Given a field K, a list X of n identifiers, and a list L of noncommutative polynomials (relations) in the n variables X, create the fp-algebra of rank n with base ring K with given quotient relations; i.e., return $K[X]/\langle L\rangle$. The angle bracket notation can be used to assign names to the indeterminates.

Example H82E6

We illustrate equivalent ways of creating FP-algebras.

```
> K := RationalField();
> A<x,y> := FPAlgebra<K, x, y | x^2*y - y*x, x*y^3 - y*x>;
> A;
Finitely Presented Algebra of rank 2 over Rational Field
Non-commutative Graded Lexicographical Order
Variables: x, y
Quotient relations:
[
    x^2*y - y*x,
    x*y^3 - y*x
]
> x;
x
> x*y;
x*y
> x^2*y;
y*x
> A;
Finitely Presented Algebra of rank 2 over Rational Field
Non-commutative Graded Lexicographical Order
Variables: x, y
Quotient relations:
[
    x*y*x^2 - y*x^2,
    x*y*x*y - y^2*x,
    x*y^2*x - y^2*x,
    x*y^3 - y*x,
    y*x^3 - y*x^2,
    y*x*y*x - y^2*x,
    y*x*y^2 - x*y*x,
    y^2*x^2 - y^2*x,
    y^2*x*y - y*x^2,
    y^3*x - y*x^2,
    x^2*y - y*x
```

```
]
```

The following is equivalent.

```
> K := RationalField();
> F<x,y> := FreeAlgebra(K, 2);
> A<x,y> := quo<F | x^2*y - y*x, x*y^3 - y*x>;
```

82.12 Operations on FP-Algebras

This section describes operations on fp-algebras. Most of the operations are very similar to those for noncommutative free algebras; such operations are done by mapping the computation to the preimage ideal and then by mapping the result back into the fp-algebra. See the corresponding functions for the noncommutative free algebras for details.

`A . i`

Given an fp-algebra A, return the i-th indeterminate of A as an element of A.

`CoefficientRing(A)`

Return the coefficient ring of the fp-algebra A.

`Rank(A)`

Return the rank of the fp-algebra A (the number of indeterminates of A).

`DivisorIdeal(I)`

Given an ideal I of an fp-algebra A which is the quotient ring F/J, where F is a free algebra and J an ideal of F, return the ideal J.

`PreimageIdeal(I)`

Given an ideal I of an fp-algebra A which is the quotient ring F/J, where F is a free algebra and J an ideal of F, return the ideal I' of F such that the image of I' under the natural epimorphism $F \to A$ is I.

`PreimageRing(A)`

Given an fp-algebra A which is the quotient ring F/J, where F is a free algebra and J an ideal of F, return the free algebra F.

`OriginalRing(A)`

Return the generic free algebra F such that A is F/J for some ideal J of F.

`IsCommutative(A)`

Return whether the algebra A is commutative.

`I eq J`

Given two ideals I and J of the same fp-algebra A, return `true` if and only if I and J are equal.

`I subset J`

Given two ideals I and J of the same fp-algebra A, return `true` if and only if I is contained in J.

`I + J`

Given two ideals I and J of the same fp-algebra A, return the sum $I + J$.

`I * J`

Given two ideals I and J of the same fp-algebra A, return the product $I * J$.

`IsProper(I)`

Given an ideal I of the fp-algebra A, return whether I is proper; that is, whether I is strictly contained in A.

`IsZero(I)`

Given an ideal I of the fp-algebra A, return whether I is the zero ideal. Note that this is equivalent to whether the preimage ideal of I is the divisor ideal of A.

82.13 Finite Dimensional FP-Algebras

If an fp-algebra A has finite dimension, considered as a vector space over its coefficient field, then extra special operations are available for A and the elements of A.

`Dimension(A)`

Given a finite dimensional fp-algebra A, return the dimension of A.

`VectorSpace(A)`

Given a finite dimensional fp-algebra A, construct the vector space V isomorphic to A, and return V together with the isomorphism f from A onto V.

`MatrixAlgebra(A)`

Given a finite dimensional fp-algebra A, construct the matrix algebra M isomorphic to A, and return M together with the isomorphism f from A onto M.

`Algebra(A)`

Given a finite dimensional fp-algebra A, construct the associative structure-constant algebra S isomorphic to A, and return S together with the isomorphism f from A onto S.

`RepresentationMatrix(f)`

Given an element f of a finite dimensional fp-algebra A, return the representation matrix of f, which is a d by d matrix over the coefficient field of A which represents f (where d is the dimension of A).

`IsUnit(f)`

Given an element f of a finite dimensional fp-algebra A defined over a field, return whether f is a unit.

`IsNilpotent(f)`

Given an element f of a finite dimensional fp-algebra A defined over a field, return whether f is nilpotent, and if so, return also the smallest q such that $f^q = 0$.

`MinimalPolynomial(f)`

Given an element f of a finite dimensional fp-algebra A defined over a field, return the minimal polynomial of f as a univariate polynomial over the coefficient field of A.

Example H82E7

We demonstrate the functions available for finite-dimensional fp-algebras.

```
> K := RationalField();
> A<x,y,z> := FPAlgebra<K, x,y,z |
>           x^2 - y*z*y + z, y^2 - y*x*y + 1, z^2 - y*x*y - x*z*x>;

82.14 Vector Enumeration

Vector enumeration (originally misnamed module enumeration) is an algorithm for converting a finitely-presented module for a finitely-presented algebra into a concrete vector space on which the algebra has explicit matrix action. The algebra may be the group algebra of an fp-group, in which case the resulting module will be a matrix representation of the group, or it might be a more general fp-algebra, such as a Hecke algebra or a quotient of a polynomial ring.

82.14.1 Finitely Presented Modules

For a ring R, let M be an R-module M, generated as an R-module by s elements $\{m_1, \ldots, m_s\}$. There is an R-module epimorphism $\psi : R^s \mapsto M$, given by

$$(r_1, \ldots, r_s) \mapsto m_1 r_1 + \cdots + m_s r_s.$$

This shows that M is isomorphic to $A^s / \ker \psi$.

If $\ker \psi$ is generated as an R-module by a finite set L then we will say that M is presented by s generators and the relators L.

82.14.2 S-algebras

Suppose there is another ring S, equipped with a ring homomorphism $\phi : S \mapsto R$, such that $\phi(S)$ is central in R. In this situation any R-module can be described as an S-module, on which R acts as a ring of S-module endomorphisms. We say that R is an S-algebra. In particular, when S is a field k, any R-module is a k-vector space. If such a module V has finite k-dimension n, then V is characterised by this dimension and R will act on it as a subring of $M_n(k)$.

82.14.3 Finitely Presented Algebras

Given a finite set X, and a ring S, we can define the free S-algebra A generated by X. This can be seen either as the monoid algebra of the free monoid of words in X, or as all expressions in X and k, combined by addition and multiplication.

Given a finite set $R \subset A$ we can define

$$P = \frac{A}{\langle ARA \rangle}.$$

We say that P is a *finitely-presented* S-algebra, with generators X and relators R, and write it

$$P = \langle X \mid R \rangle .$$

The monoid algebra of any finitely-presented monoid (or group, of course) is finitely-presented, since

$$k \langle X \mid l_1 = r_1, \ldots, l_k = r_k \rangle_{\text{monoid}} = \langle X \mid l_1 - r_1, \ldots, l_k - r_k \rangle_{k-\text{algebra}} .$$

Furthermore, any quotient of a finitely-presented algebra by a finitely-generated two-sided ideal is finitely-presented. This gives us the general form of a finitely-presented algebra in Magma, as the quotient of the monoid algebra of an fp-monoid, by the two-sided ideal generated by some additional relators.

82.14.4 Vector Enumeration

The vector enumeration algorithm explicitly reconciles these two descriptions of an R-module, in the case where R is a finitely presented k-algebra for a field k, and M is a finitely presented R-module, which also has finite k-dimension.

Given the presentation of R as k-algebra, and that of M as R-module, it computes the k-dimension of M and the matrices giving the action of the generators of R on M. If M has infinite k-dimension the algorithm will fail to terminate.

Example H82E8

We consider some examples in the abstract. Below we will see how these and other calculations may be performed in Magma.

(1) **A permutation module**

In practice, it is always better to use the classical Todd-Coxeter algorithm to construct permutation representations of groups.

We know that the group with presentation

$$\left\langle a, b \mid a^4 = b^2 = (ab)^2 = 1 \right\rangle$$

is the dihedral group of order 8. Its group algebra over any field k is thus the fp-k-algebra

$$\left\langle a, b, a', b' \mid aa' - 1, a'a - 1, bb' - 1, b'b - 1, a^4 - 1, b^2 - 1, (ab)^2 - 1 \right\rangle .$$

The permutation module of degree 4 of this algebra is presented by one generator (as it is transitive) and the submodule generator $b-1$.
Applying the algorithm to this case we obtain the matrices

$$a = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{pmatrix} \qquad b = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

and their inverses for a' and b'.
(2) **A quotient of a permutation module**
Like all permutation modules, this one fixes the all-ones vector $(1,1,1,1)$, which we can see to be an image of $1+a'(1+b+a')$. We can construct the quotient of the permutation module by this 1-dimensional submodule by adding that word to the submodule generators. This gives

$$a = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ -1 & -1 & -1 \end{pmatrix} \qquad b = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

(3) **A non-cyclic module**
A permutation module of a group-ring is cyclic (that is, generated as a module by one element) just when the permutation representation is transitive. An intransitive permutation representation can be easily constructed from its transitive components, but in general it is not so easy to construct an arbitrary module from cyclic submodules. Accordingly it can be worthwhile to construct non-cyclic modules directly.
As an example we take two copies of the representation constructed in example one, and fuse their one-dimensional submodules. The generators and relators are as before, and now $s=2$ and the submodule generators are $a^2 = \{(b-1,0),(0,b-1),(1+a'(1+a'+b),-1-a'(1+a'+b))\}$. We obtain a representation of degree seven, given by

$$a = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & -1 & 1 & 1 & 1 & -1 & -1 \end{pmatrix} \qquad b = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}.$$

82.14.5 The Isomorphism

In determining the k-dimension of M, and giving matrices representing the action of R on M, the algorithm is, in effect, constructing a k-vector space, on which R has matrix action, and which is R-module isomorphic to M, which is formally a quotient module of R^s. The algorithm also computes this isomorphism, giving images in the vector space for the s standard generators of R^s and pre-images in R^s of the basis of the vector space.

In example (1) above, we find that the module generator has image $(1,0,0,0)$, while the basis vectors have pre-images 1, a', a'^2 and b.

In example (3) the images of the two module generators are $(1,0,0,0,0,0,0)$ and $(0,1,0,0,0,0,0)$ while the basis vectors are images of $(1,0)$, $(0,1)$, $(a',0)$,$(a,0)$, $(a^2,0)$, $(0,a')$ and $(0,a)$.

82.14.6 Sketch of the Algorithm

The algorithm is based on the Haselgrove-Leech-Trotter (HLT) version of the Todd-Coxeter algorithm, which we consider as a means of constructing the permutation representation of a finitely-presented group on the cosets of a finitely generated subgroup.

The algorithm proceeds by manipulating a partial action of the free algebra on a vector space. This is represented as a table, with columns indexed by the generators of the algebra, and rows indexed by the basis of the space. Each entry is either a vector or $\perp$, signifying that no action is given.

We can extend this to a "complete action with side-effects", by adding a new row to the table whenever needed. We call this *the action with defining*.

The action of the fp-algebra P on M gives an action for the free algebra A, and our objective is to modify out partial action until it becomes this action. We know certain things about this action, which drive our modification process:

1. It is a complete action.
2. The relators of P annihilate every vector.
3. The images in the space of the relators of M are zero.
4. The space contains images of the R-module generators of M.

The algorithm begins by applying the fourth fact and creating s linearly independent vectors. It then applies the third, computing the action with defining of the relators of M (the set called L above). The fact that these images should be zero gives a linear dependence among our basis vectors (called a coincidence), which we use to reduce their number. As we do this, we have to take care not to lose the information already in the table, which may give rise to further coincidences.

We now start to exploit the second fact about M, constructing the action (with defining) of the relators of P, on the basis vectors, and applying the resulting coincidences. This process may not terminate, as we are defining new basis vectors on the one hand, and removing them through coincidences on the other. It is possible to prove, however, that if M is in fact finite-dimensional then the process will terminate.

The first fact is applied by adding the relators $x - x$ for each $x \in X$ to the relators of P, so that the image of every basis vector under each x is sure to be defined.

82.14.7 Weights

The above sketch leaves open the question of the order in which the relators are applied to the basis vectors. The proof that the algorithm completes when M is finite-dimensional imposes some rather loose constraints, but within these constraints there is considerable choice.

The implementation in MAGMA uses a system of weights. Each relator r is assigned a weight w_r by the user, and each basis vector e has a weight w_e. There is a current weight w, which increases as the computation progresses, and at weight w all basis vector, relator pairs (b, r) such that $w_b + w_r \leq w$, which have not been processed already, are processed. New basis vectors defined during this process are assigned weight w. The initial basis vectors and those defined during processing of the submodule generators are assigned weight 1. See below for details of how to set the weights, and their default values.

82.14.8 Setup Functions

For V2.11, the following functions create the old representation for fp-algebras which are necessary for the Vector Enumeration algorithm. These are compatible with older versions of Magma. See the examples below for examples of how to use these functions.

