 1 1]
```

152.10.2 Changing the Alphabet of a Code

`ExtendField(C, L)`

Given an $[n, k, d]$ code C defined over the finite field K, and an extension field L of K, construct the code C' over L corresponding to C. The function also returns the embedding map from C into C'.

`LinearCode(C, S)`

Given an $[n, k, d]$ code C defined over the finite field K, and a subfield S of K such that the degree of K over S is m, construct a new $[N = mn, k, D \geq d]$ code C' over S by replacing each component of each codeword of C by its representation as a vector over S. The function also returns the isomorphism from C onto C'.

`SubfieldRepresentationCode(C, K)`

Given a linear code over $GF(q^m)$, return a code whose codewords are obtained from those of C by expanding each coordinate in $GF(q^m)$ as a vector of dimension m over $K = GF(q)$.

`SubfieldRepresentationParityCode(C, K)`

Given a linear code over $GF(q^m)$, return a code whose codewords are obtained from those of C by expanding each coordinate in $GF(q^m)$ as a vector of dimension $m+1$ over $K = GF(q)$, including a parity check bit.

`SubfieldSubcode(C, S)`
`RestrictField(C, S)`
`SubfieldSubcode(C)`
`RestrictField(C)`

Given an $[n, k, d]$ code C defined over the field K, and a subfield S of K, construct a new $[n, K \leq k, D \geq d]$ code C' over S consisting of the codewords of C which have all their components in S. If S is omitted, it is taken to be the prime subfield of K. The function also returns the restriction map from C to the subfield subcode C'.

`SubfieldCode(C, S)`

Given an $[n, k]$ code C defined over the field K, and a subfield S of K, such that K is a degree m extension of S, construct a new $[n, k']$ code over S by expanding each element of K as a column vector over S. The new code will have $k' \leq km$.

`Trace(C, F)`
`Trace(C)`

Given a code C defined over the field K, and a subfield F of K, construct a new code C' over F consisting of the traces with respect to F of each of the codewords of L. If F is omitted, it is taken to be the prime subfield of K.

152.10.3 Combining Codes

`C1 cat C2`

Given codes $C1$ and $C2$, both defined over the same field K, return the concatenation C of $C1$ and $C2$. If A and B are the generator matrices of $C1$ and $C2$, respectively, the concatenation of $C1$ and $C2$ is the code with generator matrix whose rows consist of each row of A concatenated with each row of B.

`Juxtaposition(C1, C2)`

Given an $[n_1, k, d_1]$ code $C1$ and an $[n_2, k, d_2]$ code $C2$ of the same dimension, where both codes are defined over the same field K, the function returns a $[n_1 + n_2, k, \geq d_1 + d_2]$ code whose generator matrix is `HorizontalJoin(A, B)`, where A and B are the generator matrices for codes $C1$ and $C2$, respectively.

`ConcatenatedCode(O, I)`

Given a $[N, K, D]$-code O defined over $GF(q^k)$ and a $[n, k, d]$-code I defined over $GF(q)$, construct the $[Nn, Kk, \delta \geq dD]$ concatenated code by taking O as outer code and I as inner code.

Example H152E32

We use the function `ConcatenatedCode` to construct a $[69, 19, 22]$ code over $GF(2)$, this being the best known code for this length and dimension. While it is theoretically possible for a code of minimum weight up to 24 to exist, the best binary $[69, 19]$ code at the time of writing (July 2001) has minimum weight 22.

```
> C1 := ShortenCode( QRCode(GF(4),29) , {24..29} );
> C1:Minimal;
[23, 9] Linear Code over GF(2^2)
> C2 := ConcatenatedCode( C1 , CordaroWagnerCode(3) );
> C2:Minimal;
[69, 18] Linear Code over GF(2)
> res := C2 + RepetitionCode(GF(2),69);
> res:Minimal;
[69, 19] Linear Code over GF(2)
> MinimumWeight(res);
22
> res:Minimal;
[69, 19, 22] Linear Code over GF(2)
```

`ConstructionX(C1, C2, C3)`

Let C_1, C_2 and C_3 be codes with parameters $[n_1, k_1, d_1]$, $[n_2, k_2, d_2]$ and $[n_3, k_3, d_3]$, respectively, where $C2$ is a union of b cosets of $C1$, (so $n_1 = n_2$ and $k_2 \leq k_1$) and $k_1 = k_2 + k_3$. The construction divides $C2$ into a union of cosets of $C1$ and attaches a different codeword of $C3$ to each coset. The new code has parameters $[n_1 + n_3, k_1, \geq \min\{\ d_2, d_1 + d_3\}]$. For further details see [MS78, p.581].

`ConstructionXChain(S, C)`

Given a sequence of codes S where all codes are subcodes of the first one, apply `ConstructionX` to $S[1], S[2]$ and C. Then compute the resulting subcodes from the other codes in S.

Example H152E33

We create a $[161, 29, 53]$ code by applying construction X to two BCH codes of length 127. To maximise the resulting minimum weight we take the best known $[34, 14]$ code as C_3. The construction sets a lower bound on the minimum weight, making the calculation of the true minimum weight much faster.

```
> SetPrintLevel("Minimal");
>
> C1 := BCHCode(GF(2), 127, 43);
> C2 := BCHCode(GF(2), 127, 55);
> C3 := BKLC(GF(2), 34, 14);
> C1; C2; C3;
[127, 29, 43] BCH code (d = 43, b = 1) over GF(2)
[127, 15, 55] BCH code (d = 55, b = 1) over GF(2)
[34, 14, 10] Linear Code over GF(2)
> CX := ConstructionX(C1, C2, C3);
> CX;
[161, 29] Linear Code over GF(2)
> time MinimumWeight(CX);
53
Time: 0.010
```

`ConstructionX3(C1, C2, C3, D1, D2)`

Given a chain of codes $C1 = [n, k_1, d_1]$, $C2 = [n, k_2, d_2]$, and $C3 = [n, k_3, d_3]$ with $k_3 < k_2 < k_1$, and suffix codes $D1 = [n_1, k_1 - k_2, e_1]$ and $D2 = [n_2, k_3 - k_2, e_2]$, construct a code $C = [n+n_1+n_2, k_1, \geq min\{d_3, d_1+e_1, d_2+e_2\}$. For further details see [MS78, p.583].

`ConstructionX3u(C1, C2, C3, D1, D2)`

Given two chains of codes $C1 = [n, k_1] \subset C2 = [n, k_2] \subset C3 = [n, k_3]$ and $D1 = [n', k_1 - k_3] \subset D2 = [n', k_2 - k_3]$, return the codes $C = [n+n', k_1] \subset C' = [n+n', k_2]$ using Construction X with $C1, C3$ and $D1$ resp. $C2, C3$ and $D2$.

Example H152E34

We construct a best known $[74, 43, 11]$ code using construction X3. From a chain of BCH subcodes, we take an subcode to get the appropriate length, then use construction X3 with the best possible codes $D1, D2$. Because the construction algorithm sets a lower bound on the minimum weight, then it is quick to calculate afterwards.

```
> SetPrintLevel("Minimal");
> C1 := ExtendCode( BCHCode(GF(2), 63, 7) );
> C2 := ExtendCode( BCHCode(GF(2), 63, 9) );
> C3 := ExtendCode( BCHCode(GF(2), 63, 11) );
> C1; C2; C3;
[64, 45, 8] Linear Code over GF(2)
[64, 39, 10] Linear Code over GF(2)
[64, 36, 12] Linear Code over GF(2)
> CC := SubcodeBetweenCode(C1, C2, 43);
> CC;
[64, 43] Linear Code over GF(2)
> MinimumWeight(CC);
8
> CX3 := ConstructionX3(CC, C2, C3,
>                 BKLC(GF(2), 7, 4), BKLC(GF(2), 3, 3));
> CX3;
[74, 43] Linear Code over GF(2)
> time MinimumWeight(CX3);
11
Time: 0.000
```

`ConstructionXX(C1, C2, C3, D2, D3)`

Let the parameters of codes C_1, C_2, C_3 be $[n_1, k, d_1], [n_1, k - l_2, d_2]$ and $[n_1, k - l_3, d_3]$ respectively, where C_2 and C_3 are subcodes of C_1. Codes D_2, D_3 must have dimensions l_2, l_3, with parameters $[n_2, l_2, \delta_2], [n_3, l_3, \delta_3]$ say. The construction breaks C_1 up into cosets of C_2 and C_3 with the relevant tails added from D_2 and D_3. If the intersection of C_1 and C_2 has minimum distance d_0 then the newly constructed code will have parameters $[n_1 + n_2 + n_3, k, min\{d_0, d_2 + \delta_2, d_3 + \delta_3, d_1 + \delta_2 + \delta_3\}]$. For further details see [All84].

Example H152E35

We construct a best known $[73, 38, 13]$ code C using construction XX. For C_1, C_2, C_3 we take three cyclic (or BCH) codes of length 63, while for D_1, D_2 we use two Best Known Codes.

```
> SetPrintLevel("Minimal");
> C1 := BCHCode(GF(2),63,10,57);
> P<x> := PolynomialRing(GF(2));
> p := x^28 + x^25 + x^22 + x^21 + x^20 + x^17 + x^16
>      + x^15 + x^9 + x^8 + x^6 + x^5 + x + 1;
```

```
> C2 := CyclicCode(63, p);
> C3 := BCHCode(GF(2), 63, 10, 58);
> C1; C2; C3;
[63, 38] BCH code (d = 10, b = 57) over GF(2)
[63, 35] Cyclic Code over GF(2)
[63, 32] BCH code (d = 10, b = 58) over GF(2)
> MinimumDistance(C1 meet C2);
12
```

So the minimum distance of the code produced by Construction XX must be at least 12.

```
> C := ConstructionXX(C1, C2, C3, BKLC(GF(2),3,3), BKLC(GF(2),7,6) );
> C;
[73, 38] Linear Code over GF(2)
MinimumDistance(C);
13
```

Thus the actual minimum distance is one greater than the lower bound guaranteed by Construction XX.

`ZinovievCode(I, O)`

The arguments are as follows: The first argument must be a sequence I containing an increasing chain of r codes with parameters,

$$[n, k_1, d_1]_q \subset [n, k_2, d_2]_q \subset \ldots \subset [n, k_r, d_r]_q$$

where $0 = k_0 < k_1 < k_2 < \ldots < k_r$, (the *inner codes*). The second argument must be a sequence O of r codes with parameters $[N, K_i, D_i]_{Q_i}$, where $Q_i = q^{e_i}$ and $e_i = k_i - k_{i-1}$ for $i = 1 \ldots r$ (the *outer codes*). The function constructs a generalised concatenated $[n * N, K, D]_q$ code is constructed, where $K = e_1 K_1 + \ldots + e_r K_r$ and $D = min(d_1 D_1, \ldots, d_r D_r)$. For further details see [MS78, p.590].

Example H152E36

We create a $[72, 41, 12]$ code over $GF(2)$ using the `ZinovievCode` function, which is the best known code for this length and dimension. While it is theoretically possible for a $[72, 41]$ code to have minimum weight up to 14, at the time of writing (July 2001) the best known code has minimum weight 12. The minimum weight is not calculated since it is a lengthy calculation.

```
> I1 := RepetitionCode(GF(2),8);
> I2 := I1 + LinearCode( KMatrixSpace(GF(2),3,8) !
>                 [0,1,0,0,0,1,1,1,0,0,1,0,1,0,1,1,0,0,0,1,1,1,0,1]
>                      );
> I3 := Dual(I1);
> Inner := [I1, I2, I3];
> Inner:Minimal;
[
    [8, 1, 8] Cyclic Code over GF(2),
```

```
    [8, 4, 4] Linear Code over GF(2),
    [8, 7, 2] Cyclic Code over GF(2)
]
>
> O1 := Dual(RepetitionCode(GF(2),9));
> O2 := BCHCode(GF(8),9,3,4);
> O3 := BCHCode(GF(8),9,6,7);
> Outer := [O1, O2, O3];
> Outer:Minimal;
[
    [9, 8, 2] Cyclic Code over GF(2),
    [9, 7, 3] BCH code (d = 3, b = 4) over GF(2^3),
    [9, 4, 6] BCH code (d = 6, b = 7) over GF(2^3)
]
>
> C := ZinovievCode(Inner, Outer);
> C:Minimal;
[72, 41] Linear Code over GF(2)
```

`ConstructionY1(C)`

Apply construction $Y1$ to the code C. This construction applies the shortening operation at the positions in the support of a word of minimal weight in the dual of C. If C is a $[n, k, d]$ code, whose dual code has minimum weight d', then the returned code has parameters $[n - d', k - d' + 1, \geq d]$. For further details see [MS78, p.592].

`ConstructionY1(C, w)`

Apply construction $Y1$ to the code C. This construction applies the shortening operation at the positions in the support of a word of weight w in the dual of C. If C is a $[n, k, d]$ code, then the returned code has parameters $[n - w, k - w + 1, \geq d]$.

152.11 Coding Theory and Cryptography

One of the few public-key cryptosystems which does not rely on number theory is the McEliece cryptosystem, whose security depends on coding theory. An attack on the McEliece cryptosystem must determine the coset leader (of known weight) from a user defined error coset. In general it is assumed that the code in question has no known structure, and it treated as a random code.

The best known attacks on the McEliece cryptosystem are a series of probabilistic enumeration-based algorithms.

152.11.1 Standard Attacks

`McEliecesAttack(C, v, e)`

`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform the original decoding attack described by McEliece when he defined his cryptosystem. Random information sets are tested for being disjoint for the support of the desired error vector. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

If set to a non-zero positive value, the variable argument `MaxTime` aborts the computation if it goes to long. The argument `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

`LeeBrickellsAttack(C, v, e, p)`

`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform the decoding attack described by Lee and Brickell. Random information sets are tested for having weight less than or equal to p. For most sized codes, the optimal input parameter for this attack is $p = 2$. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

If set to a non-zero positive value, the variable argument `MaxTime` aborts the computation if it goes to long. The argument `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

`LeonsAttack(C, v, e, p, l)`

`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform the decoding attack described by Leon. For random information sets of size k, a punctured code of length $k + l$ is investigated for codewords of weight less than or equal to p. For small codes (up to length around 200), the optimal input parameter for this attack is $p = 2$ with l somewhere in the range $3 - 6$. For larger code $p = 3$ can sometimes be faster, with values of l in the range $7 - 10$. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

If set to a non-zero positive value, the variable argument `MaxTime` aborts the computation if it goes to long. The argument `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

`SternsAttack(C, v, e, p, l)`

`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform the decoding attack described by Stern. For random information sets of size k, a punctured code of length $k+l$ is split into two subspaces. Each subspace is enumerated up to information weight p and collisions found with zero non-information weight. For small to mid-range codes (up to length around 500), the optimal input parameter for this attack is $p = 2$ with l somewhere in the range $9 - 13$. For larger code $p = 3$ can sometimes be faster, with values of l from 20 to much higher. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

If set to a non-zero positive value, the variable argument `MaxTime` aborts the computation if it goes to long. The argument `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

`CanteautChabaudsAttack(C, v, e, p, l)`

`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform the decoding attack described by Canteaut and Chabaud. For random information sets of size k, a punctured code of length $k+l$ is split into two subspaces. Using the enumeration technique identical to that of Stern's attack, a different linear algebra process steps through information sets more quickly. The price for this is less independent information sets. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

For most codes (up to length around 1000), the optimal input parameter for this attack is $p = 1$ with l somewhere in the range $6 - 9$. For very large codes $p = 2$ can sometimes be faster, with values of l from 20 to much higher.

If set to a non-zero positive value, the variable argument `MaxTime` aborts the computation if it goes to long. The argument `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

152.11.2 Generalized Attacks

All of the decoding attacks on the McEliece cryptosystem can be put into a uniform framework, consisting of repeated operation of a two stage procedure. Magma allows the user to choose any combination of the implemented methods, which include improvements on the standard attacks.

`DecodingAttack(C, v, e)`

`Enumeration`	MonStgElt	*Default :* "*Standard*"
`MatrixSequence`	MonStgElt	*Default :* "*Random*"

`NumSteps`	RngIntElt	*Default :* 1
`p`	RngIntElt	*Default :* 2
`l`	RngIntElt	*Default :*
`MaxTime`	FldReElt	*Default :* ∞
`DirectEnumeration`	BoolElt	*Default :* `true`

Perform a generalized decoding attack by specifying the enumeration and matrix sequence procedures to be used. This intrinsic attempts to enumerate a vector of weight e from the error coset $v + C$ for the given vector v.

The parameter `Enumeration` can take the values `"Standard"`, `"Leon"` or `"HashTable"`, and correspond to the methods used in Lee and Brickells, Leons and Sterns attacks respectively.

The parameter `MatrixSequence` can take on the values `"Random"` or `"Stepped"`, corresponding to either a completely random sequence of information sets or a sequence of sets differing in one place.

The integer valued `NumSteps` offers a generalization of the stepped matrix process, taking a sequence of sets which differ at the specified number of places.

The parameter `p` and `l` describe the enumeration process, and their exact meaning depends on the enumeration process in question. See the earlier descriptions of the standard attacks for a full description of their meanings.

For codes of lengths anywhere between $500 - 1000$, the best performance can be obtained using a multiply stepped matrix sequence, using around 10 steps at a time. This is in conjunction with the hashtable enumeration technique using $p = 2$ and l in the range $15 - 20$.

If set to a non-zero positive value, the variable parameter `MaxTime` aborts the computation if it goes to long. The parameter `DirectEnumeration` controls whether or not the coset is enumerated directly, or whether the larger code generated by $\langle C, v\rangle$ is enumerated.

152.12 Bounds

Magma supplies various functions for computing lower and upper bounds for parameters associated with codes. It also contains tables of best known bounds for linear codes. The functions in this section only apply to codes over finite fields.

152.12.1 Best Known Bounds for Linear Codes

A Magma database allows the user access to tables giving the best known upper and lower bounds of the `Length`, `Dimension`, and `MinimumWeight` of linear codes. Tables are currently available relating to codes over $GF(2)$ and $GF(4)$ with $1 \leq$ `Length` ≤ 256, over $GF(3)$ with $1 \leq$ `Length` ≤ 243, over $GF(5), GF(8)$, and $GF(9)$ with $1 \leq$ `Length` ≤ 130, and over $GF(7)$ with $1 \leq$ `Length` ≤ 100.

`BKLCLowerBound(F, n, k)`

Returns the best known lower bound on the maximum possible minimum weight of a linear code over finite field F having length n and dimension k.

`BKLCUpperBound(F, n, k)`

Returns the best known upper bound on the minimum weight of a linear code over finite field F of length n and dimension k.

`BLLCLowerBound(F, k, d)`

Returns the best known lower bound on the minimum possible length of a linear code over finite field F having dimension k and minimum weight at least d. If the required length is out of the range of the database then no bound is available and -1 is returned.

`BLLCUpperBound(F, k, d)`

Returns the best known upper bound on the minimum possible length of a linear code over finite field F of dimension k and minimum weight at least d. If the required length is out of the range of the database then no bound is available and -1 is returned.

`BDLCLowerBound(F, n, d)`

Returns the best known lower bound on the maximum possible dimension of a linear code over finite field F having length n and minimum weight at least d.

`BDLCUpperBound(F, n, d)`

Returns the best known upper bound on the dimension of a linear code over finite field F having length n and minimum weight at least d.

152.12.2 Bounds on the Cardinality of a Largest Code

`EliasBound(K, n, d)`

Return the Elias upper bound of the cardinality of a largest code of length n and minimum distance d over the field K.

`GriesmerBound(K, n, d)`

Return the Griesmer upper bound of the cardinality of a largest code of length n and minimum distance d over the field K.

`JohnsonBound(n, d)`

Return the Johnson upper bound of the cardinality of a largest binary code of length n and minimum distance d.

`LevenshteinBound(K, n, d)`

Return the Levenshtein upper bound of the cardinality of a largest code of length n and minimum distance d over the field K.

`PlotkinBound(K, n, d)`

Return the Plotkin upper bound on the cardinality of a (possibly non-linear) code of length n and minimum distance d over the field K. The bound is formed by calculating the maximal possible average distance between codewords.

For binary codes the bound exists for $n \leq 2d$, (d even), or $n \leq 2d+1$ (d odd). For codes over general fields the bound exists for $d > (1 - 1/\#K) * n$.

`SingletonBound(K, n, d)`

Return the Singleton upper bound of the cardinality of a largest code of length n and minimum distance d over the field K.

`SpherePackingBound(K, n, d)`

Return the Hamming sphere packing upper bound on the cardinality of a largest codes of length n and minimum distance d over the field K.

`GilbertVarshamovBound(K, n, d)`

Return the Gilbert–Varshamov lower bound of the cardinality of a largest code (possibly non-linear) of length n and minimum distance d over the field K.

`GilbertVarshamovLinearBound(K, n, d)`

Return the Gilbert–Varshamov lower bound of the cardinality of a largest linear code of length n and minimum distance d over the field K.

`VanLintBound(K, n, d)`

Return the van Lint lower bound of the cardinality of a largest code of length n and minimum distance d over the field K.

Example H152E37

We compare computed and stored values of best known upper bounds of the dimension of binary linear codes of length 20. The cardinality of a linear code of dimension k over $\mathbf{F}_q$ is q^k, and so the computed bounds on cardinality are compared with the stored bounds on dimension by taking logs.

```
> n:=20;
> K := GF(2);
> [ Ilog(#K, Minimum({GriesmerBound(K, n, d), EliasBound(K, n, d),
>                       JohnsonBound(n, d) , LevenshteinBound(K, n, d),
>                       SpherePackingBound(K, n, d)})) : d in [1..n] ];
[ 20, 19, 15, 14, 12, 11, 9, 8, 5, 4, 3, 2, 2, 1, 1, 1, 1, 1, 1, 1 ]
> [ BDLCUpperBound(K, n, d) : d in [1..n] ];
[ 20, 19, 15, 14, 11, 10, 9, 8, 5, 4, 3, 2, 2, 1, 1, 1, 1, 1, 1, 1 ]
```

152.12.3 Bounds on the Minimum Distance

`BCHBound(C)`

Given a cyclic code C, return the BCH bound for C. This a lower bound on the minimum weight of C.

`GriesmerMinimumWeightBound(K, n, k)`

Return the Griesmer upper bound of the minimum weight of a linear code of length n and dimension k over the field K.

152.12.4 Asymptotic Bounds on the Information Rate

`EliasAsymptoticBound(K, delta)`

Return the Elias asymptotic upper bound of the information rate for δ in $[0, 1]$ over the field K.

`McElieceEtAlAsymptoticBound(delta)`

Return the McEliece–Rodemich–Rumsey–Welch asymptotic upper bound of the binary information rate for δ in $[0, 1]$.

`PlotkinAsymptoticBound(K, delta)`

Return the Plotkin asymptotic upper bound of the information rate for δ in $[0, 1]$ over the field K.

`SingletonAsymptoticBound(delta)`

Return the Singleton asymptotic upper bound of the information rate for δ in $[0, 1]$ over any finite field.

`HammingAsymptoticBound(K, delta)`

Return the Hamming asymptotic upper bound of the information rate for δ in $[0, 1]$ over the field K.

`GilbertVarshamovAsymptoticBound(K, delta)`

Return the Gilbert–Varshamov asymptotic lower bound of the information rate for δ in $[0, 1]$ over the field K.

152.12.5 Other Bounds

`GriesmerLengthBound(K, k, d)`

Return the Griesmer lower bound of the length of a linear code of dimension k and minimum distance d over K.

152.13 Best Known Linear Codes

An $[n, k]$ linear code C is said to be a *best known linear* $[n, k]$ *code* (BKLC) if C has the highest minimum weight among all known $[n, k]$ linear codes.

An $[n, k]$ linear code C is said to be an *optimal linear* $[n, k]$ *code* if the minimum weight of C achieves the theoretical upper bound on the minimum weight of $[n, k]$ linear codes.

MAGMA currently has databases for best known linear codes over $GF(q)$ for $q = 2, 3, 4, 5, 7, 8, 9$. There is also a database of best known quantum codes that can be found in Chapter 157. The database for codes over $GF(2)$ contains constructions of best codes of length up to $n_{\max} = 256$. The codes of length up to $n_{\text{opt}} = 31$ are optimal. The database is complete in the sense that it contains a construction for every set of parameters. Thus the user has access to 33 152 best-known binary codes.

The database for codes over $GF(3)$ contains constructions of best codes of up to length $n_{\max} = 243$. The codes of length up to $n_{\text{opt}} = 21$ are optimal. The database is complete up to length $n_{\text{complete}} = 100$. Many of the codes constructed in this database are vast improvements on the previously known bounds for best codes over $GF(3)$. The database of codes over $GF(3)$ is a contribution of Markus Grassl, Karlsruhe.

The database for codes over $GF(4)$ contains constructions of best codes of up to length $n_{\max} = 256$. The codes of length up to $n_{\text{opt}} = 18$ are optimal. The database is over 65% complete with the first missing code coming at length 98. Many of the codes constructed in this database are vast improvements on the previously known bounds for best codes over $GF(4)$.

Similar databases for other small fields have been added in V2.14. They are contributions of Markus Grassl, Karlsruhe. The statistics of all databases are summarised in the following table.

	$GF(2)$	$GF(3)$	$GF(4)$	$GF(5)$	$GF(7)$	$GF(8)$	$GF(9)$
$n_{\max}$	256	243	256	130	100	130	130
n_{opt}	31	21	18	15	14	14	16
n_{complete}	256	100	97	80	68	76	93
total	33 152	29 889	33 152	8 645	5 150	8 645	8 645
missing	0	6 545	11 379	527	381	1 763	1 333
filled	100%	78.10%	65.67%	93.90%	92.60%	79.61%	84.58%

Compared to previous released versions of the MAGMA BKLC database, 1308 codes over $GF(2)$, 102 codes over $GF(3)$ and 160 codes over $GF(4)$ have been improved, and the maximal length for codes over $GF(3)$ and $GF(4)$ has been increased to 243 and 256, respectively.

Best known upper and lower bounds on the minimum weight for $[n, k]$ linear codes are also available (see section 152.12.1).

The MAGMA BKLC database makes use of the tables of bounds compiled by A. E. Brouwer [Bro98]. The online version of these tables [Bro] has been discontinued. Similar tables are now maintained by Markus Grassl [Gra]. Any improvements, errors, or problems with the MAGMA BKLC database should be reported to `codes@codetables.de`.

It should be noted that the MAGMA BKLC database is unrelated to the similar (but rather incomplete) BKLC database forming part of GUAVA, a share package in GAP3.

A significant number of entries in the MAGMA BKLC database provide better codes than the corresponding ones listed in Brouwer's tables.

The construction of the MAGMA BKLC database has been undertaken by John Cannon (Sydney), Markus Grassl (Karlsruhe) and Greg White (Sydney). The authors wish to express their appreciation to the following people who generously supplied codes, constructions or other assistance: Nuh Aydin, Anton Betten, Michael Braun, Iliya Bouyukliev, Andries Brouwer, Tat Chan, Zhi Chen, Rumen Daskalov, Scott Duplichan, Iwan Duursma, Yves Edel, Sebastian Egner, Peter Farkas, Damien Fisher, Philippe Gaborit, Willi Geiselmann, Stephan Grosse, Aaron Gulliver, Masaaki Harada, Ray Hill, Plamen Hristov, David Jaffe, Axel Kohnert, San Ling, Simon Litsyn, Pawel Lizak, Tatsuya Maruta, Masami Mohri, Masakatu Morii, Harald Niederreiter, Ayoub Otmani, Fernanda Pambianco, James B. Shearer, Neil Sloane, Roberta Sabin, Cen Tjhai, Ludo Tolhuizen, Martin Tomlinson, Gerard van der Geer, Henk van Tilborg, Chaoping Xing, Karl-Heinz Zimmermann, Johannes Zwanzger.

Given any two of the parameters: length, dimension, and minimum weight, then MAGMA will return the code with the best possible value of the omitted parameter. Given a specified length and minimum weight, for example, will result in a corresponding code of maximal possible dimension.

The user can display the method used to construct a particular BKLC code through use of a verbose mode, triggered by the verbose flag `BestCode`. When it is set to `true`, all of the functions in this section will output the steps involved in each code they construct. While some codes are defined by stored generator matrices, and some use constructions which are not general enough, or safe enough, to be available to the user, most codes are constructed using standard MAGMA functions. Note that having the verbose flag `Code` set to `true` at the same time can produce mixed and confusing output, since the database uses functions which have verbose outputs dependent on this flag.

`BKLC(K, n, k)`

`BestKnownLinearCode(K, n, k)`

Given a finite field K, a positive integer n, and a non-negative integer k such that $k \leq n$, return an $[n, k]$ linear code over K which has the largest minimum weight among all known $[n, k]$ linear codes. A second boolean return value signals whether or not the desired code exists in the database.

The databases currently available are over $GF(q)$ for $q = 2, 3, 4, 5, 7, 8, 9$ of length up to $n_{\max}$ as given in the table above.

If the verbose flag `BestCode` is set to true then the method used to construct the code will be printed.

`BLLC(K, k, d)`

`BestLengthLinearCode(K, k, d)`

Given a finite field K, and positive integers k and d, return a linear code over K with dimension k and minimum weight at least d which has the shortest length among

known codes. A second boolean return value signals whether or not the desired code exists in the database.

The databases currently available are over $GF(q)$ for $q = 2, 3, 4, 5, 7, 8, 9$ of length up to $n_{\max}$ as given in the table above.

If the verbose flag `BestCode` is set to true then the method used to construct the code will be printed.

`BDLC(K, n, d)`

`BestDimensionLinearCode(K, n, d)`

Given a finite field K, a positive integer n, and a positive integer d such that $d \leq n$, return a linear code over K with length n and minimum weight $\geq d$ which has the largest dimension among known codes. A second boolean return value signals whether or not the desired code exists in the database.

The databases currently available are over $GF(q)$ for $q = 2, 3, 4, 5, 7, 8, 9$ of length up to $n_{\max}$ as given in the table above.

If the verbose flag `BestCode` is set to true then the method used to construct the code will be printed.

Example H152E38

We look at some best known linear codes over $GF(2)$. Since the database over $GF(2)$ is completely filled, we can ignore the second boolean return value.

```
> C := BKLC(GF(2),23,12);
> C;
[23, 12, 7] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 0]
[0 1 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1]
[0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1 0]
[0 0 0 0 1 0 0 0 0 0 0 0 0 0 1 1 1 1 0 1 1 0 1]
[0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1 0]
[0 0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 0 1 1 0 0 1 1]
[0 0 0 0 0 0 0 0 1 0 0 0 1 1 0 1 1 1 0 0 0 1 1]
[0 0 0 0 0 0 0 0 0 1 0 0 1 0 1 0 1 0 0 1 0 1 1]
[0 0 0 0 0 0 0 0 0 0 1 0 1 0 0 1 0 0 1 1 1 1 1]
[0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 0 1]
> WeightDistribution(C);
[ <0, 1>, <7, 253>, <8, 506>, <11, 1288>, <12, 1288>, <15, 506>,
<16, 253>, <23, 1> ]
> BKLCLowerBound(GF(2),23,12), BKLCUpperBound(GF(2),23,12);
7 7
```

So we see that this code is optimal, in the sense that it meets the best known upper bound on its minimum weight. (All best known binary codes of length up to 31 are optimal).

However larger best known codes are not optimal, making it theoretically possible that better codes exist.

```
> C := BKLC(GF(2),145,36);
> C:Minimal;
[145, 36, 42] Linear Code over GF(2)
> BKLCLowerBound(GF(2),145,36), BKLCUpperBound(GF(2),145,36);
42 52
```

Example H152E39

We look at some best known codes over $GF(4)$. Since this database is only approximately 66% complete, it is necessary to check the second boolean return value to know if the database contained the desired code.

```
> F<w> := GF(4);
> C, has_code := BKLC(F, 14, 9);
> has_code;
true
> C;
[14, 9, 4] Linear Code over GF(2^2)
Generator matrix:
[  1   0   0   0   0   0   0   0   0   0   0 w^2   w   1]
[  0   1   0   0   0   0   0   0   0   0   1   1   1 w^2]
[  0   0   1   0   0   0   0   0   0   0 w^2   w   0   w]
[  0   0   0   1   0   0   0   0   0   0   w   1   1   w]
[  0   0   0   0   1   0   0   0   0   0   w   0   w w^2]
[  0   0   0   0   0   1   0   0   0   0 w^2   1   1   1]
[  0   0   0   0   0   0   1   0   0   0   1   w w^2   0]
[  0   0   0   0   0   0   0   1   0   0   0   1   w w^2]
[  0   0   0   0   0   0   0   0   1   0 w^2 w^2   0   1]
> BKLCLowerBound(F, 14, 9), BKLCUpperBound(F, 14, 9);
4 4
```

Since the database over $GF(4)$ is completely filled up to length 97 the boolean value was in fact unnecessary in this case. We see that the minimum weight of this code reaches the theoretical upper bound, as do all best known codes over $GF(4)$ up to length 18.
For longer lengths we have the possibility that the database may not contain the desired code.

```
> C, has_code := BKLC(F, 98, 57);
> has_code;
false
> C;
[98, 0, 98] Cyclic Linear Code over GF(2^2)
>
> C, has_code := BKLC(F, 98, 58);
> has_code;
true
> C:Minimal;
```

```
[98, 58, 16] Linear Code over GF(2^2)
```

Example H152E40

We search for best known codes using dimension and minimum weight, looking at codes over $GF(2)$ of dimension 85. Even though the database over $GF(2)$ is 100% filled up to length 256, the code required may be longer than that so we have to check the second boolean return value.

```
> C, has_code := BestLengthLinearCode(GF(2),85,23);
> has_code;
true
> C:Minimal;
[166, 85, 23] Linear Code over GF(2)
>
> C, has_code := BestLengthLinearCode(GF(2),85,45);
> has_code;
true
> C:Minimal;
[233, 85, 45] Linear Code over GF(2)
>
> C, has_code := BestLengthLinearCode(GF(2),85,58);
> has_code;
false
```

Example H152E41

For a given minimum weight, we find the maximal known possible dimensions for a variety of code lengths over $GF(4)$.
For lengths < 98 we know the database is filled so we do not need to check the second boolean return value.