```
FreeAlgebra(R, M)
```

```
FreeAlgebra(R, G)
```

Construct the special fp-algebra over the ring R and the monoid M or the group G, for use in the Vector Enumeration algorithm.

82.14.9 The Quotient Module Function

```
QuotientModule(A, S)
```

Given an fp-k-algebra A, for a field k, with r generators, and a submodule N of the free A-module of rank s specified by S, construct an A-module isomorphic to the quotient module A^s/N together with the isomorphism.

The three values returned are:

M a sequence of r $n \times n$ matrices with entries in k;

I a sequence of s vectors of length n with entries in k;

P a sequence of n elements of the free A-module A^s.

The matrices M specify a homomorphism from A to $\mathrm{End}_k(k^n)$, under which k^n becomes an A-module isomorphic to A^s/N. That isomorphism is given in one direction by the vectors I, which are the images in k^n of the s generators $(1, 0, \ldots, 0)$, $(0, 1, 0, \ldots, 0)$, $\ldots$, $(0, \ldots, 0, 1)$ of A^s. In the other direction, the elements P give representatives for the images in A^s/N of the images of the n standard basis elements of k^n.

The submodule N may be specified by the parameter S in three ways:

(1) S may simply be N, a finitely generated submodule of a free A-module (except that such an object cannot currently be created).

(2) S may be a finitely generated right ideal of A, in which case $s = 1$ and N is S considered as a submodule of A considered as a right module for itself.

(3) S may be a sequence of elements of a free A-module A^s, in which case N is the submodule that they generate (this is a stand in for 1 and could be removed when 1 is implemented).

82.14.10 Structuring Presentations

The relations used by the vector enumeration algorithm come from three sources:

(1) The relations of the fp-group or fp-monoid underlying A.

(2) The relations of A itself.

(3) The generators of N.

The third group play the same role as subgroup generators in the Todd-Coxeter algorithm, and are treated specially, while the first two groups are logically equivalent, forming the relations of A in the variety of free finitely-generated associative algebras. However, when the underlying monoid of A is actually an fp-group G, the vector enumeration algorithm can use a more efficient technique to process the relations of G, and can take advantage of the fact that the generators of G are known to be invertible.

This greatly improves the performance of the algorithm, and so users are recommended to ensure as far as possible that:

(1) If the underlying monoid of an fp-algebra is in fact an fp-group then it should be presented to MAGMA as such.

(2) Relations which can be written as equations between monomials should be given as relations of the underlying monoid, rather than as relations of the algebra.

82.14.11 Options and Controls

The `QuotientModule` function supports a large selection of optional arguments.

82.14.12 Weights

The processing of the relations of A by the vector enumeration algorithm depends on weights which are assigned to those relations (see above). The higher the weight of a relation the later it will be processed. By default, all relations are given weight 3, except those arising from relators of an fp-group, which are given weight equal to half the length of the relator.

Separate weights are used in lookahead mode, with the same default values.

`QuotientModule(A, S)`

`MonomialWeights` [RNGINTELT] *Default :*

`MonWts` [RNGINTELT] *Default :*

This option sets the sequence of weights for the relations derived from the relations of the underlying monoid of A. The weights w_1, w_2, etc. are applied to the relations in the order in which they appear. If there are fewer weights than relations the remaining relations are assigned the default weight; if there are more weights than relations the extra weights are silently discarded.

Unless the `MonomialLookaheadweights` or `MonLWts` parameters are present, these weights are also used in lookahead mode.

`MonomialLookaheadWeights`

[RNGINTELT] *Default :*

`MonLWts` [RNGINTELT] *Default :*

This option sets the sequence of weights for the relations derived from the relations of the underlying monoid of A in lookahead mode only. It is otherwise similar to `MonomialWeights`.

`AlgebraWeights` [RNGINTELT] *Default :*

`AlgWts` [RngIntElt] *Default :*

This option sets the sequence of weights for the relations given explicitly as relations of the algebra A. It is otherwise similar to `MonomialWeights`.

`AlgebraLookaheadWeights`

[RngIntElt] *Default :*

`AlgLWts` [RngIntElt] *Default :*

This option sets the sequence of weights for the relations given explicitly as relations of the algebra A in lookahead mode only. It is otherwise similar to `AlgebraWeights`.

82.14.13 Limits

`QuotientModule(A, S)`

Options in this group set limits on the progress of the algorithm. If the calculation cannot be performed under these constraints the value `undef` is returned, unless the `ErrorOnFail` option was set, in which case a run-time error is generated.

`MaximumDimension` RngIntElt *Default :* ∞

`MaxDim` [RngIntElt] *Default :* ∞

This sets a limit of n on the dimension of the vector-space constructed, and on the dimension of the intermediate spaces used in the construction.

By default there is no limit, except for available memory.

`MaximumTime` FldReElt *Default :* ∞

`MaxTime` FldReElt *Default :* ∞

This sets a limit on the CPU time available for the vector enumeration. The limit is given as a real number t and is measured in seconds.

This limit is only checked at certain points in the calculation, so it is possible for a vector enumeration to over-run, possibly by a significant amount.

By default, there is no limit.

`MaximumWeight` RngIntElt *Default :* 100

`MaxWt` RngIntElt *Default :* 100

This sets a limit on the maximum weight of (basis vector, relation) pairs that will be used by the algorithm.

The weight of a basis vector is the weight of the pair that was being processed when it was defined. The weight of a pair is the weight of the basis vector plus the weight of the relation (see above).

The default limit is 100.

82.14.14 Logging

`QuotientModule(A, S)`

There are a number of options to control the level of detail provided in the informational message from the vector enumerator. When multiple contradictory options are given the first one given takes precedence.

`NoLogging`	BoolElt	*Default :* `false`
`NoLog`	BoolElt	*Default :* `false`
`Silent`	BoolElt	*Default :* `false`

This option turns off all the informational messages produced by the vector enumerator.

`MaximumLogging`	BoolElt	*Default :* `false`
`MaxLog`	BoolElt	*Default :* `false`

This option turns on the highest possible level of detail in the informational messages. This is *too detailed* for almost all purposes except debugging.

`LogActions`	RngIntElt	*Default :* 0
`LogAct`	RngIntElt	*Default :* 0

This option sets the level of messages about the computation of the action of the algebra on the vector space under construction. At level 0 (the default) no messages are produced. All other levels produce copious output, with all levels above 2 being equivalent.

`LogCoincidences`	RngIntElt	*Default :* 0
`LogCoin`	RngIntElt	*Default :* 0

This option sets the level of messages about the coincidences discovered and the processing of them. At level 0 (the default) no messages are produced. At level 1 every coincidence and deduction is recorded when it is discovered and when it is processed. At level 2 or higher the operation of finding the undeleted image of a vector is also recorded.

`LogInitialization`	RngIntElt	*Default :* 0
`LogInitialisation`	RngIntElt	*Default :* 0
`LogInit`	RngIntElt	*Default :* 0

This option sets the level of messages about the initialisation of new basis vectors. At level 0 (the default) no messages are produced. All other levels produce a message whenever a new basis vector is defined.

`LogPacking`	RngIntElt	*Default :* 1
`LogPack`	RngIntElt	*Default :* 1

This option sets the level of messages about the reclamation of free space in the tables used by the algorithm. At level 0 no messages are produced. At level 1 (the

default) it produces a message each time the pack routine is called. At level 2 or higher it records the exact renaming used to reclaim the space.

`LogPushes`	RngIntElt	*Default :* 0
`LogPush`	RngIntElt	*Default :* 0

This option sets the level of messages about the pushing (or tracing) of (basis vector, relation) pairs. At level 0 (the default) it produces no messages. At level 1 a message is produced for each push that is started. At level 2 or higher the outcome of the push is also recorded.

`LogProgress`	RngIntElt	*Default :* 0
`LogStages`	RngIntElt	*Default :* 0

This option sets the level of messages about the overall progress of the algorithm. At level 0 no messages are produced. At level 1, simple messages are printed as the algorithm passes through its major stages. At level 2 the relations are printed as they are read in, and the complete action on the final module is printed. At level 3 or higher the action is also printed after the processing of submodule generators is complete.

`LogWeightChanges`	RngIntElt	*Default :* 1
`LogWt`	RngIntElt	*Default :* 1

This option sets the level of messages about changes in the current weight (ie the weight of (basis vector, relation pairs) currently being pushed. At level 0 no such messages are produced. At level 1 (the default) or higher a message giving the new weight and the current dimension is printed.

82.14.15 Miscellaneous

`QuotientModule(A, S)`

`Lookahead`	BoolElt	*Default :* `true`

This option controls whether, and to what extent, lookahead is used. If x is `false` then lookahead is not used. If x is `true`, the default, the lookahead by the default amount (two weights) is used. If x is a positive integer n then lookahead n weights is used. A sufficiently large value of n is equivalent to complete lookahead. Lookahead is commenced approximately every time the dimension doubles.

`EarlyClosing`	BoolElt	*Default :* `false`
`Early`	BoolElt	*Default :* `false`

This option permits the algorithm to stop as soon as the table represents a complete action (but see below), without checking to see whether the action satisfies all the relations. In practice this action is usually correct. The default behaviour is to continue and check all the relations.

`EarlyClosingMinimum`	RngIntElt	*Default :*
`ECMin`	RngIntElt	*Default :*

This option sets a minimum dimension at which the algorithm may stop without checking all the relators. It implies `EarlyClosing`.

`EarlyClosingMaximum`	RngIntElt	*Default :*
`ECMax`	RngIntElt	*Default :*

This option sets a maximum dimension at which the algorithm aamy stop without checking all the relators. It implies `EarlyClosing`.

`ConstructMorphism`	BoolElt	*Default :* `true`
`Morphism`	BoolElt	*Default :* `true`

This option controls whether the third return value of the `QuotientModule` function is in fact computed. A small overhead of time and space is required to compute it, and many applications do not need it, so this option is provided. When b is `true` (the default) the third return value is computed, when b is `false` it is not.

`ErrorOnFail`	BoolElt	*Default :*
`ErrFail`	BoolElt	*Default :*

This option controls the behaviour of the program if there is insufficient time or space to complete the calculation, or if the calculation has not been completed when the maximum weight is reached. If it is present a run-time error is generated, otherwise the value `undef` is returned.

Example H82E9

First we repeat the examples above, in Magma. The permutation action of D_8

```
> d8<a,b> := Group<a,b | a^4 = b^2 = (a*b)^2 = 1>;
> q := RationalField();
> a1<a,b> := FreeAlgebra(q,d8);
> i1 := rideal<a1 | b-1 >;

83 MATRIX ALGEBRAS

Chapter 83
MATRIX ALGEBRAS

83.1 Introduction

Matrix algebras (or matrix rings) may be defined over any ring S. We shall regard such a matrix algebra as an *S-algebra*. Let us denote the complete algebra of $n \times n$ matrices over S by $M_n(S)$. It will often be convenient to regard $M_n(S)$ as the endomorphism ring of the free S-module $S^{(n)}$. We will then speak of $S^{(n)}$ as the natural S-module associated with $M_n(S)$.

Matrix algebras have type `AlgMat` and their elements have type `AlgMatElt`. These types inherit from `AlgMatV` and `AlgMatVElt` respectively (which cover both ordinary matrix algebras and matrix Lie algebras).

83.2 Construction of Matrix Algebras and their Elements

83.2.1 Construction of the Complete Matrix Algebra

`MatrixAlgebra(S, n)`

`MatrixRing(S, n)`

Given a positive integer n and a ring S, create the complete matrix algebra $M_n(S)$, consisting of all $n \times n$ matrices with coefficients in the ring S.

83.2.2 Construction of a Matrix

`elt< R | L >`

Given a matrix algebra defined as a subalgebra of $M_n(S)$, create the element of R defined by the list L of n^2 elements from S.

`R ! Q`

Given a matrix algebra R defined as a subalgebra of $M_n(S)$ and a sequence $Q = [a_{11}, \ldots, a_{1n}, a_{21}, \ldots, a_{2n}, \ldots, a_{n1}, \ldots, a_{nn}]$ of n^2 elements of S, return the matrix

$$\begin{pmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ a_{21} & a_{22} & \ldots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \ldots & a_{nn} \end{pmatrix}$$

as an element of R. Note that the algebra R must exist before an attempt is made to create matrices.

`CambridgeMatrix(t, K, n, Q)`

This function creates a n by n matrix over the finite field K of cardinality q specified in a "Cambridge" format in the general matrix algebra of degree n over K. The parameter t specifies the type of the format. If t is 1, then q is assumed to be less than 10 and the sequence Q must consist of n strings which give the n rows—each string must have length n and contain the entries of that row (each entry is a digit in the range $[0,\ q-1]$). If t is 3 then Q must consist of n^2 integers in the range $[0,\ q-1]$ which give the entries in row-major order. In either format, if $q = p^e$, where p is prime and $e > 1$, then an entry x is written as a vector using the base-p representation of length e of x and the corresponding element in K is used (see the Finite Fields chapter for details). This function is principally provided for the reading in of large matrices.

`CompanionMatrix(p)`

Given a monic polynomial p of degree n over a ring R, create the companion matrix C for p as an element of $M_n(R)$. The minimal and characteristic polynomial of C is then p.

`DiagonalMatrix(R, Q)`

If R is a subalgebra of $M_n(S)$ and Q is a sequence of n elements of S, create the diagonal matrix $diag(Q[1], Q[2], \ldots, Q[n])$.

`MatrixUnit(R, i, j)`

Create the matrix unit $E(i, j)$ in the matrix algebra R, i.e. the matrix having the one of the coefficient ring of R in position (i, j) and zeros elsewhere.

`Random(R)`

Create a random matrix of the matrix algebra R.

`ScalarMatrix(R, t)`

If R is a subalgebra of $M_n(S)$ and t is an element of the ring S, create the scalar matrix $t * I$ in R.

`R ! 1`

Create the identity matrix I_n of the matrix algebra R.

`R ! 0`

Create the zero matrix of the matrix algebra R.

`R ! t`

Create the scalar matrix $t * I$ of the matrix algebra R.

83.2.3 Constructing a General Matrix Algebra

```
MatrixAlgebra< S, n | L >
```

```
MatrixRing< S, n | L >
```

Given a commutative ring S and a positive integer n, create the S-algebra R consisting of the $n \times n$ matrices over the ring S generated by the elements defined in the list L. Let F denote the algebra $M_n(S)$. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n^2 elements of S defining an element of F.

(b) A set or sequence whose terms are sequences of type (a).

(c) An element of F.

(d) A set or sequence whose terms are elements of F.

(e) The null list.

The generators stored for R consist of the elements specified by terms L_i together with the stored generators for subalgebras specified by terms of L_i. Repetitions of an element and occurrences of scalar matrices are removed.

Example H83E1

We demonstrate the use of the matrix algebra constructor by creating an algebra of 3×3 lower-triangular matrices over the rational field.

```
> Q := RationalField();
> A := MatrixAlgebra< Q, 3 | [ 1/3,0,0, 3/2,3,0, -1/2,4,3],
>        [ 3,0,0, 1/2,-5,0, 8,-1/2,4] >;
> A:Maximal;
Matrix Algebra of degree 3 with 2 generators over Rational Field
Generators:
[ 1/3    0    0]
[ 3/2    3    0]
[-1/2    4    3]

[   3    0    0]
[ 1/2   -5    0]
[   8 -1/2    4]
> Dimension(A);
6
```

Example H83E2

We construct a 4 by 4 matrix over the finite field with 5 elements using the CambridgeMatrix function.

```
> K := FiniteField(5);
> x := CambridgeMatrix(1, K, 4, [ "1234", "0111", "4321", "1211" ]);
```

```
> x;
[1 2 3 4]
[0 1 1 1]
[4 3 2 1]
[1 2 1 1]
```

83.2.4 The Invariants of a Matrix Algebra

`R . i`

The i-th defining generator for the matrix algebra R.

`BaseRing(R)`

`CoefficientRing(R)`

The coefficient ring S for the matrix algebra R.

`Degree(R)`

Given a matrix algebra R, return the degree n of R.

`Generators(R)`

The set consisting of the defining generators for the matrix algebra R.

`Generic(R)`

The complete matrix algebra $M_n(S)$ in which the matrix algebra R is naturally embedded.

`BaseModule(R)`

If R is a subring of the matrix algebra $M_n(S)$, then R is considered to act on the free S-module of rank n, consisting of n-tuples over S. The function `BaseModule` returns this S-module.

`NumberOfGenerators(R)`

`Ngens(R)`

The number of defining generators for the matrix algebra R.

`Parent(a)`

Given an element a belonging to the matrix algebra R, return R, i.e. the parent structure for a.

Example H83E3

We illustrate the use of these functions by applying them to the algebra of 3×3 lower-triangular matrices over the rational field constructed above.

```
> Q := RationalField();
> A := MatrixAlgebra< Q, 3 | [ 1/3,0,0, 3/2,3,0, -1/2,4,3],
>        [ 3,0,0, 1/2,-5,0, 8,-1/2,4] >;
> CoefficientRing(A);
Rational Field
> Degree(A);
3
> Ngens(A);
2
> Generators(A);
{
    [ 1/3    0    0]
    [ 3/2    3    0]
    [-1/2    4    3],

    [   3    0    0]
    [ 1/2   -5    0]
    [   8 -1/2    4]
}
> Generic(A);
Full Matrix Algebra of degree 3 over Rational Field
> Dimension(A);
6
```

83.3 Construction of Subalgebras, Ideals and Quotient Rings

`sub< R | L >`

Given the matrix algebra R, defined as a subring of $M_n(S)$, construct the subring T of R generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) A sequence of n^2 elements of S defining an element of R;

(b) An element of R;

(c) A set or sequence of elements of R;

(d) A subring of R;

(e) A set or sequence of subrings of R.

Each element or subalgebra specified by the list must belong to the *same* complete matrix algebra. The subalgebra T will be constructed as a subalgebra of some

matrix algebra which contains each of the elements and subalgebras specified in the list.

The generators of T consist of the elements specified by the terms of the list L together with the stored generators for subalgebras specified by terms of the list. Repetitions of an element and occurrences of the identity element are removed (unless T is trivial).

The constructor returns the subalgebra T and the inclusion homomorphism $f : T \to R$.

`ideal< R | L >`

Given the matrix algebra R, construct the two-sided ideal I of R generated by the elements of R specified by the list L, where the possibilities for L are the same as for the `sub`-constructor.

`lideal< R | L >`

Given the matrix algebra R, construct the left ideal I of R generated by the elements of R specified by the list L, where the possibilities for L are the same as for the `sub`-constructor.

`rideal< R | L >`

Given the matrix algebra R, construct the right ideal I of R generated by the elements of R specified in the list L, where the possibilities for L are the same as for the `sub`-constructor.

Example H83E4

We construct the subalgebra of the matrix algebra A (defined above) that is generated by the first generator.

```
> Q := RationalField();
> A := MatrixAlgebra< Q, 3 | [ 1/3,0,0, 3/2,3,0, -1/2,4,3],
>        [ 3,0,0, 1/2,-5,0, 8,-1/2,4] >;
> B := sub< A | A.1 >;
> Dimension(B);
3
> B: Maximal;
Matrix Algebra of degree 3 and dimension 3 with 1 generator
over Rational Field
Generators:
[ 1/3    0    0]
[ 3/2    3    0]
[-1/2    4    3]

Basis:

[1 0 0]
[0 1 0]
```

```
[0 0 1]

[    0     0     0]
[    1  16/9     0]
[    0 88/27  16/9]

[   0    0    0]
[   0    0    0]
[   1 16/9    0]
```

83.4 The Construction of Extensions and their Elements

83.4.1 The Construction of Direct Sums and Tensor Products

`DirectSum(R, T)`

Given two matrix algebras R and T, where R and T have the same coefficient ring S, return the direct sum D of R and T (with the action given by the direct sum of the action of R and the action of T).

`TensorProduct(A, B)`

Given two unital matrix algebras A and B, where A and B have the same coefficient ring S, construct the tensor product of A and B.

Example H83E5

We construct the direct product and tensor product of the matrix algebra A (defined above) with itself.

```
> Q := RationalField();
> A := MatrixAlgebra< Q, 3 | [ 1/3,0,0, 3/2,3,0, -1/2,4,3],
>        [ 3,0,0, 1/2,-5,0, 8,-1/2,4] >;
> AplusA := DirectSum(A, A);
> AplusA: Maximal;
Matrix Algebra of degree 6 with 4 generators over
    Rational Field
Generators:
[ 1/3    0    0    0    0    0]
[ 3/2    3    0    0    0    0]
[-1/2    4    3    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]

[   3    0    0    0    0    0]
[ 1/2   -5    0    0    0    0]
[   8 -1/2    4    0    0    0]
```

```
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]

[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0  1/3    0    0]
[   0    0    0  3/2    3    0]
[   0    0    0 -1/2    4    3]

[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    0    0    0]
[   0    0    0    3    0    0]
[   0    0    0  1/2   -5    0]
[   0    0    0    8 -1/2    4]
> AtimesA := TensorProduct(A, A);
> AtimesA: Maximal;
Matrix Algebra of degree 9 with 4 generators over
    Rational Field
Generators:
[ 1/3    0    0    0    0    0    0    0    0]
[   0  1/3    0    0    0    0    0    0    0]
[   0    0  1/3    0    0    0    0    0    0]
[ 3/2    0    0    3    0    0    0    0    0]
[   0  3/2    0    0    3    0    0    0    0]
[   0    0  3/2    0    0    3    0    0    0]
[-1/2    0    0    4    0    0    3    0    0]
[   0 -1/2    0    0    4    0    0    3    0]
[   0    0 -1/2    0    0    4    0    0    3]

```

83.4.2 Construction of Direct Sums and Tensor Products of Elements

`DirectSum(a, b)`

Given an element a of the matrix algebra Q and an element b of the matrix algebra R, form the direct sum of matrices a and b. The square is returned as an element of the matrix algebra T, which must be the direct sum of the parent of a and the parent of b.

`ExteriorSquare(a)`

Given an element a of the matrix algebra $M_n(S)$, form the exterior square of a as an element of $M_m(S)$, where $m = n(n-1)/2$.

`ExteriorPower(a,r)`

Given an element a of the matrix algebra $M_n(S)$, form the rth exterior power of a as an element of $M_m(S)$, where $\binom{m=n}{r}$.

`SymmetricSquare(a)`

Given an element a of the matrix algebra $M_n(S)$, form the symmetric square of a as an element of $M_m(S)$, where $m = n(n+1)/2$.

`SymmetricPower(a,r)`

Given an element a of the matrix algebra $M_n(S)$, form the rth symmetric power of a as an element of $M_m(S)$, for the appropriate m.

`TensorProduct(a, b)`

Given an element a belonging to a subalgebra of $M_{n_1}(S)$ and an element b belonging to a subalgebra of $M_{n_2}(S)$, construct the tensor product of a and b as an element of the matrix algebra $M_n(S)$, where $n = n_1 * n_2$.

83.5 Operations on Matrix Algebras

`Centre(A)`

Given a matrix algebra A whose base ring is a field, return the centre of A.

`Centralizer(A, S)`

Given a matrix algebra A whose base ring is a field, together with a subalgebra S of A return the centralizer of S in A.

83.6 Changing Rings

`ChangeRing(A, S)`

Given a matrix algebra A with base ring R, together with a ring S, construct the matrix algebra B with base ring S obtained by coercing the components of elements of A into S, together with the homomorphism from A to B.

`ChangeRing(A, S, f)`

Given a matrix algebra A with base ring R, together with a ring S and a homomorphism $f : R- > S$, construct the matrix algebra B with base ring S obtained by mapping the components of elements of R into S by f, together with the homomorphism from A to B.

`hom< A -> B | f >`

Given *full* matrix algebras A and B, together with a homomorphism f from the base ring R of A to the base ring S of B, create the homomorphism from A to B which, given a matrix in A, applies f to the entries of the matrix.

83.7 Elementary Operations on Elements

83.7.1 Arithmetic

`a + b`

Sum of the matrices a and b, where a and b belong to a common matrix algebra R.

`a + t`
`t + a`

Sum of the matrix a and the scalar matrix $t * I$.

`-a`

Negation of the matrix a.

`a - b`

Difference of the matrices a and b, where a and b belong to the same matrix algebra R.

`a - t`
`t - a`

Difference of the matrix a and the scalar matrix $t * I$.

`a * b`

Product of the matrices a and b, where a and b belong to the same matrix algebra R.

`a * b`

Given a matrix a belonging to a subalgebra of $M_n(S)$ and an element b of a submodule of $\mathrm{Hom}(R^{(n)}, R^{(m)})$, construct the product of a and b as an element of $\mathrm{Hom}(R^{(n)}, R^{(m)})$.

`a * b`

Given a matrix a belonging to a submodule of $\mathrm{Hom}(R^{(n)}, R^{(m)})$ and an element b of a subalgebra of $M_m(S)$, construct the product of a and b as an element of $\mathrm{Hom}(R^{(n)}, R^{(m)})$.

`t * a`
`a * t`

Given an element a of the matrix algebra R, and an element t belonging to the coefficient ring S of R, form their scalar product.

`u * a`

Given an element u belonging to the S-module $S^{(n)}$ and an element a belonging to a subalgebra of $M_n(S)$, form the element $u * a$ of S^n.

`a ^ n`

If n is positive, form the n-th power of a; if n is zero, form the identity matrix; if n is negative, form the $(-n)$-th power of the inverse of a.

`NumberOfColumns(a)`
`Ncols(a)`

The number of columns in the matrix a.

`NumberOfRows(a)`
`Nrows(a)`

The number of rows in the matrix a.

83.7.2 Predicates

83.7.2.1 Comparison

`a eq b`

Returns `true` if the matrix a is equal to the matrix b, where a and b are elements of a common matrix algebra R.

`a ne b`

Returns `true` if the matrix a is not equal to the matrix b, where a and b are elements of a common matrix algebra R.

83.7.2.2 Properties of Elements

The functions given here test properties of matrices. See also the section in the Lattices chapter for a description of the function `IsPositiveDefinite` and related functions.

`IsDiagonal(a)`

Returns `true` iff the element a belonging to the matrix algebra R is a diagonal matrix; i.e. the only non-zero entries are on the diagonal.

`IsMinusOne(a)`

Returns `true` iff the element a belonging to the matrix algebra R is the negation of the identity element for R.

`IsOne(a)`

Returns `true` iff the element a belonging to the matrix algebra R is the identity element for R.

`IsScalar(a)`

Returns `true` iff the element a belonging to the matrix algebra R is a scalar matrix.

`IsSymmetric(a)`

Returns `true` iff the element a belonging to the matrix algebra R is a symmetric matrix; i.e. the transpose of a equals a.

`IsUnit(a)`

Returns `true` iff the matrix a belonging to the matrix algebra R is a unit.