```
> F<w> := GF(4);
> C := BDLC(F, 12, 8);
> C;
[12, 3, 8] Linear Code over GF(2^2)
Generator matrix:
[  1   0   0   w w^2   w w^2   w   w   1   w   w]
[  0   1   0   w w^2   1   0 w^2   w   0 w^2 w^2]
[  0   0   1   0   1 w^2 w^2 w^2   0 w^2   w   w]
>
> C := BDLC(F, 27, 8);
> C:Minimal;
[27, 15, 9] Linear Code over GF(2^2)
> C := BDLC(F, 67, 8);
> C:Minimal;
[67, 52, 8] Linear Code over GF(2^2)
```

But for lengths ≥ 98 there may be gaps in the database so to be safe we check the second value.

```
> C, has_code := BDLC(F, 99, 8);
```

```
> has_code;
true
> C:Minimal;
[99, 81, 8] Linear Code over GF(2^2)
> C, has_code := BDLC(F, 195, 8);
> has_code;
true
> C:Minimal;
[195, 174, 8] Linear Code over GF(2^2)
```

Example H152E42

We find the best known code of length 54 and dimension 36, then using the output of the verbose mode we re-create this code manually.

```
> SetPrintLevel("Minimal");
> SetVerbose("BestCode",true);
> a := BKLC(GF(2), 54, 36);
Construction of a [ 54 , 36 , 8 ] Code:
[1]:  [63, 46, 7] Cyclic Code over GF(2)
       CyclicCode of length 63 with generating polynomial x^17 +
       x^16 + x^15 + x^13 + x^12 + x^8 + x^6 + x^4 + x^3 + x^2 +
       1
[2]:  [64, 46, 8] Linear Code over GF(2)
       ExtendCode [1] by 1
[3]:  [54, 36, 8] Linear Code over GF(2)
       Shortening of [2] at { 55 .. 64 }
> a;
[54, 36, 8] Linear Code over GF(2)
>
> P<x> := PolynomialRing(GF(2));
> p := x^17 + x^16 + x^15 + x^13 + x^12 + x^8 + x^6 + x^4 +
>                                          x^3 + x^2 + 1;
> C1 := CyclicCode(63, p);
> C1;
[63, 46] Cyclic Code over GF(2)
> C2 := ExtendCode(C1);
> C2;
[64, 46] Linear Code over GF(2)
> C3 := ShortenCode(C2, {55 .. 64});
> C3;
[54, 36, 8] Linear Code over GF(2)
>
> C3 eq a;
true
```

152.14 Decoding

Magma supplies functions for decoding vectors from the ambient space of a linear code C. The functions in this section only apply to codes over finite fields.

`Decode(C, v: parameters)`

`Al` MonStgElt *Default :* "*Euclidean*"

Given a linear code C and a vector v from the ambient space V of C, attempt to decode v with respect to C. Currently the accessible algorithms are: syndrome decoding (which is demonstrated manually in the example in the Coset Leaders section above); and a Euclidean algorithm, which operates on alternant codes (BCH, Goppa, and Reed–Solomon codes, etc.). While the Euclidean algorithm cannot correct as many errors as can the syndrome algorithm, in general it is much faster, since the syndrome algorithm requires the coset leaders of the code and is also inapplicable as soon as the codimension of the code is moderately large. If the code is alternant, the Euclidean algorithm is used by default, but the syndrome algorithm will be used if the parameter `Al` is assigned the value `"Syndrome"`. For non-alternant codes, only syndrome decoding is possible, so the parameter `Al` is not relevant. If the decoding algorithm succeeds in computing a vector v' as the decoded version of v, then the function returns `true` and v'. (In the Euclidean case it may even happen that v' is not in C because there are too many errors in v to correct.) If the decoding algorithm does not succeed in decoding v, then the function returns `false` and the zero vector.

`Decode(C, Q: parameters)`

`Al` MonStgElt *Default :* "*Euclidean*"

Given a linear code C and a sequence Q of vectors from the ambient space V of C, attempt to decode the vectors of Q with respect to C. This function is similar to the function `Decode(C, v)` except that rather than decoding a single vector, it decodes a sequence of vectors and returns a sequence of booleans and a sequence of decoded vectors corresponding to the given sequence. The algorithm used and effect of the parameter `Al` are as for the function `Decode(C, v)`.

Example H152E43

We create a code C and a vector v of C and then perturb v to a new vector w. We then decode w to find v again.

```
> C := GolayCode(GF(2), false);
> v := C ! [1,1,1,1,0,0,0,1,0,0,1,1,0,0,0,1,0,0,0,1,1,1,1];
> w := v;
> w[5] := 1 - w[5];
> w[20] := 1 - w[20];
> v;
(1 1 1 1 0 0 0 1 0 0 1 1 0 0 0 1 0 0 0 1 1 1 1)
> w;
(1 1 1 1 1 0 0 1 0 0 1 1 0 0 0 1 0 0 0 0 1 1 1)
```

```
> v - w;
(0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0)
> b, d := Decode(C, w);
> b;
true
> d;
(1 1 1 1 0 0 0 1 0 0 1 1 0 0 0 1 0 0 0 1 1 1 1)
> d eq v;
true
> Decode(C, [w]);
[ true ]
[
    (1 1 1 1 0 0 0 1 0 0 1 1 0 0 0 1 0 0 0 1 1 1 1)
]
```

152.15 Transforms

152.15.1 Mattson–Solomon Transforms

`MattsonSolomonTransform(f, n)`

Given f, a polynomial over a finite field containing a primitive n-th root of unity, return the Mattson–Solomon transform of parameter n.

`InverseMattsonSolomonTransform(A, n)`

Given A, a polynomial over a finite field containing a primitive n-th root of unity, return the inverse Mattson–Solomon transform of parameter n.

Example H152E44

We compute the Mattson–Solomon transform of parameter $n = 7$ of the polynomial x^4+x^2+x+1 over $\mathbf{F}_{2^{12}}$.

```
> n := 7;
> K := GF(2, 12);
> FP<x> := PolynomialRing(K);
> f := x^4 + x^2 + x + 1;
> A := MattsonSolomonTransform(f, n);
> A;
x^6 + x^5 + x^3
```

152.15.2 Krawchouk Polynomials

`KrawchoukPolynomial(K, n, k)`

Return the Krawchouk polynomial of parameters k and n in K over the rational field.

`KrawchoukTransform(f, K, n)`

Return the Krawchouk transform of the polynomial f over the rational field with respect to the vector space K^n.

`InverseKrawchouk(A, K, n)`

Return the inverse Krawchouk transform of the polynomial A over the rational field with respect to the vector space K^n.

152.16 Automorphism Groups

152.16.1 Introduction

Let C be an $[n, k]$ linear code and G a permutation group of degree n. Then G acts on C in the following way: for a codeword v of C and a permutation x of G, the image of v under x is obtained from v by permuting the coordinate positions of v according to x. We call this the *permutation* action of G on C.

If C is a non-binary code over a finite field, there is also a *monomial* action on C. Let K be the alphabet of C. A monomial permutation of monomial degree n is equivalent to a permutation s on $K^* \times \{1, \ldots, n\}$ which satisfies the following property:

$$(\alpha, i)^s = (\beta, j) \text{ implies } (\gamma\alpha, i)^s = (\gamma\beta, j)$$

for all $\alpha, \beta, \gamma \in K^*$ and $i, j \in \{1, \ldots, n\}$. The actual degree of s is $(q-1)n$. Note that s is completely determined by its action on the points $(1, i)$ for each i, and the matrix representation of s is also determined by its action on the elements $(1, i)$, for $1 \leq i \leq n$. To represent a monomial permutation of monomial degree n, we number the pair (α, i) by $(q-1)(i-1)+\alpha$ and then use a permutation s of degree $(q-1)n$.

The functions in this section allow one to investigate such actions. The algorithms in MAGMA to compute with such actions are backtrack searches due to Jeff Leon [Leo82][Leo97]. There are 4 algorithms which are provided for codes of length n over a field of cardinality q:

(a) *Automorphism group* or *Monomial group.* Computes the group of monomials which map a code into itself, where monomials are represented as permutations of degree $(q-1)n$ (so the group has degree $(q-1)n$). For this function q may be any small prime or 4.

(b) *Permutation group.* Computes the group of permutations which map a code into itself (so the group has degree n). For this function q may be any small prime or 4.

(c) *Equivalence test.* Computes whether there is a monomial permutation which maps a code to another code and, if so, returns the monomial as a permutation of degree $(q-1)n$. For this function, q may be any small prime or 4.

(d) *Isomorphism test.* Computes whether there is a permutation which maps a code to another code and returns the permutation (of degree n) if so. For this function q may only be 2.

For more information on permutation group actions and orbits, see Chapter 58.

152.16.2 Group Actions

`v ^ x`

Given a codeword v belonging to the $[n, k]$ code C and an element x belonging to a permutation group G, construct the vector w obtained from v by the action of x. If G has degree n, the permutation action is used; otherwise G should have degree $n(q-1)$ and the monomial action is used.

`v ^ G`

Given a codeword v belonging to the $[n, k]$ code C and a permutation group G (with permutation or monomial action on C), construct the vector orbit Y of v under the action of G. The orbit Y is a G-set for the group G.

`C ^ x`

Given an $[n, k]$ code C and an element x belonging to a permutation group G (with permutation or monomial action on C), construct the code consisting of all the images of the codewords of C under the action of x.

`C ^ G`

Given an $[n, k]$ code C and a permutation group G (with permutation or monomial action on C), construct the orbit Y of C under the action of G. The orbit Y is a G-set for the group G.

`S ^ x`

Given a set or sequence S of codewords belonging to the $[n, k]$ code C and an element x belonging to a permutation group (with permutation or monomial action on the codewords), construct the set or sequence of the vectors obtained by permuting the coordinate positions of v, for each v in S, according to the permutation x.

`S ^ x`

Given a set or sequence S of codes of length n and an element x belonging to a permutation group (with permutation or monomial action on the codes) construct the set or sequence of the codes consisting of all the images of the codewords of C under the action of x.

`Fix(C, G)`

Given an $[n, k]$ code C and a permutation group G of degree n, find the subcode of C which consists of those vectors of C which are fixed by the elements of G. That is, the subcode consists of those codewords that are fixed by the group G.

152.16.3 Automorphism Group

`AutomorphismGroup(C: parameters)`

`MonomialGroup(C: parameters)`

`Weight` RngIntElt *Default :* 0

The automorphism group A of the $[n, k]$ linear code C over the field K, where A is the group of all monomial-action permutations which preserve the code. Thus both permutation of coordinates and multiplication of components by non-zero elements from K is allowed, and the degree of A is $n(q-1)$ where q is the cardinality of K. A power structure P and transfer map t are also returned, so that, given a permutation g from A, one can create a map $f = t(g)$ which represents the automorphism g as a mapping $P : C \to C$.

If the code is known to have very few words of low weight, then it may take some time to compute the *support* of the code (a set of low weight words). The optional parameter `Weight` can be used to specify the set of vectors of the specified weight to be used as the support in the algorithm. This set should be of a reasonable size, (possibly hundreds for a large code), while also keeping the weight as small as possible.

Warning: If `Weight` specifies a set that is too small, then the algorithm risks getting stuck.

`PermutationGroup(C)`

The permutation group G of the $[n, k]$ linear code C over the field K, where G is the group of all permutation-action permutations which preserve the code. Thus only permutation of coordinates is allowed, and the degree of G is always n. A power structure P and transfer map t are also returned, so that, given a permutation g from G, one can create a map $f = t(g)$ which represents the automorphism g as a mapping $P : C \to C$.

`AutomorphismSubgroup(C)`

`MonomialSubgroup(C)`

A subgroup of the (monomial) automorphism group A of the code C. If the automorphism group of C is already known then the group returned is the full automorphism group, otherwise it will be a subgroup generated by one element. This allows one to find just one automorphism of C if desired. A power structure P and transfer map t are also returned, so that, given a permutation g from A, one can create a map $f = t(g)$ which represents the automorphism g as a mapping $P : C \to C$.

`AutomorphismGroupStabilizer(C, k)`

`MonomialGroupStabilizer(C, k)`

The subgroup of the (monomial) automorphism group A of the code C, which stabilizes the first k base points as chosen by the backtrack search. These base points may be different to those of the returned group. A power structure P and transfer map t are also returned, so that, given a permutation g from A, one can create a map $f = t(g)$ which represents the automorphism g as a mapping $P : C \to C$.

`Aut(C)`

The power structure A of all automorphisms of the code C (with monomial action), together with the transfer map t into A from the generic symmetric group associated with the automorphism group of C.

`Aut(C, T)`

The power structure A of all automorphisms of the code C, together with the transfer map t into A from the generic symmetric group associated with the automorphism group of C; the string T determines which action type should be used: `"Monomial"` or `"Permutation"`.

Example H152E45

We compute the automorphism group of the second order Reed–Muller code of length 64.

```
> C := ReedMullerCode(2, 6);
> aut := AutomorphismGroup(C);
> FactoredOrder(aut);
[ <2, 21>, [3, 4>, <5, 1>, <7, 2>, <31, 1> ]
> CompositionFactors(aut);
    G
    |  A(5, 2)                = L(6, 2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
```

Example H152E46

We compute the automorphism group of a BCH code using the set of vectors of minimal weight as the invariant set. We look first at its weight distribution to confirm that there is sufficient vectors.

```
> C := BCHCode(GF(2),23,2);
> C;
[23, 12, 7] BCH code (d = 2, b = 1) over GF(2)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 1 1 1 0 1 0]

        23, 19, 13, 15)
```

152.16.4 Equivalence and Isomorphism of Codes

`IsIsomorphic(C, D: parameters)`

`IsEquivalent(C, D: parameters)`

`AutomorphismGroups`	MonStgElt	*Default :* "*Right*"
`Weight`	RngIntElt	*Default :* 0

Given $[n, k]$ codes C and D, this function returns `true` if and only if C is equivalent to D. If C is equivalent to D, an equivalence map f is also returned from C onto D. The equivalence is with respect to the monomial action. The function first computes none, one, or both of the automorphism groups of the left and right codes. This may assist the isomorphism testing.

The parameter `AutomorphismGroups`, with valid string values `Both`, `Left`, `Right`, `None`, may be used to specify which of the automorphism groups should be constructed first if not already known. The default is `Right`.

In rare cases this algorithm can get stuck, due to an insufficient set of invariant vectors. In this case, the optional parameter `Weight` can be used to specify this set to be the vectors of the specified weight. This set should be of a reasonable size, (possibly hundreds for large codes), while also keeping the weight as small as possible.

Warning: If `Weight` specifies a set that is too small, then the algorithm risks getting stuck.

153 ALGEBRAIC-GEOMETRIC CODES

Chapter 153
ALGEBRAIC-GEOMETRIC CODES

153.1 Introduction

Algebraic–Geometric Codes (AG–codes) are a family of linear codes described by Goppa in [Gop81a, Gop81b]. Let $\mathcal{X}$ be an irreducible projective plane curve of genus g, defined by a (absolutely irreducible) homogeneous polynomial $H(X, Y, Z)$ over a finite field $K = \mathbf{F}_q$. A *place* of $\mathcal{X}$ is the maximal ideal of a discrete valuation subring of $\overline{K}(\mathcal{X})$. We denote by v_P the valuation at place P. Its *degree* is the degree of its residue class field over K. A *divisor* is an element D of the free abelian group over the set of places of $\mathcal{X}$. Namely, such an element can be written additively:

$$D = \sum_{P \in \mathrm{Pl}(\mathcal{X})} n_P \cdot P \, ,$$

where all but finitely many $n_P \in \mathbf{Z}$ are zero. The set of places with nonzero multiplicity is the *support* of D, denoted by Supp$D$. The set of divisors can be equipped with a natural partial order $\leq$ defined by:

$$D = \sum_{P \in \mathrm{Pl}(\mathcal{X})} n_P \cdot P \leq D' = \sum_{P \in \mathrm{Pl}(\mathcal{X})} n'_P \cdot P \quad \Longleftrightarrow \quad n_P \leq n'_P \text{ for all } P.$$

If $f \in K(\mathcal{X})$, then one can define the *principal divisor*:

$$(f) = \sum_{P \in \mathrm{Pl}(\mathcal{X})} v_P(f) \cdot P \, .$$

A divisor D is said to be *defined* over K if it is stable under the natural action of $\mathrm{Gal}(\overline{\mathrm{K}}/\mathrm{K})$.

If $(P_1, \ldots, P_n)$ is a tuple of places of degree 1, then for a function $f \in K(\mathcal{X})$, $f(P_i)$ can be seen as an element of K. If D is a divisor defined over K, then the *Riemann–Roch* space $\mathcal{L}(D)$ of D is the K-vector space of dimension k:

$$\mathcal{L}(D) = \{f \in K(\mathcal{X})^* \mid (f) + D \geq 0\} \cup \{0\}.$$

Now provided D has support disjoint from $S = \{P_1, \ldots, P_n\}$, we can define the *algebraic geometric code* to be the $[n, k]_q$-code:

$$C = C(S, D) = \{(f(P_1), \ldots, f(P_n)) \, , f \in \mathcal{L}(D)\}.$$

If $\langle f_1, \ldots, f_k \rangle$ is a base of $\mathcal{L}_K(D)$ as a K-vector space, then a generator matrix for C is:

$$G = \begin{pmatrix} f_1(P_1) & \cdots & f_1(P_n) \\ \vdots & \ddots & \vdots \\ f_k(P_1) & \cdots & f_k(P_n) \end{pmatrix}.$$

Standard references are [Sti93] and [TV91].

There are two different implementations of the construction of AG–Codes in MAGMA. The first was implemented by Lancelot Pecquet and is based on the work of Hache [HLB95, Hac96]. The second approach exploits the divisor machinery for function fields implemented by Florian Hess. In MAGMA V2.8, only the second implementation is exported. It is intended to rework the Pecquet version to take advantage of the new curve machinery before releasing it.

153.2 Creation of an Algebraic Geometric Code

`AlgebraicGeometricCode(S, D)`

`AGCode(S, D)`

Suppose X is an irreducible plane curve. Let S be a sequence of places of X having degree 1 and let D be a divisor of X whose support is disjoint from the support of S. The function returns the (weakly) algebraic–geometric code obtained by evaluating functions of the Riemann–Roch space of D at the points of S. The degree of D need not be bounded by the cardinality of S.

`AlgebraicGeometricDualCode(S, D)`

`AGDualCode(S, D)`

Construct the dual of the algebraic geometric code constructed from the sequence of places S and the divisor D, which corresponds to a differential code. In order to take advantage of the algebraic geometric structure, the dual must be constructed in this way, and not by directly calling the function `Dual`.

`HermitianCode(q, r)`

Given the prime power q and a positive integer r, construct a Hermitian code C with respect to the Hermitian curve

$$X = x^{(q+1)} + y^{(q+1)} + z^{(q+1)}$$

defined over $\mathbf{F}_{q^2}$. The support of C consists of all places of degree one of X over $\mathbf{F}_{q^2}$, with the exception of the place over $P = (1 : 1 : 0)$. The divisor used to define a Riemann–Roch space is $r * P$.

Example H153E1

We construct a $[25, 9, 16]$ code over F_{16} using the genus 1 curve $x^3 + x^2z + y^3 + y^2z + z^3$.

```
> F<w> := GF(16);
> P2<x,y,z> := ProjectiveSpace(F, 2);
> f := x^3+x^2*z+y^3+y^2*z+z^3;
> X := Curve(P2, f);
> g := Genus(X);
> g;
1
> places1 := Places(X, 1);
> #places1;
25
```

We now need to find an appropriate divisor D. Since we require a code of dimension $k = 9$ we take the divisor corresponding to a place of degree $k + g - 1 = 9$ (g is the genus of the curve).

```
> found, place_k := HasPlace(X, 9+g-1);
> D := DivisorGroup(X) ! place_k;
> C := AlgebraicGeometricCode(places1, D);
> C;
[25, 9] Linear Code over GF(2^4)
Generator matrix:

   w^5 w^13]
[0 0 0 0 0 0 0 1 0 w^13 w^6 w^12 w^2 w^3 w^7 w^3 w^4 w^14 w^4 w^11 w^4 w
   w^6 w^4 w^14]
[0 0 0 0 0 0 0 0 1 0 w^11 w w^7 w^12 w^4 w^3 w^6 w^12 w^3 w^13 w^2 w^11
   w^10 w^3 1]
> MinimumDistance(C);
16
```

Example H153E2

We construct a $[44, 12, 29]$ code over F_{16} using the genus 4 curve $(y^2 + xy + x^2)z^3 + y^3z^2 + (xy^3 + x^2y^2 + x^3y + x^4)z + x^3y^2 + x^4y + x^5$ and taking as the divisor a multiple of a degree 1 place.

```
> k<w> := GF(16);
> P2<x,y,z> := ProjectiveSpace(k, 2);
> f := (y^2+x*y+x^2)*z^3+y^3*z^2+(x*y^3+x^2*y^2+x^3*y+x^4)*z+x^3*y^2+x^4*y+x^5;
> X := Curve(P2, f);
> g := Genus(X);
> g;
4
```

We find all the places of degree 1.

```
> places1 := Places(X, 1);
> #places1;
45
```

We choose as our divisor $15 * P1$, where $P1$ is a place of degree 1. Before applying the AG-Code construction we must remove $P1$ from the set of places of degree 1.

```
> P1 := Random(places1);
> Exclude(~places1, P1);
> #places1;
44
> D := 15 * (DivisorGroup(X) ! P1);
> C := AlgebraicGeometricCode(places1, D);
> C:Minimal;
[44, 12] Linear Code over GF(2^4)
> MinimumWeight(C);
29
```

153.3 Properties of AG–Codes

`IsWeaklyAG(C)`

Return `true` if and only if the code C is a weakly algebraic–geometric code, i.e. C has been constructed as an algebraic–geometric code with respect to a divisor of any degree.

`IsWeaklyAGDual(C)`

Return `true` if and only if the code C was constructed as the dual of a weakly algebraic–geometric code.

`IsAlgebraicGeometric(C)`

Return `true` if and only if the code C is of algebraic–geometric construction of length n, built from a divisor D with $deg(D) < n$.

`IsStronglyAG(C)`

Return `true` if and only if C is an algebraic–geometric code of length n constructed from a divisor D satisfying $2g - 2 < deg(D) < n$, where g is the genus of the curve.

153.4 Access Functions

At the time an AG–Code is constructed a number of attributes describing its construction are stored along with the code. The functions in this section give the user access to these attributes.

`Curve(C)`

Given an algebraic–geometric code C, returns the curve from which C was defined.

`GeometricSupport(C)`

Given an algebraic–geometric code C, return the sequence of places which forms the support for C.

`Divisor(C)`

Given an algebraic–geometric code C, return the divisor from which C was constructed.

`GoppaDesignedDistance(C)`

Given an algebraic–geometric code C constructed from a divisor D, return the Goppa designed distance $n - deg(D)$.

153.5 Decoding AG Codes

Specialized decoding algorithms exist for differential code, those which are the duals of the standard algebraic-geometric codes. These algorithms generally require as input another divisor on the curve whose support is disjoint from the divisor defining the code.

`AGDecode(C, v, Fd)`

Decode the received vector v of the dual algebraic geometric code C using the divisor Fd.

Example H153E3

An algebraic-geometric code with Goppa designated distance of 3 is used to correct one error.

```
> q := 8;
> F<a> := GF(q);
> PS<x,y,z> := ProjectiveSpace(F, 2);
> W := x^3*y + y^3*z + x*z^3;
> Cv := Curve(PS, W);
> FF<X,Y> := FunctionField(Cv);
> Pl := Places(Cv, 1);
> plc := Place(Cv ! [0,1,0]);
> P := [ Pl[i] : i in [1..#Pl] | Pl[i] ne plc ];
> G := 11*plc;
> C := AGDualCode(P, G);
>
> v := Random(C);
> rec_vec := v;
> rec_vec[Random(1,Length(C))] +:= Random(F);
> res := AGDecode(C, v, 4*plc);
> res eq v;
true
```

153.6 Toric Codes

`ToricCode(P, q)`

The linear code C over the finite field $\mathbf{F}_q$ associated with the lattice points of the polygon P.

To achieve this, after a translation so that the lattice points of P lie in the first quadrant, as close to the origin as possible, these points must lie in the box $[0, q-2] \times [0, q-2]$. Then the code is the monomial evaluation code where each point (a, b) corresponds to the monomial $x^a y^b$, and these monomials are evaluated at the points of the torus $(\mathbf{F}_q^*)^2$.

`ToricCode(S, q)`

`ToricCode(S, q)`

The linear code C over the finite field $\mathbf{F}_q$ associated with the lattice points in S. (Note that the points will be translated to lie within a box at the origin of the first quadrant, as is usual.)

Example H153E4

We construct the toric code based on the lattice points in the polygon with vertices $(3,0)$, $(5,0)$, $(3,3)$, $(1,5)$, $(0,3)$, $(0,1)$.

```
> P := Polytope( [[3,0], [5,0], [3,3], [1,5], [0,3], [0,1]] );
> C := ToricCode(P, 7);
> [ Length(C), Dimension(C), MinimumDistance(C) ];
[ 36, 19, 12 ]
```

We can compare this with the current database of best known linear codes.

```
> BKLCLowerBound(Field(C), Length(C), Dimension(C));
11
```

154 LOW DENSITY PARITY CHECK CODES

Chapter 154
LOW DENSITY PARITY CHECK CODES

154.1 Introduction

Low density parity check (LDPC) codes are among the best performing codes in practice, being capable of correcting errors close to the Shannon limit. MAGMA provides facilities for the construction, decoding, simulation and analysis of LDPC codes.

154.1.1 Constructing LDPC Codes

LDPC codes come in two main varieties, *regular* and *irregular*, defined by the row and column weights of the sparse parity check matrix. If all columns in the parity check matrix have some constant weight a, and all rows have some constant weight b, then the LDPC code is said to be (a, b)-regular. When either the columns or the rows have a distribution of weights, the LDPC code is said to be irregular.

Currently, there do not exist many techniques for the explicit construction of LDPC codes. More commonly, these codes are selected at random from an ensemble, and their properties determined through simulation.

`LDPCCode(H)`

Given a sparse binary matrix H, return the LDPC code which has H as its parity check matrix.

`GallagerCode(n, a, b)`

Return a random (a, b)-regular LDPC code of length n, using Gallager's original method of construction. The row weight a must dividethe length n.

`RegularLDPCEnsemble(n, a, b)`

Return a random code from the ensemble of (a, b)-regular binary LDPC codes.

`IrregularLDPCEnsemble(n, Sv, Sc)`

Given (unnormalized) distributions for the variable and check weights, return length n irregular LDPC codes whose degree distributions match the given distribution. The arguments Sv and Sc are sequences of real numbers, where the i-th entry indicates what percentage of the variable (resp. check) nodes should have weight i.

Note that the distributions will not be matched perfectly unless everything is in complete balance.

`MargulisCode(p)`

Return the (3,6)-regular binary LDPC code of length $2(p^3 - p)$ using the group-based construction of Margulis.

Example H154E1

Most LDPC constructions are generated pseudo-randomly from an ensemble, so the same function will return a different code each time. To be able to re-use an LDPC code, the sparse parity check matrix which must be saved.

```
> C1 := RegularLDPCEnsemble(10, 2, 4);
> C2 := RegularLDPCEnsemble(10, 2, 4);
> C1 eq C2;
false
> LDPCMatrix(C1):Magma;
SparseMatrix(GF(2), 5, 10, [
    4, 2,1, 3,1, 4,1, 6,1,
    4, 1,1, 7,1, 9,1, 10,1,
    4, 1,1, 2,1, 3,1, 7,1,
    4, 5,1, 6,1, 8,1, 9,1,
    4, 4,1, 5,1, 8,1, 10,1
])
> H := SparseMatrix(GF(2), 5, 10, [
>     4, 2,1, 3,1, 4,1, 6,1,
>     4, 1,1, 7,1, 9,1, 10,1,
>     4, 1,1, 2,1, 3,1, 7,1,
>     4, 5,1, 6,1, 8,1, 9,1,
>     4, 4,1, 5,1, 8,1, 10,1 ]);
> C3 := LDPCCode(H);
> C3 eq C1;
true
```

154.1.2 Access Functions

Since a code can have many different parity check matrices, the matrix which defines a code as being LDPC must be assigned specifically. Any parity check matrix can be assigned for this purpose, and once a code is assigned an LDPC matrix it is considered by MAGMA to be an LDPC code (regardless of the density or other properties of the matrix). The matrix must be of sparse type (`MtrxSprs`).

`IsLDPC(C)`

Return true if C is an LDPC code (which is true if it has been assigned an LDPC matrix).

`AssignLDPCMatrix(~C, H)`

Given a sparse matrix H which is a parity check matrix of the code C, assign H as the LDPC matrix of C.

`LDPCMatrix(C)`

Given an LDPC code C, return the sparse matrix which has been assigned as its low density parity check matrix.

`LDPCDensity(C)`

Given an LDPC code C, return the density of the sparse matrix which has been assigned as its low density parity check matrix.

`IsRegularLDPC(C)`

Returns true if C is an LDPC code and has regular column and row weights. If true, the row and column weights are also returned.

`TannerGraph(C)`

For an LDPC code C, return its Tanner graph. If there are n variables and m checks, then the graph has $n+m$ nodes, the first n of which are the variable nodes.

`LDPCGirth(C)`

For an LDPC code C, return the girth of its Tanner graph.

`LDPCEnsembleRate(v, c)`

`LDPCEnsembleRate(Sv, Sc)`

Return the theoretical rate of LDPC codes from the ensemble described by the given inputs.

Example H154E2

In MAGMA, whether or not a code is considered LDPC is based solely on whether or not an LDPC matrix has been assigned. This example shows that any code can be made to be considered LDPC, although a random parity check matrix without low density will perform very badly using LDPC decoding.

```
> C := RandomLinearCode(GF(2),100,50);
> IsLDPC(C);
false
> H := SparseMatrix(ParityCheckMatrix(C));
> H;
Sparse matrix with 50 rows and 100 columns over GF(2)
> AssignLDPCMatrix(~C, H);
> IsLDPC(C);
true
> LDPCDensity(C);
0.25340000000000014122036873232
```

The density of the parity check matrices of LDPC codes is much lower than that of randomly generated codes.

```
> C1 := RegularLDPCEnsemble(100,3,6);
```

```
> C1:Minimal;
[100, 50] Linear Code over GF(2)
> LDPCDensity(C1);
0.059999999999999977795539507497
```

154.1.3 LDPC Decoding and Simulation

The impressive performance of LDPC codes lies in their iterative decoding algorithm. MAGMA provides facilities to decode using LDPC codes, as well as simulating transmission over a binary symmetric or white Gaussian noise channels.

The binary symmetric channel transmits binary values and is defined by $p < 0.5$. Each individual bit independently sustains a "bit-flip" error with probability p.

The Gaussian channel is analog, transmitting real-values, and is defined by a standard deviation σ. Binary values are mapped to -1 and 1 before being transmitted. Each value independently sustains an errors which are normally distributed about 0 with standard deviation σ.

`LDPCDecode(C, v)`

`Channel`	MONSTGELT	*Default :* "*BinarySymmetric*"
`p`	RNGRESUBELT	*Default :* 0.1
`StdDev`	RNGRESUBELT	*Default :* 0.25
`Iterations`	RNGINTELT	*Default :* `Dimension(C)`

For an LDPC code C and a received vector v, decode v to a codeword of C using the LDPC iterative decoding algorithm.

The nature of the channel from which v is received is described by the variable argument `Channel`, which can either be the `BinarySymmetric` channel or the `Gaussian` channel. Errors on the binary symmetric channel is described by the argument `p`, while on the Gaussian channel they are described by `StdDev`.

The vector v must be over a ring corresponding to the channel which is selected. For the binary symmetric channel v must be a binary vector over F_2, while for the Gaussian channel it must be real-valued.

Since the decoding algorithm is iterative and does not necessarily terminate on its own, a maximum number of iterations needs to be specified using the argument `Iterations`. The default value is much larger than would normally be used in practice, giving maximum error-correcting performance (at possibly some cost to efficiency).

Example H154E3

Errors in the binary symmetric channel are just bit flips.

```
> n := 500;
> C := RegularLDPCEnsemble(n, 4, 8);
> e := 5;
```

```
> Errs := {};
> repeat Include(~Errs, Random(1,n)); until #Errs eq e;
> v := Random(C);
> ev := AmbientSpace(C)![ (i in Errs) select 1 else 0 : i in [1..n]];
> rec_vec := v + ev;
> time res := LDPCDecode(C, rec_vec : Channel:="BinarySymmetric", p:=0.2);
Time: 0.000
> res eq v;
true
```

Example H154E4

For the Gaussian channel binary vectors are considered to be transmitted as sequences of the values 1 and -1. Errors are normally distributed with a standard deviation defined by the channel. To simulate a Gaussian channel requires obtaining normally distributed errors. This can be done (discretely) by generating a multiset of possible errors.

```
> sigma := 0.5;
> MaxE := 3.0;
> N := 100;
> V := [ MaxE*(i/N)     : i in [-N div 2..N div 2]];
> E := [ 0.5*(1+Erf(x/(sigma*Sqrt(2)))) : x in V ];
> Dist := {* V[i]^^Round(1000*(E[i]-E[i-1])) : i in [2..#V]*};
```

A codeword of an LDPC code needs to be mapped into the real domain.

```
> n := 500;
> C := RegularLDPCEnsemble(n, 4, 8);
> v := Random(C);
> R := RealField();
> RS := RSpace(R, n);
> vR := RS ! [ IsOne(v[i]) select 1 else -1 : i in [1..n]];
```

Normally distributed errors are then introduced, and the received vector decoded.