`IsZero(a)`

Returns `true` iff the element a belonging to the matrix algebra R is the zero element for R.

`IsNilpotent(a)`

Return `true` if some power of the matrix a belonging to a matrix algebra is the zero of the matrix algebra. Also returns the minimum exponent n such that $a^n = 0$.

`IsUnipotent(a)`

Return `true` if the matrix a belonging to a matrix algebra is the identity of that algebra plus a nilpotent matrix. Also returns the index of nilpotence of $a - I$.

`Rank(a)`

Return the rank of the element a belonging to the matrix algebra R.

`Determinant(A)`

`MonteCarloLevel`	RngIntElt	*Default :* 0
`Proof`	BoolElt	*Default :* `true`
`pAdic`	BoolElt	*Default :* `true`
`Divisor`	RngIntElt	*Default :* 0

Given a square matrix A over the ring R, return the determinant of A as an element of R. R may be any commutative ring. The determinant of the 0×0 matrix over R is defined to be `R!1`.

If the coefficient ring is the integer ring $\mathbf{Z}$ or the rational field $\mathbf{Q}$ then a modular algorithm based on that of Abbott et al. [ABM99] is used, which first computes a divisor d of the determinant D using a fast p-adic nullspace computation, and then computes the quotient D/d by computing the determinant D modulo enough small primes to cover the Hadamard bound divided by d. This always yields a correct answer.

If the parameter `MonteCarloLevel` is set to a small positive integer s, then a probabilistic Monte-Carlo modular technique is used. Rather than using sufficient primes to cover the Hadamard bound divided by the divisor d, this version of the algorithm terminates when the constructed residue remains constant for s steps. The probability of this being wrong is non-zero but extremely small, even if s is only 1 or 2. If the level is set to 0, then the normal deterministic algorithm is used. Setting the parameter `Proof` to `false`is equivalent to setting `MonteCarloLevel` to 2.

If the coefficient ring is $\mathbf{Z}$ and the parameter `Divisor` is set to an integer d, then d must be a known exact divisor of the determinant (the sign does not matter), and the algorithm may be sped up because of this knowledge.

`Trace(a)`

Given an element a of a subalgebra of $M_n(S)$, return the trace of a as an element of S.

`Transpose(a)`

Given an element a of a subalgebra of $M_n(S)$, return the transpose of a as an element of $M_n(S)$.

`Order(a)`

Given an invertible matrix a over any commutative ring, determine the order of a. If a has infinite order, the function may become stuck indefinitely since it cannot prove such.

`FactoredOrder(a)`

Given an invertible matrix a over a finite field, return the order of a in factored form.

`ProjectiveOrder(a)`

Given an invertible matrix a over a finite field, return the projective order o of a and a scalar s such that $a^o = sI$.

`FactoredProjectiveOrder(a)`

Given an invertible matrix a over a finite field, return the projective order o of a in factored form and a scalar s such that $a^o = sI$.

`CharacteristicPolynomial(a:` *parameters*`)`

`Al`	MonStgElt	*Default :* "*Modular*"
`Proof`	BoolElt	*Default :* `true`

The characteristic polynomial of the element a belonging to the algebra $M_n(R)$, where R can be any commutative ring. The parameter `Al` may be used to specify the algorithm used. The algorithm `Modular` (the default) can be used for matrices over Z and Q—in such a case the parameter `Proof` can also be used to suppress proof of correctness. The algorithm `Hessenberg`, allowed for matrices over fields, works by first reducing the matrix to Hessenberg form. The algorithm `Interpolation`, allowed for matrices over Z and Q, works by evaluating the characteristic matrix of a at various points and then interpolating. The algorithm `Trace`, allowed for matrices over fields, works by calculating the traces of powers of a.

`MinimalPolynomial(a)`

The minimal polynomial of the element a belonging to the module $M_n(R)$, where R is a field or Z.

`HessenbergForm(a)`

The Hessenberg form for the matrix a belonging to the algebra $M_n(K)$, where the coefficient ring K must be a field. The form has zero entries above the super-diagonal. (This form is used in one of the characteristic polynomial algorithms.)

`Adjoint(a)`

The adjoint of the matrix a belonging to the algebra $M_n(K)$, where the coefficient ring K must be a ring with exact division whose characteristic must be zero or greater than the degree of a.

`Eigenvalues(a)`

The eigenvalues of the matrix a returned as a set of pairs, each of which gives the value of a distinct eigenvalue and its multiplicity. The coefficient ring must have a polynomial roots algorithm.

`Eigenspace(a, e)`

The eigenspace of the matrix a, corresponding to the eigenvalue e, returned as a submodule of the base module for the parent algebra of a (i.e. the kernel of $a - eI$). If the ring element e is not a eigenvalue for the matrix a then the trivial space is returned.

83.8 Elements of M_n as Homomorphisms

The matrix algebra $M_n(S)$ may also be viewed as the module $\mathrm{Hom}(S^{(n)}, S^{(n)})$. At present this will not happen automatically so that in order to treat elements of $M_n(S)$ as homomorphisms, it is necessary to explicitly coerce the matrix into $\mathrm{Hom}(S^{(n)}, S^{(n)})$. However, two fundamental homomorphism-type operators are provided for elements of $M_n(S)$.

`Image(a)`
`RowSpace(a)`

Given an element of $M_n(S)$, return the image of the module $S^{(n)}$ under the homomorphism represented by the matrix a (as an element of $S^{(n)}$).

`Kernel(a)`
`NullSpace(a)`

`Al` MonStgElt *Default :* "*Default*"

Given an element of $M_n(S)$, return the kernel of the homomorphism represented by the matrix a (as an element of $S^{(n)}$).

`RowNullSpace(a)`
`NullspaceOfTranspose(a)`

Given an element of $M_n(S)$, return the row nullspace of the homomorphism represented by the matrix a (as an element of $S^{(n)}$). This is equal to the kernel of the transpose of a.

83.9 Elementary Operations on Subalgebras and Ideals

83.9.1 Bases

The functions described here assume that the matrix algebra R is defined over a ring S with a matrix echelonization algorithm. MAGMA computes a basis for R considered as a S-module when necessary so then operations like membership testing can be performed. The following functions allow one to access this basis.

`Dimension(R)`

Assuming that R is a subalgebra of $M_n(S)$, return the dimension of R, considered as a S-module.

`Basis(R)`

Assuming that R is a subalgebra of $M_n(S)$, return the S-basis of R, considered as a S-module. The basis is returned as a sequence of matrices of R.

`BasisElement(R, i)`

Given R a subalgebra of $M_n(S)$, return the i-th element of the S-basis of R, where i must be between 1 and the dimension of R.

`Coordinates(R, X)`

Assuming that R is a subalgebra of $M_n(S)$, and given an element X of R, return the coordinates of X with respect to the basis of R. If R has dimension k over its coefficient ring S, and R has basis $U_1, \ldots, U_k$, the coordinates are returned as the unique sequence $[a_1, \ldots, a_k]$ of elements of S such that $X = a_1U_1 + \ldots + a_rU_r$.

83.9.2 Intersection of Subalgebras

`R meet T`

Given algebras R and S that are subalgebras of the same complete algebra $M_n(S)$, where S is a PIR, this operator constructs their intersection.

83.9.3 Membership and Equality

The operations described here assume that the matrix algebra is defined over a principal ideal ring.

`x in R`
`X subset R`
`T subset R`

Given a matrix x (set of matrices X, matrix algebra T) and a matrix algebra R all belonging to a common matrix algebra defined over a PIR, return `true` if x (X, T, respectively) is contained in R, `false` otherwise.

`x notin R`
`X notsubset R`
`T notsubset R`

Given a matrix x (set of matrices X, matrix algebra T) and a matrix algebra R all belonging to a common matrix algebra defined over a PIR, return `true` if x (X, T, respectively) is not contained in R, `false` otherwise.

`R eq T`

Given a matrix algebra R, and a matrix algebra T, return `true` if R is equal to T, `false` otherwise.

`R ne T`

Given a matrix algebra R and a matrix algebra T, return `true` if R is not equal to T, `false` otherwise.

83.10 Accessing and Modifying a Matrix

83.10.1 Indexing

`a[i]`

Given an element a belonging to the matrix algebra R over the ring S, return the i-th row of a as an element of the natural S-module associated with R.

`a[i] := u`

Given an element a belonging to the matrix algebra R over the ring S, an integer i in the range $[1, n]$ and an element u of the natural S-module associated with R, replace the i-th row of a by the vector u.

`a[i, j]`

Given an element a belonging to the matrix algebra R over the ring S, return the (i, j)-th entry of a as an element of S.

`a[i, j] := t`

Given an element a belonging to the matrix algebra R over the ring S, integers i and j in the range $[1, n]$, and an element t of S, replace the (i, j)-th entry of a by t.

`ElementToSequence(a)`
`Eltseq(a)`

Given an element a of the matrix algebra R over S, where $a = (a_{ij})$, $1 \leq i, j \leq n$, return a as the sequence of elements of S:

$$[a_{11}, \ldots, a_{1n}, a_{21}, \ldots, a_{2n}, \ldots, a_{n1}, \ldots, a_{nn}].$$

83.10.2 Extracting and Inserting Blocks

`Submatrix(a, i, j, p, q)`

`ExtractBlock(a, i, j, p, q)`

Given a matrix a belonging to a subalgebra of $M_n(S)$ and integers i, j, p and q satisfying the conditions, $1 \leq i + p \leq m$, $1 \leq j + q \leq n$, create the matrix b consisting of the $p \times q$ submatrix of a whose first entry is the (i, j)-th entry of a. If $p \neq q$, the matrix b is created as an element of $\mathrm{Hom}(P, Q)$, where $\mathrm{Rank}(P) = p$, $\mathrm{Rank}(Q) = q$. Otherwise it is created as an element of $M_p(S)$.

`InsertBlock(~a, b, i, j)`

(Procedure.) Given that the matrix a belongs to a subalgebra of $M_n(S)$ and the $p \times q$ matrix b is also over S, the integers i, j, p and q must satisfy the conditions, $1 \leq i + p \leq m$, $1 \leq j + q \leq n$. This procedure modifies a so that the $p \times q$ block beginning at the (i, j)-th entry of a is replaced by b.

83.10.3 Joining Matrices

`HorizontalJoin(X, Y)`

Given matrices X with r rows and c columns, and Y with r rows and d columns, both over the same coefficient ring R, return the matrix over R with r rows and $(c + d)$ columns obtained by joining X and Y horizontally (placing Y to the right of X).

`HorizontalJoin(Q)`

Given a sequence Q of matrices, each having the same number of rows and being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q horizontally in order.

`VerticalJoin(X, Y)`

Given matrices X with r rows and c columns and Y with s rows and c columns, both over the same coefficient ring R, return the matrix with $(r + s)$ rows and c columns over R obtained by joining X and Y vertically (placing Y underneath X).

`VerticalJoin(Q)`

Given a sequence Q of matrices, each having the same number of columns and being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q vertically in order.

`DiagonalJoin(X, Y)`

Given matrices X with a rows and b columns and Y with c rows and d columns, both over the same coefficient ring R, return the matrix with $(a+c)$ rows and $(b+d)$ columns over R obtained by joining X and Y diagonally (placing Y diagonally to the right of and underneath X, with zero blocks above and below the diagonal).

`DiagonalJoin(Q)`

Given a sequence Q of matrices, each being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q diagonally in order.

83.10.4 Row and Column Operations

For the following operations, a is an element of a subring of the matrix algebra $M_n(S)$, u is a non-zero element of S, and i and j are integers in the range $[1, n]$. Each of the operations described here acts on the matrix in place, and is therefore implemented as a procedure.

`SwapRows(~a, i, j)`

Mutate the matrix a by interchanging rows i and j.

`MultiplyRow(~a, u, j)`

Mutate the matrix a by multiplying row j by the scalar u.

`AddRow(~a, u, i, j)`

Mutate the matrix a by adding u times row i to row j.

`SwapColumns(~a, i, j)`

Mutate the matrix a by interchanging columns i and j.

`MultiplyColumn(~a, u, i)`

Mutate the matrix a by multiplying column i by the scalar u.

`AddColumn(~a, u, i, j)`

Mutate the matrix a by adding u times column i to column j.

83.11 Canonical Forms

83.11.1 Canonical Forms for Matrices over Euclidean Domains

The functions given here apply to matrices defined over Euclidean Domains. See also the section on Reduction in the Lattices chapter for a description of the function `LLL` and related functions.

`EchelonForm(a)`

The (row) echelon form of matrix a belonging to a submodule of the module $M_n(S)$. This function returns two values:

(a) The (row) echelon form e of a; and

(b) A matrix b such that $b * a = e$, i.e. b is a product of elementary matrices that transforms a into echelon form.

`ElementaryDivisors(a)`

The elementary divisors of the matrix a belonging to a submodule of the module $M_n(S)$. The divisors are returned as a sequence $[e_1, \ldots, e_d]$, $e_i | e_{i+1}$ $(i = 1, \ldots, d-1)$ of d elements of R (which may include ones), where d is the rank of a. If R is a field, the result is always the sequence of r ones, where r is the rank of a.

`HermiteForm(X)`

`Al`	MonStg	*Default :* "*LLL*"
`Optimize`	BoolElt	*Default :* `true`
`Integral`	BoolElt	*Default :* `true`

The row Hermite normal form of an matrix X belonging to the matrix algebra $M_n(R)$. The coefficient ring R must be an Euclidean domain. This function returns two values:

(a) The Hermite normal form H of X; and

(b) A unimodular matrix T such that $T \cdot X = H$, i.e., T is the product of elementary matrices which transforms X into Hermite normal form.

If R is the ring of integers $\mathbf{Z}$ and the matrix T is requested (i.e., if an assignment statement is used with two variables on the left side), then the LLL algorithm will be used by default to improve T (using the kernel of X) so that the size of its entries are very small. If the parameter `Optimize` is set to `false`, then this will not happen (which will be faster but the entries of T will not be as small). If the parameter `Integral` is set to `true`, then the integral (de Weger) LLL method will be used in the LLL step, instead of the default floating point method. The integral method will often be faster if the rank of the kernel of X is very large (say 200 or more).

If R is the ring of integers $\mathbf{Z}$ and the parameter `Al` is set to the string `"Sort"`, then the sorting-gcd algorithm will be used. However, the new algorithm will practically always perform better than the sorting-gcd algorithm.

`SmithForm(a)`

The Smith normal form for the matrix a belonging to a submodule of the module $M_n(S)$, where S is a Euclidean Domain. This function returns three values:

(a) The Smith normal form s of a; and

(b) Unimodular matrices b and c such that $b * a * c = s$, i.e. b and c are matrices that transform a into Smith normal form.

Example H83E6

We illustrate some of these operations in the context of the algebra $M_4(K)$, where K is the field $\mathbf{F}_8$.

```
> K<w> := FiniteField(8);
> M := MatrixAlgebra(K, 4);
> A := M ! [1, w, w^5, 0,  w^3, w^4, w, 1,  w^6, w^3, 1, w^4, 1, w, 1, w ];
```

```
> A;
[  1   w w^5   0]
[w^3 w^4   w   1]
[w^6 w^3   1 w^4]
[  1   w   1   w]
> EchelonForm(A);
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
```

83.11.2 Canonical Forms for Matrices over a Field

The functions in this group apply to elements of matrix algebras whose coefficient rings are fields which allow factorization of univariate polynomials over them.

`PrimaryRationalForm(a)`

The primary rational canonical form of a matrix a belonging to $M_n(K)$, where the coefficient ring K must be a field allowing factorization of univariate polynomials over it. Each block corresponds to a power of an irreducible polynomial. This function returns three values:

(a) The primary rational canonical form p of a;

(b) A non-singular matrix t such that $t * a * t^{-1} = p$;

(c) A sequence of pairs corresponding to the blocks of p where each pair consists of the irreducible polynomial and multiplicity making up the block.

`JordanForm(a)`

The (generalized) Jordan canonical form for the matrix a belonging to the algebra $M_n(K)$, where the coefficient ring K must be a field allowing factorization of univariate polynomials over it. This function returns three values:

(a) The (generalized) Jordan canonical form j of a;

(b) A non-singular matrix t such that $t * a * t^{-1} = j$;

(c) A sequence of pairs corresponding to the blocks of j where each pair consists of the irreducible polynomial and multiplicity making up the block.

`RationalForm(a)`

The rational canonical form of a matrix a belonging to $M_n(K)$, where the coefficient ring K must be a field allowing factorization of univariate polynomials over it. For each block before the last block, the polynomial corresponding to that block divides the polynomial corresponding to the next block. This function returns three values:

(a) The rational canonical form f of a;

(b) A non-singular matrix t such that $t * a * t^{-1} = f$;

(c) A sequence containing the polynomials corresponding to each block (each non-last one dividing the next).

`PrimaryInvariantFactors(a)`

The primary invariant factors of the matrix a. This is the same as the third return value of `PrimaryRationalForm(a)` or `JordanForm(a)`. The coefficient ring must be a field allowing factorization of univariate polynomials over it.

`InvariantFactors(a)`

The invariant factors of the matrix a. This is the same as the third return value of `RationalForm(a)`. The coefficient ring must be a field allowing factorization of univariate polynomials over it.

`IsSimilar(a, b)`

Returns `true` iff the matrix a is similar to the matrix b. If a is similar to b, a transformation matrix t is also returned with $t * a * t^{-1} = b$. The coefficient ring must be a field allowing factorization of univariate polynomials over it.

Example H83E7

We consider the algebra $M_5(P)$, where P is the polynomial ring in indeterminate x over the field $\mathbf{F}_5$. We take the matrix having $x^i + x^j$ in its (i, j)-th position.

```
> K := GaloisField(5);
> P<x> := PolynomialAlgebra(K);
> M := MatrixAlgebra(P, 5);
> a := M ! [x^i + x^j: i, j in [1..5]];
> a;

2

Example H83E8

We construct a 5 by 5 matrix over the finite field with 5 elements and then calculate various canonical forms. We verify the correctness of the polynomial invariant factors corresponding to the rational form by calculating the Smith form of the characteristic matrix of the original matrix.

```
> K := GF(5);
> P<x> := PolynomialRing(K);
> A := MatrixAlgebra(K, 5);
> a := A !
> [
>     0, 2, 4, 2, 0,
>     2, 2, 2, 3, 3,
>     3, 4, 4, 1, 3,
>     0, 0, 0, 0, 1,
>     0, 0, 0, 1, 0
> ];
> a;
[0 2 4 2 0]
[2 2 2 3 3]
[3 4 4 1 3]
[0 0 0 0 1]
[0 0 0 1 0]
> PrimaryInvariantFactors(a);
[
    <x + 1, 1>,
    <x + 1, 1>,
    <x + 4, 1>,
    <x + 4, 1>,
    <x + 4, 1>
]
> r, t, f := RationalForm(a);
> r;
[1 0 0 0 0]
[0 0 1 0 0]
[0 1 0 0 0]
[0 0 0 0 1]
[0 0 0 1 0]
> t;
[1 3 0 2 1]
[2 1 2 2 0]
[3 4 3 4 1]
[1 0 0 0 0]
[0 2 4 2 0]
> f;

```

83.12 Diagonalising Commutative Algebras over a Field

The functions in this group apply to (elements of) matrix algebras whose coefficient rings are fields which allow the construction of splitting fields of univariate polynomials over them. Specifically, the base field must be the rationals, a number field, a finite field, or an algebraically closed field.

`CommonEigenspaces(Q)`

The common eigenspaces of the sequence Q of pairwise-commuting matrices. If the first sequence returned is V and the second is E, then $E[i][j]$ is the eigenvalue of $Q[i]$ corresponding to the common eigenspace $V[j]$.

`CommonEigenspaces(A)`

The common eigenspaces of the commutative matrix algebra A. If the first sequence returned is V and the second is E, then $E[i][j]$ is the eigenvalue of $A.i$ corresponding to the common eigenspace $V[j]$.

`Diagonalisation(Q)`

`Diagonalization(Q)`

The diagonalisation of the sequence Q of pairwise-commuting matrices. That is, a sequence of diagonal matrices of the form $[P * Q[1] * P^{-1}, P * Q[2] * P^{-1}, \ldots]$. The second value returned is the matrix P. Note that the returned values may have a larger base field than the input.

`Diagonalisation(A)`

`Diagonalization(A)`

The diagonalisation of the commutative matrix algebra A. That is, an algebra with diagonal generators $[P * A.1 * P^{-1}, P * A.2 * P^{-1}, \ldots]$. The second value returned is the matrix P.

Example H83E9

```
> M := MatrixAlgebra(Rationals(),2);
> x := M![0,1,-2,0];
> y := M![0,3,-6,0];
> CommonEigenspaces([x,y]);

```

83.13 Solutions of Systems of Linear Equations

`IsConsistent(A, w)`

Given a matrix A belonging to $M_n(R)$ and a vector w belonging to the tuple module $R^{(n)}$, return `true` iff the system of linear equations $v * A = w$ is consistent. If the system is consistent, then the function will also return:

(a) A particular solution v;

(b) The kernel K of A so that $(v + k) * A = w$ for $k \in K$.

`IsConsistent(A, W)`

Given a matrix A belonging to $M_n(R)$ and a sequence W of vectors belonging to the tuple module $R^{(m)}$, return `true` iff the system of linear equations $V[i] * A = W[i]$ for each i is consistent. If the systems are all consistent, then the function will also return:

(a) A solution sequence V;

(b) The kernel K of A so that $(V[i] + k) * A = W[i]$ for $k \in K$.

`Solution(A, w)`

Given a matrix A belonging to $M_n(R)$ and a vector w belonging to the tuple module $R^{(n)}$, solve the system of linear equations $v*A = w$. The function returns two values:

(a) A particular solution v;

(b) The kernel K of A so that $(v + k) * A = w$ for $k \in K$.

`Solution(A, W)`

Given a matrix A belonging to $M_n(R)$ and a sequence W of vectors belonging to the tuple module $R^{(n)}$, solve the system of linear equations $V[i] * A = W[i]$ for each i. The function returns two values:

(a) A solution sequence V;

(b) The kernel K of A so that $(V[i] + k) * A = W[i]$ for $k \in K$.

83.14 Presentations for Matrix Algebras

Magma has the capability of constructing a presentation for an algebra A generated by a collection $\alpha_1, \ldots, \alpha_t$ of $n \times n$ matrices over a finite field k. The presentation has the form

$$A \cong P/I$$

where P is a free algebra in noncommuting variable and I is a two-sided ideal in P. The presentation is obtained by computing a set of primitive idempotents for the algebra and extracting generators for the radical of the algebra. For such an algebra there is a sequence

$$0 \longrightarrow \mathrm{Rad}(A) \longrightarrow A \longrightarrow A/\mathrm{Rad}(A) \longrightarrow 0$$

which is split in the sense that $A/\mathrm{Rad}(A)$ is a subalgebra A. Moreover, $A/\mathrm{Rad}(A)$ is a direct sum of complete matrix algebras A_i over extensions K_i of the field k. Each complete matrix algebra A_i is generated by two elements b_i and t_i. The element b_i has minimal rank and $b_i^{n_i-1} = e_i$ is a primitive idempotent where n_i is the number of elements in the field K_i. That is, b_i is a generator for the multiplicative group of nonzero elements of $e_i A_i e_i \cong K_i$. The element t_i is conjugate to a permutation matrix of degree n_i in A_i. The elements $z_1, \ldots, z_s$ are generators of the radical of A. These elements are computed so as to lie in the condensed algebra eAe where $e = \sum e_i$.

The calculation produces also a set of generators and relations for the condensed algebra eAe. This algebra is Morita equivalent to A, and hence shares many of the same homological properties of the algebra A.

In the course of obtaining the presentation, several aspects of the algebra are computed.

83.14.1 Quotients and Idempotents

`NaturalFreeAlgebraCover(A)`

Returns the map of a free algebra onto the matrix algebra A, such that the variables of the free algebra go to the generators of A.

`SimpleQuotientAlgebras(A)`

The simple quotient algebras of the matrix algebra A. The output is a record having the following fields:

(a) The actual simple algebras that are the quotients of the algebra A. The function returns the sequence of mappings from the natural free-algebra cover of A to the quotients. The variable corresponding to a generator of A is mapped to the corresponding generator of the quotient. (field name `SimpleQuotients`)

(b) The degrees of the quotients as matrix algebras over their centers (field name `DegreesOverCenters`).

(c) The degrees of the extension of center of the quotient algebra over the base field of A (field name `DegreesOfCenters`).

(d) The number of elements in the center of the quotient algebra (field name `OrdersOfCenters`).

`PrimitiveIdempotentData(A)`

The initial data for a decomposition of the matrix algebra A. The output is a sequence of records, one for each simple quotient algebra of A, each consisting of the following fields.

(a) `AlgebraIdempotent` : An idempotent whose image in the simple quotient is the identity matrix.

(b) `PrimitiveIdempotent` : A primitive idempotents whose image in the quotient is primitive.

(c) `PrimitiveIdempotentOnQuotient` : The image of the primitive idempotent in the quotient algebra.

(d) `FieldGenerator` : A multiple of the primitive idempotent which is a field generator for the center of the algebra.

(e) `FieldGeneratorOnQuotient` : The image of the field generator in the quotient algebra.

(f) `GeneratingPolForCenter` : The minimal polynomial for the matrix of the field generator.

`PrimitiveIdempotents(A)`

A list of primitive idempotent for the matrix algebra A, one idempotent for each irreducible module.

`RanksOfPrimitiveIdempotents(A)`

The sequence of ranks of the primitive idempotents for the matrix algebra A.

`NaturalFreeAlgebraCover(A)`

Returns the map of a free algebra onto the matrix algebra A, such that the variables of the free algebra go the generators of the algebra.

`CondensedAlgebra(A)`

Returns the algebra eAe where e is a sum of primitive idempotents, one for each simple A-module.

Example H83E10

We form a matrix algebra over the field with three elements generated by two elements. The algebra is block upper triangular, where the upper left block is a field extension of degree three and the lower block is a filed extension of degree 2.

```
> a1 := KMatrixSpace(GF(3),3,3)![0,1,0,0,0,1,-1,0,1];
> a2 := KMatrixSpace(GF(3),2,2)![0,1,-1,0];
> z1 := KMatrixSpace(GF(3),5,5)!0;
> z2 := InsertBlock(z1,a1,1,1);
> z2;
[0 1 0 0 0]
```

```
[0 0 1 0 0]
[2 0 1 0 0]
[0 0 0 0 0]
[0 0 0 0 0]
> z3 := InsertBlock(z1,a2,4,4);
```

$z2$ and $z3$ are the matrices of the field extensions. Next, add an entry to $z3$ that is an extension class between the two algebras.