```
> for i in [1..n] do
>    vR[i] +:= Random(Dist);
> end for;
> time res := LDPCDecode(C, vR : Channel:="Gaussian", StdDev:=sigma);
Time: 0.000
> res eq v;
true
```

`LDPCSimulate(C, N)`

`Channel`	MonStgElt	*Default :* "*BinarySymmetric*"
`p`	RngReSubElt	*Default :* 0.1
`StdDev`	RngReSubElt	*Default :* 0.25
`Iterations`	RngIntElt	*Default :* `Dimension(C)`

For an LDPC code C, simulate N transmissions across the given channel and return the accumulated bit error rate and word error rate.

The variable arguments are as described for the function `LDPCDecode`. The channel which is described controls not only the way the decoding algorithm functions, but also the nature of the errors introduced during the simulation.

Example H154E5

The more noise that is introduced into the channel the error rate increases. Note that the bit error rate (the first return value) is always lower than the word error rate (the second return value).

```
> C := RegularLDPCEnsemble(200, 3, 6);
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.7);
0.0011824999999999999739519143001 0.006199999999999999978211873141731
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.75);
0.0074949999999999999292617016886243 0.041000000000000000172084568816 90
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.8);
0.033722000000000001973532448 5737 0.15970000000000000086153306710 91
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.85);
0.085617499999999999916067139338 34 0.37080000000000001847411112976 3
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.9);
0.162790999999999991265653420669 0.64049999999999999582556142740 94
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 0.95);
0.237657499999999993756105709508 0.84009999999999999579003429062 14
> LDPCSimulate(C, 10000 : Channel := "Gaussian", StdDev := 1.0);
0.296526500000000026169288958044 0.94479999999999999731770117250 56
```

154.1.4 Density Evolution

The asymptotic performance of ensembles of LDPC codes can be determined using *density evolution*. An ensemble of LDPC codes (either regular or irregular) is defined by a pair of degree distributions, corresponding to the degrees at the variable and check nodes of the Tanner graph.

Over a specific channel, the critical parameter which defines the asymptotic performance of a given ensemble is its *threshold*, which is a value of the channel parameter (i.e., the probability of error p for the binary symmetric channel, and the standard deviation σ for the Gaussian channel). When the channel parameter is less than the threshold, asymptotically a code from the ensemble will decode with an error probability tending to zero. However,

at any channel parameter above the threshold there will be a non-vanishing finite error probability.

Determining the threshold of an ensemble over the binary symmetric channel is relatively trivial, however over the real-valued Gaussian channel it can involve extensive computations. The speed depends heavily on the granularity of the discretization which is used, though this also affects the accuracy of the result.

The default settings of the MAGMA implementation use a reasonably coarse discretization, emphasizing speed over accuracy. These (still quite accurate) approximate results can then be used to help reduce the workload of calculations over finer discretizations if more accuracy is required.

```
LDPCBinarySymmetricThreshold(v, c)
```

```
LDPCBinarySymmetricThreshold(Sv, Sc)
```

`Precision` RngReSubElt *Default :* 0.00005

Determines the threshold of the described ensemble of LDPC codes over the binary symmetric channel, which is the critical value of the channel parameter above which there is a non-vanishing error probability (asymptotically). The ensemble can either be defined by two integers for (v, c)-regular LDPC codes, or by two density distributions Sv and Sc, which are sequences of non-negative real numbers. The density distributions do not ned to be normalized, though the first entry (corresponding to weight 1 nodes in the Tanner graph) should always be zero.

The computation proceeds by establishing lower and upper bounds on the threshold, then narrowing this range by repeatedly performing density evolution on the midpoint. The argument `Precision` controls the precision to which the threshold is desired.

```
DensityEvolutionBinarySymmetric(v, c, p)
```

```
DensityEvolutionBinarySymmetric(Sv, Sc, p)
```

Perform density evolution on the binary symmetric channel using channel parameter p and determine the asymptotic behaviour for the given LDPC ensemble. The return value is boolean, where `true` indicates that p is below the threshold and the ensemble has error probability asymptotically tending to zero.

Example H154E6

Density evolution on the binary symmetric channel is not computationally intensive.

```
> time LDPCBinarySymmetricThreshold(3, 6);
0.039414062500000000000000000000000
Time: 0.010
> time LDPCBinarySymmetricThreshold(4, 8);
0.047392578125000000000000000000001
Time: 0.110
> time LDPCBinarySymmetricThreshold(4, 10);
0.036835937500000000000000000000000
```

```
Time: 0.090
```

`LDPCGaussianThreshold(v, c)`

`LDPCGaussianThreshold(Sv, Sc)`

`Lower`	RngReSubElt	*Default :* 0
`Upper`	RngReSubElt	*Default :* ∞
`Points`	RngIntElt	*Default :* 500
`MaxLLR`	RngReSubElt	*Default :* 25
`MaxIterations`	RngIntElt	*Default :* ∞
`QuickCheck`	BoolElt	*Default :* `true`
`Precision`	RngReSubElt	*Default :* 0.00005

Determines the threshold of the described ensemble of LDPC codes over the Gaussian channel, which is the critical value of the standard deviation above which there is a non-vanishing error probability (asymptotically). The ensemble can either be defined by two integers for (v, c)-regular LDPC codes, or by two density distributions Sv and Sc, which are sequences of non-negative real numbers. The density distributions do not ned to be normalized, though the first entry (corresponding to weight 1 nodes in the Tanner graph) should always be zero.

The computation proceeds by establishing lower and upper bounds on the threshold, then narrowing this range by repeatedly performing density evolution on the midpoint. If the threshold is approximately known then manually setting tight `Lower` and `Upper` bounds can reduce the length of the calculation.

The speed with which these evolutions are computed depends on how fine the discretization is, controlled by the variable argument `Points`. If the threshold is needed to high levels of accuracy then an initial computation with fewer points is recommended to get a reduced searched range. The specific meaning of eachvariable argument is described below.

`Lower` and `Upper` are real-valued bounds on the threshold, which (if tight) can help to reduce the search range and speed up the threshold determination. The validity of an input bound is verified before the search begins, and an error is returned if it is incorrect.

`Points` and `MaxLLR` define the discretized basis of log likelihood ratios on which density evolution is performed, and have integer and real values resp. Specifically, the probability mass function is defined on the range [$-$`MaxLLR`, . . . ,`MaxLLR`] on $2 * Points + 1$ discretized points.

`MaxIterations` allows the user to set a finite limit of iterations that a density evolution should perform in determining the asymptotic behaviour at each channel parameter. Although this may help reduce the time of a computation, it should be kept in mind that the result may not be valid.

`QuickCheck` defines the method by which the asymptotic behaviour at each channel parameter is identified. If set to `false`, then the probability density must evolve all the way to within an infinitesimal value of unity. When set to `true`, if the rate of change of the probability density is seen to be successively increasing then the asymptotic behaviour is assumed to go to unity. Empirically this method seems to give accurate results and so the default behaviour is `true`, however it has no theoretical justification.

`Precision` is a real-valued parameter defining the precision to which the threshold should be determined.

Setting the verbose mode `Code` prints out the bounds on the threshold as subsequent density evolutions narrow the search range.

`DensityEvolutionGaussian(v, c, σ)`

`DensityEvolutionGaussian(Sv, Sc, σ)`

`Points`	RngIntElt	*Default :* 500
`MaxLLR`	RngReSubElt	*Default :* 25
`MaxIterations`	RngIntElt	*Default :* ∞
`QuickCheck`	BoolElt	*Default :* `true`

Perform density evolution on the Gaussian channel using standard deviation σ and determine the asymptotic behaviour for the given LDPC ensemble. The return value is boolean, where `true` indicates that σ is below the threshold and the ensemble has error probability asymptotically tending to zero.

See the description of `LDPCGaussianThreshold` for a description of the variable arguments.

`GoodLDPCEnsemble(i)`

Access a small database of density distributions defining good irregular LDPC ensembles. Returned is the published threshold of the ensemble over the Gaussian channel, along with the variable and check degree distributions. The input i is a non-negative integer, which indexes the database (in no particular order).

Example H154E7

Since performing density evolution on a large number of discrete points is time consuming, it is normally better to first get an estimate with an easier computation.
In this example a published value of the threshold of an ensemble (obtained using a different implementation) can be compared to the outputs from different levels of discretization.

```
> thresh, Sv, Sc := GoodLDPCEnsemble(5);
> R4 := RealField(4);
> [R4| x : x in Sv];
[ 0.0000, 0.3001, 0.2839, 0.0000, 0.0000, 0.0000, 0.0000, 0.4159 ]
> [R4| x : x in Sc];
[ 0.0000, 0.0000, 0.0000, 0.0000, 0.0000, 0.2292, 0.7708 ]
> thresh;
```

```
0.94970000000000000000000000000
> time approx1 := LDPCGaussianThreshold(Sv, Sc:
>         Points := 500, Precision := 0.001);
Time: 19.400
> approx1;
0.960976562499999964472863211995
> time approx2 := LDPCGaussianThreshold(Sv, Sc:
>       Points := 3000,
>       Lower := approx1-0.02, Upper := approx1+0.02);
Time: 873.560
> approx2;
0.951210937499999964472863211995
```

This estimate can now be used to narrow the search range of accurate density evolution. For the very long calculation the verbose mode is used to keep track of the progress of the calculation.

```
> SetVerbose("Code", true);
> time approx3 := LDPCGaussianThreshold(Sv, Sc:
>        Points := 5000,
>        Lower := approx2-0.005, Upper := approx2+0.0005);

```

The thresholds given in the database are published values taken from other implementations, and so are not guaranteed to match up exactly with the values obtained using MAGMA.

155 LINEAR CODES OVER FINITE RINGS

Chapter 155
LINEAR CODES OVER FINITE RINGS

155.1 Introduction

This chapter describes those functions which are applicable to linear codes over finite rings. MAGMA currently supports the basic facilities for codes over integer residue rings and galois rings, including cyclic codes, and the complete weight enumerator calculation. Additional functionality is available for the special case of codes over Z_4, the integers modulo 4.

For modules defined over rings with zero divisors, it is of course not possible to talk about the concept of dimension (the modules are not free). But in MAGMA each code over such a ring has a *unique* generator matrix corresponding to the *Howell form*. The number of rows k in this unique generator matrix will be called the *pseudo-dimension* of the code. It should be noted that this pseudo-dimension is not invariant between equivalent codes, and so does not provide structural information like the dimension of a code over a finite field.

Note that the rank of the generator matrix is always well-defined and unique (based on the Smith form which is well-defined over PIRs), but k may sometimes be larger than the rank.

Without a concept of dimension, codes over finite rings are referenced by their cardinality. A code C is called an (n, M, d) *code* if it has length n, cardinality M and minimum Hamming weight d.

In this chapter, as for codes over finite fields, the term "code" will refer to a linear code, unless otherwise specified.

The reader is referred to [Wan97] as a general reference on $\mathbf{Z}_4$-codes.

155.2 Construction of Codes

155.2.1 Construction of General Linear Codes

```
LinearCode< R, n | L >
```

Create a code as a subspace of the R-space $V = R^{(n)}$ which is generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) An element of V.

(b) A set or sequence of elements of V.

(c) A sequence of n elements of R, defining an element of V.

(d) A set or sequence of sequences of type (c).

(e) A subspace of V.

(f) A set or sequence of subspaces of V.

`LinearCode(U)`

Let V be the R-space $R^{(n)}$ and suppose that U is a subspace of V. The effect of this function is to define the linear code C corresponding to the subspace U.

`LinearCode(A)`

Given a $k \times n$ matrix A over the ring R, construct the linear code generated by the rows of A. Note that it is not assumed that the rank of A is k. The effect of this constructor is otherwise identical to that described above.

`PermutationCode(u, G)`

Given a finite permutation group G of degree n, and a vector u belonging to the n-dimensional vector space V over the ring R, construct the code C corresponding to the subspace of V spanned by the set of vectors obtained by applying the permutations of G to the vector u.

Example H155E1

The octacode O_8 over $\mathbf{Z}_4$ [Wan97, Ex. 1.3] can be defined as follows:

```
> Z4 := IntegerRing(4);
> O8 := LinearCode<Z4, 8 |
>     [1,0,0,0,3,1,2,1],
>     [0,1,0,0,1,2,3,1],
>     [0,0,1,0,3,3,3,2],
>     [0,0,0,1,2,3,1,1]>;
> O8;
[8, 4, 4] Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2 1]
[0 1 0 0 1 2 3 1]
[0 0 1 0 3 3 3 2]
[0 0 0 1 2 3 1 1]
```

Alternatively, if we want to see the code as a subspace of $R^{(8)}$, where $R = \mathbf{Z}_4$, we could proceed as follows:

```
> O8 := LinearCode(sub<RSpace(Z4, 8) |
>     [1,0,0,0,3,1,2,1],
>     [0,1,0,0,1,2,3,1],
>     [0,0,1,0,3,3,3,2],
>     [0,0,0,1,2,3,1,1]>);
```

Example H155E2

We define a code by constructing a matrix over GR$(4, 3)$, and using its rowspace to generate the code:

```
> R<w> := GaloisRing(4,3);
> S := [1, 1, 0, w^2, w, w + 2, 2*w^2, 2*w^2 + w + 3];
> G := Matrix(R, 2, 4, S);
> G;
[            1             1             0           w^2]
[            w         w + 2         2*w^2 2*w^2 + w + 3]
> C := LinearCode(G);
> C;
(4, 512, 3) Linear Code over GaloisRing(2, 2, 3)
Generator matrix:
[          1           1           0         w^2]
[          0           2       2*w^2 2*w^2 + 2*w]
> #C;
512
```

Example H155E3

We define G to be a permutation group of degree 7 and construct the code C as the $\mathbf{Z}_4$-code generated by applying the permutations of G to a certain vector:

```
> G := PSL(3, 2);
> G;
Permutation group G of degree 7
    (1, 4)(6, 7)
    (1, 3, 2)(4, 7, 5)
> Z4 := IntegerRing(4);
> V := RSpace(Z4, 7);
> u := V ! [1, 0, 0, 1, 0, 1, 1];
> C := PermutationCode(u, G);
> C;
[7, 6, 2] Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 1 0 1 1]
[0 1 0 1 1 1 0]
[0 0 1 0 1 1 1]
[0 0 0 2 0 0 2]
[0 0 0 0 2 0 2]
[0 0 0 0 0 2 2]
```

155.2.2 Construction of Simple Linear Codes

`ZeroCode(R, n)`

Given a ring R and positive integer n, return the $(n, 0, n)$ code consisting of only the zero code word, (where the minimum weight is by convention equal to n).

`RepetitionCode(R, n)`

Given a ring R and positive integer n, return the length n code with minimum Hamming weight n, generated by the all-ones vector.

`ZeroSumCode(R, n)`

Given a ring R and positive integer n, return the length n code over R such that for all codewords $(c_1, c_2, \ldots, c_n)$ we have $\sum_i c_i = 0$.

`UniverseCode(R, n)`

Given a ring R and positive integer n, return the length n code with minimum Hamming weight 1, consisting of all possible codewords.

`RandomLinearCode(R, n, k)`

Given a finite ring R and positive integers n and k, such that $0 < k \leq n$, the function returns a random linear code of length n over R with k generators.

Example H155E4

The repetition and zero sum codes are dual over all rings.

```
> R := Integers(9);
> C1 := RepetitionCode(R, 5);
> C1;
(5, 9, 5) Linear Code over IntegerRing(9)
Generator matrix:
[1 1 1 1 1]
> C2 := ZeroSumCode(R, 5);
> C2;
(5, 6561, 2) Linear Code over IntegerRing(9)
Generator matrix:
[1 0 0 0 8]
[0 1 0 0 8]
[0 0 1 0 8]
[0 0 0 1 8]
> C1 eq Dual(C2);
true
```

155.2.3 Construction of General Cyclic Codes

Cyclic codes form an important family of linear codes over all rings. A cyclic code is one which is generated by all of the cyclic shifts of a given codeword:

$$(c_0, c_1, \ldots, c_{n-1}, c_n), (c_n, c_0, \ldots, c_{n-2}, c_{n-1}), \ldots, (c_1, c_2, \ldots, c_n, c_0)$$

Using the correspondence $(c_0, c_1, \ldots, c_n) \iff c_0 + c_1 x + \cdots + c_n x^n$, the cyclic codes of length n over the ring R are in one-to-one correspondence with the principal ideals of $R[x]/(x^n - 1)R[x]$.

`CyclicCode(u)`

Given a vector u belonging to the R-space $R^{(n)}$, construct the length n cyclic code generated by the right cyclic shifts of the vector u.

`CyclicCode(n, g)`

Let R be a ring. Given a positive integer n and a univariate polynomial $g(x) \in R[x]$, construct the length n cyclic code generated by $g(x)$.

`CyclotomicFactors(R, n)`

Given a Galois ring R (which is possibly an integer residue ring with a prime power modulus), and a positive integer n which is coprime to the characteristic of R, return a factorisation of $x^n - 1$ over R.

Note that since factorisation is not necessarily unique over R, the factorisation returned is the one obtained by first factoring over the residue field of R and then performing Hensel lifting.

Example H155E5

We construct some cyclic codes over $\mathbf{Z}_4$ by factorizing $x^n - 1$ over $\mathbf{Z}_4$ for $n = 7, 23$ and using some of the irreducible factors found.

```
> Z4 := IntegerRing(4);
> P<x> := PolynomialRing(Z4);
> n := 7; L := CyclotomicFactors(Z4, n); L;
[
    x + 3,
    x^3 + 2*x^2 + x + 3,
    x^3 + 3*x^2 + 2*x + 3
]
> CyclicCode(n, L[1]);
[7, 6, 2] Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 0 3]
[0 1 0 0 0 0 3]
[0 0 1 0 0 0 3]
[0 0 0 1 0 0 3]
```

```
[0 0 0 0 1 0 3]
[0 0 0 0 0 1 3]
> CyclicCode(n, L[2]);
[7, 4, 3] Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2]
[0 1 0 0 2 1 1]
[0 0 1 0 1 1 3]
[0 0 0 1 3 2 3]
> CyclicCode(n, L[3]);
[7, 4, 3] Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 2 3]
[0 1 0 0 3 1 1]
[0 0 1 0 1 1 2]
[0 0 0 1 2 1 3]
> n := 23; L := CyclotomicFactors(Z4, n); L;
[
    x + 3,
    x^11 + 2*x^10 + 3*x^9 + 3*x^7 + 3*x^6 + 3*x^5 + 2*x^4 + x + 3,
    x^11 + 3*x^10 + 2*x^7 + x^6 + x^5 + x^4 + x^2 + 2*x + 3
]
> CyclicCode(n, L[2]);
[23, 12] Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 3 1 0 0 2 3 3 3 0 3 2]
[0 1 0 0 0 0 0 0 0 0 0 0 2 1 1 0 0 0 1 1 3 2 3]
[0 0 1 0 0 0 0 0 0 0 0 0 3 3 1 1 2 3 3 0 1 2 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 3 3 1 1 2 3 3 0 1 2]
[0 0 0 0 1 0 0 0 0 0 0 0 2 2 3 3 1 3 0 1 3 2 1]
[0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1 0]
[0 0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1]
[0 0 0 0 0 0 0 0 1 0 0 0 1 3 0 1 3 3 0 2 2 1 3]
[0 0 0 0 0 0 0 0 0 1 0 0 3 2 3 0 3 2 2 3 2 1 3]
[0 0 0 0 0 0 0 0 0 0 1 0 3 0 2 3 2 2 1 1 3 1 3]
[0 0 0 0 0 0 0 0 0 0 0 1 3 0 0 2 1 1 1 0 1 2 3]
```

Example H155E6

We create a cyclic code of length 5 over $\mathtt{GR}(4, 2)$.

```
> R<w> := GR(4,2);
> P<x> := PolynomialRing(R);
> g := CyclotomicFactors(R, 5)[2];
> g;
x^2 + (3*w + 2)*x + 1
> C := CyclicCode(5, g);
```

```
> C;
(5, 4096, 3) Cyclic Code over GaloisRing(2, 2, 2)
Generator matrix:
[      1       0       0       1 3*w + 2]
[      0       1       0   w + 2   w + 2]
[      0       0       1 3*w + 2       1]
```

155.3 Invariants of Codes

`#C`

Given a code C, return the number of codewords belonging to C.

`C . i`
`Name(C, i)`

Given a code C and a positive integer i, return the i-th generator of C.

`Alphabet(C)`

The underlying ring (or alphabet) R of the code C.

`AmbientSpace(C)`

The ambient space of the code C, i.e., the generic R-space V in which C is contained.

`Basis(C)`

The basis of the linear code C, returned as a sequence of elements of C.

`Generators(C)`

The generators for the linear code C, returned as a set.

`GeneratorMatrix(C)`

The generator matrix for the linear code C. This gives a unique canonical generating set for the code.

`Generic(C)`

Given a length n code C over a ring R, return the generic $(n, \#R^n, 1)$ code in which C is contained.

`Length(C)`

Given an code C, return the block length n of C.

`PseudoDimension(C)`

`NumberOfGenerators(C)`

`Ngens(C)`

The number of generators (which equals the pseudo-dimension k) of the linear code C.

`ParityCheckMatrix(C)`

The parity check matrix for the code C, which can be defined as the canonical generator matrix of the dual of C.

`Random(C)`

A random codeword of the code C.

`RSpace(C)`

Given a length n linear code C, defined as a subspace U of the n-dimensional space V, return U as a subspace of V with basis corresponding to the rows of the generator matrix for C.

`InformationRate(C)`

Given a code C over a ring with cardinality q, return the information rate of C, that is, the ratio $Log_q(\#C)/n$.

155.4 Codes over $\mathbf{Z}_4$

The ring $\mathbf{Z}_4$, the ring of integers modulo 4, is a special case for which extra functionality is available. Error correcting codes over $\mathbf{Z}_4$ are often referred to as *quaternary* codes.

Important concepts when discussing quaternary codes are *Lee weight* and the *Gray map*, which maps linear codes over $\mathbf{Z}_4$ to (possibly non-linear) codes over $\mathbf{Z}_2$. Many good non-linear binary codes can be defined as the images of simple linear quaternary codes.

155.4.1 The Gray Map

For an element $x \in \mathbf{Z}_4$, the *Gray map* $\phi : \mathbf{Z}_4 \to \mathbf{Z}_2^2$ is defined by:

$$0 \mapsto 00, \quad 1 \mapsto 01, \quad 2 \mapsto 11, \quad 3 \mapsto 10.$$

This map is extended to a map from $\mathbf{Z}_4^n$ onto $\mathbf{Z}_2^{2n}$ in the obvious way (by concatenating the images of each component). The resulting map is a weight- and distance-preserving map from $\mathbf{Z}_4^n$ (with Lee weight metric) to $\mathbf{Z}_2^{2n}$ (with Hamming weight metric). See [Wan97, Chapter 3] for more information (but note that that author has a different order for the components of the image of a vector).

`GrayMap(C)`

Given a $\mathbf{Z}_4$-linear code C, this function returns the Gray map for C. This is the map ϕ from C to $\mathbf{F}_2^{2n}$, as defined above.

`GrayMapImage(C)`

Given a $\mathbf{Z}_4$-linear code C, this function returns the image of C under the Gray map as a sequence of vectors in $\mathbf{F}_2^{2n}$. As the resulting image may not be a $\mathbf{F}_2$-linear code, a sequence of vectors is returned rather than a code.

`HasLinearGrayMapImage(C)`

Given a $\mathbf{Z}_4$-linear code C, this function returns true if and only if the image of C under the Gray map is a $\mathbf{F}_2$-linear code. If so, the function also returns the image B as a $\mathbf{F}_2$-linear code, together with the bijection $\phi : C \to B$.

Example H155E7

Let $\phi(O_8)$ be the image of the octacode O_8 under the Gray map. This image is not a $\mathbf{F}_2$-linear code, but it is the non-linear $(8, 256, 6)$ Nordstrom-Robinson code [Wan97, Ex.3.4]. We demonstrate that the Hamming weight distribution of the $\mathbf{F}_2$ image is identical to the Lee weight distribution of the linear $\mathbf{Z}_4$ code.

```
> Z4 := IntegerRing(4);
> O8 := LinearCode<Z4, 8 |
>     [1,0,0,0,3,1,2,1],
>     [0,1,0,0,1,2,3,1],
>     [0,0,1,0,3,3,3,2],
>     [0,0,0,1,2,3,1,1]>;
> HasLinearGrayMapImage(O8);
false
> NR := GrayMapImage(O8);
> #NR;
256
> LeeWeightDistribution(O8);
[ <0, 1>, <6, 112>, <8, 30>, <10, 112>, <16, 1> ]
> {* Weight(v): v in NR *};
{* 0, 16, 6^^112, 8^^30, 10^^112 *}
```

For the code K_8, we first note the image of some of the vectors under the Gray map.

```
> Z4 := IntegerRing(4);
> K8 := LinearCode< Z4, 8 |
>     [1,1,1,1,1,1,1,1],
>     [0,2,0,0,0,0,0,2],
>     [0,0,2,0,0,0,0,2],
>     [0,0,0,2,0,0,0,2],
>     [0,0,0,0,2,0,0,2],
>     [0,0,0,0,0,2,0,2],
>     [0,0,0,0,0,0,2,2]>;
> f := GrayMap(K8);
> K8.1;
(1 1 1 1 1 1 1 1)
> f(K8.1);
```

```
(0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1)
> K8.2;
(0 2 0 0 0 0 0 2)
> f(K8.2);
(0 0 1 1 0 0 0 0 0 0 0 0 0 0 1 1)
```

Finally, we see that the image of K_8 is linear over $\mathbf{F}_2$.

```
> l, B, g := HasLinearGrayMapImage(K8);
> l;
true
> B;
[16, 8, 4] Linear Code over GF(2)
Generator matrix:
[1 0 0 1 0 1 0 1 0 1 0 1 0 1 1 0]
[0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1]
[0 0 1 1 0 0 0 0 0 0 0 0 0 0 1 1]
[0 0 0 0 1 1 0 0 0 0 0 0 0 0 1 1]
[0 0 0 0 0 0 1 1 0 0 0 0 0 0 1 1]
[0 0 0 0 0 0 0 0 1 1 0 0 0 0 1 1]
[0 0 0 0 0 0 0 0 0 0 1 1 0 0 1 1]
[0 0 0 0 0 0 0 0 0 0 0 0 1 1 1 1]
> g(K8.1) in B;
true
```

155.4.2 Families of Codes over $\mathbf{Z}_4$

This section gives some standard constructions for $\mathbf{Z}_4$-linear codes. Further constructions will be available in the future.

`KerdockCode(m)`

Given an integer $m \geq 2$, return the quaternary Kerdock code $K(m)$ of length $2^m - 1$ defined by a default primitive polynomial $h \in \mathbf{Z}_4[x]$ of degree m.

`PreparataCode(m)`

Given an integer $m \geq 2$, return the quaternary Preparata code $P(m)$ of length $2^m - 1$ defined by a default primitive polynomial $h \in \mathbf{Z}_4[x]$ of degree m.

`ReedMullerCodeZ4(r, m)`

Given an integer $m \geq 2$ and an integer r such that $0 \leq r \leq m$ this function returns the r-th order Reed-Muller code over Z_4 of length 2^m.

`GoethalsCode(m)`

Given a positive integer m, where m must be an odd and greater than or equal to 3, return the Goethals code of length 2^m.

`DelsarteGoethalsCode(m, delta)`

Return the Delsarte-Goethals Code of length 2^m.

`GoethalsDelsarteCode(m, delta)`

Return the Goethals-Delsarte code of length 2^m

`QRCodeZ4(p)`

Given a prime number p such that 2 is a quadratic residue modulo p, return the quadratic residue code of length p over Z_4.

`GolayCodeZ4(e)`

Return the Golay Code over Z_4. If e is `true` then return the extended Golay Code

`SimplexAlphaCodeZ4(k)`

Return the simplex alpha code over Z_4 of degree k.

`SimplexBetaCodeZ4(k)`

Return the simplex beta code over Z_4 of degree k.

Example H155E8

We compute some default Kerdock and Preparata codes and their minimum Lee weights.

```
> PreparataCode(3);
(8, 256, 4) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2 1]
[0 1 0 0 2 1 1 3]
[0 0 1 0 1 1 3 2]
[0 0 0 1 3 2 3 3]
> MinimumLeeWeight($1);
6
> KerdockCode(4);
[16, 5, 8] Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 1 1 3 0 3 3 0 2 1 2 3]
[0 1 0 0 0 2 3 3 3 2 1 3 0 0 1 1]
[0 0 1 0 0 3 1 0 3 0 3 1 1 3 2 2]
[0 0 0 1 0 2 1 3 0 1 2 3 1 3 3 0]
[0 0 0 0 1 1 3 0 3 3 0 2 1 2 1 3]
> MinimumLeeWeight($1);
12
> KerdockCode(5);
(32, 4096, 16) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 0 3 3 3 2 0 3 2 2 0 3 0 1 0 1 3 1 1 0 3 1 2 3 2 2 3 3]
[0 1 0 0 0 0 3 2 2 1 2 3 1 0 2 3 3 1 1 1 0 0 2 1 3 0 3 1 1 0 1 2]
```

```
[0 0 1 0 0 0 1 0 3 0 1 3 1 3 0 3 3 2 1 0 2 3 3 2 2 2 2 0 3 3 1 3]
[0 0 0 1 0 0 1 2 1 1 0 2 1 3 3 1 3 2 2 0 1 1 2 3 3 1 0 3 2 1 0 0]
[0 0 0 0 1 0 0 1 2 1 1 0 2 1 3 3 1 3 2 2 0 1 1 2 3 3 1 0 3 2 1 0]
[0 0 0 0 0 1 1 1 2 0 1 2 2 0 1 0 3 0 3 1 3 3 0 1 3 2 1 2 2 1 3 1]
> MinimumLeeWeight($1);
28
```

`HadamardCodeZ4(δ, m)`

Given an integer $m \geq 2$ and an integer δ such that $1 \leq \delta \leq \lfloor (m+1)/2 \rfloor$, return a Hadamard code over $\mathbf{Z}_4$ of length 2^{m-1} and type $2^\gamma 4^\delta$, where $\gamma = m + 1 - 2\delta$. Moreover, return a generator matrix with $\gamma + \delta$ rows constructed in a recursive way from the `Plotkin` and `BQPlotkin` constructions defined in Section 155.4.5.

A Hadamard code over $\mathbf{Z}_4$ of length 2^{m-1} is a code over $\mathbf{Z}_4$ such that, after the Gray map, give a binary (not necessarily linear) code with the same parameters as the binary Hadamard code of length 2^m.

`ExtendedPerfectCodeZ4(δ, m)`

Given an integer $m \geq 2$ and an integer δ such that $1 \leq \delta \leq \lfloor (m+1)/2 \rfloor$, return an extended perfect code over $\mathbf{Z}_4$ of length 2^{m-1}, such that its dual code is of type $2^\gamma 4^\delta$, where $\gamma = m + 1 - 2\delta$. Moreover, return a generator matrix constructed in a recursive way from the `Plotkin` and `BQPlotkin` constructions defined in Section 155.4.5.

An extended perfect code over $\mathbf{Z}_4$ of length 2^{m-1} is a code over $\mathbf{Z}_4$ such that, after the Gray map, give a binary (not necessarily linear) code with the same parameters as the binary extended perfect code of length 2^m.

Example H155E9

We compute codes over $\mathbf{Z}_4$ such that, after the Gray map, they are binary codes with the same parameters as some well-known families of binary linear codes.
First, we define a Hadamard code C over $\mathbf{Z}_4$ of length 8 and type $2^1 4^2$. The matrix Gc is the quaternary matrix used to generate C and obtained in a recursive way from `Plotkin` and `BQPlotkin` constructions.

```
> C, Gc := HadamardCodeZ4(2,4);
> C;
((8, 4^2 2^1)) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 3 2 1 0 3 2]
[0 1 2 3 0 1 2 3]
[0 0 0 0 2 2 2 2]
> Gc;
[1 1 1 1 1 1 1 1]
[0 1 2 3 0 1 2 3]
[0 0 0 0 2 2 2 2]
> HasLinearGrayMapImage(C);
```

```
true [16, 5, 8] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 0 1 1 1 0 1 1 1 1 0 0 0]
[0 1 0 0 1 0 1 1 0 1 0 0 1 0 1 1]
[0 0 1 0 1 1 0 1 0 0 1 0 1 1 0 1]
[0 0 0 1 1 1 1 0 0 0 0 1 1 1 1 0]
[0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1]
Mapping from: CodeLinRng: C to [16, 5, 8] Linear Code over GF(2) given by a rule
```

Then, we define an extended perfect code D over $\mathbf{Z}_4$ of length 8, such that its dual code is of type $2^1 4^2$. The matrix Gd is the quaternary matrix which is used to generate D and obtained in a recursive way from `Plotkin` and `BQPlotkin` constructions. Note that the code D is the Kronecker dual code of C.