```
> z3[1][4] := 1;
> z3;
[0 0 0 1 0]
[0 0 0 0 0]
[0 0 0 0 0]
[0 0 0 0 1]
[0 0 0 2 0]
> A := MatrixAlgebra<GF(3),5|z2,z3>;
```

We can check to see if the quotients came out as expected.

```
> SimpleQuotientAlgebras(A);
rec<recformat<SimpleQuotients: SeqEnum, DegreesOverCenters:
SeqEnum, DegreesOfCenters: SeqEnum, OrdersOfCenters: SeqEnum> |
    SimpleQuotients := [
        Mapping from: Free associative algebra of rank 2 over
                GF(3) to Matrix Algebra of degree 3 with 2
            generators over GF(3),
        Mapping from: Free associative algebra of rank 2 over
                GF(3) to Matrix Algebra of degree 2 with 2
            generators over GF(3)
    ],
    DegreesOverCenters := [ 1, 1 ],
    DegreesOfCenters := [ 3, 2 ],
    OrdersOfCenters := [ 27, 9 ]
```

Here are the idempotents.

```
> PrimitiveIdempotents(A);
[
    [1 0 0 0 0]
    [0 1 0 0 0]
    [0 0 1 0 2]
    [0 0 0 0 0]
    [0 0 0 0 0],
    [0 0 0 0 0]
    [0 0 0 0 0]
    [0 0 0 0 1]
    [0 0 0 1 0]
    [0 0 0 0 1]
```

```
]
```

Finally we have the Cartan matrix.

```
> CartanMatrix(A);
[1 3]
[0 1]
```

83.14.2 Generators and Presentations

We use the idempotents as the first step in the presentation process. The generators of the algebra consist of the field generators, each of which is a generator of the center of a simple quotient algebra multiplied by a corresponding primitive idempotent, permutation matrices, one for each simple quotient algebra and generators for the radical, all of which can be taken to be in the subalgebra eAe where e is the sum of one primitive idempotent for each simple quotient algebra.

For display purposes the variables for the free algebra of the presentations are given names. The variables $b.i$ represent field generators, while the $t.i$'s are permutation matrices and the $z.i$'s are the generators of the radical. The reader should be warned that these names are not suitable for input into other function.

`SemisimpleGeneratorData(A)`

The data on the semisimple generators of the algebra A, that is the generators in A of $A/Rad(A)$. Some of the output is intended for use in other functions. The return is a sequence of records, one for each simple quotient algebra. Each record consists of the following fields.

(a) `PowersOfFieldGenerators` : A record consisting of look-up tables for the powers of the field generators as elements both of the algebra A and the simple quotient algebra.

(b) `Permutation` : The permutation matrix of the quotient algebra as an element of A.

(c) `PermutationOnQuotient` : The permutation matrix on the quotient.

(d) `FieldGenerator` : The matrix of the field generator as an element of A.

(e) `FieldGeneratorOnQuotient` : The matrix of the field generator as an element of the quotient algebra.

(f) `PrimitiveIdempotent` : The matrix of the primitive idempotent on A.

(g) `PrimitiveIdempotentOnQuotient` : The matrix of the primitive idempotent on the quotient algebra.

(h) `GeneratingPolForCenter` : The Galois polynomial for the extension of the center of the quotient algebra over the base ring.

`AlgebraGenerators(A)`

The standard generators of the matrix algebra A. The output is a record consisting of the following fields.

(a) `FieldGenerators` : The sequence of matrices of the field generators, one for each simple quotient algebra.

(b) `PermutationMatrices` : The sequence of permutation matrices for the quotient algebras as elements of A, one for each quotient algebra.

(c) `PrimitiveIdempotents` : The sequence of primitive idempotents for A, one for each quotient algebra.

(d) `RadicalGenerators` : A set of generators for the radical of A arranged as a list of lists of generators of the radical of e_iAe_j for e_i and e_j primitive idempotents.

(e) `SequenceRadicalGenerators` : A sequence of minimal generators of radical of A.

(f) `GeneratingPolynomialsForCenters` : The galois polynomials of the centers over the base field.

(g) `StandardFormConjugationMatrices` : The matrices which conjugate the element of A into the standard form relative to the computed primitive idempotents for A.

`AlgebraStructure(A)`

The accumulated structure of the matrix algebra A. The return is a record with the following fields. Some of this information is saved to be used in other calculations.

(a) `FreeAlgebra` : The free algebra in the newly computed variables for the algebra.

(b) `RelationsIdeal` : The ideal of relations among the new computed generators.

(c) `StandardFreeAlgebraCover` : The map from the free algebra to A.

(d) `FieldGenerators` : The matrices in A of the generators of the centers of the simple quotient algebras of A.

(e) `PermutationMatrices` : The permutation matrices each of which together with the corresponding field generator, generates a simple quotient algebra as a subalgebra of A.

(f) `PrimitiveIdempotents` : The primitive idempotents, each of which is a power of the corresponding field generator.

(g) `RadicalGenerators` : A list of lists giving the generators of the radical of A which are in e_iAe_j where $\{e_i\}$ are the primitive idempotents.

(h) `CondensedRadicalBasis` : The condensed matrices in eAe of a basis for the radical of the algebra. The output is a list of lists giving the basis for e_iAe_j. Each entry in the list of lists is a tuple consisting of a matrix in the condensed algebra and the monomial which expresses this matrix as a product of the generators.

(i) `CondensedFieldGenerators` : The condensed matrices in eAe of the field generators.

(j) `FieldPolynomials` : The sequence of minimal polynomials of the field generators.

(k) `DegreesOfSimpleModules` : The dimensions of the Simple modules of A.

(l) `DegreeOfFieldExtensions` : The degrees of the centers of simple quotient algebras of A over the base field of A.

(m) `SimpleQuotientAlgebras` : The simple quotient algebras of A.

(n) `StandardFormConjugationMatrices` : The matrices which conjugate the algebra A into standard form with respect to the computed system of primitive idempotents.

`Presentation(A)`

The presentation in generators and relations of the matrix algebra A. The function returns the free algebra and the relations ideal calculated in the algebra structure program, as well as the map from the free algebra to A.

`StandardFormConjugationMatrices(A)`

Returns the pair (M and M^{-1}) of matrices that conjugate the matrix algebra A into standard form with respect to a chosen set of primitive idempotents.

`CondensationMatrices(A)`

The matrices, conjugating by which, gives the condensation of A.

`SequenceOfRadicalGenerators(A)`

The sequence of matrices of elements that generate the radical of A.

`CartanMatrix(A)`

The Cartan Matrix of the algebra A.

Example H83E11

In this example we form the permutation module M of the symmetric group G on seven letters by the Young subgroup that is the direct product H of two copies of the symmetric group on three letters. The algebra A is the image of the group algebra in the ring of endomorphisms of M.

```
> G := Sym(7);
> H := sub<G| G!(1,2,3),G!(1,2),G!(4,5,6), G!(4,5)>;
> M := PermutationModule(G, H, GF(5));
> M;
GModule M of dimension 140 over GF(5)
> A := Action(M);
```

We see that A has seven simple quotients.

```
> SimpleQuotientAlgebras(A);
```

```
rec<recformat<SimpleQuotients: SeqEnum, DegreesOverCenters:
SeqEnum, DegreesOfCenters: SeqEnum, OrdersOfCenters: SeqEnum> |
    SimpleQuotients := [
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 35 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 15 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 13 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 8 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 8 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 6 with 2
            generators over GF(5),
        Mapping from: Free associative algebra of rank 2 over
                GF(5) to Matrix Algebra of degree 1 with 2
            generators over GF(5)
    ],
    DegreesOverCenters := [ 35, 15, 13, 8, 8, 6, 1 ],
    DegreesOfCenters := [ 1, 1, 1, 1, 1, 1, 1 ],
    OrdersOfCenters := [ 5, 5, 5, 5, 5, 5, 5 ]
    >
> RanksOfPrimitiveIdempotents(A);
[ 1, 1, 3, 2, 1, 4, 3 ]
```

The condensed algbra of A is a much smaller object.

```
> B := CondensedAlgebra(A);
> B;
Matrix Algebra of degree 15 with 13 generators over GF(5)
> CartanMatrix(A);
[1 0 0 0 0 0 0]
[0 1 0 0 0 0 0]
[0 0 2 0 1 0 1]
[0 0 0 1 0 1 0]
[0 0 1 0 1 0 0]
[0 0 0 1 0 2 0]
[0 0 1 0 0 0 2]
```

From the Cartan Matrix we can see that A has four blocks. The first and second simple subalgebras are in blocks by themselves. The subalgebras numbers 3, 5, and 7 form another block as do the

subalgebras 4 and 6. Note that B, being Morita equivalent to A, has the same Cartan Matrix and the same block structure.

83.14.3 Solving the Word Problem

The presentation machinery also gives a test for membership in a matrix algebra. If A is a subalgebra of the $n \times n$ matrices generated by some collection of matrices, MAGMA can tell if any $n \times n$ matrix is an element of A. If the element is in A then MAGMA can write the element as a polynomial in the polynomial ring of the presentation.

`WordProblemData(A)`

The data needed for the solution to the word problem. The output is a list of lists of basis elements for the radical together with the corresponding monomials in the generators of the free algebra.

`WordProblem(A, x)`

Returns `true` if the matrix x is in the subalgebra A, and if true returns also an expression of the element x as a polynomial in the presentation of A.

Example H83E12

In this example we form the permutation module for the symmetric group G acting on the coset space of the normalizer H of Sylow 3-subgroup of G. The coefficients are in the field with two elements. The algebra A is the image of the group algebra in the endomorphism ring of the permutation module.

```
> G := Sym(5);
> H := Normalizer(G,Sylow(G,3));
> M := PermutationModule(G,H, GF(2));
> M;
GModule M of dimension 10 over GF(2)
> A := Action(M);
```

Here we get the presentation of A.

```
> P, I, mu  := Presentation(A);
> Dimension(P/I);
42
```

Thus the dimension of A is 42.

```
> CartanMatrix(A);
[1 0 1]
[0 1 0]
[1 0 2]
> B := CondensedAlgebra(A);
> Q, J, theta := Presentation(B);
```

The presentation of B has the form:

```
> J;
```

```
Two-sided ideal of Free associative algebra of rank 5 over GF(2)
Non-commutative Graded Lexicographical Order
Variables: b_1, b_2, b_3, z_1, z_2
Groebner basis:
[
    b_2^2 + b_2,
    b_2*b_3,
    b_2*z_1,
    b_2*z_2,
    b_3*b_2,
    b_3^2 + b_3,
    b_3*z_1,
    b_3*z_2 + z_2,
    z_1*b_2,
    z_1*b_3 + z_1,
    z_1^2,
    z_1*z_2,
    z_2*b_2,
    z_2*b_3,
    z_2^2,
    b_1 + b_2 + b_3 + 1
]
```

The matrix $A.1$ is the first of the original generators for A. We can check that $A.1$ is an element of the algebra generated by the computed generators of A.

```
> boo, y := WordProblem(A,A.1);
> boo;
true
```

The element y is the expression of $A.1$ as a polynomial in the free algebra P in the new computed generators for A.

```
> y;
t_1^4*b_1*t_1^3 + t_2^4*b_2*t_2^3 + t_1^4*b_1*t_1^2 +
    t_2^3*b_2*t_2^3 + t_1^2*b_1*t_1^3 + t_1^4*b_1*t_1 +
    t_2^2*b_2*t_2^3 + t_2^3*b_2*t_2^2 + t_2^4*b_2*t_2 +
    t_1^2*b_1*t_1^2 + t_1^3*b_1*t_1 + t_1^4*b_1 + t_1^4*z_1 +
    t_2*b_2*t_2^3 + t_2^2*b_2*t_2^2 + t_2^3*b_2*t_2 +
    t_1*b_1*t_1^2 + t_1^3*b_1 + t_3*z_2*t_1^2 + t_1^2*b_1 +
    t_2*b_2*t_2 + t_2^2*b_2 + t_1*b_1 + t_2*b_2 + t_3*b_3 +
    t_3*z_2
```

The mapping mu is the function from the free algebra P into A.

```
> mu(y);
[0 1 0 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 1 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0]
```

```
[0 0 0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 0 0 1]
[1 0 0 0 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0]
```

The ultimate check of the accuracy of the computation is that the polynomial expressions give back the original generators.

```
> mu(y) eq A.1;
true
```

Finally we can check whether a random 10×10 matrix is an element of A.

```
> b := Random(Generic(A));
> WordProblem(A,b);
false
```

84 GROUP ALGEBRAS

Chapter 84
GROUP ALGEBRAS

84.1 Introduction

Group algebras (or group rings) may be defined over any unital ring R and any group G in which elements have a canonical form (for example permutation groups, matrix groups or polycyclic groups). Basic operations, such as simple arithmetic of elements, may be applied in any such group algebra. Certain functions, however, place stricter requirements on R and G, such as requiring that R have a matrix echelon algorithm in MAGMA.

84.2 Construction of Group Algebras and their Elements

84.2.1 Construction of a Group Algebra

There are two different representations of group algebra elements used in MAGMA. Which is most suitable depends on the group G and on the operations required, and must be decided upon when the algebra is created.

The first representation, which requires that G is not too large, is to choose (once and for all) an ordering $(g_1, g_2, \ldots, g_n)$ of the elements of G (where $n = |G|$), and then to store elements of the group algebra $A = R[G]$ as coefficient vectors relative to the basis $(g_1, g_2, \ldots, g_n)$ of A. So an element $a = a_1 * g_1 + a_2 * g_2 + \ldots + a_n * g_n$ $(a_i \in R)$ of A will be stored as the vector $(a_1, a_2, \ldots, a_n)$. This makes for fast arithmetic and allows the use of matrix echelonization for dealing with subalgebras and ideals (if R has a matrix echelon algorithm).

The alternative representation, necessary when dealing with large groups, stores an element $a \in A = R[G]$ as a pair of parallel arrays giving the terms of the element. One array contains the nonzero coefficients of the element and the other contains their associated group elements. This representation allows group algebras to be defined over any group in which the elements have a canonical form, including potentially infinite matrix groups over a ring of characteristic 0 or even free groups. Note however, that operations in such algebras are limited, as the length of the representing arrays may grow exponentially with the number of multiplications performed.

`GroupAlgebra( R, G: parameters)`

`GroupAlgebra< R, G: parameters >`

`Rep`	MONSTGELT	*Default :*
`Table`	BOOLELT	*Default :*

Given a unital ring R and a group G (which is not a finitely presented group), create the group algebra $R[G]$. There are two optional arguments associated with this creation function.

The optional parameter `Rep` can be used to specify which representation should be chosen for elements of the algebra. Its possible values are `"Vector"` and `"Terms"`. If `Rep` is not assigned, then MAGMA chooses the vector representation if $|G| \leq 1000$ and the term representation otherwise. If `Rep` is set to `"Vector"`, MAGMA has to compute the order of G. If it does not succeed in that or the order is too large to construct vectors of this size, then an error message is displayed.

The second optional parameter `Table` can be used to specify whether or not the multiplication table of the group should be computed and stored upon creation of the algebra. Storing the multiplication table makes multiplication of algebra elements (and all other group algebra operations using this) much faster. Building this table does, however, increase the time needed to create the algebra. The table can only be stored if the vector representation of elements is used. If the `Table` parameter is not set, then MAGMA stores the multiplication table only if $G \leq 200$.

Example H84E1

We first construct the default group algebra $A = R[G]$ where R is the ring of integers and G is the symmetric group on three points.

```
> G := SymmetricGroup(3);
> R := Integers();
> A := GroupAlgebra( R, G );
> A;
Group algebra with vector representation and stored multiplication table
Coefficient ring: Integer Ring
Group: Permutation group G acting on a set of cardinality 3
    Order = 6 = 2 * 3
        (1, 2, 3)
        (1, 2)
```

Next we construct the group algebra $A = R[G]$ where $R = GF(5)$ and G is the dihedral group of order 100, given as a polycyclic group. This time we specify that the term representation should be used for elements.

```
> G := PCGroup( DihedralGroup(50) );
> A := GroupAlgebra( GF(5), G: Rep := "Terms" );
> A;
Group algebra with terms representation
Coefficient ring: Finite field of size 5
Group: GrpPC : G of order 100 = 2^2 * 5^2
    PC-Relations:
        G.1^2 = Id(G),
        G.2^2 = Id(G),
        G.3^5 = G.4,
        G.4^5 = Id(G),
        G.3^G.1 = G.3^4 * G.4^4,
        G.4^G.1 = G.4^4
```

84.2.2 Construction of a Group Algebra Element

`elt< A | r, g >`

Given a group algebra $A = R[G]$, a ring element $r \in R$ and a group element $g \in G$, create the element $r * g$ of A.

`A ! g`

Given a group element $g \in G$ create the element $1_R * g$ of the group algebra $A = R[G]$.

`A ! r`

Given a ring element $r \in R$, create the element $r * 1_G$ of the group algebra $A = R[G]$.

`A ! [`$c_1, \ldots, c_n$`]`

Given a group algebra $A = R[G]$ in vector representation and a sequence $[c_1, \ldots, c_n]$ of $n = |G|$ elements of R, create the element $c_1 * g_1 + \ldots + c_n * g_n$, where $(g_1, \ldots, g_n)$ is the fixed basis of A.

`Eta(A)`

For a group algebra $A = R[G]$ in vector representation, create the element $\sum_{g \in G} 1_R * g$ of A.

Example H84E2

We check that $Eta(A)/|G|$ is an idempotent in A (provided the characteristic of R does not divide the order of G).

```
> G := Alt(6);
> A := GroupAlgebra( GF(7), G );
> e := Eta(A) / #G;
> e^2 - e;
0
```

84.3 Construction of Subalgebras, Ideals and Quotient Algebras

Let $A = R[G]$ be a group algebra defined in MAGMA, where R is a unital ring with a matrix echelon algorithm and G is a group. If A was constructed to use the vector representation for its elements, then subalgebras and left, right and two-sided ideals of A can be constructed. If R is a field, then quotient algebras of A are also possible.

A subalgebra or ideal of a group algebra A is not in general a group algebra; hence, a different type is needed for these objects. Two possibilities are provided in MAGMA. The first is to construct the subalgebra or ideal to have type `AlgGrpSub`: a subalgebra (which may be an ideal) of a group algebra. Its elements are elements of the group algebra and it remains closely connected to its defining group algebra. By default, ideals of group algebras will be of this type.

The alternative is to create the subalgebra or ideal as an associative algebra given by structure constants (type `AlgAss`). The required structure constants are easily computable from the group algebra. This is the default MAGMA uses when creating subalgebras of a group algebra.

Regardless of the type given to a subalgebra or ideal, the inclusion map back into the group algebra is also provided.

```
sub< cat : A | L >
```

`cat` CAT *Default :* `AlgGrpSub`

Create the subalgebra S of the group algebra A generated by the elements defined by L, where L is a list of one or more items of the following types:

(a) an element of A;

(b) a set or sequence of elements of A;

(c) a subalgebra of A;

(d) a set or sequence of subalgebras of A;

(e) a sequence of ring elements specifying an element of A, as returned when the `ElementToSequence` (or `Eltseq`) function is applied to the element.

The constructor returns the subalgebra as an element of the category `cat`, where `cat` is either `AlgGrpSub` (the default) or `AlgAss`. As well as the subalgebra itself, the constructor returns the inclusion homomorphism $f : S \to A$.

```
lideal< cat : A | L >
```

`cat` CAT *Default :* `AlgGrpSub`

Create the left ideal of the group algebra A, generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the ideal as an element of the category `cat`, where `cat` is either `AlgGrpSub` (the default) or `AlgAss`. As well as the ideal itself, the constructor returns the inclusion homomorphism $f : I \to A$.

`rideal< cat : A | L >`

`cat` CAT *Default :* `AlgGrpSub`

Create the right ideal of the group algebra A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the ideal as an element of the category `cat`, where `cat` is either `AlgGrpSub` (the default) or `AlgAss`. As well as the ideal itself, the constructor returns the inclusion homomorphism $f : I \to A$.

`ideal< cat : A | L >`

`cat` CAT *Default :* `AlgGrpSub`

Create the (two-sided) ideal I of the group algebra A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the ideal as an element of the category `cat`, where `cat` is either `AlgGrpSub` (the default) or `AlgAss`. As well as the ideal itself, the constructor returns the inclusion homomorphism $f : I \to A$.

The above operations can also be applied with a subalgebra (type `AlgGrpSub`) S in place of the group algebra A. In this case the subalgebra and ideal closures are taken in S.

`a * I`

For a right ideal I of the group algebra A construct the right ideal $\{a * b : b \in I\}$.

`I * a`

For a left ideal I of the group algebra A construct the left ideal $\{b * a : b \in I\}$.

`quo< A | L >`

Create the quotient of the group algebra A by the ideal of A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the quotient as an associative algebra. As well as the quotient Q itself, the constructor returns the natural homomorphism $f : A \to Q$.

`A / S`

The quotient of the algebra A by the ideal closure of its subalgebra S.

Example H84E3

We demonstrate how the degrees of the absolutely irreducible characters of a group can be found by computing the Wedderburn decomposition of the group algebra over a suitable finite field. Of course, this is neither the smartest nor the quickest way to get this information. In the example we deal with an extraspecial group of order 3^3.

```
> G := ExtraSpecialGroup(3, 1);
> Exponent(G);
```

```
3
```

We have to choose a finite field that contains the roots of unity that may be required by the absolutely irreducible characters. This is the case for $GF(q)$ if the exponent of G divides $q-1$. In our example, $q = 4$ or $q = 7$ are possible choices.

```
> FG := GroupAlgebra(GF(4), G);
> FG;
Group algebra with vector representation and stored multiplication table
Coefficient ring: Finite field of size 2^2
Group: Permutation group G acting on a set of cardinality 27
    Order = 27 = 3^3
        (1, 19, 10)(2, 20, 11)(3, 21, 12)(4, 22, 13)(5, 23, 14)(6, 24, 15)(7,
            25, 16)(8, 26, 17)(9, 27, 18)
        (1, 7, 4)(2, 8, 5)(3, 9, 6)(10, 18, 14)(11, 16, 15)(12, 17, 13)(19, 26,
            24)(20, 27, 22)(21, 25, 23)
        (1, 3, 2)(4, 6, 5)(7, 9, 8)(10, 12, 11)(13, 15, 14)(16, 18, 17)(19, 21,
            20)(22, 24, 23)(25, 27, 26)
> MI := MinimalIdeals(FG);
> #MI;
11
```

The minimal ideals are the simple Wedderburn components of the group algebra, corresponding to the absolutely irreducible characters of the group, and their dimensions are the squares of the character degrees.

```
> [ Isqrt(Dimension(I)) : I in MI ];
[ 1, 1, 1, 1, 1, 1, 1, 1, 1, 3, 3 ]
```

Hence, there are 9 linear characters and two of degree 3 (which we might have concluded immediately from the fact that the derived quotient of G has order 9).

84.4 Operations on Group Algebras and their Subalgebras

84.4.1 Operations on Group Algebras

The operations in this section can only be applied to a full group algebra. Functions accepting also a subalgebra of type `AlgGrpSub` are dealt with in the next section.

`Algebra(A)`

For a group algebra A given in vector representation, construct the associative structure constant algebra B isomorphic to A together with the isomorphism $A \to B$.

`AugmentationMap(A)`

The augmentation map of A. That is, the map $A \to R : \sum_{g \in G} r_g * g \to \sum_{g \in G} r_g$.

`AugmentationIdeal(A)`

The augmentation ideal of the group algebra A given in vector representation. This is defined as the kernel of the augmentation map.

`RepresentationType(A)`

Given a group algebra A, return either `"Vector"` or `"Terms"` depending on which representation is used for the elements of A.

`ChangeRepresentationType(A, Rep)`

Given a group algebra A, construct an isomorphic group algebra B in which the elements are represented as specified by `Rep` which may be `"Vector"` or `"Terms"`, together with the homomorphism from A to B.

`ConstructTable(A)`

Procedure which, given a group algebra $A = R[G]$ in vector representation, constructs the multiplication table for the group G to speed up multiplication in A. If the multiplication table already exists, nothing is done.

`CoefficientRing(A)`

`BaseRing(A)`

The coefficient ring (base ring) of A.

84.4.2 Operations on Subalgebras of Group Algebras

The functions in this section can be applied to group algebras and their subalgebras of type `AlgGrpSub`.

`S ! 1`

Create the identity element of the group algebra (subalgebra) S. Note that for a proper subalgebra of the full group algebra this may be different from the identity element of the group.

`Group(S)`

The group G for the group algebra (subalgebra) S.

`GroupAlgebra(S)`

The group algebra of which S is a subalgebra.

`Module(S)`

For a subalgebra S of the group algebra $A = R[G]$, return the submodule of the module underlying A which corresponds to S. This is an R-module of dimension `Dimension(S)` and degree `Dimension(A)`. Also returns (as a second return value) the natural map from the subalgebra to the module.

`CoefficientRing(A)`

`BaseRing(A)`

The coefficient ring (base ring) of A.

`BasisMatrix(S)`

For a subalgebra S of the group algebra $A = R[G]$ return the coefficient matrix of the basis of S with respect to the basis of A. If S has dimension m this is an $m \times |G|$-matrix over R where the i-th row are the coefficients of the i-th basis vector of S with respect to the fixed basis of A.

`Coordinates(S, a)`

Given an element a which lies in the subalgebra S, return a sequence giving the coordinates of a with respect to the basis of S.

`IsLeftIdeal(S)`

Returns `true` if S is a left ideal of its group algebra; otherwise `false`.

`IsRightIdeal(S)`

Returns `true` if S is a right ideal of its group algebra; otherwise `false`.

`IsIdeal(S)`

Returns `true` if S is a (two-sided) ideal of its group algebra; otherwise `false`.

`Centraliser(S)`

`Centralizer(S)`

The centralizer of the subalgebra S of a group algebra A (in A).

`Idealiser(S)`

`Idealizer(S)`

The largest subalgebra T of A such that S is an ideal in T.

`LeftAnnihilator(S)`

For a subalgebra S of the group algebra A construct the left annihilator of S, that is, the subalgebra of A consisting of all elements a such that $a * s = 0$ for all $s \in S$.

`RightAnnihilator(S)`

For a subalgebra S of the group algebra A construct the right annihilator of S, that is, the subalgebra of A consisting of all elements a such that $s * a = 0$ for all $s \in S$.

Example H84E4

We construct the group algebra of an elementary abelian group over $GF(2)$ and get its Jacobson ideal.