```
> D, Gd := ExtendedPerfectCodeZ4(2,4);
> D;
((8, 4^5 2^1)) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 1 0 0 1 3]
[0 1 0 1 0 0 2 2]
[0 0 1 1 0 0 1 1]
[0 0 0 2 0 0 0 2]
[0 0 0 0 1 0 3 2]
[0 0 0 0 0 1 2 3]
> Gd;
[1 1 1 1 1 1 1 1]
[0 1 2 3 0 1 2 3]
[0 0 1 1 0 0 1 1]
[0 0 0 2 0 0 0 2]
[0 0 0 0 1 1 1 1]
[0 0 0 0 0 1 2 3]
> DualKroneckerZ4(C) eq D;
true
```

`ReedMullerCodeZ4(r, m)`

`ReedMullerCodeQRMZ4(r, m)`

Given an integer $m \geq 2$ and an integer r such that $0 \leq r \leq m$, return the r-th order Reed-Muller code over $\mathbf{Z}_4$ of length 2^m.

The binary image under the modulo 2 map is the binary linear r-th order Reed-Muller code of length 2^m. For $r = 1$ and $r = m - 2$, the function returns the quaternary linear Kerdock and Preparata code, respectively.

`ReedMullerCodesLRMZ4(r, m)`

Given an integer $m \geq 1$ and an integer r such that $0 \leq r \leq m$, return a set of r-th order Reed-Muller codes over $\mathbf{Z}_4$ of length 2^{m-1}.

The binary image under the Gray map of any of these codes is a binary (not necessarily linear) code with the same parameters as the binary linear r-th order Reed-Muller code of length 2^m. Note that for these codes neither the usual inclusion nor duality properties of the binary linear Reed-Muller family are satisfied.

`ReedMullerCodeRMZ4(s, r, m)`

Given an integer $m \geq 1$, an integer r such that $0 \leq r \leq m$, and an integer s such that $0 \leq s \leq \lfloor (m-1)/2 \rfloor$, return a r-th order Reed-Muller code over $\mathbf{Z}_4$ of length 2^{m-1}, denoted by $RM_s(r, m)$.

The binary image under the Gray map is a binary (not necessarily linear) code with the same parameters as the binary linear r-th order Reed-Muller code of length 2^m. Note that the inclusion and duality properties are also satisfied, that is, the code $RM_s(r-1, m)$ is a subcode of $RM_s(r, m)$, $r > 0$, and the code $RM_s(r, m)$ is the Kronecker dual code of $RM_s(m-r-1, m)$, $r < m$.

Example H155E10

We define $RM_1(1, 4)$ and $RM_1(2, 4)$. We can see that the former is a subcode of the latter. Note that $RM_1(1, 4)$ and $RM_1(2, 4)$ are the same as the ones given in Example H155E9 by `HadamardCodeZ4(2,4)` and `ExtendedPerfectCodeZ4(2,4)`, respectively.

```
> C1,G1 := ReedMullerCodeRMZ4(1,1,4);
> C2,G2 := ReedMullerCodeRMZ4(1,2,4);
> C1;
((8, 4^2 2^1)) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 3 2 1 0 3 2]
[0 1 2 3 0 1 2 3]
[0 0 0 0 2 2 2 2]
> C2;
((8, 4^5 2^1)) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 1 0 0 1 3]
[0 1 0 1 0 0 2 2]
[0 0 1 1 0 0 1 1]
[0 0 0 2 0 0 0 2]
[0 0 0 0 1 0 3 2]
[0 0 0 0 0 1 2 3]
> C1 subset C2;
true
> DualKroneckerZ4(C2) eq C1;
true
```

`ReedMullerCodesRMZ4(s, m)`

Given an integer $m \geq 1$, and an integer s such that $0 \leq s \leq \lfloor (m-1)/2 \rfloor$, return the family of Reed-Muller codes over $\mathbf{Z}_4$ of length 2^{m-1}, that is, the codes $RM_s(r, m)$, for all $0 \leq r \leq m$.

The binary image of these codes under the Gray map gives a family of binary (not necessarily linear) codes with the same parameters as the binary linear Reed-Muller family of codes of length 2^m. Note that $RM_s(0, m) \subset RM_s(1, m) \subset \ldots \subset RM_s(m, m)$.

Example H155E11

We construct the family of Reed-Muller codes over $\mathbf{Z}_4$ of length 2^2 given by $s = 0$.

```
> F := ReedMullerCodesRMZ4(0,3);
> F;
[((4, 4^0 2^1)) Cyclic Linear Code over IntegerRing(4)
Generator matrix:
[2 2 2 2],
((4, 4^1 2^2)) Cyclic Linear Code over IntegerRing(4)
Generator matrix:
[1 1 1 1]
[0 2 0 2]
[0 0 2 2],
((4, 4^3 2^1)) Cyclic Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 1]
[0 1 0 1]
[0 0 1 1]
[0 0 0 2],
((4, 4^4 2^0)) Cyclic Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]]
> F[1] subset F[2] and F[2] subset F[3] and F[3] subset F[4];
true
```

155.4.3 Derived Binary Codes

As well as the binary image of a quaternary code under the Gray map (see section 155.4.1), there are also two other associated canonical binary codes. They are known the *residue* and *torsion* codes, the former being a subcode of the latter.

From any binary code-subcode pair $C_1 \subset C_2$, a quaternary code C can be constructed such that the residue and torsion codes of C will be C_1 and C_2 respectively. Note that this quaternary code is not unique.

`BinaryResidueCode(C)`

Given a quaternary code C, return the binary code formed by taking each codeword in C modulo 2. This is known as the *binary residue code* of C.

`BinaryTorsionCode(C)`

Given a quaternary code C, return the binary code formed by the support of each codeword in C which is zero modulo 2. This is known as the *binary torsion code* of C.

`Z4CodeFromBinaryChain(C1, C2)`

Given binary code C_1 and C_2 such that $C_1 \subset C_2$, return a quaternary code such that its binary residue code is C_1 and its binary torsion code is C_2.

Example H155E12

We look at the derived binary codes of the $\mathbf{Z}_4$ Golay code, which are in fact equal to the binary Golay code.

```
> C := GolayCodeZ4(false);
> C;
(23, 16777216) Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 0 0 0 0 0 0 0 3 1 0 0 2 3 3 3 0 3 2]
[0 1 0 0 0 0 0 0 0 0 0 0 2 1 1 0 0 0 1 1 3 2 3]
[0 0 1 0 0 0 0 0 0 0 0 0 3 3 1 1 2 3 3 0 1 2 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 3 3 1 1 2 3 3 0 1 2]
[0 0 0 0 1 0 0 0 0 0 0 0 2 2 3 3 1 3 0 1 3 2 1]
[0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1 0]
[0 0 0 0 0 0 0 1 0 0 0 0 0 0 1 1 2 3 1 2 0 1 1]
[0 0 0 0 0 0 0 0 1 0 0 0 1 3 0 1 3 3 0 2 2 1 3]
[0 0 0 0 0 0 0 0 0 1 0 0 3 2 3 0 3 2 2 3 2 1 3]
[0 0 0 0 0 0 0 0 0 0 1 0 3 0 2 3 2 2 1 1 3 1 3]
[0 0 0 0 0 0 0 0 0 0 0 1 3 0 0 2 1 1 1 0 1 2 3]
>
> CRes := BinaryResidueCode(C);
> CTor := BinaryResidueCode(C);
> CRes eq CTor;
true
```

```
> CRes:Minimal;
[23, 12, 7] Linear Code over GF(2)
> AreEq, _ := IsEquivalent( CRes, GolayCode(GF(2), false) );
> AreEq;
true
```

Note that the canonical code over $\mathbf{Z}_4$ corresponding to the derived binary codes $CRes$ and $CTor$ is not the same as the one we started from.

```
> C1 := Z4CodeFromBinaryChain(CRes, CTor);
> C1:Minimal;
(23, 16777216) Linear Code over IntegerRing(4)
> C eq C1;
false
```

155.4.4 The Standard Form

A $\mathbf{Z}_4$-linear code is in *standard form* if its generator matrix is of the form:

$$\begin{pmatrix} I_{k_1} & A & B \\ 0 & 2I_{k_2} & 2C \end{pmatrix}$$

where I_{k_1} and I_{k_2} are the $k_1 \times k_1$ and $k_2 \times k_2$ identity matrices, respectively, A and C are $\mathbf{Z}_2$-matrices, and B is a $\mathbf{Z}_4$-matrix. Any $\mathbf{Z}_4$-linear code C is permutation-equivalent to a code S which is in standard form. Furthermore, the integers k_1 and k_2, defined above, are unique [Wan97, Prop. 1.1].

`StandardForm(C)`

This function, given any $\mathbf{Z}_4$-linear code C, returns a permutation-equivalent code S in standard form, together with the corresponding isomorphism from C onto S.

Example H155E13

We compute the standard form of a certain code. Note that the number of rows in the generator matrix of the standard code may be less than that of the original code.

```
> Z4 := IntegerRing(4);
> C := LinearCode<Z4, 4 | [2,2,1,1], [0,2,0,2]>;
> C;
[4, 3, 2] Linear Code over IntegerRing(4)
Generator matrix:
[2 0 1 3]
[0 2 0 2]
[0 0 2 2]
> S, f := StandardForm(C);
> S;
[4, 2, 2] Linear Code over IntegerRing(4)
Generator matrix:
[1 1 2 2]
```

```
[0 2 2 0]
> #S;
8
> #C;
8
> f(C.1);
(1 3 0 2)
> f(C.2);
(0 2 2 0)
> f(C.3);
(2 2 0 0)
> S.1@@f;
(2 2 1 1)
> S.2@@f;
(0 2 0 2)
```

155.4.5 Constructing New Codes from Old

The functions described here produce a new code over $\mathbf{Z}_4$ by modifying in some way the codewords of some given codes over $\mathbf{Z}_4$.

`PlotkinSum(A, B)`

Given matrices A and B both over the same ring and with the same number of columns, return the P_{AB} matrix over the same ring of A and B, where

$$P_{AB} = \begin{pmatrix} A & A \\ 0 & B \end{pmatrix}.$$

`PlotkinSum(C, D)`

Given codes C and D both over the same ring and of the same length, construct the Plotkin sum of C and D. The Plotkin sum consists of all vectors of the form $(u|u+v)$, where $u \in C$ and $v \in D$.

Note that the Plotkin sum is computed using generator matrices of C and D and the `PlotkinSum` function for matrices, that is, this function returns the code over $\mathbf{Z}_4$ generated by the matrix P_{AB} defined above, where A and B are generators matrices of C and D, respectively.

`QuaternaryPlotkinSum(A, B)`

Given two matrices A and B over $\mathbf{Z}_4$, both with the same number of columns, return the QP_{AB} matrix over $\mathbf{Z}_4$, where

$$QP_{AB} = \begin{pmatrix} A & A & A & A \\ 0 & B & 2B & 3B \end{pmatrix}.$$

`QuaternaryPlotkinSum(C, D)`

Given two codes C and D over $\mathbf{Z}_4$, both of the same length, construct the Quaternary Plotkin sum of C and D. The Quaternary Plotkin sum is a code over $\mathbf{Z}_4$ that consists of all vectors of the form $(u, u+v, u+2v, u+3v)$, where $u \in C$ and $v \in D$.

Note that the Quaternary Plotkin sum is computed using generator matrices of C and D and the `QuaternaryPlotkinSum` function for matrices, that is, this function returns the code over $\mathbf{Z}_4$ generated by the matrix QP_{AB} defined above, where A and B are generators matrices of C and D, respectively.

`BQPlotkinSum(A, B, C)`

Given three matrices A, B, and C over $\mathbf{Z}_4$, all with the same number of columns, return the BQP_{ABC} matrix over $\mathbf{Z}_4$, where

$$BQP_{ABC} = \begin{pmatrix} A & A & A & A \\ 0 & B' & 2B' & 3B' \\ 0 & 0 & \hat{B} & \hat{B} \\ 0 & 0 & 0 & C \end{pmatrix},$$

B' is obtained from B replacing the twos with ones in the rows of order two, and $\hat{B}$ is obtained from B removing the rows of order two.

`BQPlotkinSum(D, E, F)`

Given three codes D, E and F over $\mathbf{Z}_4$, all of the same length, construct the BQ Plotkin sum of D, E and F. Let Ge be a generator matrix of the code E of type $2^\gamma 4^\delta$. The code E' over $\mathbf{Z}_4$ is obtained from E replacing the twos with ones in the γ rows of order two of Ge, and the code $\hat{E}$ over $\mathbf{Z}_4$ is obtained from E removing the γ rows of order two of Ge." The BQ Plotkin sum is a code over $\mathbf{Z}_4$ that consists of all vectors of the form $(u, u+v', u+2v'+\hat{v}, u+3v'+\hat{v}+z)$, where $u \in Gd$, $v' \in Ge'$ $\hat{v} \in \hat{G}e$, and $z \in Gf$, where Gd, Ge', $\hat{G}e$ and Gf are generators matrices of D, E', $\hat{E}$ and F, respectively.

Note that the BQPlotkin sum is computed using generator matrices of D, E and F and the `BQPlotkinSum` function for matrices. However, this function does not necessarily return the same code over $\mathbf{Z}_4$ generated by the matrix QP_{ABC} defined above, where A, B and C are generators matrices of D, E and F, respectively, as shown in Example H2E4.

`DoublePlotkinSum(A, B, C, D)`

Given four matrices A, B, C, and D over $\mathbf{Z}_4$, all with the same number of columns, return the DP_{ABC} matrix over $\mathbf{Z}_4$, where

$$DP_{ABCD} = \begin{pmatrix} A & A & A & A \\ 0 & B & 2B & 3B \\ 0 & 0 & C & C \\ 0 & 0 & 0 & D \end{pmatrix}.$$

`DoublePlotkinSum(E, F, G, H)`

Given four codes E, F, G and H over $\mathbf{Z}_4$, all of the same length, construct the Double Plotkin sum of E, F, G and H. The Double Plotkin sum is a code over $\mathbf{Z}_4$ that consists of all vectors of the form $(u, u+v, u+2v+z, u+3v+z+t)$, where $u \in E$, $v \in F$, $z \in G$ and $t \in H$.

Note that the Double Plotkin sum is computed using generator matrices of E, F, G and H and the `DoublePlotkinSum` function for matrices, that is, this function returns the code over $\mathbf{Z}_4$ generated by the matrix DP_{ABCD} defined above, where A, B, C and D are generators matrices of E, F, G and H, respectively.

`DualKroneckerZ4(C)`

Given a code C over $\mathbf{Z}_4$ of length 2^m, return its Kronecker dual code. The Kronecker dual code of C is $C^{\perp}_{\otimes} = \{x \in \mathbf{Z}_4^{2^m} : x \cdot K_{2^m} \cdot y^t = 0, \forall y \in C\}$, where $K_{2^m} = \otimes_{j=1}^{m} K_2$, $K_2 = \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix}$ and $\otimes$ denotes the Kronecker product of matrices. Equivalently, K_{2^m} is a quaternary matrix of length 2^m with the vector $(1, 3, 3, 1, 3, 1, 1, 3, \ldots)$ in the main diagonal and zeros elsewhere.

Example H155E14

In this example, we show that the codes over $\mathbf{Z}_4$ constructed from the `BQPlotkinSum` function for matrices are not necessarily the same as the ones constructed from the `BQPlotkinSum` function for codes.

```
> Z4:=IntegerRing(4);
> Ga:=Matrix(Z4,1,2,[1,1]);
> Gb:=Matrix(Z4,2,2,[1,2,0,2]);
> Gc:=Matrix(Z4,1,2,[2,2]);
> Ca:=LinearCode(Ga);
> Cb:=LinearCode(Gb);
> Cc:=LinearCode(Gc);
> C:=LinearCode(BQPlotkinSum(Ga,Gb,Gc));
> D:=BQPlotkinSum(Ca,Cb,Cc);
> C eq D;
false
```

Example H155E15

```
> Ga := GeneratorMatrix(ReedMullerCodeRMZ4(1,2,3));
> Gb := GeneratorMatrix(ReedMullerCodeRMZ4(1,1,3));
> Gc := GeneratorMatrix(ReedMullerCodeRMZ4(1,0,3));
> C := ReedMullerCodeRMZ4(1,2,4);
> Cp := LinearCode(PlotkinSum(Ga, Gb));
> C eq Cp;
true
> D := ReedMullerCodeRMZ4(2,2,5);
> Dp := LinearCode(BQPlotkinSum(Ga, Gb, Gc));
> D eq Dp;
true
```

155.4.6 Invariants of Codes over $\mathbf{Z}_4$

`SpanZ2CodeZ4(C)`

Given a code C over $\mathbf{Z}_4$ of length n, return $S_C = \Phi^{-1}(S_{bin})$ as a code over $\mathbf{Z}_4$, and the linear span of C_{bin}, $S_{bin} = \langle C_{bin} \rangle$, as a binary linear code of length $2n$, where $C_{bin} = \Phi(C)$ and Φ is the Gray map.

`KernelZ2CodeZ4(C)`

Given a code C over $\mathbf{Z}_4$ of length n, return its kernel K_C as a subcode over $\mathbf{Z}_4$ of C, and $K_{bin} = \Phi(K_C)$ as a binary linear subcode of C_{bin} of length $2n$, where $C_{bin} = \Phi(C)$ and Φ is the Gray map.

The kernel K_C contains the codewords v such that $2v * u \in C$ for all $u \in C$, where $*$ denotes the component-wise product. Equivalently, the kernel $K_{bin} = \Phi(K_C)$ contains the codewords $c \in C_{bin}$ such that $c + C_{bin} = C_{bin}$, where $C_{bin} = \Phi(C)$ and Φ is the Gray map.

`DimensionOfSpanZ2(C)`

`RankZ2(C)`

Given a code C over $\mathbf{Z}_4$, return the dimension of the linear span of C_{bin}, that is, the dimension of $\langle C_{bin} \rangle$, where $C_{bin} = \Phi(C)$ and Φ is the Gray map.

`DimensionOfKernelZ2(C)`

Given a code C over $\mathbf{Z}_4$, return the dimension of the Gray map image of its kernel K_C over $\mathbf{Z}_4$, that is the dimension of $K_{bin} = \Phi(K_C)$, where Φ is the Gray map. Note that K_{bin} is always a binary linear code.

Example H155E16

```
> C := ReedMullerCodeRMZ4(0,3,5);
> DimensionOfKernelZ2(C);
20
> DimensionOfSpanZ2(C);
27
> K, Kb := KernelZ2CodeZ4(C);
> S, Sb := SpanZ2CodeZ4(C);
> K subset C;
true
> C subset S;
true
> Dimension(Kb) eq DimensionOfKernelZ2(C);
true
> Dimension(Sb) eq DimensionOfSpanZ2(C);
true
```

155.4.7 Other $\mathbf{Z}_4$ functions

`Correlation(v)`

Let v be a codeword over $\mathbf{Z}_4$. Define $w_j = \#\{k : v[k] = j\}$ for $j = 0, \ldots, 3$. Then the *correlation* of v is the Gaussian integer $(w_0 - w_2) + i * (w_1 - w_3)$.

155.5 Construction of Subcodes of Linear Codes

155.5.1 The Subcode Constructor

`sub< C | L >`

Given a length n linear code C over R, construct the subcode of C, generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) An element of C;

(b) A set or sequence of elements of C;

(c) A sequence of n elements of R, defining an element of C;

(d) A set or sequence of sequences of type (c);

(e) A subcode of C;

(f) A set or sequence of subcodes of C.

`Subcode(C, t)`

Given a length n linear code C with k generators and an integer t, $1 \leq t < k$, return a subcode of C of pseudo-dimension t.

`Subcode(C, S)`

Given a length n linear code C with k generators and a set S of integers, each of which lies in the range $[1, k]$, return the subcode of C generated by the basis elements whose positions appear in S.

Example H155E17

We construct a subcode of a code over a Galois ring by multiplying each of its generators by a zero divisor.

```
> R<w> := GR(4,2);
> C := RandomLinearCode(R, 4, 2);
> C;
(4, 256, 3) Linear Code over GaloisRing(2, 2, 2)
Generator matrix:
[      1       0   w + 1 3*w + 2]
[      0       1 3*w + 1       1]
> #C;
256
>
> C1 := sub< C | 2*C.1, 2*C.2 >;
> C1;
(4, 16, 3) Linear Code over GaloisRing(2, 2, 2)
Generator matrix:
[      2       0 2*w + 2     2*w]
[      0       2 2*w + 2       2]
> #C1;
16
```

155.6 Weight Distributions

In the case of a linear code, weight and distance distributions are equivalent (in particular minimum weight and minimum distance are equivalent).

155.6.1 Hamming Weight

For an element $x \in \mathbf{R}$ for any finite ring R, the *Hamming weight* $w_H(x)$ is defined by:

$$w_H(x) = 0 \iff x = 0, \qquad w_H(x) = 1 \iff x \neq 0$$

The *Hamming weight* $w_H(v)$ of a vector $v \in R^n$ is defined to be the sum (in $\mathbf{Z}$) of the Hamming weights of its components.

The *Hamming weight* is often referred to as simply the *weight*.

`MinimumWeight(C)`

`MinimumDistance(C)`

Determine the minimum (Hamming) weight of the words belonging to the code C, which is also the minimum distance between any two codewords.

`WeightDistribution(C)`

Determine the (Hamming) weight distribution for the code C. The distribution is returned in the form of a sequence of tuples, where the i-th tuple contains the i-th weight, w_i say, and the number of codewords having weight w_i.

`DualWeightDistribution(C)`

The (Hamming) weight distribution of the dual code of C. For more explanation, see `WeightDistribution`.

Example H155E18

We calculate the weight distribution of a cyclic code over the Galois ring of size 81.

```
> R<w> := GR(9,2);
> P<x> := PolynomialRing(R);
> L := CyclotomicFactors(R, 4);
> g := L[3] * L[4];
> g;
x^2 + (8*w + 7)*x + w + 1
> C := CyclicCode(4, g);
> C;
(4, 6561, 3) Cyclic Code over GaloisRing(3, 2, 2)
Generator matrix:
[      1       0   w + 1 8*w + 7]
[      0       1       w 8*w + 8]
> WeightDistribution(C);
[ <0, 1>, <3, 320>, <4, 6240> ]
```

155.6.2 Lee Weight

For an element $x \in \mathbf{Z}_4$, the *Lee weight* $w_L(x)$ is defined by:

$$w_L(0) = 0, \quad w_L(1) = w_L(3) = 1, \quad w_L(2) = 2.$$

The *Lee weight* $w_L(v)$ of a vector $v \in \mathbf{Z}_4^n$ is defined to be the sum (in $\mathbf{Z}$) of the Lee weights of its components. See [Wan97, p. 16].

`LeeWeight(a)`

The Lee weight of the element $a \in \mathbf{Z}_4$.

`LeeWeight(v)`

The Lee weight of the codeword v.

`LeeDistance(u, v)`

The Lee distance between the codewords u and v, where u and v belong to the same code C. This is defined to be the Lee weight of $(u - v)$.

`MinimumLeeWeight(C)`

`MinimumLeeDistance(C)`

The minimum Lee weight of the code C.

`LeeWeightDistribution(C)`

The Lee weight distribution of the code C.

`DualLeeWeightDistribution(C)`

The Lee weight distribution of the dual of the code C (see `LeeWeightDistribution`)

`WordsOfLeeWeight(C, w)`

`Cutoff` RngIntElt *Default :* ∞

Given a linear code C, return the set of all words of C having Lee weight w. If `Cutoff` is set to a non-negative integer c, then the algorithm will terminate after a total of c words have been found.

`WordsOfBoundedLeeWeight(C, l, u)`

`Cutoff` RngIntElt *Default :* ∞

Given a linear code C, return the set of all words of C having Lee weight between l and u, inclusive. If `Cutoff` is set to a non-negative integer c, then the algorithm will terminate after a total of c words have been found.

Example H155E19

We calculate the Lee weight distribution of a Reed Muller code over $\mathbf{Z}_4$ and enumerate all words of Lee weight 8.

```
> C := ReedMullerCodeZ4(1, 3);
> C;
(8, 256, 4) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2 1]
[0 1 0 0 2 1 1 3]
[0 0 1 0 1 1 3 2]
[0 0 0 1 3 2 3 3]
> LeeWeightDistribution(C);
[ <0, 1>, <6, 112>, <8, 30>, <10, 112>, <16, 1> ]
> W := WordsOfLeeWeight(C, 8);
```

```
> #W;
30
```

155.6.3 Euclidean Weight

For an element $x \in \mathbf{Z}_4$, the *Euclidean weight* $w_E(x)$ is defined by:

$$w_E(0) = 0, \quad w_E(1) = w_E(3) = 1, \quad w_E(2) = 4.$$

The *Euclidean weight* $w_E(v)$ of a vector $v \in \mathbf{Z}_4^n$ is defined to be the sum (in $\mathbf{Z}$) of the Euclidean weights of its components. See [Wan97, p. 16].

`EuclideanWeight(a)`

The Euclidean weight of the element $a \in \mathbf{Z}4$.

`EuclideanWeight(v)`

The Euclidean weight of the $\mathbf{Z}_4$-codeword v.

`EuclideanDistance(u, v)`

The Euclidean distance between the $\mathbf{Z}_4$-codewords u and v, where u and v belong to the same code C. This is defined to be the Euclidean weight of $(u - v)$.

`MinimumEuclideanWeight(C)`

`MinimumEuclideanDistance(C)`

The minimum Euclidean weight of the $\mathbf{Z}_4$-code C.

`EuclideanWeightDistribution(C)`

The Euclidean weight distribution of the $\mathbf{Z}_4$-code C.

`DualEuclideanWeightDistribution(C)`

The Euclidean weight distribution of the dual of the $\mathbf{Z}_4$-code C.

Example H155E20

We calculate the Euclidean weight distribution of quadratic residue code over $\mathbf{Z}_4$

```
> C := QRCodeZ4(17);
> C;
(17, 262144) Cyclic Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 0 0 0 0 0 1 1 3 0 3 0 3 1]
[0 1 0 0 0 0 0 0 0 3 0 2 3 1 3 1 2]
[0 0 1 0 0 0 0 0 0 2 1 2 2 1 1 1 3]
[0 0 0 1 0 0 0 0 0 1 3 0 2 1 1 0 2]
[0 0 0 0 1 0 0 0 0 2 3 1 0 0 1 3 2]
[0 0 0 0 0 1 0 0 0 2 0 1 1 2 0 3 1]
[0 0 0 0 0 0 1 0 0 3 1 1 1 2 2 1 2]
[0 0 0 0 0 0 0 1 0 2 1 3 1 3 2 0 3]
[0 0 0 0 0 0 0 0 1 1 3 0 3 0 3 1 1]
> EuclideanWeightDistribution(C);
[ <0, 1>, <7, 136>, <8, 170>, <9, 170>, <10, 408>, <11, 544>, <12, 986>, <13,
1768>, <14, 3128>, <15, 5032>, <16, 6120>, <17, 6360>, <18, 8432>, <19, 12512>,
<20, 12682>, <21, 11152>, <22, 14416>, <23, 17680>, <24, 16048>, <25, 15164>,
<26, 17952>, <27, 16864>, <28, 13328>, <29, 14144>, <30, 14144>, <31, 10064>,
<32, 7837>, <33, 8024>, <34, 6800>, <35, 4896>, <36, 3485>, <37, 2992>, <38,
2992>, <39, 1768>, <40, 510>, <41, 1258>, <42, 1224>, <44, 238>, <45, 408>, <46,
136>, <47, 136>, <48, 34>, <68, 1> ]
```

155.7 Weight Enumerators

`CompleteWeightEnumerator(C)`

Let C be a code over a finite ring R of cardinality q, and suppose that the elements of R are ordered in some way. Then for a codeword $v \in C$ and the i-th element $a \in R$, let $s_i(v)$ denote the number of components of v equal to a.

This function returns the complete weight enumerator $\mathcal{W}_C(X_0, X_1, \ldots, X_{q-1})$ of C, which is defined by:

$$\mathcal{W}_C(X_0, X_1, \ldots, X_{q-1}) = \sum_{v \in C} {X_0}^{s_0(v)} {X_1}^{s_1(v)} \cdots {X_{q-1}}^{s_{q-1}(v)}.$$

See [Wan97, p. 9] for more information. The result will lie in a global multivariate polynomial ring over $\mathbf{Z}$ with q variables. The angle-bracket notation may be used to assign names to the indeterminates.

`SymmetricWeightEnumerator(C)`

Suppose C is a $\mathbf{Z}_4$-code. This function returns the symmetric weight enumerator $\mathrm{swe}_C(X_0, X_1, X_2)$ of C, which is defined by:

$$\mathrm{swe}_C(X_0, X_1, X_2) = \mathcal{W}_C(X_0, X_1, X_2, X_1),$$

where $\mathcal{W}_C$ is the complete weight enumerator, defined above. See [Wan97, p. 14] for more information. The result will lie in a global multivariate polynomial ring over $\mathbf{Z}$ with three variables. The angle-bracket notation may be used to assign names to the indeterminates.

`WeightEnumerator(C)`

`HammingWeightEnumerator(C)`

Suppose C is a code over some finite ring R. This function returns the Hamming weight enumerator $\mathrm{Ham}_C(X, Y)$ of C, which is defined by:

$$\mathrm{Ham}_C(X, Y) = \sum_{v \in C} X^{n - w_H(v)} Y^{w_H(v)},$$

where $w_H(v)$ is the Hamming weight function. The result will lie in a global multivariate polynomial ring over $\mathbf{Z}$ with two variables. The angle-bracket notation may be used to assign names to the indeterminates.

`LeeWeightEnumerator(C)`

Suppose C is a $\mathbf{Z}_4$-code. This function returns the Lee weight enumerator $\mathrm{Lee}_C(X, Y)$ of C, which is defined by:

$$\mathrm{Lee}_C(X, Y) = \sum_{v \in C} X^{2*n - w_L(v)} Y^{w_L(v)},$$

where $w_L(v)$ is the Lee weight function, defined in Section 155.6.2. The result will lie in a global multivariate polynomial ring over $\mathbf{Z}$ with two variables. The angle-bracket notation may be used to assign names to the indeterminates.

`EuclideanWeightEnumerator(C)`

Suppose C is a $\mathbf{Z}_4$-code. This function returns the Euclidean weight enumerator $\mathrm{Euclidean}_C(X, Y)$ of C, which is defined by:

$$\mathrm{Euclidean}_C(X, Y) = \sum_{v \in C} X^{4*n - w_E(v)} Y^{w_E(v)},$$

where $w_E(v)$ is the Euclidean weight function, defined in Section 155.6.3. The result will lie in a global multivariate polynomial ring over $\mathbf{Z}$ with two variables. The angle-bracket notation may be used to assign names to the indeterminates.

Example H155E21

We compute the complete weight enumerator of a cyclic code over the Galois ring GR$(4, 2)$.

```
> R<w> := GR(4,2);
> P<x> := PolynomialRing(R);
> L := CyclotomicFactors(R, 3);
> g := L[1];
> g;
x + 3
> C := CyclicCode(3, g);
> C;
(3, 256, 2) Cyclic Code over GaloisRing(2, 2, 2)
Generator matrix:
[1 0 3]
[0 1 3]
> CWE<[X]> := CompleteWeightEnumerator(C);
> CWE;
X[1]^3 + 6*X[1]*X[2]*X[4] + 3*X[1]*X[3]^2 + 6*X[1]*X[5]*X[13] +
    6*X[1]*X[6]*X[16] + 6*X[1]*X[7]*X[15] + 6*X[1]*X[8]*X[14] +
    3*X[1]*X[9]^2 + 6*X[1]*X[10]*X[12] + 3*X[1]*X[11]^2 +
    3*X[2]^2*X[3] + 6*X[2]*X[5]*X[16] + 6*X[2]*X[6]*X[15] +
    6*X[2]*X[7]*X[14] + 6*X[2]*X[8]*X[13] + 6*X[2]*X[9]*X[12] +
    6*X[2]*X[10]*X[11] + 3*X[3]*X[4]^2 + 6*X[3]*X[5]*X[15] +
    6*X[3]*X[6]*X[14] + 6*X[3]*X[7]*X[13] + 6*X[3]*X[8]*X[16] +
    6*X[3]*X[9]*X[11] + 3*X[3]*X[10]^2 + 3*X[3]*X[12]^2 +
    6*X[4]*X[5]*X[14] + 6*X[4]*X[6]*X[13] + 6*X[4]*X[7]*X[16] +
    6*X[4]*X[8]*X[15] + 6*X[4]*X[9]*X[10] + 6*X[4]*X[11]*X[12] +
    3*X[5]^2*X[9] + 6*X[5]*X[6]*X[12] + 6*X[5]*X[7]*X[11] +
    6*X[5]*X[8]*X[10] + 3*X[6]^2*X[11] + 6*X[6]*X[7]*X[10] +
    6*X[6]*X[8]*X[9] + 3*X[7]^2*X[9] + 6*X[7]*X[8]*X[12] +
    3*X[8]^2*X[11] + 3*X[9]*X[13]^2 + 6*X[9]*X[14]*X[16] +
    3*X[9]*X[15]^2 + 6*X[10]*X[13]*X[16] + 6*X[10]*X[14]*X[15] +
    6*X[11]*X[13]*X[15] + 3*X[11]*X[14]^2 + 3*X[11]*X[16]^2 +
    6*X[12]*X[13]*X[14] + 6*X[12]*X[15]*X[16]
```

Example H155E22

We compute the various weight enumerators of the octacode. To ensure the polynomials print out nicely, we assign names to the polynomial ring indeterminates in each case. These names will persist if further calls to these functions (over $\mathbf{Z}_4$) are made.

```
> Z4 := IntegerRing(4);
> O8 := LinearCode<Z4, 8 |
>     [1,0,0,0,3,1,2,1],
>     [0,1,0,0,1,2,3,1],
>     [0,0,1,0,3,3,3,2],
>     [0,0,0,1,2,3,1,1]>;
> #O8;
```

```
256
> CWE<X0,X1,X2,X3> := CompleteWeightEnumerator(O8);
> CWE;
X0^8 + 14*X0^4*X2^4 + 56*X0^3*X1^3*X2*X3 + 56*X0^3*X1*X2*X3^3 +
    56*X0*X1^3*X2^3*X3 + 56*X0*X1*X2^3*X3^3 + X1^8 + 14*X1^4*X3^4 +
    X2^8 + X3^8
> SWE<X0,X1,X2> := SymmetricWeightEnumerator(O8);
> SWE;
X0^8 + 14*X0^4*X2^4 + 112*X0^3*X1^4*X2 + 112*X0*X1^4*X2^3 + 16*X1^8 +
    X2^8
> HWE<X,Y> := HammingWeightEnumerator(O8);
> HWE;
X^8 + 14*X^4*Y^4 + 112*X^3*Y^5 + 112*X*Y^7 + 17*Y^8
> LeeWeightEnumerator(O8);
X^16 + 112*X^10*Y^6 + 30*X^8*Y^8 + 112*X^6*Y^10 + Y^16
> EuclideanWeightEnumerator(O8);
X^32 + 128*X^24*Y^8 + 126*X^16*Y^16 + Y^32
```

155.8 Constructing New Codes from Old

The operations described here produce a new code by modifying in some way the code words of a given code.

155.8.1 Sum, Intersection and Dual

For the following operators, C and D are codes defined as subsets (or subspaces) of the same R-space V.

`C + D`

The (vector space) sum of the linear codes C and D, where C and D are contained in the same R-space V.

`C meet D`

The intersection of the linear codes C and D, where C and D are contained in the same R-space V.

`Dual(C)`

The dual D of the linear code C. The dual consists of all codewords in the R-space V which are orthogonal to all codewords of C.

Example H155E23

Verify some simple results from the sum and intersection of subcodes.

```
> R<w> := GR(9,2);
> P<x> := PolynomialRing(R);
> g := x^2 + 7*w*x + 1;
> C := CyclicCode(5, g);
> C;
(5, 43046721) Cyclic Code over GaloisRing(3, 2, 2)
Generator matrix:
[  1   0   0   1   w]
[  0   1   0 2*w 2*w]
[  0   0   1   w   1]
[  0   0   0   3   0]
[  0   0   0   0   3]
>
> C1 := sub< C | C.1 >;
> C1;
(5, 81, 3) Linear Code over GaloisRing(3, 2, 2)
Generator matrix:
[1 0 0 1 w]
> C2 := sub< C | C.4 >;
> C2;
(5, 9, 1) Linear Code over GaloisRing(3, 2, 2)
Generator matrix:
[0 0 0 3 0]
> C3 := sub< C | { C.1 , C.4} >;
> C3;
(5, 729, 1) Linear Code over GaloisRing(3, 2, 2)
Generator matrix:
[1 0 0 1 w]
[0 0 0 3 0]
> (C1 + C2) eq C3;
true
> (C1 meet C3) eq C1;
true
```

155.8.2 Standard Constructions

`DirectSum(C, D)`

Given a length n_1 code C and a length n_2 code D, both over the same ring R, construct the direct sum of C and D. The direct sum consists of all length $n_1 + n_2$ vectors $u|v$, where $u \in C$ and $v \in D$.

`DirectProduct(C, D)`

Given a length n_1 code C and a length n_2 code D, both over the same ring R, construct the direct product of C and D. The direct product has length $n_1 \cdot n_2$ and its generator matrix is the Kronecker product of the basis matrices of C and D.

`C1 cat C2`

Given codes $C1$ and $C2$, both defined over the same ring R, return the concatenation C of $C1$ and $C2$. If A and B are the generator matrices of $C1$ and $C2$, respectively, the concatenation of $C1$ and $C2$ is the code with generator matrix whose rows consist of each row of A concatenated with each row of B.

`ExtendCode(C)`

Given a length n code C form a new code C' from C by adding the appropriate extra coordinate to each vector of C such that the sum of the coordinates of the extended vector is zero.

`ExtendCode(C, n)`

Return the code C extended n times.

`PadCode(C, n)`

Add n zeros to the end of each codeword of C.

`PlotkinSum(C, D)`

Given codes C and D both over the same ring R and of the same length n, construct the Plotkin sum of C and D. The Plotkin sum consists of all vectors $u|u+v$, $u \in C$ and $v \in D$.

`PunctureCode(C, i)`

Given an length n code C, and an integer i, $1 \leq i \leq n$, construct a new code C' by deleting the i-th coordinate from each code word of C.

`PunctureCode(C, S)`

Given a length n code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$ each of which lies in the range $[1, n]$, construct a new code C' by deleting the components $i_1, \cdots, i_r$ from each code word of C.

`ShortenCode(C, i)`

Given a length n code C and an integer i, $1 \leq i \leq n$, construct a new code from C by selecting only those codewords of C having a zero as their i-th component and deleting the i-th component from these codewords. Thus, the resulting code will have length $n - 1$.

`ShortenCode(C, S)`

Given a length n code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$, each of which lies in the range $[1, n]$, construct a new code from C by selecting only those codewords of C having zeros in each of the coordinate positions $i_1, \cdots, i_r$, and deleting these components. Thus, the resulting code will have length $n - r$.

Example H155E24

We combine codes in various ways and look at the length of the new code.

```
> R<w> := GR(8,2);
> C1 := RandomLinearCode(R, 4, 2);
> C2 := RandomLinearCode(R, 5, 3);
> Length(C1);
4
> Length(C2);
5
> C3 := DirectSum(C1, C2);
> Length(C3);
9
> C4 := DirectProduct(C1, C2);
> Length(C4);
20
> C5 := C1 cat C2;
> Length(C5);
9
```

Example H155E25

We note that, in general, puncturing a code over $\mathbf{Z}_4$ reduces the minimum Lee distance by 2.

```
> C := PreparataCode(3);
> C;
(8, 256, 4) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2 1]
[0 1 0 0 2 1 1 3]
[0 0 1 0 1 1 3 2]
[0 0 0 1 3 2 3 3]
> MinimumLeeWeight(C);
6
> C1 := PunctureCode(C,8);
> C1;
(7, 256, 3) Linear Code over IntegerRing(4)
Generator matrix:
[1 0 0 0 3 1 2]
[0 1 0 0 2 1 1]
[0 0 1 0 1 1 3]

155.9 Operations on Codewords

155.9.1 Construction of a Codeword

`C ! [a1, ..., an]`

`elt< C | a1, ..., an >`

Given a code C which is defined as a subset of the R-space $R^{(n)}$, and elements $a_1, \ldots, a_n$ belonging to R, construct the codeword $(a_1, \ldots, a_n)$ of C. It is checked that the vector $(a_1, \ldots, a_n)$ is an element of C.

`C ! u`

Given a code C which is defined as a subset of the R-space $V = R^{(n)}$, and an element u belonging to V, create the codeword of C corresponding to u. The function will fail if u does not belong to C.

`C ! 0`

The zero word of the code C.

Example H155E26

We create some elements of a code over a finite ring.

```
> R<w> := GR(16,2);
> P<x> := PolynomialRing(R);
> L := CyclotomicFactors(R, 7);
> C := CyclicCode(7, L[2]);
> C ! [1, 2*w, 0, w+3, 7*w, 12*w+3, w+3];
(       1      2*w        0    w + 3      7*w 12*w + 3    w + 3)
> elt< C | 0, 3, 0, 2*w + 5, 6*w + 9, 4*w + 5, 14*w + 14 >;
(        0         3         0   2*w + 5   6*w + 9   4*w + 5 14*w + 14)
```

If the given vector does not lie in the given code then an error will result.

```
>  C ! [0,0,0,0,0,0,1];
>> C ! [0,0,0,0,0,0,1];
     ^
Runtime error in '!': Result is not in the given structure
>  elt< C | 1, 0, 1, 0, 1, 0, 1>;
>> elt< C | 1, 0, 1, 0, 1, 0, 1>;
      ^
Runtime error in elt< ... >: Result is not in the lhs of the constructor
```

155.9.2 Operations on Codewords and Vectors

`u + v`

Sum of the codewords u and v, where u and v belong to the same linear code C.

`-u`

Additive inverse of the codeword u belonging to the linear code C.

`u - v`

Difference of the codewords u and v, where u and v belong to the same linear code C.

`a * u`

Given an element a belonging to the ring R, and a codeword u belonging to the linear code C, return the codeword $a * u$.

`Weight(v)`

The Hamming weight of the codeword v, i.e., the number of non-zero components of v.

`Distance(u, v)`

The Hamming distance between the codewords u and v, where u and v belong to the same code C.

`Support(w)`

Given a word w belonging to the length n code C, return its support as a subset of the integer set $\{1..n\}$. The support of w consists of the coordinates at which w has non-zero entries.

`(u, v)`

`InnerProduct(u, v)`

Inner product of the vectors u and v with respect to the Euclidean norm, where u and v belong to the parent vector space of the code C.

`Coordinates(C, u)`

Given a length n linear code C and a codeword u of C return the coordinates of u with respect to C. The coordinates of u are returned as a sequence $Q = [a_1, \ldots, a_k]$ of elements from the alphabet of C so that $u = a_1 * C.1 + \ldots + a_k * C.k$.

`Normalize(u)`

Given an element u of a code defined over the ring R, return the normalization of u, which is the unique vector v such that $v = a \cdot u$ for some scalar $a \in R$ such that the first non-zero entry of v is the canonical associate in R of the first non-zero entry of u (v is zero if u is zero).

`Rotate(u, k)`

Given a vector u, return the vector obtained from u by cyclically shifting its components to the right by k coordinate positions.

`Rotate(~u, k)`

Given a vector u, destructively rotate u by k coordinate positions.

`Parent(w)`

Given a word w belonging to the code C, return the ambient space V of C.

Example H155E27

Given a code over a finite ring, we explore various operations on its code words.

```
> R<w> := GR(4, 4);
> P<x> := PolynomialRing(R);
> g := x + 2*w^3 + 3*w^2 + w + 2;
> C := CyclicCode(3, g);
> C;
(3, 1048576) Cyclic Code over GaloisRing(2, 2, 4)
Generator matrix:
[          1           0     w^2 + w]
[          0           1 w^2 + w + 1]
[          0           0           2]
> u := C.1;
> v := C.2;
> u;
(      1       0 w^2 + w)
> v;
(          0           1 w^2 + w + 1)
> u + v;
(              1               1 2*w^2 + 2*w + 1)
> 2*u;
(          2           0 2*w^2 + 2*w)
> 4*u;
(0 0 0)
> Weight(u);
2
> Support(u);
{ 1, 3 }
```

155.9.3 Accessing Components of a Codeword

`u[i]`

Given a codeword u belonging to the code C defined over the ring R, return the i-th component of u (as an element of R).

`u[i] := x;`

Given an element u belonging to a subcode C of the full R-space $V = R^n$, a positive integer i, $1 \leq i \leq n$, and an element x of R, this function returns a vector in V which is u with its i-th component redefined to be x.

155.10 Boolean Predicates

For the following operators, C and D are codes defined as a subset (or subspace) of the R-space V.

`u in C`

Return `true` if and only if the vector u of V belongs to the code C.

`u notin C`

Return `true` if and only if the vector u of V does not belong to the code C.

`C subset D`

Return `true` if and only if the code C is a subcode of the code D.

`C notsubset D`

Return `true` if and only if the code C is not a subcode of the code D.

`C eq D`

Return `true` if and only if the codes C and D are equal.

`C ne D`

Return `true` if and only if the codes C and D are not equal.

`IsCyclic(C)`

Return `true` if and only if the linear code C is a cyclic code.

`IsSelfDual(C)`

Return `true` if and only if the linear code C is self-dual (or self-orthogonal) (i.e., C equals the dual of C).

`IsSelfOrthogonal(C)`

Return `true` if and only if the linear code C is self-orthogonal; that is, return whether C is contained in the dual of C.

`IsProjective(C)`

Returns `true` if and only if the (non-quantum) code C is projective.

`IsZero(u)`

Return `true` if and only if the codeword u is the zero vector.

Example H155E28

We consider an [8, 7] linear code K_8 over Z_4 and examine some of its properties.

```
> Z4 := IntegerRing(4);
> K8 := LinearCode< Z4, 8 |
>     [1,1,1,1,1,1,1,1],
>     [0,2,0,0,0,0,0,2],
>     [0,0,2,0,0,0,0,2],
>     [0,0,0,2,0,0,0,2],
>     [0,0,0,0,2,0,0,2],
>     [0,0,0,0,0,2,0,2],
>     [0,0,0,0,0,0,2,2]>;
> K8;
[8, 7, 2] Linear Code over IntegerRing(4)
Generator matrix:
[1 1 1 1 1 1 1 1]
[0 2 0 0 0 0 0 2]
[0 0 2 0 0 0 0 2]
[0 0 0 2 0 0 0 2]
[0 0 0 0 2 0 0 2]
[0 0 0 0 0 2 0 2]
[0 0 0 0 0 0 2 2]
> IsCyclic(K8);
true
> IsSelfDual(K8);

156 ADDITIVE CODES

Chapter 156
ADDITIVE CODES

156.1 Introduction

The concept of a linear codes over a finite field (see Chapter 152) can be generalized to the notion of an *additive* code. Given a finite field F and the space of all n-tuples of F, an additive code is a subset of $F^{(n)}$ which is a K-linear subspace for some subfield $K \subseteq F$.

Additive codes have become increasingly important recently due to their application to the construction of quantum error-correcting codes, though they are also of interest in their own right. A MAGMA package for quantum error-correcting codes is built on the machinery for additive codes.

In MAGMA an additive code has both an *alphabet* F and a *coefficient field* K, which is a subfield of F. An error-correcting code is considered to be defined by its wordset, so there may be several different ways of presenting a given code using different coefficient fields.

Since a given code may be presented over different coefficient rings, the *dimension* k of an additive code is defined relative to the alphabet of the code, $\#C = (\#F)^k$, leading to possibility of *fractional* dimensions. Consequently, the number of generators of an additive code will not equal its dimension, there being $[F : K]$ times as many generators. So a length n K-additive code over F has between zero and $n * [F : K]$ generators.

For example, consider the two length 3 vectors over F_4: $(1, 0, \omega^2), (0, \omega, 0)$. The linear code generated by these vectors consists of all scalar multiples and sums, resulting in a total of $4^2 = 16$ vectors. But the F_2-additive code generated by these two vectors contains *only their sums*, resulting in a total of $2^2 = 4$ vectors. These vectors are $(0, 0, 0), (1, 0, \omega^2), (0, \omega, 0), (1, \omega, \omega^2)$. The alphabet of this code is F_4, its coefficient field is F_2, it has 2 generators and is of dimension 1.

A length n, dimension k K-additive code over F with k_g generators is represented in MAGMA as an $[n, k : k_g]$ K-additive code over F. The concepts of weight, distance and their respective distributions and enumerators transfer directly from linear codes. An $[n, k : k_g, d]$ K-additive code over F is a K-linear subset of $F^{(n)}$ which has fractional dimension k, k_g generators and a minimum weight of d.

As a general rule, additive and linear codes may be used interchangeably. Indeed any linear code can be expressed as an additive code, using either its alphabet or any subfield as its coefficient field. So any linear code over a finite field, of type `CodeLinFld`, is in fact also an additive code, of type `CodeAdd`. The theory of purely linear codes is more general than that of additive codes so unfortunately not all operations are transferable.

156.2 Construction of Additive Codes

156.2.1 Construction of General Additive Codes

```
AdditiveCode< F, K, n | L >
```

Create the K-additive code in $F^{(n)}$ of length n which is generated by the elements specified by the list L, where K is a subfield of F and L is one or more items of the following types:

(a) An element of $F^{(n)}$;

(b) A set or sequence of elements of $F^{(n)}$;

(c) A sequence of n elements of F, defining an element of $F^{(n)}$;

(d) A set or sequence of sequences of type (c);

(e) A subcode of $F^{(n)}$;

```
AdditiveCode(G)
```

```
AdditiveCode(K, G)
```

Given a matrix G over a field F and a subfield K of F, return the K-additive code over F generated by the rows of G. If no coefficient field K is specified, then the prime field of F is used.

Example H156E1

Starting with two linearly independent vectors in $\mathbf{F}_4^{(3)}$, we compare the linear code over F_4 they generate with the corresponding F_2-additive code.

```
> F<w> := GF(4);
> G := Matrix(F, 2, 3, [1,0,w^2,0,w,0]);
> G;
[  1   0 w^2]
[  0   w   0]
> C1 := LinearCode(G);
> C2 := AdditiveCode(GF(2), G);
> #C1;
16
> #C2;
4
> C2 subset C1;
true
```

The codewords of C_2 are arise only through addition of the generators: scalar multiplication is not permitted.

```
> { v : v in C2 };
{
    (  1   w w^2),
    (  0   0   0),
    (  1   0 w^2),
```

```
    (  0   w   0)
}
```

Example H156E2

We define an $\mathbf{F}_2$-additive code over $\mathbf{F}_8$ by constructing a random matrix and considering the code generated by its rows. Note that the number of generators exceeds the length of the code.

```
> K<w> := GF(8);
> M := KMatrixSpace(K, 5, 4);
> C := AdditiveCode(GF(2), Random(M));
> C;
[4, 1 2/3 : 5] GF(2)-Additive Code over GF(2^3)
Generator matrix:
[  1   1 w^2   0]
[  w w^2   w   1]
[w^2 w^2 w^2   1]
[  0 w^4 w^4 w^5]
[  0   0   1   0]
> WeightDistribution(C);
[ <0, 1>, <1, 1>, <2, 2>, <3, 9>, <4, 19> ]
> C;
[4, 1 2/3 : 5, 1] GF(2)-Additive Code over GF(2^3)
Generator matrix:
[  1   1 w^2   0]
[  w w^2   w   1]
[w^2 w^2 w^2   1]
[  0 w^4 w^4 w^5]
[  0   0   1   0]
```

`AdditiveCode(K, C)`

Given a code (linear or additive) C over some finite field F, and a subfield K of F such that the wordset of C forms a K-linear subspace, then return C as a K-additive code.

Example H156E3

Any linear code can be regarded as an additive code with respect to a subfield of its alphabet.

```
> C := RandomLinearCode(GF(4), 8, 3);
> C:Minimal;
[8, 3, 4] Linear Code over GF(2^2)
> A1 := AdditiveCode(GF(4), C);
> A1:Minimal;
[8, 3 : 3, 4] GF(2^2)-Additive Code over GF(2^2)
> { v : v in C } eq {v : v in A1 };
true
```

```
>
> A2 := AdditiveCode(GF(2), C);
> A2:Minimal;
[8, 3 : 6, 4] GF(2)-Additive Code over GF(2^2)
> { v : v in C } eq {v : v in A2 };
true
```

Example H156E4

A K-additive code over F can be viewed as an E-additive code for any subfield $E \subseteq K$.

```
> C4 := RandomAdditiveCode(GF(16), GF(4), 8, 5);
> C4:Minimal;
[8, 2 1/2 : 5] GF(2^2)-Additive Code over GF(2^4)
>
> C2 := AdditiveCode(GF(2), C4);
> C2:Minimal;
[8, 2 1/2 : 10] GF(2)-Additive Code over GF(2^4)
> { v : v in C2 } eq {v : v in C4 };
true
```

But for any E such that $K \subset E \subseteq F$ we can create an E-additive code if and only if the wordset is in fact an E-linear subspace.

```
> C2:Minimal;
[8, 2 1/2 : 10] GF(2)-Additive Code over GF(2^4)
> A1 := AdditiveCode(GF(4), C2);
> A1 eq C4;
true
>  A2 := AdditiveCode(GF(16), C2);
>> A2 := AdditiveCode(GF(16), C2);
                      ^
Runtime error in 'AdditiveCode': Code is not additive over given field
```

156.2.2 Some Trivial Additive Codes

`AdditiveZeroCode(F, K, n)`

Given a field F and subfield $K \subseteq F$ along with a positive integer n, return the $[n, 0, n]$ code consisting of only the zero code word, (where the minimum weight is by convention equal to n).

`AdditiveRepetitionCode(F, K, n)`

Given a field F and subfield $K \subseteq F$ along with a positive integer n, return the $[n, 1, n]$ code consisting of all repeating codewords.

`AdditiveZeroSumCode(F, K, n)`

Given a field F and subfield $K \subseteq F$ along with a positive integer n, return the $[n, n-1, 2]$ K-additive code over F such that for all codewords $(c_1, c_2, \ldots, c_n)$, we have $\sum_i c_i = 0$.

`AdditiveUniverseCode(F, K, n)`

Given a field F and subfield $K \subseteq F$ along with a positive integer n, return the $[n, n, 1]$ K-additive code over F consisting of all possible codewords.

`RandomAdditiveCode(F, K, n, k)`

Given a field F and subfield $K \subseteq F$ along with positive integers n and k, such that $0 < k \leq n * [F : K]$, and k, return a random K-additive code of length n and k generators over the field F.

Example H156E5

Over any finite field chain $K \subseteq F$, the zero code of length n is contained in every code of length n, and similarly every code of length n is contained in the universe code of length n.

```
> F := GF(9);
> K := GF(3);
> U := AdditiveUniverseCode(F, K, 5);
> Z := AdditiveZeroCode(F, K, 5);
> R := RandomAdditiveCode(F, K, 5, 2);
> (Z subset R) and (R subset U);
true
```

156.3 Invariants of an Additive Code

156.3.1 The Ambient Space and Alphabet

A length n additive code has an alphabet F and coefficient field $K \subseteq F$. The code consists of codewords which are a K-linear subspace of $F^{(n)}$.

`Alphabet(C)`

`Field(C)`

The underlying field (or alphabet) of the codewords of the additive code C. A length n additive code with alphabet F consists of codewords from $F^{(n)}$.

`CoefficientField(C)`

The field over which the codewords of the additive code C are considered linear. This will be a subfield of the alphabet of C.

`AmbientSpace(C)`

The ambient space of the additive code C, i.e. the generic R-space V in which C is contained.

`Generic(C)`

Given a length n additive code C, return the generic $[n, n, 1]$ code in which C is contained.

Example H156E6

A code can often be represented using several different coefficient fields.

```
> F<w> := GF(5,4);
> K := GF(5,2);
> C := RandomAdditiveCode(F, K, 12, 5);
> C:Minimal;
[12, 2 1/2 : 5] GF(5^2)-Additive Code over GF(5^4)
> #C;
9765625
> Alphabet(C);
Finite field of size 5^4
> CoefficientField(C);
Finite field of size 5^2
>
> C1 := AdditiveCode(GF(5), C);
> C1:Minimal;
[12, 2 1/2 : 10] GF(5)-Additive Code over GF(5^4)
> #C1;
9765625
> Alphabet(C1);
Finite field of size 5^4
> CoefficientField(C1);
Finite field of size 5
```

156.3.2 Basic Numerical Invariants

`Length(C)`

Return the block length n of an additive code C.

`Dimension(C)`

The (rational) dimension k of C. If the alphabet of C is F, then the dimension is defined by the equation $\#C = (\#F)^k$.

Note that since any basis of the additive code C is relative to the coefficient field K, this dimension is not necessarily equal to the number of generators of C and is not even necessarily integral.

`NumberOfGenerators(C)`

`Ngens(C)`

The number of generators of the additive code C. Note that if the coefficient ring of C is not the same as its alphabet then this will be different from the dimension of C.

`#C`

Given an additive code C, return the number of codewords belonging to C.

`InformationRate(C)`

The information rate of the $[n, k]$ code C. This is the ratio k/n.

156.3.3 The Code Space

`GeneratorMatrix(C)`

`BasisMatrix(C)`

The generator matrix for an $[n, k(k_g)]$ K-additive code C over F is a $k_g \times n$ matrix over F, whose k_g rows form a basis for C when considered as vectors over K.

`Basis(C)`

`Generators(C)`

A basis for the K-additive code C, returned as a sequence of codewords over the alphabet of C, which generate the code over K.

`C . i`

Given an $[n, k(k_g)]$ K-additive code C and a positive integer i, $1 \leq i \leq k_g$, return the i-th element of the current basis of C over K.

156.3.4 The Dual Space

`Dual(C)`

The code that is dual to the code C. For an additive code C, this is the nullspace with respect to the trace inner product of the coefficient field.

`ParityCheckMatrix(C)`

The parity check matrix for the code C, returned as an element of $\mathrm{Hom}(V, U)$.

156.4 Operations on Codewords

156.4.1 Construction of a Codeword

`C ! [a1, ..., an]`

`elt< C | a1, ..., an >`

Given a length n additive code C with alphabet F, then the codewords of C lie in $F^{(n)}$. Given elements $a_1, \ldots, a_n$ belonging to F, construct the codeword $(a_1, \ldots, a_n)$ of C. A check is made that the vector $(a_1, \ldots, a_n)$ is an element of C.

`C ! u`

Given an additive code C which is defined as a subset of the F-space $V = F^{(n)}$, and an element u belonging to V, create the codeword of C corresponding to u. The function will fail if u does not belong to C.

`C ! 0`

The zero word of the additive code C.

`Random(C)`

A random codeword of the additive code C.

156.4.2 Arithmetic Operations on Codewords

`u + v`

Sum of the codewords u and v, where u and v belong to the same linear code C.

`-u`

Additive inverse of the codeword u belonging to the linear code C.

`u - v`

Difference of the codewords u and v, where u and v belong to the same linear code C.

`a * u`

Given an element a belonging to the alphabet F, and a codeword u belonging to the additive code C, return the codeword $a * u$.

`Normalize(u)`

Normalize a codeword u of an additive code C, returning a scalar multiple of u such that its first non-zero entry is 1.

156.4.3 Distance and Weight

`Distance(u, v)`

The Hamming distance between the codewords u and v, where u and v belong to the same additive code C.

`Weight(u)`

The Hamming weight of the codeword u, i.e., the number of non-zero components of u.

156.4.4 Vector Space and Related Operations

`(u, v)`

`InnerProduct(u, v)`

Inner product of the vectors u and v with respect to the Euclidean norm, where u and v belong to the parent vector space of the code C.

`TraceInnerProduct(K, u, v)`

Given vectors u and v defined over a finite field L and a subfield K of L, this function returns the trace of the inner product of the vectors u and v with respect to K.

`Support(w)`

Given a word w belonging to the $[n, k]$ code C, return its support as a subset of the integer set $\{1..n\}$. The support of w consists of the coordinates at which w has non-zero entries.

`Coordinates(C, u)`

Given an $[n, k : k_g]$ K-additive code C and a codeword u of C return the coordinates of u with respect to the current basis of C. The coordinates of u are returned as a sequence $Q = [a_1, \ldots, a_{k_g}]$ of elements from K such that $u = a_1 * C.1 + \ldots + a_{k_g} * C.k_g$.

`Parent(w)`

Given a word w belonging to the code C, return the ambient space V of C.

`Rotate(u, k)`

Given a vector u, return the vector obtained from u by cyclically shifting its components to the right by k coordinate positions.

`Rotate(~u, k)`

Given a vector u, destructively rotate u by k coordinate positions.

`Trace(u, S)`

`Trace(u)`

Given a vector u with components in K, and a subfield S of K, construct the vector with components in S obtained from u by taking the trace of each component with respect to S. If S is omitted, it is taken to be the prime field of K.

156.4.5 Predicates for Codewords

`u eq v`

The function returns `true` if and only if the codewords u and v belonging to the same additive code are equal.

`u ne v`

The function returns `true` if and only if the codewords u and v belonging to the same additive code are not equal.

`IsZero(u)`

The function returns `true` if and only if the codeword u is the zero vector.

156.4.6 Accessing Components of a Codeword

`u[i]`

Given a codeword u belonging to the code C defined over the ring R, return the i-th component of u (as an element of R).

`u[i] := x;`

Given an element u belonging to a subcode C of the full R-space $V = R^n$, a positive integer i, $1 \leq i \leq n$, and an element x of R, this function returns a vector in V which is u with its i-th component redefined to be x.

156.5 Subcodes

156.5.1 The Subcode Constructor

`sub< C | L >`

Given a K-additive linear code C over F, construct the subcode of C, generated (over K) by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) An element of C;

(b) A set or sequence of elements of C;

(c) A sequence of n elements of F, defining an element of C;

(d) A set or sequence of sequences of type (c);

(e) A subcode of C;

`Subcode(C, k)`

Given an additive code C and an integer k, where k is less than the number of generators of C, then return a subcode of C with k generators.

`Subcode(C, S)`

Suppose C is an additive code and S is a set of positive integers, each of which is less than the number of generators of C. The function returns the subcode of C generated by the generators of C indexed by S.

`SubcodeBetweenCode(C1, C2, k)`

Given an additive code C_1 and a subcode C_2 of C_1, return a subcode of C_1 with k generators containing C_2.

`SubcodeWordsOfWeight(C, w)`

Given a length n additive code C and an integer which lies in the range $[1, n]$, return the subcode of C generated by those words of C of weight w.

`SubcodeWordsOfWeight(C, S)`

Given a length n additive code C and a set S of integers, each of which lies in the range $[1, n]$, return the subcode of C generated by those words of C whose weights lie in S.

Example H156E7

We give an example of how `SubcodeBetweenCode` may be used to create a code nested in between a subcode pair.

```
> F<w> := GF(8);
> C1 := AdditiveRepetitionCode(F, GF(2), 6);
> C1;
[6, 1 : 3, 6] GF(2)-Additive Code over GF(2^3)
Generator matrix:
[  1   1   1   1   1   1]
[  w   w   w   w   w   w]
[w^2 w^2 w^2 w^2 w^2 w^2]
> C3 := AdditiveZeroSumCode(F, GF(2), 6);
> C3;
[6, 5 : 15, 2] GF(2)-Additive Code over GF(2^3)
Generator matrix:
[  1   0   0   0   0   1]
[  w   0   0   0   0   w]
[w^2   0   0   0   0 w^2]
[  0   1   0   0   0   1]
[  0   w   0   0   0   w]
[  0 w^2   0   0   0 w^2]
[  0   0   1   0   0   1]
[  0   0   w   0   0   w]
[  0   0 w^2   0   0 w^2]
[  0   0   0   1   0   1]
[  0   0   0   w   0   w]
[  0   0   0 w^2   0 w^2]
```

```
[  0   0   0   0   1   1]
[  0   0   0   0   w   w]
[  0   0   0   0 w^2 w^2]
> C1 subset C3;
true
> C2 := SubcodeBetweenCode(C3, C1, 11);
> C2;
[6, 3 2/3 : 11] GF(2)-Additive Code over GF(2^3)
Generator matrix:
[  1   0   0   0   1   0]
[  w   0   0   0   w   0]
[w^2   0   0 w^2 w^2 w^2]
[  0   1   0   0   0   1]
[  0   w   0   0   0   w]
[  0 w^2   0   0   0 w^2]
[  0   0   1   0   0   1]
[  0   0   w   0   0   w]
[  0   0 w^2   0   0 w^2]
[  0   0   0   1   0   1]
[  0   0   0   w   0   w]
> (C1 subset C2) and (C2 subset C3);
true
```

156.5.2 Sum, Intersection and Dual

For the following operators, C and D are additive codes defined as subsets (or subspaces) of the same R-space F^n.

`C + D`

Given two additive codes which have the same length, which are defined over the same alphabet, and which have the same coefficient ring F, return the sum of these two codes with respect to F.

`C meet D`

The intersection of the additive codes C and D.

`Dual(C)`

The code that is dual to the code C. For an additive code C, this is the code generated by the nullspace of C, relative to the trace inner product.

156.5.3 Membership and Equality

`u in C`

Return `true` if and only if the vector u of V belongs to the additive code C, where V is the generic vector space containing C.

`u notin C`

Return `true` if and only if the vector u does not belong to the additive code C, where V is the generic vector space containing C.

`C subset D`

Return `true` if and only if the wordset of the code C is a subset of the wordset of the code D. (Either code may possibly be additive).

`C notsubset D`

Return `true` if and only if the wordset of the code C is not a subset of the wordset of the code D. (Either code may possibly be additive).

`C eq D`

Return `true` if and only if the codes C and D have the same wordsets. (Either code may possibly be additive).

`C ne D`

Return `true` if and only if the codes C and D have different wordsets. (Either code may possibly be additive).

156.6 Properties of Codes

For the following operators, C and D are codes defined as a subset (or subspace) of the vector space V.

`IsSelfDual(C)`

Return `true` if and only if the linear code C is self-dual (or self-orthogonal) (i.e. C equals the dual of C).

`IsSelfOrthogonal(C)`

Return `true` if and only if the linear code C is self-orthogonal (i.e. C is contained in the dual of C).

`IsPerfect(C)`

Return `true` if and only if the linear code C is perfect; that is, if and only if the cardinality of C is equal to the size of the sphere packing bound of C.

`IsProjective(C)`

Returns `true` if and only if the (non-quantum) code C is projective over its alphabet.

`IsAdditiveProjective(C)`

Returns `true` if and only if the additive code C is projective over its coefficient field. It is possible that some of the columns may not be independent with respect to the alphabet of the code.

156.7 The Weight Distribution

156.7.1 The Minimum Weight

An adaptation of the minimum weight algorithm for linear codes (see Section 152.8.1) has been developed for additive codes by Markus Grassl and Greg White.

From a user's perspective, the description given in 152.8.1 is sufficient to understand the additive case. The algorithm is still new, and has yet to be optimised to its full potential.

`MinimumWeight(C: parameters)`

`MinimumDistance(C: parameters)`

`RankLowerBound`	RngIntElt	*Default :* 0
`MaximumTime`	RngReSubElt	*Default :* ∞

Determine the minimum weight of the words belonging to the code C, which is also the minimum distance between any two codewords. The parameter `RankLowerBound` sets a minimum rank on the informations sets used in the calculation, while the parameter `MaximumTime` sets a time limit (in seconds of "user time") after which the calculation is aborted.

By setting the verbose flag `"Code"`, information about the progress of the computation can be printed. An example to demonstrate the interpretation of the verbose output follows:

```
> SetVerbose("Code", true);
> SetSeed(1);
> MinimumWeight(RandomAdditiveCode(GF(4),GF(2),82,39));
GF(2)-Additive code over GF(4) of length 82 with 39 generators.
Is not cyclic
Lower Bound: 1, Upper Bound: 64
Constructed 5 distinct generator matrices
Total Ranks:     21  20  20  20  20
Relative Ranks:  21  20  20  20   1
Starting search for low weight codewords... 0.020
     Discarding non-contributing rank 1 matrix
Enumerating using 1 generator at a time:
     New codeword identified of weight 48, time 0.020
     New codeword identified of weight 46, time 0.020
     New codeword identified of weight 44, time 0.020
     New codeword identified of weight 42, time 0.020
```

```
   Completed Matrix  1:  lower =  5, upper = 42. Time so far: 0.030
     New codeword identified of weight 41, time 0.030
   Completed Matrix  2:  lower =  6, upper = 41. Time so far: 0.030
   Completed Matrix  3:  lower =  7, upper = 41. Time so far: 0.040
     New codeword identified of weight 40, time 0.040
   Completed Matrix  4:  lower =  8, upper = 40. Time so far: 0.040
Enumerating using 2 generators at a time:
     New codeword identified of weight 37, time 0.050
   Completed Matrix  1:  lower =  9, upper = 37. Time so far: 0.050
   Completed Matrix  2:  lower = 10, upper = 37. Time so far: 0.050
   Completed Matrix  3:  lower = 11, upper = 37. Time so far: 0.060
     New codeword identified of weight 36, time 0.060
   Completed Matrix  4:  lower = 12, upper = 36. Time so far: 0.060
Enumerating using 3 generators at a time:
     New codeword identified of weight 34, time 0.070
   Completed Matrix  1:  lower = 13, upper = 34. Time so far: 0.070
     New codeword identified of weight 33, time 0.080
   Completed Matrix  2:  lower = 14, upper = 33. Time so far: 0.090
   Completed Matrix  3:  lower = 15, upper = 33. Time so far: 0.100
   Completed Matrix  4:  lower = 16, upper = 33. Time so far: 0.110
Enumerating using 4 generators at a time:
     New codeword identified of weight 32, time 0.120
   Completed Matrix  1:  lower = 17, upper = 32. Time so far: 0.170
   Completed Matrix  2:  lower = 18, upper = 32. Time so far: 0.250
   Completed Matrix  3:  lower = 19, upper = 32. Time so far: 0.320
   Completed Matrix  4:  lower = 20, upper = 32. Time so far: 0.390
Termination predicted with 7 generators at matrix 4
Enumerating using 5 generators at a time:
   Completed Matrix  1:  lower = 21, upper = 32. Time so far: 0.960
   Completed Matrix  2:  lower = 22, upper = 32. Time so far: 1.570
   Completed Matrix  3:  lower = 23, upper = 32. Time so far: 2.160
   Completed Matrix  4:  lower = 24, upper = 32. Time so far: 2.750
Termination predicted at 118 s (1 m 57 s) with 7 generators at matrix 4
Enumerating using 6 generators at a time:
   Completed Matrix  1:  lower = 25, upper = 32. Time so far: 6.680
   Completed Matrix  2:  lower = 26, upper = 32. Time so far: 10.969
   Completed Matrix  3:  lower = 27, upper = 32. Time so far: 15.149
   Completed Matrix  4:  lower = 28, upper = 32. Time so far: 19.440
Termination predicted at 114 s (1 m 54 s) with 7 generators at matrix 4
Enumerating using 7 generators at a time:
   Completed Matrix  1:  lower = 29, upper = 32. Time so far: 41.739
   Completed Matrix  2:  lower = 30, upper = 32. Time so far: 66.239
   Completed Matrix  3:  lower = 31, upper = 32. Time so far: 90.780
   Completed Matrix  4:  lower = 32, upper = 32. Time so far: 115.510
```

```
Final Results: lower = 32, upper = 32, Total time: 115.510
32
```

Verbose output can be invaluable in the case of lengthy minimum weight calculations.

The algorithm constructs different (equivalent) generator matrices, each of which has pivots in different column positions of the code, called its *information set*. The *relative rank* of a generator matrix is the size of its information set independent of the previously constructed matrices.

When enumerating all generators taken r at a time, once r exceeds the difference between the total rank of a matrix, and its relative rank, the lower bound on the minimum weight will be incremented by 1 for that step.

The upper bound on the minimum weight is determined by the minimum weight of codewords that are enumerated. As soon as these bounds become equal, the computation is complete.

Example H156E8

We illustrate the much greater efficiency of the minimum weight algorithm compared to computing the full weight distribution.

```
> SetVerbose("Code",true);
> C := RandomAdditiveCode(GF(9),GF(3),39,25);
> MinimumWeight(C);
GF(3)-Additive code over GF(9) of length 39 with 25 generators. Is not cyclic
Lower Bound: 1, Upper Bound: 28
Constructed 4 distinct generator matrices
Total Ranks:     13  13  13  13
Relative Ranks:  13  13  12   1
Starting search for low weight codewords... 0.009
     Discarding non-contributing rank 1 matrix
Enumerating using 1 generator at a time:
     New codeword identified of weight 25, time 0.009
     New codeword identified of weight 23, time 0.009
     New codeword identified of weight 21, time 0.009
   Completed Matrix  1:  lower =  3, upper = 21. Time so far: 0.009
   Completed Matrix  2:  lower =  4, upper = 21. Time so far: 0.009
   Completed Matrix  3:  lower =  5, upper = 21. Time so far: 0.009
Enumerating using 2 generators at a time:
     New codeword identified of weight 20, time 0.009
     New codeword identified of weight 19, time 0.009
     New codeword identified of weight 18, time 0.009
   Completed Matrix  1:  lower =  6, upper = 18. Time so far: 0.009
   Completed Matrix  2:  lower =  7, upper = 18. Time so far: 0.019
   Completed Matrix  3:  lower =  8, upper = 18. Time so far: 0.019
Enumerating using 3 generators at a time:
     New codeword identified of weight 17, time 0.070
   Completed Matrix  1:  lower =  9, upper = 17. Time so far: 0.089
   Completed Matrix  2:  lower = 10, upper = 17. Time so far: 0.149
```

```
   Completed Matrix  3:  lower = 11, upper = 17. Time so far: 0.210
Enumerating using 4 generators at a time:
   Completed Matrix  1:  lower = 12, upper = 17. Time so far: 1.379
   Completed Matrix  2:  lower = 13, upper = 17. Time so far: 2.539
   Completed Matrix  3:  lower = 14, upper = 17. Time so far: 3.719
Termination predicted at 49 s with 5 generators at matrix 3
Enumerating using 5 generators at a time:
   Completed Matrix  1:  lower = 15, upper = 17. Time so far: 19.409
   Completed Matrix  2:  lower = 16, upper = 17. Time so far: 35.019
   Completed Matrix  3:  lower = 17, upper = 17. Time so far: 50.649
Final Results: lower = 17, upper = 17, Total time: 50.649
17

156.7.2 The Weight Distribution

`WeightDistribution(C)`

This function determines the weight distribution for the code C. The distribution is returned in the form of a sequence of tuples, where the i-th tuple contains the i-th weight, w_i say, and the number of codewords having weight w_i.

`DualWeightDistribution(C)`

The weight distribution of the code which is dual to the additive code C (see `WeightDistribution`).

156.7.3 The Weight Enumerator

`WeightEnumerator(C)`

The (Hamming) weight enumerator $W_C(x, y)$ for the additive code C. The weight enumerator is defined by

$$W_C(x, y) = \sum_{u \in C} x^{n-wt(u)} y^{wt(u)}.$$

`CompleteWeightEnumerator(C)`

The complete weight enumerator $\mathcal{W}_C(z_0, \ldots, z_{q-1})$ for the additive code C where q is the size of the alphabet E of C. Let the q elements of E be denoted by $\omega_0, \ldots, \omega_{q-1}$.

If E is a prime field, we let ω_i be i (i.e. take the natural representation of each number). If E is a non-prime field, we let ω_0 be the zero element of E and let ω_i be α^{i-1} for $i = 1 \ldots q-1$ where α is the primitive element of E. Now for a codeword u of C, let $s_i(u)$ be the number of components of u equal to ω_i. The complete weight enumerator is defined by

$$\mathcal{W}_C(z_0, \ldots, z_{q-1}) = \sum_{u \in C} {z_0}^{s_0(u)} \ldots {z_{q-1}}^{s_{q-1}(u)}.$$

`CompleteWeightEnumerator(C, u)`

The complete weight enumerator $\mathcal{W}_{C+u}(z_0, \ldots, z_{q-1})$ for the coset $C + u$, where u is an element of the generic vector space for the code C.

156.7.4 The MacWilliams Transform

`MacWilliamsTransform(n, k, q, W)`

Let C be a hypothetical $[n, k]$ linear code over a finite field of cardinality q. Let W be the weight distribution of C (in the form as returned by the function `WeightDistribution`). This function applies the MacWilliams transform to W to obtain the weight distribution W' of the dual code of C. The transform is a combinatorial algorithm based on n, k, q and W alone. Thus C itself need not exist—the function simply works with the sequence of integer pairs supplied by the user. Furthermore, if W is not the weight distribution of an actual code, the result W' will be meaningless and even negative weights may be returned.

156.7.5 Words

The functions in this section only apply to codes over finite fields.

`Words(C, w: parameters)`

`Cutoff`	RngIntElt	*Default :* ∞
`StoreWords`	BoolElt	*Default :* `true`

Given a linear code C defined over a finite field, return the set of all words of C having weight w. If `Cutoff` is set to a non-negative integer c, then the algorithm will terminate after a total of c words have been found. If `StoreWords` is `true` then the words generated will be stored internally.

`NumberOfWords(C, w)`

Given a linear code C defined over a finite field, return the number of words of C having weight w.

`WordsOfBoundedWeight(C, l, u: parameters)`

`Cutoff`	RngIntElt	*Default :* ∞
`StoreWords`	BoolElt	*Default :* `true`

Given a linear code C defined over a finite field, return the set of all words of C having weight between l and u, inclusive. If `Cutoff` is set to a non-negative integer c, then the algorithm will terminate after a total of c words have been found. If `StoreWords` is `true` then any words of a *single weight* generated will be stored internally.

156.8 Families of Linear Codes

156.8.1 Cyclic Codes

While cyclic linear codes are always generated by a single generating polynomial (vector), this is not the case for additive codes. Cyclic additive codes may be created in Magma using either a single generator, or a sequence of generators.

In the important case of $GF(2)$-additive vectors over $GF4$, all cyclic codes can be described in terms of two generators with one generator taken over $GF(4)$ and the other over $GF(2)$. A special function is provided for this construction.

`AdditiveCyclicCode(v)`
`AdditiveCyclicCode(K, v)`
`AdditiveCyclicCode(Q)`
`AdditiveCyclicCode(K, Q)`

Given either a single vector v or sequence of vectors Q over some finite field F, return the K-additive code over F generated by all shifts of the inputs. The field K must be a subfield of F and if it is the prime subfield of F, it may be omitted.

`AdditiveCyclicCode(n, f)`
`AdditiveCyclicCode(K, n, f)`
`AdditiveCyclicCode(n, Q)`
`AdditiveCyclicCode(K, n, Q)`

Given either a single polynomial f or sequence Q of polynomials over some finite field F, return the K-additive code of length n over F generated by all shifts of the inputs. The field K must be a subfield of F, and if it is the prime subfield of F, it may be omitted.

```
AdditiveCyclicCode(v4, v2)
```

Given two vectors of equal length n, where v_4 is over $GF(4)$ and v_2 is over $GF(2)$, return the F_2–additive code generated by all of their cyclic shifts. Note that for the case of $GF(2)$-additive codes over $GF(4)$, two generators suffice to generate any such code.

```
AdditiveCyclicCode(n, f4, f2)
```

Given two polynomials f_4 and f_2, where f_4 is over $GF(4)$ and f_2 is over $GF(2)$, return the F_2–additive code of length n generated by all of their cyclic shifts. The degree of the polynomials f_4 and f_2 must not exceed $n-1$. Note that for the case of $GF(2)$-additive codes over $GF(4)$, two generators suffice to generate any such code.

156.8.2 Quasicyclic Codes

Quasicyclic codes are a generalisation of cyclic codes. In MAGMA quasicyclic codes consist of horizontally joined cyclic blocks.

```
AdditiveQuasiCyclicCode(n, Q)
```

```
AdditiveQuasiCyclicCode(K, n, Q)
```

Given an integer n, and a sequence Q of polynomials over some finite field F, return the K–additive quasicyclic code, whose cyclic blocks are generated by the polynomials in Q. The field K must be a subfield of F, and if it is the prime subfield of F, it may be omitted.

```
AdditiveQuasiCyclicCode(n, Q, h)
```

```
AdditiveQuasiCyclicCode(K, n, Q, h)
```

Given an integer n, and a sequence Q of polynomials over some finite field F, and an integer h, then return the K–additive quasicyclic code, whose cyclic blocks are generated by the polynomials in Q and stacked 2-dimensionally of height h. The field K must be a subfield of F, and if it is the prime subfield of F, it may be omitted.

```
AdditiveQuasiCyclicCode(Q)
```

```
AdditiveQuasiCyclicCode(K, Q)
```

Given a sequence Q of vectors over some finite field F, then return the K–additive quasicyclic code, whose cyclic blocks are generated by the vectors in Q. The field K must be a subfield of F, and if it is the prime subfield of F, it may be omitted.

```
AdditiveQuasiCyclicCode(Q, h)
```

```
AdditiveQuasiCyclicCode(K, Q, h)
```

Given a sequence Q of vectors over some finite field F, and an integer h, then return the K–additive quasicyclic code, whose cyclic blocks are generated by the vectors in Q and stacked 2-dimensionally of height h. The field K must be a subfield of F, and if it is the prime subfield of F, it may be omitted.

156.9 New Codes from Old

The operations described here produce a new code by modifying in some way the codewords of a given code.

156.9.1 Standard Constructions

`AugmentCode(C)`

Construct a new additive code by including the all-ones vector with the words of the additive code C.

`CodeComplement(C, S)`

Given a subcode S of the code C, return a code C' such that $C = S + C'$. Both C and S must be defined over the same field.

`DirectSum(C, D)`

Given codes C and D, form the code that is direct sum of C and D. The direct sum consists of all vectors $u|v$, where $u \in C$ and $v \in D$.

`DirectSum(Q)`

Given a sequence of codes $Q = [C_1, \ldots, C_r]$, all defined over the same field F, construct the direct sum of the C_i.

`DirectProduct(C, D)`

Given an $[n_1, k_1]$ code C and an $[n_2, k_2]$ code D, both over the same ring R, construct the direct product of C and D. The direct product has length $n_1 \cdot n_2$ and its generator matrix is the Kronecker product of the basis matrices of C and D.

`ExtendCode(C)`

Given an $[n, k, d]$ additive code C, form a new code C' from C by adding the appropriate extra coordinate to each vector of C such that the sum of the coordinates of the extended vector is zero.

`ExtendCode(C, n)`

Return the code obtained by extending the code C extended n times.

`PadCode(C, n)`

Add n zeros to the end of each codeword of the code C.

`PlotkinSum(C1, C2)`

Given codes C_1 and C_2 defined over the same alphabet, return the code consisting of all vectors of the form $u|u + v$, where $u \in C1$ and $v \in C2$. Zeros are appended where needed to make up any length differences in the two codes.

`PlotkinSum(C1, C2, C3: parameters)`

`a` FldFinElt *Default :* -1

Given three codes C_1, C_2 and C_3 defined over the same alphabet K, return the code consisting of all vectors of the form $u|u+a*v|u+v+w$, where $u \in C1$, $v \in C2$ and $w \in C3$. The default value of the multiplier a is a primitive element of K. Zeros are appended where needed to ensure that every codeword has the same length.

`PunctureCode(C, i)`

Given an $[n, k]$ code C, and an integer i, $1 \leq i \leq n$, construct a new code C' by deleting the i-th coordinate from each code word of C.

`PunctureCode(C, S)`

Given an $[n, k]$ code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$ each of which lies in the range $[1, n]$, construct a new code C' by deleting the components $i_1, \cdots, i_r$ from each code word of C.

`ShortenCode(C, i)`

Given an $[n, k]$ code C and an integer i, $1 \leq i \leq n$, construct a new code from C by selecting only those codewords of C having a zero as their i-th component and deleting the i-th component from these codewords. Thus, the resulting code will have length $n - 1$.

`ShortenCode(C, S)`

Given an $[n, k]$ code C and a set S of distinct integers $\{i_1, \cdots, \mathrm{i}_r\}$, each of which lies in the range $[1, n]$, construct a new code from C by selecting only those codewords of C having zeros in each of the coordinate positions $i_1, \cdots, i_r$, and deleting these components. Thus, the resulting code will have length $n - r$.

156.9.2 Combining Codes

`C1 cat C2`

Given codes $C1$ and $C2$, both defined over the same field K, return the concatenation C of $C1$ and $C2$. The generators of the resultant code are the concatenations of the generators of $C1$ and $C2$.

`Juxtaposition(C1, C2)`

Given an $[n_1, k, d_1]$ code $C1$ and an $[n_2, k, d_2]$ code $C2$ of the same dimension, where both codes are defined over the same field K, this function returns a $[n_1 + n_2, k, \geq d_1 + d_2]$ code whose generator matrix is `HorizontalJoin(A, B)`, where A and B are the generator matrices for codes $C1$ and $C2$, respectively.

156.10 Automorphism Group

`AutomorphismGroup(C)`

The automorphism group of the additive code C. Currently, this function is only available for additive codes over $GF(4)$.

`PermutationGroup(C)`

The subgroup of the automorphism group of the additive code C consisting of permutations of the coordinates. Currently, this function is only available for additive codes over $GF(4)$.

157 QUANTUM CODES

Chapter 157
QUANTUM CODES

157.1 Introduction

Interest in quantum computing has grown rapidly following the discovery by Peter Shor in 1994 of a polynomial-time algorithm for integer factorization [Sho94]. In a classical computer a sequence of N binary digits defines one specific configuration among the 2^N possible values. However, in a quantum computer a collection of N "qubits" has a state function (in 'ket' notation) $|\psi\rangle$ in a *Hilbert space*, which can be in a superposition of all 2^N possible values

$$|\psi\rangle = \sum_{\mathbf{v}\in\mathbf{Z}_2^N} \alpha_{\mathbf{v}}|\mathbf{v}\rangle, \qquad \alpha_{\mathbf{v}} \in \mathbf{C}, \quad \sum_{\mathbf{v}} |\alpha_{\mathbf{v}}|^2 = 1.$$

A basic theorem in quantum information theory states that it is impossible to clone a quantum state. Since this implies that it is not possible to copy quantum information, it was initially believed that error-correction would be impossible on a quantum computer. However, in 1995 Shor showed that it *was* possible to encode quantum information in such a way that errors can be corrected, assuming an error model in which errors occur independently in distinct qubits [Sho95].

Following this discovery, an class of quantum error-correcting codes known as *stabilizer codes* were developed. In [CRSS98] (which is the major reference for this chapter of the MAGMA Handbook), it was shown that stabilizer codes can be represented in terms of additive codes over finite fields (see chapter 156 for a description of additive codes). This remarkable result reduces the problem of constructing fault-tolerant encodings on a continuous Hilbert space to that of constructing certain discrete codes, allowing the use of many of the tools developed in classical coding theory.

The current MAGMA package for quantum codes deals exclusively with finite field representations of stabilizer codes. It is important to keep in mind that, although a quantum code is *represented* by a code over a finite field, an actual quantum code is in fact a totally different object. The full theory behind quantum stabilizer codes will not be described here, for that the reader should consult the main reference [CRSS98]. A brief synopsis will outline how the finite field representation of a stabilizer code is to be interpreted, and the specifics of this representation in MAGMA.

Many of the conventions and functions for classical error-correcting code types in MAGMA can be ambiguous in the context of quantum codes. For this reason the handbook should be carefully consulted before assuming that any particular aspect of a quantum code follows naturally from classical coding theory definitions.

The reduction of the problem of continuous errors on a Hilbert space to a problem employing a discrete finite field representation is achieved by confining attention to a

finite *error group*. An element of the error group, acting on the N qubits, is expressed as a combination of bit flip errors, designated by the operator X, and phase shift errors, designated by the operator Z (as well as an overall phase factor that will be ignored here):

$$X(\mathbf{a})Z(\mathbf{b})|\mathbf{v}\rangle = (-1)^{\mathbf{v}\cdot\mathbf{b}}|\mathbf{v}+\mathbf{a}\rangle$$

The error group is given by the set $\{X(\mathbf{a})Z(\mathbf{b}) : \mathbf{a},\mathbf{b} \in \mathbf{Z}_2^n\}$ and its elements can be written as length $2N$ binary vectors $(\mathbf{a}|\mathbf{b})$. An error represented by such a vector in MAGMA is said to be in *extended format* which is distinct from the default representation. A more common (and practical) representation is as the element $\mathbf{w}$ of $F_4^{(N)}$ given by $\mathbf{w} = \mathbf{a} + \omega\mathbf{b}$, where ω is a primitive element of $GF(4)$. This representation is referred to as the *compact format*, and is the default format used in MAGMA for quantum codes. Note that this is slightly different to the representation $\widehat{\mathbf{w}} = \omega\mathbf{a} + \overline{\omega}\mathbf{b}$ used in [CRSS98] for binary quantum codes, but they are equivalent: $\mathbf{w} = \overline{\omega} * \widehat{\mathbf{w}}$.

The MAGMA package also supports non-binary quantum codes, which are obtained by generalizing from the binary case in a natural way. For quantum codes based on qubits over $GF(q)$, the compact format in $GF(q^2)$ will be $\mathbf{w} = \mathbf{a} + \lambda\mathbf{b}$, where λ is a fixed element returned by the function `QuantumBasisElement`$(GF(q^2))$.

A symplectic inner product is defined on the group of errors, in its representation as a set of $GF(q)$-vectors. For vectors in extended format this is defined by

$$(\mathbf{a}_1|\mathbf{b}_1) * (\mathbf{a}_2|\mathbf{b}_2) = \mathbf{a}_1 \cdot \mathbf{b}_2 - \mathbf{a}_2 \cdot \mathbf{b}_1$$

In compact format (over $GF(4)$) the equivalent inner product is defined by

$$\mathbf{w}_1 * \mathbf{w}_2 = \mathrm{Trace}(\mathbf{w}_1 \cdot \overline{\mathbf{w}}_2).$$

Since the commutator of two errors is given by

$$\begin{aligned}
&\Big[\big(X(\mathbf{a}_1)Z(\mathbf{b}_1)\big)\big(X(\mathbf{a}_2)Z(\mathbf{b}_2)\big) - \big(X(\mathbf{a}_2)Z(\mathbf{b}_2)\big)\big(X(\mathbf{a}_1)Z(\mathbf{b}_1)\big)\Big]|\mathbf{v}\rangle \\
&\qquad = (-1)^{\mathbf{v}\cdot\mathbf{b}_2+(\mathbf{v}+\mathbf{a}_2)\cdot\mathbf{b}_1}|\mathbf{v}+\mathbf{a}_1+\mathbf{a}_2\rangle + (-1)^{\mathbf{v}\cdot\mathbf{b}_1+(\mathbf{v}+\mathbf{a}_1)\cdot\mathbf{b}_2}|\mathbf{v}+\mathbf{a}_1+\mathbf{a}_2\rangle \\
&\qquad = \Big[(-1)^{\mathbf{a}_2\cdot\mathbf{b}_1} - (-1)^{\mathbf{a}_1\cdot\mathbf{b}_2}\Big](-1)^{\mathbf{v}\cdot(\mathbf{b}_1-\mathbf{b}_2)}|\mathbf{v}+\mathbf{a}_1+\mathbf{a}_2\rangle \\
&\qquad = \Big[1 - \delta_{\mathbf{a}_1\cdot\mathbf{b}_2,\,\mathbf{a}_2\cdot\mathbf{b}_1}\Big]\cdots
\end{aligned}$$

then clearly errors will commute if and only if their finite field representations are orthogonal with respect to the symplectic inner product.

A quantum stabilizer code is defined by an abelian subgroup of the error group. In the context of its finite field representation this translates to a self-orthogonal additive code under the symplectic inner product. So a quantum stabilizer code Q is defined by a symplectic self-orthogonal additive code S, which is (with some redundancy) termed the stabilizer code of Q.

The error-correcting capability of a code is determined by the set of errors which can not be detected. For classical linear codes these undetectable errors are precisely the non-zero codewords of the code, while for a quantum code, the undetectable errors are given by the set $S^{\perp}\backslash S$, where $S^{\perp}$ is the symplectic dual of S.

The most important measure of the ability of a quantum code to correct errors is its *minimum weight*, that is, is the minimum of the weights of the words of $S^{\perp}\backslash S$. An exception to this definition occurs in the case of quantum codes having dimension zero, which are defined by symplectic self-dual stabilizer codes. These are termed "self-dual quantum codes" and are defined to have a minimum weight equal to the (classical) minimum weight of their stabilizer code.

157.2 Constructing Quantum Codes

A quantum code of length n over $GF(q)$ is defined in terms of a symplectic self-orthogonal stabilizer code, which is given either as a length n additive code over $GF(q^2)$ (compact format) or as a length $2n$ additive code over $GF(q)$ (extended format). If Q is a quantum code with generator matrix G_1 in compact format, and generator matrix $G_2 = (A|B)$ in extended format, then

$$G_1 = A + \lambda B,$$

where λ is a fixed element returned by the function `QuantumBasisElement`$(GF(q^2))$. By default MAGMA assumes the compact format. However, the extended format can be flagged by setting the variable argument `ExtendedFormat` to `true`.

An $[n, k]$ symplectic self-orthogonal linear code over $GF(q^2)$ will generate an $[[n, n/2 - k]]$ quantum stabilizer code. A (compact format) additive symplectic self-orthogonal code C over $GF(q^2)$ will give a quantum code of the same length and "dimension" $\log_q(N)$, where N is the number of code words in C.

157.2.1 Construction of General Quantum Codes

`QuantumCode(S)`

`ExtendedFormat` BOOLELT *Default :* `false`

Given an additive code S which is self-orthogonal with respect to the symplectic inner product, return the quantum code defined by S. By default, S is interpreted as being in compact format, that is, a length n additive code over $GF(q^2)$. If `ExtendedFormat` is set *true*, then S is interpreted as being in extended format, that is, a length $2n$ additive code over $GF(q)$.

Example H157E1

A linear code over $GF(4)$ that is *even* is symplectic self-orthogonal. Note that when a quantum code is printed in MAGMA, an *additive* stabilizer matrix over $GF(q^2)$ is displayed.

```
> F<w> := GF(4);
> M := Matrix(F, 2, 6, [1,0,0,1,w,w, 0,1,0,w,w,1]);
```

```
> C := LinearCode(M);
> C;
[6, 2, 4] Linear Code over GF(2^2)
Generator matrix:
[  1   0   0   1   w   w]
[  0   1   0   w   w   1]
> IsEven(C);
true
> IsSymplecticSelfOrthogonal(C);
true
> Q := QuantumCode(C);
> Q;
[[6, 2]] Quantum code over GF(2^2), stabilized by:
[  1   0   0   1   w   w]
[  w   0   0   w w^2 w^2]
[  0   1   0   w   w   1]
[  0   w   0 w^2 w^2   w]
> MinimumWeight(Q);
1
> Q;
[[6, 2, 1]] Quantum code over GF(2^2), stabilized by:
[  1   0   0   1   w   w]
[  w   0   0   w w^2 w^2]
[  0   1   0   w   w   1]
[  0   w   0 w^2 w^2   w]
```

Example H157E2

Any stabilizer code used to construct a quantum code, may be expressed in either compact or extended format. The length 6 quaternary additive code S in the previous example (H157E1) is equivalent to a length 12 binary additive code in extended format.
Note that the code will still be displayed in compact format.

```
> F<w> := GF(4);
> C := LinearCode<GF(2), 12 |
>      [ 1, 0, 0, 0, 0, 1, 1, 1, 0, 0, 1, 1 ],
>      [ 0, 1, 0, 0, 0, 1, 0, 0, 0, 1, 1, 0 ],
>      [ 0, 0, 0, 1, 0, 1, 1, 1, 0, 0, 0, 0 ],
>      [ 0, 0, 0, 0, 1, 1, 1, 0, 0, 1, 1, 1 ] >;
> C;
[12, 4, 4] Linear Code over GF(2)
Generator matrix:
[1 0 0 0 0 1 1 1 0 0 1 1]
[0 1 0 0 0 1 0 0 0 1 1 0]
[0 0 0 1 0 1 1 1 0 0 0 0]
[0 0 0 0 1 1 1 0 0 1 1 1]
> Q := QuantumCode(C : ExtendedFormat := true);
> Q;
```

```
[[6, 2]] Quantum code over GF(2^2), stabilized by:
[  1   0   0   1   w   w]
[  w   0   0   w w^2 w^2]
[  0   1   0   w   w   1]
[  0   w   0 w^2 w^2   w]
```

Example H157E3

Any self-orthogonal code which has a rate of 1/2 must be self-dual, and gives rise to a dimension zero quantum code (which is also termed self-dual). In this example we construct the hexacode, which is the unique extremal length 6 self-dual quantum code of minimum weight 4.

```
> F<w> := GF(4);
> M := Matrix(F, 3, 6, [0,0,1,1,1,1, 0,1,0,1,w,w^2, 1,0,0,1,w^2,w]);
> C := LinearCode(M);
> C;
[6, 3, 4] Linear Code over GF(2^2)
Generator matrix:
[  1   0   0   1 w^2   w]
[  0   1   0   1   w w^2]
[  0   0   1   1   1   1]
> IsSymplecticSelfOrthogonal(C);
true
> Q := QuantumCode(C);
> MinimumWeight(Q);
4
> Q;
[[6, 0, 4]] self-dual Quantum code over GF(2^2), stabilized by:
[  1   0   0   1 w^2   w]
[  w   0   0   w   1 w^2]
[  0   1   0   1   w w^2]
[  0   w   0   w w^2   1]
[  0   0   1   1   1   1]
[  0   0   w   w   w   w]
```

Example H157E4

Stabilizer codes neither have to be linear nor even and indeed any additive code which is symplectic self-orthogonal will generate a quantum code. The following code was randomly generated.

```
> F<w> := GF(4);
> M := Matrix(F, 3, 7, [1,w,w,w,0,0,1, w,0,1,0,w^2,0,1, 0,w^2,w,w^2,w,0,0]);
> C := AdditiveCode(GF(2),M);
> C;
[7, 1 1/2 : 3, 4] GF(2)-Additive Code over GF(2^2)
Generator matrix:
[  1   w   w   w   0   0   1]
[  w   0   1   0 w^2   0   1]
```

```
[  0 w^2   w w^2   w   0   0]
> IsSymplecticSelfOrthogonal(C);
true
```

The code C can be shown to be neither linear nor even: in fact it has the same number of even and odd codewords.

```
> IsLinear(C);
false
> {* Weight(v) mod 2 : v in C *};
{* 0^^4, 1^^4 *}
>
> Q := QuantumCode(C);
> MinimumWeight(Q);
1
> Q;
[[7, 4, 1]] Quantum code over GF(2^2), stabilized by:
[  1   w   w   w   0   0   1]
[  w   0   1   0 w^2   0   1]
[  0 w^2   w w^2   w   0   0]
```

`QuantumCode(M)`

`ExtendedFormat` BoolElt *Default :* `false`

Given a matrix M over $GF(q^2)$ for which the $GF(q)$ additive span of its rows is a self-orthogonal code S with respect to the symplectic inner product, return the quantum code defined by S. By default, M is interpreted as being in compact format, that is, a matrix whose rows are length n vectors over $GF(q^2)$. However, if `ExtendedFormat` is set `true`, then M will be interpreted as being in extended format, that is, a matrix whose rows are length $2n$ vectors over $GF(q)$.

Example H157E5

A quantum code can be constructed directly from an additive stabilizer matrix, thereby avoiding creation of the stabilizer code. The quantum code given in example H157E4 could have also been constructed as follows:

```
> F<w> := GF(4);
> M := Matrix(F, 3, 7, [1,w,w,w,0,0,1, w,0,1,0,w^2,0,1, 0,w^2,w,w^2,w,0,0]);
> Q := QuantumCode(M);
> Q;
[[7, 4]] Quantum code over GF(2^2), stabilized by:
[  1   w   w   w   0   0   1]
[  w   0   1   0 w^2   0   1]
[  0 w^2   w w^2   w   0   0]
```

`QuantumCode(G)`

Given a graph G, return the self-dual (dimension 0) quantum code defined by the adjacency matrix of G.

Example H157E6

The unique extremal $[[6, 0, 4]]$ hexacode can be defined in terms of a graph representing a 5–spoked wheel. The graph is specified by listing the edges comprising its circumference, followed by the spokes radiating out from the center.

```
> G := Graph<6 | {1,2},{2,3},{3,4},{4,5},{5,1}, <6, {1,2,3,4,5}> >;
> Q := QuantumCode(G);
> Q:Minimal;
[[6, 0]] self-dual Quantum code over GF(2^2)
> MinimumWeight(Q);
4
> Q:Minimal;
[[6, 0, 4]] self-dual Quantum code over GF(2^2)
```

Example H157E7

The unique extremal $[[12, 0, 6]]$ dodecacode can also be described by a graph with a nice mathematical structure. The graph construction is derived from the diagram given by Danielson in [Dan05]. In order to employ modular arithmetic, the graph vertices are numbered from 0 to 11.

```
> S := {@ i : i in [0 .. 11] @};
> G := Graph<S |
>     { {4*k+i,4*k+i+2}                    : i in [0..1], k in [0..2] },
>     { {4*k+i,4*k+(i+1) mod 4}            : i in [0..3], k in [0..2] },
>     { {4*k+i,4*((k+1) mod 3)+(i+1) mod 4} : i in [0..3], k in [0..2] } >;
> Q := QuantumCode(G);
> MinimumWeight(Q);
6
> Q:Minimal;
[[12, 0, 6]] self-dual Quantum code over GF(2^2)
```

`RandomQuantumCode(F, n, k)`

Let F be a degree 2 extension of a finite field $GF(q)$. Given positive integers n and k such that $n \geq k$, this function returns a random $[[n, k]]$ quantum stabilizer code over F. The field F is assumed to be given in compact format.

Example H157E8

We construct a random $[[10, 6]]$ quantum code over $GF(4)$.

```
> F<w> := GF(4);
> Q := RandomQuantumCode(F, 10, 6);
> Q;
[[10, 6]] Quantum code over GF(2^2), stabilized by:
[  w   0   0   w   1   1   w w^2   w w^2]
[  0   1   0   w   1 w^2 w^2   1   w   w]
[  0   w   1   1   1   0 w^2   0   0   0]
[  0   0   w   1   1   0   1 w^2   1   w]
```

`Subcode(Q, k)`

Given a quantum code Q of dimension $k_Q \geq k$ then return a subcode of Q of dimension k.

157.2.2 Construction of Special Quantum Codes

`Hexacode()`

Return the $[[6, 0, 4]]$ self-dual quantum hexacode.

`Dodecacode()`

Return the $[[12, 0, 6]]$ self-dual quantum dodecacode.

157.2.3 CSS Codes

`CSSCode(C1, C2)`

`CalderbankShorSteaneCode(C1, C2)`

Given two classical linear binary codes C_1 and C_2 of length n such that C_2 is a subcode of C_1, form a quantum code using the construction of Calderbank, Shor and Steane [CS96, Ste96a, Ste96b].

Example H157E9

Let C_1 denote the $[7, 4, 3]$ Hamming code and C_2 denote its dual. Observing that C_1 contains C_2, we may apply the CSS construction using C_1 and C_2 to obtain a $[[7, 1, 3]]$ code.

```
> F<w> := GF(4);
> C1 := HammingCode(GF(2), 3);
> C1;
[7, 4, 3] "Hamming code (r = 3)" Linear Code over GF(2)
Generator matrix:
[1 0 0 0 1 1 0]
[0 1 0 0 0 1 1]
[0 0 1 0 1 1 1]
[0 0 0 1 1 0 1]
> C2 := Dual(C1);
> C2;
[7, 3, 4] Cyclic Linear Code over GF(2)
Generator matrix:
[1 0 0 1 0 1 1]
[0 1 0 1 1 1 0]
[0 0 1 0 1 1 1]
> C2 subset C1;
true
> Q := CSSCode(C1, C2);
> MinimumWeight(Q);
3
> Q;
[[7, 1, 3]] CSS Quantum code over GF(2^2), stabilised by:
[  1   0   0   1   0   1   1]
[  w   0   0   w   0   w   w]
[  0   1   0   1   1   1   0]
[  0   w   0   w   w   w   0]
[  0   0   1   0   1   1   1]
[  0   0   w   0   w   w   w]
```

157.2.4 Cyclic Quantum Codes

Cyclic quantum codes are those having cyclic stabilizer codes. Conditions are listed in [CRSS98] for generating polynomials which give rise to symplectic self-orthogonal stabilizer codes.

`QuantumCyclicCode(v)`

`QuantumCyclicCode(Q)`

`LinearSpan` BoolElt *Default :* `false`

Given either a single vector v or sequence of vectors Q defined over a finite field F, return the quantum code generated by the span of the cyclic shifts of the supplied

vectors. The span must be self-orthogonal with respect to the symplectic inner product. By default, the additive span is taken over the prime field, but if the variable argument `LinearSpan` is set to `true`, then the linear span will be taken.

Example H157E10

A large number of good cyclic quantum codes exist. For example, the best known binary self-dual quantum code of length 15 is cyclic.

```
> F<w> := GF(4);
> v := VectorSpace(F, 15) ! [w,1,1,0,1,0,1,0,0,1,0,1,0,1,1];
> Q := QuantumCyclicCode(v);
> MinimumWeight(Q);
6
> Q:Minimal;
[[15, 0, 6]] self-dual Quantum code over GF(2^2)
```

`QuantumCyclicCode(n, f)`

`QuantumCyclicCode(n, Q)`

`LinearSpan` BoolElt *Default :* `false`

Let n be a positive integer. Given either a single polynomial f or a sequence of polynomials Q over some finite field F, return the quantum code of length n generated by the additive span of their cyclic shifts. The additive span must be symplectic self-orthogonal. By default, the additive span is taken over the prime field, but if the variable argument `LinearSpan` is set to `true`, then the linear span will be taken.

Example H157E11

Since classical cyclic codes correspond to factors of cyclotomic polynomials it is frequently convenient to specify a cyclic code in terms of polynomials. Here we construct the best known binary quantum codes with parameters $[[23, 12, 4]]$ and $[[25, 0, 8]]$.

```
> F<w> := GF(4);
> P<x> := PolynomialRing(F);
> f := x^16 + x^15 + x^13 + w*x^12 + x^11 + w*x^10 + x^9 + x^8 + w^2*x^7 +
>      x^6 + x^5 + w*x^4 + w^2*x^3 + w*x^2 + w^2*x + w^2;
> Q := QuantumCyclicCode(23, f);
> MinimumWeight(Q);
4
> Q:Minimal;
[[23, 12, 4]] Quantum code over GF(2^2)
>
> f := x^12 + x^11 + x^10 + x^8 + w*x^6 + x^4 + x^2 + x + 1;
> Q := QuantumCyclicCode(25, f);
> MinimumWeight(Q);
```

```
8
> Q:Minimal;
[[25, 0, 8]] self-dual Quantum code over GF(2^2)
```

`QuantumCyclicCode(v4, v2)`

In the important case of $GF(2)$-additive codes over $GF(4)$, any cyclic code can be specified by two generators. Given vectors $v4$ and $v2$ both of length n, where v_4 is over $GF(4)$ and v_2 is over $GF(2)$, this function returns the length n quantum code generated by the additive span of their cyclic shifts. This span must be self-orthogonal with respect to the symplectic inner product.

Example H157E12

Any cyclic binary quantum code of length n is determined by a cyclic stabilizer code, which can be defined uniquely in terms of an n-dimensional vector over $GF(4)$ together with an n-dimensional vector over $GF(2)$. We construct the best known $[[21, 0, 8]]$ and $[[21, 5, 6]]$ cyclic binary quantum codes.

```
> F<w> := GF(4);
> v4 := RSpace(F, 21) ! [w^2,w^2,1,w,0,0,1,1,1,1,0,1,0,1,1,0,1,1,0,0,0];
> v2 := RSpace(GF(2),21) ! [1,0,1,1,1,0,0,1,0,1,1,1,0,0,1,0,1,1,1,0,0];
> Q := QuantumCyclicCode(v4,v2);
> MinimumWeight(Q);
8
> Q:Minimal;
[[21, 0, 8]] self-dual Quantum code over GF(2^2)
>
> v4 := RSpace(F, 21) ! [w,0,w^2,w^2,w,w^2,w^2,0,w,1,0,0,1,0,0,0,0,1,0,0,1];
> v2 := RSpace(GF(2), 21) ! [1,0,1,1,1,0,0,1,0,1,1,1,0,0,1,0,1,1,1,0,0];
> Q := QuantumCyclicCode(v4,v2);
> MinimumWeight(Q);
6
> Q:Minimal;
[[21, 5, 6]] Quantum code over GF(2^2)
```

157.2.5 Quasi-Cyclic Quantum Codes

Quasi-cyclic quantum codes are those having quasi-cyclic stabilizer codes.

`QuantumQuasiCyclicCode(n, Q)`

`LinearSpan` BoolElt *Default :* `false`

Given an integer n, and a sequence Q of polynomials over some finite field F, let S be the quasi-cyclic classical code generated by the span of the set of vectors formed by concatenating cyclic blocks generated by the polynomials in Q. Assuming that S is self-orthogonal with respect to the symplectic inner product, this function returns the quasi-cyclic quantum code with stabiliser code S. If the span of the vectors is not symplectic self-orthogonal, an error will be flagged.

By default the additive span is taken over the prime field, but if the variable argument `LinearSpan` is set to `true`, then the linear span will be taken.

`QuantumQuasiCyclicCode(Q)`

`LinearSpan` BoolElt *Default :* `false`

Given a sequence Q of vectors, return the quantum code whose additive stabilizer matrix is constructed from the length n cyclic blocks generated by the cyclic shifts of the vectors in Q. If the variable argument `LinearSpan` is set to `true`, then the linear span of the shifts will be used, else the additive span will be used (default).

Example H157E13

Most quasi-cyclic quantum codes currently known are linear, since this is where most research on quasi-cyclic codes has been focused. In this example we construct the best known quasi-cyclic binary quantum codes with parameters $[[14, 0, 6]]$ and $[[18, 6, 5]]$.

```
> F<w> := GF(4);
> V7 := VectorSpace(F, 7);
> v1 := V7 ! [1,0,0,0,0,0,0];
> v2 := V7 ! [w^2,1,w^2,w,0,0,w];
> Q := QuantumQuasiCyclicCode([v1, v2] : LinearSpan := true);
> MinimumWeight(Q);
6
> Q:Minimal;
[[14, 0, 6]] self-dual Quantum code over GF(2^2)
>
> V6 := VectorSpace(F, 6);
> v1 := V6 ! [1,1,0,0,0,0];
> v2 := V6 ! [1,0,1,w^2,0,0];
> v3 := V6 ! [1,1,w,1,w,0];
> Q := QuantumQuasiCyclicCode([v1, v2, v3] : LinearSpan := true);
> MinimumWeight(Q);
5
> Q:Minimal;
[[18, 6, 5]] Quantum code over GF(2^2)
```

157.3 Access Functions

`QuantumBasisElement(F)`

Given a degree 2 extension field $F = GF(q^2)$, return the element $\lambda \in F$ which acts to connect the extended and compact formats. For a vector $(\mathbf{a}|\mathbf{b})$ in extended format, the corresponding compact format of this vector will be $\mathbf{w} = \mathbf{a} + \lambda\mathbf{b}$.

`StabilizerCode(Q)`

`StabiliserCode(Q)`

`ExtendedFormat` BoolElt *Default :* `false`

The additive stabiliser code S which defines the quantum code Q. By default S is returned in the compact format of a length n code over $GF(q^2)$, but if `ExtendedFormat` is set to `true`, then it will be returned in extended format as a length $2n$ code over $GF(q)$.

`StabilizerMatrix(Q)`

`StabiliserMatrix(Q)`

`ExtendedFormat` BoolElt *Default :* `false`

Given a quantum code Q return the additive stabiliser matrix M defining Q. By default M is returned in the compact format of a length n code over $GF(q^2)$, but if `ExtendedFormat` is set to `true`, then it will be returned in the extended format as a length $2n$ code over $GF(q)$.

`NormalizerCode(Q)`

`NormaliserCode(Q)`

`ExtendedFormat` BoolElt *Default :* `false`

The additive normalizer code N which defines the quantum code Q. By default N is returned in the compact format of a length n code over $GF(q^2)$, but if `ExtendedFormat` is set to `true`, then it will be returned in extended format as a length $2n$ code over $GF(q)$.

`NormalizerMatrix(Q)`

`NormaliserMatrix(Q)`

`ExtendedFormat` BoolElt *Default :* `false`

Given a quantum code Q return the additive normalizer matrix M defining Q. By default M is returned in the compact format of a length n code over $GF(q^2)$, but if `ExtendedFormat` is set to `true`, then it will be returned in the extended format as a length $2n$ code over $GF(q)$.

157.3.1 Quantum Error Group

As described in the introduction to this chapter, vectors over a finite field used to describe a quantum stabilizer code actually represent elements of the corresponding quantum error group. For a p-ary N qubit system (where p is prime) this error group is the extra-special group with order 2^{2N+1} consisting of combinations of N bit-flip errors, N phase flip errors, and an overall phase shift. All groups in this section use a polycyclic group representation.

`QuantumErrorGroup(p, n)`

Return the abelian group representing all possible errors for a length n p-ary qubit system, which is an extra-special group of order p^{2n+1} with $2n+1$ generators. The generators correspond to the qubit-flip operators $X(i)$, the phase-flip operators $Z(i)$, and an overall phase multiplication W by the p-th root of unity. The generators appear in the order $X(1), Z(1), \ldots, X(n), Z(n), W$.

`QuantumBinaryErrorGroup(n)`

Return the abelian group representing all possible errors on a length n binary qubit system, which is an extra special group of order 2^{2n-1}.

Example H157E14

The image of a vector in the error group is easily obtained from its extended format representation. We illustrate the connection between symplectic orthogonality as a vector, and commutativity as an element of the error group.

```
> n := 5;
> VSn  := VectorSpace(GF(2), n);
> VS2n := VectorSpace(GF(2), 2*n);
> E := QuantumBinaryErrorGroup(n);
> BitFlips   := [E.i : i in [1..2*n] | IsOdd(i)  ];
> PhaseFlips := [E.i : i in [1..2*n] | IsEven(i) ];
```

We first take two vectors which are not orthogonal and show their images in the error group do not commute.

```
> v1a := VSn ! [0,1,1,0,1]; v1b := VSn ! [0,1,1,0,1];
> v1  := VS2n ! HorizontalJoin(v1a, v1b);
> v2a := VSn ! [1,0,1,1,0]; v2b := VSn ! [0,1,0,1,1];
> v2  := VS2n ! HorizontalJoin(v2a, v2b);
> SymplecticInnerProduct(v1,v2 : ExtendedFormat := true);
1
>
> e1 := &*[ BitFlips[i]   : i in Support(v1a) ] *
>       &*[ PhaseFlips[i] : i in Support(v1b) ];
> e2 := &*[ BitFlips[i]   : i in Support(v2a) ] *
>       &*[ PhaseFlips[i] : i in Support(v2b) ];
> e1*e2 eq e2*e1;
```

```
false
```

Next a pair of orthogonal vectors is shown to commute.

```
> v1a := VSn ! [1,1,0,1,0]; v1b := VSn ! [0,0,1,1,0];
> v1  := VS2n ! HorizontalJoin(v1a, v1b);
> v2a := VSn ! [0,1,1,1,0]; v2b := VSn ! [0,1,1,1,0];
> v2  := VS2n ! HorizontalJoin(v2a, v2b);
> SymplecticInnerProduct(v1,v2 : ExtendedFormat := true);
0
>
> e1 := &*[ BitFlips[i]   : i in Support(v1a) ] *
>       &*[ PhaseFlips[i] : i in Support(v1b) ];
> e2 := &*[ BitFlips[i]   : i in Support(v2a) ] *
>       &*[ PhaseFlips[i] : i in Support(v2b) ];
> e1*e2 eq e2*e1;
true
```

`QuantumErrorGroup(Q)`

For a quantum code Q of length n, return the group of all errors on n qubits. This is the full error group, the ambient space containing all possible errors.

`StabilizerGroup(Q)`

`StabiliserGroup(Q)`

Return the abelian group of errors that defines the quantum code Q, which is a subgroup of the group returned by `QuantumErrorGroup(Q)`.

`StabilizerGroup(Q, G)`

`StabiliserGroup(Q, G)`

Given a quantum code Q with error group G (an extra-special group), return the abelian group of errors of Q as a subgroup of G.

Example H157E15

The stabilizer group of any quantum stabilizer code over $GF(4)$ will be abelian.

```
> F<w> := GF(4);
> Q := RandomQuantumCode(F, 10, 6);
> G := StabilizerGroup(Q);
> IsAbelian(G);
true
```

Example H157E16

In order to make stabilizer groups from distinct codes compatible with one another, the groups must be created within the same super-structure. This is done by first creating a copy of the full error group, and then generating each instance of a stabilizer group as a subgroup.
In this example, the intersection of the stabilizer groups of two random codes is formed. An error group E which will be a common over group for the two stabilizer groups is first created.

```
> F<w> := GF(4);
> Q1 := RandomQuantumCode(F, 15, 8);
> Q2 := RandomQuantumCode(F, 15, 8);
>
> E := QuantumErrorGroup(Q1);
> S1 := StabilizerGroup(Q1, E);
> S2 := StabilizerGroup(Q2, E);
> #(S1 meet S2);
2
```

157.4 Inner Products and Duals

The functions described in this section use the symplectic inner product defined for quantum codes.

`SymplecticInnerProduct(v1, v2)`

`ExtendedFormat` BoolElt *Default :* `false`

Let $v1$ and $v2$ be two vectors belonging to the vector space $K^{(n)}$, where K is a finite field. This function returns the inner product of $v1$ and $v2$ with respect to the symplectic inner product. The symplectic inner product in extended format is defined by $(a|b)*(c|d) = ad-bc$, and its definition transfers naturally to the compact format.

For binary quantum codes whose compact format is over $GF(4)$, the symplectic inner product is given by `Trace`$(v_1 \cdot \overline{v}_2)$.

`SymplecticDual(C)`

`ExtendedFormat` BoolElt *Default :* `false`

The dual of the additive (or possibly linear) code C with respect to the symplectic inner product. By default, C is interpreted as being in the compact format (a length n code over $GF(q^2)$), but if `ExtendedFormat` is set to `true`, then it will be interpreted as being in extended format (a code of length $2n$ over $GF(q)$).

`IsSymplecticSelfDual(C)`

`ExtendedFormat` BoolElt *Default :* `false`

Return `true` if the code C is equal to its symplectic dual and `false` otherwise. By default, C is interpreted as being in the compact format (a length n code over $GF(q^2)$), but if `ExtendedFormat` is set to `true`, then it will be interpreted as being in extended format (a code of length $2n$ over $GF(q)$).

`IsSymplecticSelfOrthogonal(C)`

`ExtendedFormat` BoolElt *Default :* `false`

Return `true` if the code C is contained in its symplectic dual. By default, C is interpreted as being in the compact format (a length n code over $GF(q^2)$), but if `ExtendedFormat` is set to `true`, then it will be interpreted as being in extended format (a code of length $2n$ over $GF(q)$).

Example H157E17

Vectors which are symplectically orthogonal to one another can be used to construct symplectic self-orthogonal codes.

```
> F<w> := GF(4);
> V5 := VectorSpace(F, 5);
> v := V5 ! [1,0,w,0,1];
> w := V5 ! [w,1,0,w,w];
> SymplecticInnerProduct(v,w);
0
> C := AdditiveCode<F, GF(2), 5 | v, w>;
> C;
[5, 1 : 2] GF(2)-Additive Code over GF(2^2)
Generator matrix:
[  1   0   w   0   1]
[  w   1   0   w   w]
> D := SymplecticDual(C);
> D;
[5, 4 : 8] GF(2)-Additive Code over GF(2^2)
Generator matrix:
[  1   0   0   0   1]
[  w   0   0   0   w]
[  0   1   0   0   0]
[  0   w   0   0   1]
[  0   0   1   0   w]
[  0   0   w   0   0]
[  0   0   0   1   1]
[  0   0   0   w   0]
> C subset D;
true
> Q := QuantumCode(C);
> Q;
```

```
[[5, 3]] Quantum code over GF(2^2), stabilised by:
[  1   0   w   0   1]
[  w   1   0   w   w]
```

Example H157E18

Any vector over $GF(4)$ will be symplectically orthogonal to itself.

```
> V5 := VectorSpace(GF(4), 5);
> { SymplecticInnerProduct(v, v) : v in V5 };
{ 0 }
```

157.5 Weight Distribution and Minimum Weight

The weight distribution of a quantum code Q consists of three separate distributions:

- The weight distribution of the stabilizer code S.
- The weight distribution of the symplectic dual $S^\perp$ of S.
- The weight distribution of the codewords in $S^\perp \backslash S$. Note that this set is not a linear space.

For a quantum code Q with stabilizer code S, the weights of the undetectable errors are the weights of the codewords in $S^\perp \backslash S$.

For a quantum code to be considered *pure*, its minimum weight must be less than or equal to the weight of its stabilizer code.

`WeightDistribution(Q)`

Given a quantum code Q with stabiliser code S, return its weight distribution. Recall that the quantum weight distribution comprises the weight distributions of S, $S^\perp$ and $S^\perp \backslash S$. The function returns each distribution as a separate value. Each weight distribution is returned in the form of a sequence of tuples consisting of a weight and the number of code words of that weight.

Example H157E19

Looking at a small quantum code from the database of best known codes. Its first weight distribution is of its stabilizer code S, the second of its normalizer code $S^\perp$, and the final weight distribution is of those non-zero codewords in $S^\perp \backslash S$.

```
> F<w> := GF(4);
> Q := QECC(GF(4),6,3);
> Q;
[[6, 3, 2]] Quantum code over GF(2^2), stabilised by:
[  1   0   1   1   1   0]
[  w   w   w   w   w   w]
[  0   1   0   0   0   1]
```

```
> WD_S, WD_N, WD := WeightDistribution(Q);
> WD_S eq WeightDistribution(StabiliserCode(Q));
true
> WD_N eq WeightDistribution(NormaliserCode(Q));
true
> WD;
[ <2, 28>, <3, 56>, <4, 154>, <5, 168>, <6, 98> ]
```

`MinimumWeight(Q)`

`Method`	MonStgElt	*Default :* "*Auto*"
`RankLowerBound`	RngIntElt	*Default :* 0
`MaximumTime`	RngReSubElt	*Default :* ∞

For the quantum code Q with stabilizer code S, return the minimum weight of Q, which is the minimum weight of the codewords in $S^{\perp}\backslash S$. For self-dual quantum codes (those of dimension 0), the minimum weight is defined to be the minimum weight of S. The default algorithm is based on the minimum weight algorithm for classical linear codes which is described in detail in section 152.8.1. For a description of the algorithm and its variable argument parameters please consult the full description provided there. The minimum weight may alternatively be calculated by finding the complete weight distribution. This algorithm may be selected by setting the value of the variable argument `Method` to "`Distribution`".

Example H157E20

The verbose output can be used in long minimum weight calculations to estimate the remaining running time. The algorithm terminates once the lower bound reaches the upper bound. The example below finishes in a very short period of time.

```
> F<w> := GF(4);
> V5 := VectorSpace(F, 5);
> gens := [V5| [0,0,1,w,w], [0,1,1,w,1], [0,0,1,0,w^2],
>              [0,0,1,w,1], [0,0,1,0,1], [1,w,1,w,w^2],
>              [1,1,1,w^2,w], [0,1,w,1,w^2] ];
> Q := QuantumQuasiCyclicCode(gens : LinearSpan := true);
> Q:Minimal;
[[40, 30]] Quantum code over GF(2^2)
> SetVerbose("Code",true);
> MinimumWeight(Q);
Quantum GF(2)-Additive code over GF(4) of length 40 with 70 generators.
Lower Bound: 1, Upper Bound: 40

Enumerating using 2 generators at a time:
   Completed Matrix  1:  lower =  3, upper =  4. Elapsed: 0.00s
Termination predicted with 3 generators at matrix 1
predicting enumerating (1820) 60725 vectors (0.000000% of 40 40 code)
Enumerating using 3 generators at a time:
   Completed Matrix  1:  lower =  4, upper =  4. Elapsed: 0.03s
Final Results: lower = 4, upper = 4, Total time: 0.03
4
```

`IsPure(Q)`

Return `true` if Q is a *pure* quantum code. That is, if the minimum weight of Q is less than or equal to the minimum weight of its stabiliser code.

Example H157E21

Many good codes are impure, the purity of best known quantum codes of length 15 are investigated.

```
> F<w> := GF(4);
> n := 15;
> time {* IsPure(QECC(F, n, k)) : k in [1..n] *};
{* false^^10, true^^5 *}
Time: 0.410
```

157.6 New Codes From Old

`DirectSum(Q1, Q2)`

Given an $[[n_1, k_1, d_1]]$ quantum code Q_1, and an $[[n_2, k_2, d_2]]$ quantum code Q_2, return the $[[n_1+n_n, k_1+k_2, \min\{d_1, d_2\}]]$ quantum code which is their direct product.

`ExtendCode(Q)`

Given an $[[n, k, d]]$ quantum code Q, return the extended $[[n+1, k, d]]$ quantum code.

`ExtendCode(Q, m)`

Perform m extensions on the $[[n, k, d]]$ quantum code Q, returning the extended $[[n + m, k, d]]$ quantum code.

`PunctureCode(Q, i)`

Given a $[[n, k, d]]$ quantum code Q, and a coordinate position i, return the $[[n - 1, k, d' >= d - 1]]$ quantum code produced by puncturing at position i.

`PunctureCode(Q, I)`

Given a $[[n, k, d]]$ quantum code Q, and a set of coordinate positions I of size s, return the $[[n - s, k, d' >= d - s]]$ quantum code produced by puncturing at the positions in I.

`ShortenCode(Q, i)`

Given a $[[n, k, d]]$ quantum code Q, and a coordinate position i, return the $[[n - 1, k' >= k - 1, d' >= d]]$ quantum code produced by shortening at position i.

This process will not necessarily result in a valid (symplectic self-orthogonal) quantum code, and an error will be given if it fails.

`ShortenCode(Q, I)`

Given a $[[n, k, d]]$ quantum code Q, and a set of coordinate positions I of size s, return the $[[n - s, k' >= k - s, d' >= d]]$ quantum code produced by shortening at the positions in I.

This process will not necessarily result in a valid (symplectic self-orthogonal) quantum code, and an error will be given if it fails.

Example H157E22

Good quantum codes can be created by combining stabilizer codes, using methods which are not general enough to warrant a specific quantum code function. This example creates a $[[28, 8, 6]]$ quantum code from $[[14, 8, 3]]$ and $[[14, 0, 6]]$ quantum codes using a Plotkin sum. It relies on the stabilizer codes forming a subcode chain, as described in Theorem 12 in [CRSS98].

```
> F<w> := GF(4);
> V7 := VectorSpace(F, 7);
> v1 := V7 ! [1,0,0,0,0,0,0];
> v2 := V7 ! [w^2,1,w^2,w,0,0,w];
> Q1 := QuantumQuasiCyclicCode([v1, v2] : LinearSpan := true);
> _ := MinimumWeight(Q1);
> Q1:Minimal;
[[14, 0, 6]] self-dual Quantum code over GF(2^2)
>
> v1 := V7 ! [1,0,1,1,1,0,0];
> v2 := V7 ! [1,w^2,w,w,1,0,w^2];
> Q2 := QuantumQuasiCyclicCode([v1, v2] : LinearSpan := true);
> _ := MinimumWeight(Q2);
> Q2:Minimal;
[[14, 8, 3]] Quantum code over GF(2^2)
>
> S1 := StabilizerCode(Q1);
> S2 := StabilizerCode(Q2);
> S2 subset S1;
true
>
> S3 := PlotkinSum(SymplecticDual(S1), S2);
> Q3 := QuantumCode(S3);
> _ := MinimumWeight(Q3);
> Q3:Minimal;
[[28, 8, 6]] Quantum code over GF(2^2)
```

157.7 Best Known Quantum Codes

An $[[n, k]]$ quantum stabiliser code Q is said to be a *best known* $[[n, k]]$ *quantum code* (BKQC) if C has the highest minimum weight among all known $[[n, k]]$ quantum codes. The acronym QECC (Quantum Error Correcting Code) will be used to more easily distinguish from the best known linear codes database (BKLC).

MAGMA currently has a database for binary quantum codes, though it should be noted that these codes are considered to be over the alphabet $GF(4)$, not $GF(2)$. The database for codes over $GF(4)$ currently contains constructions of all best known quantum codes of length 35. This includes self-dual quantum codes up to length 35, which are stored in the database as dimension 0 quantum codes.

Quantum codes of length up to 12 are optimal, in the sense that their minimum weights meet the upper bound. Thus the user has access to 665 best-known binary quantum codes.

The MAGMA QECC database uses the tables of bounds and constructions compiled by Markus Grassl (Karlsruhe), available online at [Gra], which are based on the results in [CRSS98]. Good codes have also been contributed by Eric Rains and Zlatko Varbanov.

The user can display the method used to construct a particular QECC code through use of a verbose mode, triggered by the verbose flag `BestCode`. When it is set to `true`, all of the functions in this section will output the steps involved in each code they construct.

`QECC(F, n, k)`

`BKQC(F, n, k)`

`BestKnownQuantumCode(F, n, k)`

Given a finite field F, and positive integers n and k such that $k \leq n$, return an $[[n, k]]$ quantum code over F which has the largest minimum weight among all known $[[n, k]]$ quantum codes. A second boolean return value signals whether or not the desired code exists in the database.

The database currently exists for $GF(4)$ (which are in fact binary quantum codes) up to length 35.

Example H157E23

The weight distribution of a small best known quantum code is calculated, verifying its minimum weight. Note that the *larger* the dimension of a quantum code, the easier it is to calculate its weight distribution.

```
> F<w> := GF(4);
> Q := QECC(F,25,16);
> Q:Minimal;
[[25, 16, 3]] Quantum code over GF(2^2)
> time WD_S, WD_N, WD := WeightDistribution(Q);
Time: 0.010
> WD_S;
[ <0, 1>, <1, 2>, <2, 1>, <14, 4>, <15, 16>, <16, 38>, <17, 79>, <18, 126>, <19,
129>, <20, 77>, <21, 27>, <22, 9>, <23, 3> ]
> WD_N;

> WD;
[ <3, 399>, <4, 6527>, <5, 75363>, <6, 707543>, <7, 5404369>, <8, 34084490>, <9,
180107319>, <10, 804255370>, <11, 3052443894>, <12, 9883860222>, <13,
27348684334>, <14, 64649758922>, <15, 130286413842>, <16, 222912028959>, <17,
321704696673>, <18, 387985433575>, <19, 385943416906>, <20, 310898936198>, <21,
```

```
197566276644>, <22, 95232787554>, <23, 32688613818>, <24, 7109768160>, <25,
735493959> ]
```

So the $[[25, 16]]$ code is impure, and has a minimum distance of 3.

Example H157E24

Unlike linear codes, dimension 0 quantum codes are non-trivial and are the subject of much study. These are the *self-dual* quantum codes, which form a special subclass of quantum stabilizer codes. It can be seen that a length n self-dual code is described by a $n \times n$ generator matrix, an indication of the non-triviality of its structure.

```
> F<w> := GF(4);
> C := QECC(GF(4),8, 0);
> C;
[[8, 0, 4]] self-dual Quantum code over GF(2^2), stabilised by:
[  1   0   0   1   0   1   1   0]
[  w   0   0   w   0   w   w   0]
[  0   1   0   1   0   1   0   1]
[  0   w   0   w   0   w   0   w]
[  0   0   1   1   0   0   1   1]
[  0   0   w   w   0   0   w   w]
[  0   0   0   0   1   1   1   1]
[  0   0   0   0   w   w   w   w]
```

Example H157E25

The verbose flag `BestCode` will show the method by which the best code is constructed in the database. In this example the construction of a $[[25, 11, 4]]$ quantum code is described.

```
> SetVerbose("BestCode",true);
> F<w> := GF(4);
> Q := QECC(F,25,11);
Construction of a [[ 25 , 11 , 4 ]] Quantum Code:

```

```
[[25, 11, 4]] Quantum code over GF(2^2)
```

157.8 Best Known Bounds

Along with the database of best known quantum codes in the previous section, there is also a database of best known upper and lower bounds on the maximal possible minimum weights of quantum codes. The upper bounds are not currently known with much accuracy, while the lower bounds match the minimum weights of the best known quantum codes database.

`QECCLowerBound(F, n, k)`

Return the best known lower bound on the maximal minimum distance of $[[n, k]]$ quantum codes over F. The bounds are currently available for binary quantum codes (which corresponds to $F = GF(4)$) up to length 35.

`QECCUpperBound(F, n, k)`

Return the best known upper bound on the minimum distance of $[[n, k]]$ quantum codes over F. The bounds are currently available for binary quantum codes (which corresponds to $F = GF(4)$) up to length 35.

Example H157E26

The best known lower bound on the minimum weight will always correspond to the best known quantum code from the MAGMA database. In this example the first code is in fact optimal, while the second one does not meet the upper bound, and so there is a theoretical possibility of an improvement.

```
> F<w> := GF(4);
> Q1 := QECC(F, 20, 10);
> Q1:Minimal;
[[20, 10, 4]] Quantum code over GF(2^2)
> QECCLowerBound(F, 20, 10);
4
> QECCUpperBound(F, 20, 10);
4
>
> Q2 := QECC(F, 25, 13);
> Q2:Minimal;
[[25, 13, 4]] Quantum code over GF(2^2)
> QECCLowerBound(F, 25, 13);
4
> QECCUpperBound(F, 25, 13);
5
```

157.9 Automorphism Group

Automorphisms acting on a quantum code are a slight generalization of those which act on the underlying additive stabilizer code. Automorphisms consists of both a permutation action on the columns of a stabilizer code, combined with a monomial action on the individual columns which permute the values.

The automorphism group of a length n additive stabilizer code over $\mathbf{F}_4$ is a subgroup of $Z_3 \wr Sym(n)$ of order $3 * n!$. However the automorphism group of the quantum code it generates is a subgroup of $Sym(3) \wr Sym(n)$ of order $3! * n!$ because of the more general action on the values in the columns.

In MAGMA automorphisms are returned as permutations, either as length $3n$ permutations for the full monomial action on a code, or as length n permutations when the automorphism is restricted to only the permutation action on the columns.

`AutomorphismGroup(Q)`

The automorphism group of the quantum code Q. Currently this function only applies to binary quantum codes.

`PermutationGroup(Q)`

The subgroup of the automorphism group of the quantum code Q consisting of those automorphisms which permute the coordinates of codewords. Currently this function only applies to binary quantum codes.

Example H157E27

The full automorphism group and its subgroup of coordinate permutations are calculated for the dodecacode.

```
> F<w> := GF(4);
> Q := Dodecacode();
> Q;
[[12, 0, 6]] self-dual Quantum code over GF(2^2), stabilised by:
[  1   0   0   0   0   0 w^2 w^2   0   w   1   w]
[  w   0   0   0   0   0   w   0   w   w   w   1]
[  0   1   0   0   0   0   1   0   1 w^2 w^2   1]
[  0   w   0   0   0   0   0   w   1   w   w   w]
[  0   0   1   0   0   0   0   1   1   1 w^2 w^2]
[  0   0   w   0   0   0 w^2   1 w^2   w   w   0]
[  0   0   0   1   0   0   w   w   1   1   0   1]
[  0   0   0   w   0   0   w   1   w w^2 w^2   0]
[  0   0   0   0   1   0   w   w   w   0   1   w]
[  0   0   0   0   w   0 w^2   1   1 w^2   0   w]
[  0   0   0   0   0   1 w^2 w^2 w^2   1   0 w^2]
[  0   0   0   0   0   w   w   1   0   1   w   w]
>
> AutomorphismGroup(Q);
Permutation group acting on a set of cardinality 36
Order = 648 = 2^3 * 3^4
```

```
    (1, 4, 32)(2, 5, 33)(3, 6, 31)(7, 13, 29)(8, 14, 30)(9, 15, 28)(10, 35, 22)
        (11, 36, 23)(12, 34, 24)(16, 19, 26)(17, 20, 27)(18, 21, 25)
    (4, 23, 8, 29, 10, 20, 18, 36, 32)(5, 24, 9, 30, 11, 21, 16, 34, 33)
        (6, 22, 7, 28, 12, 19, 17, 35, 31)(13, 14, 15)(25, 27, 26)
    (7, 35)(8, 36)(9, 34)(10, 20)(11, 21)(12, 19)(13, 26)(14, 27)(15, 25)
        (16, 30)(17, 28)(18, 29)(22, 31)(23, 32)(24, 33)
    (4, 29, 18)(5, 30, 16)(6, 28, 17)(7, 19, 31)(8, 20, 32)(9, 21, 33)
        (10, 36, 23)(11, 34, 24)(12, 35, 22)
> PermutationGroup(Q);
Permutation group acting on a set of cardinality 12
    (1, 7, 9, 3, 5, 11)(2, 8, 10, 4, 6, 12)
    (1, 2)(3, 4)(5, 10)(6, 9)(7, 12)(8, 11)
    (2, 4)(5, 9)(6, 12)(7, 11)(8, 10)
```

Example H157E28

The automorphism group for a quantum code is larger than that of its stabilizer code. In this example that is shown for the Hexacode.

```
> F<w> := GF(4);
> Q := Hexacode();
> Q:Minimal;
[[6, 0, 4]] self-dual Quantum code over GF(2^2)
> A_Q := AutomorphismGroup(Q);
> A_Q;
Permutation group A_Q acting on a set of cardinality 18
Order = 2160 = 2^4 * 3^3 * 5
    (1, 4)(2, 6)(3, 5)(7, 8)(10, 12)(13, 14)(17, 18)
    (2, 3)(5, 6)(7, 8)(10, 18)(11, 16)(12, 17)(13, 14)
    (4, 7)(5, 8)(6, 9)(13, 17)(14, 16)(15, 18)
    (7, 13)(8, 14)(9, 15)(10, 17)(11, 16)(12, 18)
    (7, 12)(8, 10)(9, 11)(13, 18)(14, 17)(15, 16)
> S := StabilizerCode(Q);
> A_S := AutomorphismGroup(S);
> A_S;
Permutation group A_S acting on a set of cardinality 18
Order = 180 = 2^2 * 3^2 * 5
    (1, 4)(2, 5)(3, 6)(7, 13)(8, 14)(9, 15)
    (4, 7, 12)(5, 8, 10)(6, 9, 11)(13, 15, 14)(16, 18, 17)
    (4, 6, 5)(7, 14, 11)(8, 15, 12)(9, 13, 10)(16, 18, 17)
> A_S subset A_Q;
true
```

157.10 Hilbert Spaces

In this first release, MAGMA offers a basic package for creating and computing with quantum Hilbert spaces. A Hilbert space in MAGMA can either be *densely* or *sparsely* represented, depending on how many qubits are required and how dense the desired quantum states will be. While a dense representation has a speed advantage in computations, the sparse representation uses less memory. Currently there are capabilities for doing basic unitary transformations and manipulations of quantum states.

In future versions, functionality will be added for more complex unitary transformations and measurements, allowing for a more general simulation of quantum computations. There will also be machinery for encoding quantum states using quantum error correcting codes, and testing their effectiveness by simulating a noisy quantum channel and decoding the results.

`HilbertSpace(F, n)`

`IsDense` BOOLELT *Default :*

Given a complex field F and a positive integer n, return then quantum Hilbert Space on n qubits over F.

If the variable argument `IsDense` is set to either `true` or `false` then return a densely or sparsely represented quantum space respectively. If no value is set for `IsDense` then MAGMA will decide automatically.

`Field(H)`

Given a Hilbert space H, return the complex field over which the coefficients of states of H are defined.

`NumberOfQubits(H)`

`Nqubits(H)`

Given a Hilbert space H, return the number of qubits which comprises the space.

`Dimension(H)`

Given a Hilbert space H, return its dimension. This is 2^n, where n is the number of qubits of H.

`IsDenselyRepresented(H)`

Return `true` if the quantum Hilbert space H uses a dense representation.

`H1 eq H2`

Return `true` if the Hilbert spaces are equal.

`H1 ne H2`

Return `true` if the Hilbert spaces are not equal.

Example H157E29

A Hilbert space over 5 qubits will by default be a densely represented quantum space. It can however be manually chosen to use a sparse representation, it can be seen that these two space are not considered equal.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 5);
> H;
A densely represented Hilbert Space on 5 qubits to precision 4
> Dimension(H);
32
> IsDenselyRepresented(H);
true
>
> H1 := HilbertSpace(F, 5 : IsDense := false);
> H1;
A sparely represented Hilbert Space on 5 qubits to precision 4
> IsDenselyRepresented(H1);
false
> H eq H1;
false
```

157.10.1 Creation of Quantum States

`QuantumState(H, v)`

`QuantumState(H, v)`

Given a Hilbert space H and coefficients v (which can be either a dense or a sparse vector), of length equal to the dimension of H, then return the quantum state in H defined by v.

`H ! i`

Return the i-th quantum basis state of the Hilbert space H. This corresponds to the basis state whose qubits giving a binary representation of i.

`H ! s`

Given a sequence s of binary values, whose length is equal to the number of qubits of the Hilbert space H, return the quantum basis state corresponding to s.

`SetPrintKetsInteger(b)`

Input is a boolean value b, which controls a global variable determining the way quantum states are printed. If set to `false` (which is the default) then values in basis kets will be printed as binary sequences such as $|1010\rangle$. If set to `true` then basis kets will be printed using integer values to represent the binary sequences, the previous example becoming $|5\rangle$.

Example H157E30

One way to create a quantum state is to specify each coefficient of the state with a vector of length equal to the dimension of the Hilbert space.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 4);
> KS := KSpace(F, Dimension(H));
> v := KS! [F| i,    1,    0, -i,
>             2,    0,    0, 1+i,
>             -i-1, -3*i, 7, 0.5,
>             2.5*i, 0,   0, 1.2];
> v;
(1.000*i 1.000 0.0000 -1.000*i 2.000 0.0000 0.0000 1.000 + 1.000*i
    -1.000 - 1.000*i -3.000*i 7.000 0.5000 2.500*i 0.0000 0.0000
    1.200)
> e := QuantumState(H, v);
> e;
1.000*i|0000> + |1000> - 1.000*i|1100> + 2.000|0010> + (1.000 +
1.000*i)|1110> - (1.000 + 1.000*i)|0001> - 3.000*i|1001> + 7.000|0101>
+ 0.5000|1101> + 2.500*i|0011> + 1.200|1111>
```

Example H157E31

Quantum states can be created by combining basis states, input as either integer values or binary sequences.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 12);
> Dimension(H);
4096
> e1 := H!1 + (1+i)*(H!76) - H!3000;
> e1;
|100000000000> + (1.000 + 1.000*i)|001100100000> - |000111011101>
> e2 := H![1,0,1,1,1,0,0,0,1,1,0,0] - H![1,1,0,1,0,0,0,0,1,1,0,1];
> e2;
|101110001100> - |110100001101>
```

By using the function `SetPrintKetsInteger` basis states can also be printed as either integer values of binary sequences.

```
> SetPrintKetsInteger(true);
> e1;
|1> + (1.000 + 1.000*i)|76> - |3000>
> e2;
|797> - |2827>
```

157.10.2 Manipulation of Quantum States

`a * e`

Given a complex scalar value a, multiply the coefficients of the quantum state e by a.

`-e`

Negate all coefficients of the quantum state e.

`e1 + e2`
`e1 - e2`

Addition and subtraction of the quantum states e_1 and e_2.

`Normalisation(e)`
`Normalisation(~e)`
`Normalization(e)`
`Normalization(~e)`

Normalize the coefficients of the quantum state e, giving an equivalent state whose normalization coefficient is equal to one. Available either as a procedure or a function.

`NormalisationCoefficient(e)`
`NormalizationCoefficient(e)`

Return the normalisation coefficient of the quantum state e

`e1 eq e2`

Return `true` if and only if the quantum states e_1 and e_2 are equal. States are still considered equal if they have different normalizations.

`e1 ne e2`

Return `true` if and only if the quantum states e_1 and e_2 are not equal. States are still considered equal if they have different normalizations.

Example H157E32

Although a quantum state can be expressed with any normalisation, in reality a quantum state occupies a ray in a Hilbert space. So two quantum states are still considered equal if they lie on the same ray.

```
> F<i> := ComplexField(8);
> H := HilbertSpace(F, 1);
> e := H!0 + H!1;
> e;
|0> + |1>
> NormalisationCoefficient(e);
2.0000000
> e1 := Normalisation(e);
> e1;
0.70710678|0> + 0.70710678|1>
> NormalisationCoefficient(e1);
0.99999999
> e eq e1;
true
```

157.10.3 Inner Product and Probabilities of Quantum States

`InnerProduct(e1, e2)`

Return the inner product of the quantum states e_1 and e_2.

`ProbabilityDistribution(e)`

Return the probability distribution of the quantum state as a vector over the reals.

`Probability(e, i)`

Return the probability of basis state i being returned as the result of a measurement on the quantum state e.

`Probability(e, v)`

Given a binary vector v of length equal to the number of qubits in the quantum state e, return the probability of basis state corresponding to v being returned as the result of a measurement on e.

`PrintProbabilityDistribution(e)`

Print the probability distribution of the quantum state.

`PrintSortedProbabilityDistribution(e)`

`Max`	RngIntElt	*Default :* ∞
`MinProbability`	RngIntElt	*Default :* 0

Print the probability distribution of the quantum state in sorted order, with the most probable states printed first.

If the variable argument `Max` is set to a positive integer, then it will denote the maximum number of basis states to be printed.

If the variable argument `MinProbability` is set to some integer between 1 and 100, then it will denote the minimum probability of any basis state to be printed. This is useful for investigating those basis states which will are the likely results of any measurement.

Example H157E33

From a quantum state it is possible to either access the full probability distribution, or the probabilities of individual basis states.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 3);
> e := -0.5*H!0 + 6*i*H!3 + 7*H!4 - (1+i)*H!7;
> ProbabilityDistribution(e);
(0.002865 0.0000 0.0000 0.4126 0.5616 0.0000 0.0000 0.02292)
> Probability(e, 0);
0.002865
> Probability(e, 1);
0.0000
```

It is also possible to print out the full probability distribution.

```
> PrintProbabilityDistribution(e);
Non-zero probabilities:
|000>:  0.2865%
|110>:  41.26%
|001>:  56.16%
|111>:  2.292%
```

Example H157E34

It is usually only those basis states with large probabilities that are of interest. With the function `PrintSortedProbabilitydistribution` these basis states can be identified.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 4);
> KS := KSpace(F, 2^4);
> v := KS! [F| i,   11,   0, -3*i,
>              2,   0,    0, 6+i,
>             -i-1, -3*i, 7, -0.5,
>             2.5*i, 0,   0, 9.2];
```

```
> e := QuantumState(H, v);
> e;
1.000*i|0000> + 11.00|1000> - 3.000*i|1100> + 2.000|0010> + (6.000 +
1.000*i)|1110> - (1.000 + 1.000*i)|0001> - 3.000*i|1001> + 7.000|0101>
- 0.5000|1101> + 2.500*i|0011> + 9.200|1111>
> PrintSortedProbabilityDistribution(e);
Non-zero probabilities:
|1000>:         37.45%
|1111>:         26.19%
|0101>:         15.16%
|1110>:         11.45%
|1100>:         2.785%
|1001>:         2.785%
|0011>:         1.934%
|0010>:         1.238%
|0001>:         0.6190%
|0000>:         0.3095%
|1101>:         0.07737%
```

A useful way to isolate the important basis states is to provide a minimum cutoff probability.

```
> PrintSortedProbabilityDistribution(e: MinProbability := 15);
Non-zero probabilities:
|1000>:         37.45%
|1111>:         26.19%
|0101>:         15.16%
Reached Minimum Percentage
```

Another way is to supply the maximum number basis states that should be printed. A combination of these methods can also be used

```
> PrintSortedProbabilityDistribution(e: Max := 6);
Non-zero probabilities:
|1000>:         37.45%
|1111>:         26.19%
|0101>:         15.16%

157.10.4 Unitary Transformations on Quantum States

In this first release MAGMA offers a small selection of unitary transformations on quantum states. In future versions this list will be expanded to include more complex operations.

`BitFlip(e, k)`

`BitFlip(~e, k)`

Flip the value of the k-th qubit of the quantum state e.

`BitFlip(e, B)`

`BitFlip(~e, B)`

Given a set of positive integers B, flip the value of the qubits of the quantum state e indexed by the entries in B.

`PhaseFlip(e, k)`

`PhaseFlip(~e, k)`

Flip the phase on the k-th qubit of the quantum state e.

`PhaseFlip(e, B)`

`PhaseFlip(~e, B)`

Given a set of positive integers B, flip the phase on the qubits of the quantum state e indexed by the entries in B.

`ControlledNot(e, B, k)`

`ControlledNot(~e, B, k)`

Flip the k-th bit of the quantum state e if all bits contained in B are set to 1.

`HadamardTrasformation(e)`

`HadamardTrasformation(~e)`

Perform a Hadamard transformation on the quantum state e, which must be densely represented.

Example H157E35

The behaviours of several of the available unitary transformations are displayed on a quantum state.

```
> F<i> := ComplexField(4);
> H := HilbertSpace(F, 4);
> e := H!0 + H!3 + H!6 + H!15;
> PhaseFlip(~e, 4); e;
|0000> + |1100> + |0110> - |1111>
> ControlledNot(~e, {1,2}, 4); e;
|0000> + |0110> - |1110> + |1101>
> BitFlip(~e, 2); e;
```

```
|0100> + |0010> - |1010> + |1001>
> ControlledNot(~e, {2}, 3); e;
|0010> - |1010> + |0110> + |1001>
```

CRYPTOGRAPHY

158 PSEUDO-RANDOM BIT SEQUENCES

Chapter 158
PSEUDO-RANDOM BIT SEQUENCES

158.1 Introduction

MAGMA provides some tools for the creation and analysis of pseudo-random bit sequences. The universe of these sequences is generally $\mathbf{F}_2$. However, some functions, such as `BerlekampMassey`, may be applied to sequences defined over arbitrary finite fields.

158.2 Linear Feedback Shift Registers

For a linear feedback shift register (LFSR) of length L, initial state $s_0, \ldots, s_{L-1} \in \mathbf{F}_q$, and connection polynomial $C(D) = 1 + c_1 D + c_2 D^2 + \ldots + c_L D^L$ (also over $\mathbf{F}_q$), the j'th element of the sequence is computed as $s_j = -\sum_{i=1}^{L} c_i s_{j-i}$ for $j \geq L$.

`LFSRSequence(C, S, t)`

Computes the first t sequence elements of the LFSR with connection polynomial C and initial state the sequence S (thus, the length of the LFSR is assumed to be the length of S). C must be at least degree 1, its coefficients must come from the same finite field as the universe of S, and its constant coefficient must be 1. Also, the sequence S must have at least as many terms as the degree of C.

`LFSRStep(C, S)`

Computes the next state of the LFSR having connection polynomial C and current state the sequence S (thus, the length of the LFSR is assumed to be the length of S). C must be at least degree 1, its coefficients must come from the same finite field as the universe of S, and its constant coefficient must be 1. Also, the sequence S must have at least as many terms as the degree of C.

`BerlekampMassey(S)`

`ConnectionPolynomial(S)`

`CharacteristicPolynomial(S)`

Given a sequence S of elements from $\mathbf{F}_q$, return the connection polynomial $C(D)$ and the length L of a LFSR that generates the sequence S.

Note that it is possible that the `BerlekampMassey` will return a singular LFSR (i.e. the degree of $C(D)$ is less than L), and therefore one must be sure to use the first L elements of S to regenerate the sequence.

Example H158E1

We first create a sequence and then use `BerlekampMassey` to get the connection polynomial and its length:

```
> S:= [GF(2)| 1,1,0,1,0,1,1,1,0,0,1,0];
> C<D>, L := BerlekampMassey(S);
> C;
D^3 + D^2 + 1
> L;
5
```

Now create a new sequence T containing the first L elements of S, and reconstruct the sequence from $C(D)$ and T.

```
> T := S[1..L];
> LFSRSequence(C, T, #S);
[ 1, 1, 0, 1, 0, 1, 1, 1, 0, 0, 1, 0 ]
```

`ShrinkingGenerator(C1, S1, C2, S2, t)`

Outputs a sequence of t bits from the shrinking generator having connection polynomials C_1 and C_2 and initial states sequences S_1 and S_2 (thus, the lengths of the LFSRs are assumed to be the lengths of S_1 and S_2). Bits are represented as elements from $\mathbf{F}_2$. Polynomial coefficients and sequence elements must be from $\mathbf{F}_2$. The degrees of the connection polynomials must be at least 1 and their trailing coefficients must be 1. The number of elements in the initial states must be at least as large as the degrees of the corresponding connection polynomials.

158.3 Number Theoretic Bit Generators

`RandomSequenceRSA(b, t)`

Generates a sequence of t bits using the RSA pseudo-random bit generator with an RSA modulus of approximately b bits in length. The modulus n is computed by finding (pseudo-)random primes with the `RandomPrime` function. If $\gcd(\phi(n),\ 3)$ is 1, then the exponent 3 will be used. Otherwise, a (pseudo-)random exponent e is chosen so that $\gcd(\phi(n),\ e) = 1$. The seed is also chosen as a (pseudo-)random number modulo n. Bits are represented as elements of $\mathbf{F}_2$.

Example H158E2

The code below counts the number of 1's that appear in a sequence of 1000 bits generated from a 100-bit RSA modulus.

```
> Z := Integers();
> &+[ Z | b : b in RandomSequenceRSA(100, 1000) ];
497
```

`RandomSequenceRSA(n, e, s, t)`

Generates a sequence of t bits using the RSA pseudo-random bit generator with modulus n, exponent e, and seed value s. Bits are represented as elements from $\mathbf{F}_2$. The integer n must be larger than 1.

`RSAModulus(b)`

Returns an RSA Modulus n of b bits in length, and an exponent e such that `Gcd(EulerPhi(`n`),`e`)=1`. The resulting values can be used to generate random bits with the function `RandomSequenceRSA`. The argument b must be at least 16. *Warning*: RSA Moduli generated by MAGMA should not be used for real world cryptographic applications. Such applications require a "true random" source to seed the random number generator. MAGMA's method of seeding may not be sufficiently random to meet the requirements of cryptographic standards.

`RSAModulus(b, e)`

Returns an RSA Modulus n of b bits in length such that `Gcd(EulerPhi(`n`),`e`)=1`. The resulting value can be used with e for the exponent to generate random bits with the function `RandomSequenceRSA`. The argument b must be at least 16. The argument e must be odd and must also be in the range $1 < e < 2^b$. *Warning*: RSA Moduli generated by MAGMA should not be used for real world cryptographic applications. Such applications require a "true random" source to seed the random number generator. MAGMA's method of seeding may not be sufficiently random to meet the requirements of cryptographic standards.

`RandomSequenceBlumBlumShub(b, t)`

`BlumBlumShub(b, t)`

Generates a sequence of t bits using the Blum-Blum-Shub pseudo-random bit generator with a Blum-Blum-Shub modulus of approximately b bits in length. The modulus n is computed within MAGMA by finding (pseudo-)random primes with the `RandomPrime` function (the condition being that the primes are congruent to 3 mod 4). The seed is chosen as a (pseudo-)random number modulo n. Bits are represented as elements from $\mathbf{F}_2$. b must be at least 16.

`RandomSequenceBlumBlumShub(n, s, t)`

`BlumBlumShub(n, s, t)`

Generates a sequence of t bits using the Blum-Blum-Shub pseudo-random bit generator with modulus n and seed value s. Bits are represented as elements from $\mathbf{F}_2$. The argument n must be larger than 1 and $\gcd(s, n)$ must be 1.

`BBSModulus(b)`

`BlumBlumShubModulus(b)`

Returns a Blum-Blum-Shub Modulus b bits in length. The resulting value can be used to generate random bits with the function `RandomSequenceBlumBlumShub`. The argument b must be at least 16. *Warning*: Blum-Blum-Shub Moduli generated by MAGMA should not be used for real world cryptographic applications. Such applications require a "true random" source to seed the random number generator. MAGMA's method of seeding may not be sufficiently random to meet the requirements of cryptographic standards.

158.4 Correlation Functions

`AutoCorrelation(S, t)`

Computes the autocorrelation of a sequence S, where S must have universe $\mathbf{F}_2$. The autocorrelation is defined to be

$$C(t) = \sum_{i=1}^{L} (-1)^{S[i]+S[i+t]}$$

where L is the length of the sequence, and the values of $S[i+t]$ wrap around to the beginning of the sequence when $i + t > L$.

Example H158E3

It is well known that the LFSR's with maximal periods have nice autocorrelation properties. This is illustrated below.

```
> C<D> := PrimitivePolynomial (GF(2), 5);
> C;
D^5 + D^2 + 1
> s := [GF(2)|1,1,1,1,1];
> t := LFSRSequence(C, s, 31);
> t;
[ 1, 1, 1, 1, 1, 0, 0, 1, 1, 0, 1, 0, 0, 1, 0, 0, 0, 0, 1, 0, 1, 0, 1, 1, 1, 0,
1, 1, 0, 0, 0 ]
> AutoCorrelation (t, 2);
-1
```

`CrossCorrelation(S1, S2, t)`

Computes the crosscorrelation of two binary sequences S_1 and S_2, where S_1 and S_2 must each have universe $\mathbf{F}_2$, and they must have the same length L. The crosscorrelation is defined to be:

$$C(t) = \sum_{i=1}^{L} (-1)^{S_1[i]+S_2[i+t]}$$

and the values of $S_2[i+t]$ wrap around to the beginning of the sequence when $i + t > L$.

158.5 Decimation

`Decimation(S, f, d)`

Given a binary sequence S, and integers f and d, return the decimation of S. This is the sequence containing elements $S[f]$, $S[f+d]$, $S[f+2d]$, ... where the indices in S are interpreted with wrap-around as integers between 1 and $\#S$.

`Decimation(S, f, d, t)`

Decimation of the sequence S. Returns a new sequence containing the first t elements of $S[f]$, $S[f+d]$, $S[f+2d]$, ... where the indices in S are interpreted with wrap-around as integers between 1 and $\#S$.

Example H158E4

Given a primitive polynomial over $\mathbf{F}_q$, one can obtain another primitive polynomial by decimating an LFSR sequence obtained from the initial polynomial. This is demonstrated in the code below.

```
> K := GF(7);
> C<D> := PrimitivePolynomial(K, 2);
> C;
D^2 + 6*D + 3
```

In order to generate an LFSR sequence, we must first multiply this polynomial by a suitable constant so that the trailing coefficient becomes 1.

```
> C := C * Coefficient(C,0)^-1;
> C;
5*D^2 + 2*D + 1
```

We are now able to generate an LFSR sequence of length $7^2 - 1$. The initial state can be anything other than $[0, 0]$.

```
> t := LFSRSequence (C, [K| 1,1], 48);
> t;
[ 1, 1, 0, 2, 3, 5, 3, 4, 5, 5, 0, 3, 1, 4, 1, 6, 4, 4, 0, 1, 5, 6, 5, 2, 6, 6,
```

```
0, 5, 4, 2, 4, 3, 2, 2, 0, 4, 6, 3, 6, 1, 3, 3, 0, 6, 2, 1, 2, 5 ]
```

We decimate the sequence by a value d having the property $\gcd(d, 48) = 1$.

```
> t := Decimation(t, 1, 5);
> t;
[ 1, 5, 0, 6, 5, 6, 4, 4, 3, 1, 0, 4, 1, 4, 5, 5, 2, 3, 0, 5, 3, 5, 1, 1, 6, 2,
0, 1, 2, 1, 3, 3, 4, 6, 0, 3, 6, 3, 2, 2, 5, 4, 0, 2, 4, 2, 6, 6 ]
> B := BerlekampMassey(t);
> B;
3*D^2 + 5*D + 1
```

To get the corresponding primitive polynomial, we multiply by a constant to make it monic.

```
> B := B * Coefficient(B, 2)^-1;
> B;
D^2 + 4*D + 5
> IsPrimitive(B);
true
```

PART XXIII
OPTIMIZATION

159 LINEAR PROGRAMMING

Chapter 159
LINEAR PROGRAMMING

159.1 Introduction

A Linear Program in n variables $x_1, \cdots, x_n$ with m constraints of the form

$$\sum_{j=1}^{n} a_j x_j \ \leq \ c$$

(the relations in any of the constraints may also be $=$ or $\geq$) may be represented in matrix form as:

$$\begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{m1} & \cdots & a_{mn} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} \quad (\,REL\,) \quad \begin{pmatrix} c_1 \\ \vdots \\ c_n \end{pmatrix}$$

where $(\,REL\,)$ represents a componentwise relation between vectors, with each element $=$, $\leq$, or $\geq$.

Note that there is an additional implicit constraint, wherein all variables are assumed to be nonnegative.

We wish to find a solution $(\,x_i\,)$ that maximises (or minimises) the objective function:

$$\sum_{i=1}^{n} o_i x_i$$

Magma provides two methods for solving LP problems. The first is to set up suitable constraint matrices and then use an explicit LP solving function to solve the problem. The second involves creating an instance of the `LP` process, which is of category `LP`. Constraints are added and options set before calling `Solution` to get a solution to the problem.

All functions that actually solve an LP problem return a solution vector together with an integer code representing the state of the solution, provided by the lp_solve library. The codes are:

0 Optimal Solution

1 Failure

2 Infeasible problem

3 Unbounded problem

4 Failure

Magma supports LP problems over Integer, Rational, and Real rings. For Integer and Real problems, the solutions will be provided as Integer and Real vectors respectively. For LP problems provided in Rationals, the solution is a Real vector.

Linear programming in Magma is implemented using the lp_solve library written by Michel Berkelaar (michel@ics.ele.tue.nl). The library source may be found at `ftp://ftp.ics.ele.tue.nl/pub/lp_solve/`.

For further reference see [Naz87], [Chv83], [OH68] and [NW88].

159.2 Explicit LP Solving Functions

Each explicit LP solving function takes four arguments to represent an LP problem in n variables with m constraints:

1 `LHS` : $m \times n$ matrix, representing the left-hand-side coefficients of the m constraints.

2 `relations` : $m \times 1$ matrix over the same ring as `LHS`, representing the relations for each constraint, with a positive entry representing $\geq$, a zero entry representing $=$, and a negative entry representing $\leq$.

3 `RHS` : $m \times 1$ matrix over the same ring as `LHS`, representing the right-hand-side values of the m constraints.

4 `objective` : $1 \times n$ matrix over the same ring as `LHS`, representing the coefficients of the objective function to be optimised.

Each function returns a vector representing an optimal solution to the problem, and an integer indicating the state of the solution, as described in the introduction.

```
MaximalSolution(LHS, relations, RHS, objective)
```

The vector maximising the LP problem, with an integer describing the state of the solution.

```
MinimalSolution(LHS, relations, RHS, objective)
```

The vector minimising the LP problem, with an integer describing the state of the solution.

```
MaximalIntegerSolution(LHS, relations, RHS, objective)
```

The integer vector maximising the LP problem, with an integer describing the state of the solution.

```
MinimalIntegerSolution(LHS, relations, RHS, objective)
```

The integer vector minimising the LP problem, with an integer describing the state of the solution.

```
MaximalZeroOneSolution(LHS, relations, RHS, objective)
```

The vector with each entry either zero or one maximising the LP problem, with an integer describing the state of the solution.

```
MinimalZeroOneSolution(LHS, relations, RHS, objective)
```

The vector with each entry either zero or one minimising the LP problem, with an integer describing the state of the solution.

Example H159E1

We solve the LP maximising

$$F(x, y) = 8x + 2y \quad x, y \in \mathbf{R}$$

subject to the constraints

$$10x + 21y \leq 156$$

$$2x + y \leq 22$$

```
> R := RealField( );
> lhs := Matrix(R, 2, 2, [10, 21, 2, 1]);
> rhs := Matrix(R, 2, 1, [156, 22]);
> rel := Matrix(R, 2, 1, [-1, -1]); // negative values - less-or-equal relation
> obj := Matrix(R, 1, 2, [8, 15]);
> MaximalSolution(lhs, rel, rhs, obj);
[9.562500000000000000 2.875000000000000888]
0
```

Example H159E2

We find solutions to the LP maximising

$$F(x_1, \cdots, x_7) = 592x_1 + 381x_2 + 273x_3 + 55x_4 + 48x_5 + 37x_6 + 23x_7$$

subject to the constraint

$$3534x_1 + 2356x_2 + 2767x_3 + 589x_4 + 528x_5 + 451x_6 + 304x_7 \leq 119567$$

with $(x_1, \cdots, x_7)$ taking real values, integer values, and zero/one values.

```
> R := RealField( );
> lhs := Matrix(R, 1, 7, [3534, 2356, 2767, 589, 528, 451, 304]);
> rhs := Matrix(R, 1, 1, [119567]);
> rel := Matrix(R, 1, 1, [-1]);
> obj := Matrix(R, 1, 7, [592, 381, 273, 55, 48, 37, 23]);
> MaximalSolution(lhs, rel, rhs, obj);
[33.83333333333333570 0.E-92 0.E-92 0.E-92 0.E-92 0.E-92 0.E-92]
0
> MaximalIntegerSolution(lhs, rel, rhs, obj);
[33.00000000000000000 1.000000000000000000 0.E-92 1.000000000000000000 0.E-92
    0.E-92 0.E-92]
0
> MaximalZeroOneSolution(lhs, rel, rhs, obj);
[1.000000000000000000 1.000000000000000000 1.000000000000000000
    1.000000000000000000 1.000000000000000000 1.000000000000000000
    1.000000000000000000]
0
```

159.3 Creation of LP objects

`LPProcess(R, n)`

A Linear Program over the ring R in n variables.

Example H159E3

We create an LP representing a problem in 2 real variables:

```
> R := RealField( );
> L := LPProcess(R, 2);
> L;
LP <Real Field, 2 variables>
Minimising objective function: [0 0]
Subject to constraints:
Variables bounded above by: [ ]
Variables bounded below by: [ ]
Solving in integers for variables [ ]
```

159.4 Operations on LP objects

`AddConstraints(L, lhs, rhs)`

`Rel` MonStgElt *Default : "eq"*

Add some constraints to the LP problem L. All constraints will have the same relation, given by `Rel`, which may be set to `"eq"` for strict equality (the default), `"le"` for less-or-equal constraints, or `"ge"` for greater-or-equal constraints.

Constraints are of the form

$$\sum_{j=1}^{n} \texttt{lhs}_{ij} \quad \texttt{Rel} \quad \texttt{rhs}_{i1}$$

where *lhs* and *rhs* are described in Section 159.2.

`NumberOfConstraints(L)`

The number of constraints in the LP problem L.

`NumberOfVariables(L)`

The number of variables in the LP problem L.

`EvaluateAt(L, p)`

Evaluate the objective function of the LP problem L at the point p given by a matrix.

`Constraint(L, n)`

The LHS, RHS and relation (-1 for $\leq$, 0 for $=$, 1 for $\geq$) of the n-th constraint of the LP problem L.

`IntegerSolutionVariables(L)`

Sequence of indices of the variables in the LP problem L to be solved in integers.

`ObjectiveFunction(L)`

The objective function of the LP problem L.

`IsMaximisingFunction(L)`

Returns `true` if the LP problem L is set to maximise its objective function, `false` if set to minimise.

`RemoveConstraint(L, n)`

Remove the n-th constraint from the LP problem L.

`SetIntegerSolutionVariables(L, I, m)`

Set the variables of the LP problem L indexed by elements of the sequence I to be solved in integers if m is `true`, or in the usual ring if `false`.

`SetLowerBound(L, n, b)`

Set the lower bound on the n-th variable in the LP problem L to b.

Note that for all LP problems in MAGMA there is an implicit constraint that all variables are ≥ 0. This constraint is overridden if a lower bound is specified by using this function (e.g., specifying a lower bound of -5 works as expected), but the lower bound can currently not be completely removed.

`SetMaximiseFunction(L, m)`

Set the LP problem L to maximise its objective function if m is `true`, or to minimise the objective function if m is false.

`SetObjectiveFunction(L, F)`

Set the objective function of the LP problem L to the matrix F.

`SetUpperBound(L, n, b)`

Set the upper bound on the n-th variable in the LP problem L to b.

`Solution(L)`

Solve the LP problem L; returns a point representing an optimal solution, and an integer representing the state of the solution.

`UnsetBounds(L)`

Remove any bounds on all variables in the LP problem L.

Note that this reactivates the implicit constraint that all variables are ≥ 0.

Example H159E4

We use an LP object to solve the LP maximising

$$F(x, y) = 3x + 13y$$

subject to constraints

$$2x + 9y <= 40$$

$$11x - 8y <= 82$$

```
> R := RealField( );
> L := LPProcess(R, 2);
> SetObjectiveFunction(L, Matrix(R, 1, 2, [3,13]));
> lhs := Matrix(R, 2, 2, [2, 9, 11, -8]);
> rhs := Matrix(R, 2, 1, [40, 82]);
> AddConstraints(L, lhs, rhs : Rel := "le");
> SetMaximiseFunction(L, true);
> L;
LP <Real Field, 2 variables>
Maximising objective function: [ 3 13]
Subject to constraints:
1 : [2 9] <= [40]
2 : [11 -8] <= [82]
Variables bounded above by: [ ]
Variables bounded below by: [ ]
Solving in integers for variables [ ]
> Solution(L);
[9.199999999999999289 2.400000000000000355]
0
```

Now, we place some bounds on y:

```
> SetUpperBound(L, 2, R!2);
> SetLowerBound(L, 2, R!1);
> Solution(L);
[8.909090909090908283 2.000000000000000000]
0
```

And find integer solutions:

```
> SetIntegerSolutionVariables(L, [1,2], true);
> Solution(L);
[8.000000000000000000 2.000000000000000000]
0
```

Now, removing the 2nd constraint:

```
> RemoveConstraint(L, 2);
> L;
LP <Real Field, 2 variables>
```

```
Maximising objective function: [ 3 13]
Subject to constraints:
1 : [2 9] <= [40]
Variables bounded above by: [ 2:2 ]
Variables bounded below by: [ 2:1 ]
Solving in integers for variables [ 1, 2 ]
> Solution(L);
[11.00000000000000000 2.000000000000000000]
0
```

And removing the restriction to Integer values for y,

```
> SetIntegerSolutionVariables(L, [2], false);
> Solution(L);