```
> A := AbelianGroup([2,2,2,2,2]);
> FG := GroupAlgebra(GF(2), A);
> J := JacobsonRadical(FG);
> J;
Ideal of dimension 31 of the group algebra FG
```

We now check that the Jacobson radical is nilpotent and get its nilpotency class.

```
> JPow := [ J ];
> I := J;
> while Dimension(I) ne 0 do
>     I := I*J;
>     Append(~JPow, I);
> end while;
> [ Dimension(I) : I in JPow ];
[ 31, 26, 16, 6, 1, 0 ]
```

Thus, J is nilpotent of class 6. However, every non-zero element of J is of course nilpotent of class 2.

```
> IsNilpotent(Random(J));
true 2
```

84.5 Operations on Elements

The operations in this section can be applied to elements of either a group algebra or of a group algebra subalgebra of type `AlgGrpSub`. Only those operations are listed, which are additional to those available for general algebras.

`a + r`
`r + a`

The sum of the group algebra element $a \in R[G]$ and the scalar $r \in R$.

`a + g`
`g + a`

The sum of the group algebra element $a \in R[G]$ and the group element $g \in G$.

`a - r`
`r - a`

The difference of the group algebra element $a \in R[G]$ and the scalar $r \in R$.

`a - g`
`g - a`

The difference of the group algebra element $a \in R[G]$ and the group element $g \in G$.

`a * r`
`r * a`

The product of the group algebra element $a \in R[G]$ and the scalar $r \in R$.

`g * a`
`a * g`

The product of the group algebra element $a \in R[G]$ and the group element $g \in G$.

`Support(a)`

The support of a; that is, the sequence of group elements whose coefficients in a are non-zero.

`Trace(a)`

The trace of a; that is, the coefficient of 1_G in a.

`Augmentation(a)`

The augmentation of the group algebra element a; that is, $\sum_{g \in G} r_g$ where $a = \sum_{g \in G} r_g * g$.

`Involution(a)`

If $a = \sum_{g \in G} r_g * g$, returns $\sum_{g \in G} r_g * g^{-1}$.

`Coefficient(a, g)`
`a[g]`

The coefficient of $g \in G$ in $a \in R[G]$.

`ElementToSequence(a)`
`Eltseq(a)`

If a is an element from a group algebra A given in vector representation, this returns the sequence of coefficients with respect to the fixed basis of A. If A is given in terms representation, this returns a sequence of tuples, where the second entry is a group element and the first is the coefficient of that group element in a.

`Coefficients(a)`

For an element a from a group algebra A given in vector representation, this returns the sequence of coefficients with respect to the fixed basis of A.

Centraliser(a)
Centralizer(a)

The centralizer in the group algebra A of the element a of A.

Centraliser(S, a)
Centralizer(S, a)

The centralizer of the element a (of a group algebra A) in the subalgebra S of A.

Example H84E5

We use the group algebra to determine the diameter of the Cayley graph of a group.

```
> G := Alt(6);
> QG := GroupAlgebra( Rationals(), G );
> e := QG!1 + &+[ QG!g : g in Generators(G) ];
> e;
Id(G) + (1, 2)(3, 4, 5, 6) + (1, 2, 3)
```

The group elements that can be expressed as words of length at most n in the generators of G have non-zero coefficient in e^n. The following function returns for a group algebra element e a sequence with the cardinalities of the supports of e^n and breaks when the group order is reached.

```
> wordcount := function(e)
>     f := e;
>     count := [ #Support(f) ];
>     while count[#count] lt #Group(Parent(e)) do
>         f *:= e;
>         Append(~count, #Support(f));
>     end while;
>     return count;
> end function;
```

Now apply this function to the above defined element:

```
> wordcount( e );
[ 3, 7, 14, 26, 47, 83, 140, 219, 293, 345, 360 ]
```

Thus, every element in A_6 can be expressed as a word of length at most 11 in the generators $(1,2)(3,4,5,6)$ and $(1,2,3)$. A better 2-generator set is for example $(1,2,3,4,5)$ and $(1,5,3,6,4)$, where all elements can be expressed as words of length at most 10 and this is in fact optimal. A worst 2-generator set is given by $(1,2)(3,4)$ and $(1,5,3,2)(4,6)$.

```
> wordcount( QG!1 + G!(1,2,3,4,5) + G!(1,5,3,6,4) );
[ 3, 7, 15, 31, 60, 109, 183, 274, 350, 360 ]
> wordcount( QG!1 + G!(1,2)(3,4) + G!(1,5,3,2)(4,6) );
[ 3, 6, 11, 18, 28, 43, 63, 88, 119, 158, 206, 255, 297, 329, 352, 360 ]
```

Example H84E6

The group algebra can also be used to investigate the random distribution of words of a certain length in the generators of the group.

```
> M11 := sub< Sym(11) | (1,11,9,10,4,3,7,2,6,5,8), (1,5,6,3,4,2,7,11,9,10,8) >;
> A := GroupAlgebra(RealField(16), M11 : Rep := "Vector");
> A;
Group algebra with vector representation
Coefficient ring: Real Field of precision 16
Group: Permutation group M11 acting on a set of cardinality 11
    Order = 7920 = 2^4 * 3^2 * 5 * 11
        (1, 11, 9, 10, 4, 3, 7, 2, 6, 5, 8)
        (1, 5, 6, 3, 4, 2, 7, 11, 9, 10, 8)
> e := (A!M11.1 + A!M11.2) / 2.0;
> eta := Eta(A) / #M11;
```

For growing n, the words of length n in the generators of `M11` converge towards a random distribution iff $\texttt{e}^n$ converges towards `eta`. We look at the quadratic differences of the coefficients of $\texttt{e}^n$`-eta` for $n = 10, 20, 30, 40, 50$.

```
> e10 := e^10;
> f := A!1;
> for i in [1..5] do
>     f *:= e10;
>     print &+[ c^2 : c in Eltseq(f - eta) ];
> end for;
0.0012050667195213
1.289719354694155e-5
5.9390965208879e-7
3.394099291966e-8
2.19432454574986e-9
```

85 BASIC ALGEBRAS

Chapter 85
BASIC ALGEBRAS

85.1 Introduction

A basic algebra is a finite dimensional algebra A over a field, all of whose simple modules have dimension one. In the literature such an algebra is known as a "split" basic algebra. Every algebra is Morita equivalent to a basic algebra, though a field extension may be necessary to obtain the split basic algebra. MAGMA has several functions that create the basic algebras corresponding to algebras of different types.

The type `AlgBas` in MAGMA is optimized for the purposes of doing homological calculations. A basic algebra A is generated by elements $a_1, a_2, \ldots, a_t$ where $a_1, \ldots, a_s$ are the primitive idempotent generators and $a_{s+1}, \ldots, a_t$ are the nonidempotent generators. Each nonidempotent generator, a_k must have the property that $a_i * a_k * a_j = a_k$ for specific idempotent generators a_i and a_j. The projective indecomposable modules have the form $P_i = a_i \cdot A$ for $i = 1, \ldots, s$ and the simple modules have the form $S_i = P_i/\mathrm{Rad}(P_i)$, where $\mathrm{Rad}(P_i)$ is the radical of P_i.

85.2 Basic Algebras

In the MAGMA implementation the algebra is given as the sequence of projective modules $P_1, \ldots, P_s$ together with a path tree for each projective module. A projective module consists of a matrix for each generator $a_1, a_2, \ldots, a_t$ giving the action of the generator on the vector space of the module. The basis $b_1, b_2, \ldots, b_n$ for the vector space of P_i is chosen so that each basis element is the image of a basis element of lower index under multiplication by a nonidempotent generator of A. The structure of the basis is recorded in the path tree which is a sequence $[< 1, i >, < j, k >, \ldots]$ of 2-tuples of length $n =$ `Dimension`(P_i). The first entry $< 1, i >$ indicates that $b_1 = b_1 * a_i$ where a_i is the primitive idempotent in the algebra A such that $P_i = A \cdot a_i$. Similarly, if entry number k in the path tree is $\langle u, v \rangle$ then $b_k = b_u * a_v$ where $v > s$ if $k > 1$.

85.2.1 Creation

The first function for creating a basic algebra is the most basic, in which the user supplies the projective modules and the path trees directly.

`BasicAlgebra(Q)`

Given a sequence $[Q_i, \ldots, Q_s]$ of 2-tuples such that each $Q_i =< M_i, T_i >$ consisting of a module for a matrix algebra M_i and a path tree T_i for M_i, the function creates the basic algebra whose projective modules are the first entries $M_1, \ldots, M_s$ and the path trees are the corresponding second entries.

The next two functions create a basic algebra from generators and relations. The user must, additionally, specify the quiver with relations, giving the number of idempotents and the beginning and end points of the arrows in the quiver.

`BasicAlgebra(F,R,s,P)`

Creates the basic algebra given by the presentation. Here F is a free algebra and R is the sequence of relation for the nonidempotent generators of the algebra. If the free algebra F is generated by elements $a_1, \ldots, a_t$, the function assumes that $a_1, \ldots, a_s$ are the mutually orthogonal primitive idempotents and it creates all of the appropriate relations including $a_1 + \ldots + a_s = 1$. The nonidempotent generators are then $a_{s+1}, \ldots, a_t$. So $\ell_k = \langle i, j \rangle$ for $i, j \leq s$ means that $a_{s+k} = a_i * a_{s+k} * a_j$. Each of the relations in R is given as a linear combination of words in the nonidempotent generators $a_{s+1}, \ldots, a_t \in F$. The sequence P is a sequence of 2-tuples, one for each nonidempotent generator, giving the beginning and ending nodes of the generator. That is, each tuple is the pair of indices of the idempotents which multiply as the identity on the nonidempotent generator on the left and on the right.

`BasicAlgebra(F,R)`

Creates the basic algebra of a local algebra from the presentation of the algebra. Here F is a free algebra whose variable represent the nonidempotent generators and R is the sequence of relations among those variables.

`TensorProduct(A, B)`

The tensor product of the basic algebras A and B.

The modular group algebra of a p-group is naturally a basic algebra. The next function create the basic algebra from the group information.

`BasicAlgebra(G, k)`

`BasicAlgebra(G, k)`

`BasicAlgebra(G)`

Given a finite p-group G and a finite field k of characteristic p, returns the group algebra kG in the form of a basic algebra. If no field k is supplied then the prime field of characteristic p is assumed to be the field of coefficients.

85.2.2 Special Basic Algebras

There are several functions that create basic algebras of special interest. The most basic of these creates the basic algebra that is Morita equivalent to a matrix algebra defined over a finite field by first condensing the algebra and then splitting the irreducible modules as needed.

Included among these constructions are the basic algebras of Schur algebras and Hecke algebras over finite fields. The Schur algebras arise in the representation theory of symmetric groups. The Schur algebras have finite global dimension and hence their ext-algebras have finite dimension. By a Hecke algebra, we mean the algebra of endomorphisms of a permutation module of a finite group.

`BasicAlgebra(A)`

`BasicAlgebraOfMatrixAlgebra(A)`

This function creates the split basic algebra of the matrix algebra A. The function first produces a presentation and condensed algebra for A. In the event that the field of coefficients k of A is not a splitting field, then the returned basic algebra is defined over the minimal extension of k that is a splitting field for A.

`BasicAlgebraOfEndomorphismAlgebra(M)`

Returns the split basic algebra of the endomorphism ring of the module M. In the event that the field of coefficients of M is not a splitting field for M, then the field is extended and the basic algebra is defined over the minimal extension needed to split M.

`BasicAlgebraOfHeckeAlgebra(G, H, F)`

Returns the basic algebra of the Hecke algebra which is the algebra of endomorphisms of the permutation module over G with point stabilizer H and field of coefficients F. In the event that F is not a splitting field then the field F is extended to a splitting field which is the field of coefficients of the returned basic algebra.

`BasicAlgebraOfSchurAlgebra(n, r, F)`

Creates the basic algebra of the Schur algebra $S(n, r)$ over the field F. The Schur algebra is the algebra of endomorphisms of the module over the symmetric group $Sym(r)$ that is the tensor product of r copies of a vector space V over F of dimension n, the group $Sym(r)$ acting by permuting the r copies.

`BasicAlgebraOfGroupAlgebra(G,F)`

`BasicAlgebraOfGroupAlgebra(G,F)`

`BasicAlgebraOfGroupAlgebra(G,F)`

The function returns the basic algebra of the group algebra of G with coefficients in the field F. The function requires the creation of the projective indecomposable FG-modules. In the event that the field F is not a splitting field for the irreducible FG-modules then the base ring of the returned algebra is the minimal extension of F that is necessary to get a splitting field.

`BasicAlgebra(S)`

Returns the basic algebra of the action algebra on the module which is the direct sum of the modules in the sequence S. In the event that the irreducible composition factors of the modules in S are not absolutely irreducible, then the returned basic algebra is defined over the splitting field for the irreducible modules.

`BasicAlgebraOfBlockAlgebra(S)`

Returns the basic algebra of the block algebra, the projective modules of which are given in the sequence S. In the event that the irreducible composition factors of the modules in S are not absolutely irreducible, then the returned basic algebra is defined over the splitting field for the irreducible modules.

`BasicAlgebraOfPrincipalBlock(G,k)`

Returns the basic algebra of the principal block of the group algebra of G. If the simple modules in the principal kG block are all absolutely simple, then the ordering of the projective modules for the returned basic algebra is exactly the same as the ordering of the projectives modules in the principal block returned by the function `IndecomposableProjectives`. Otherwise, the base ring of the returned basic algebra is the least extension of k necessary to split the simple modules in the principal block and the simple modules of the returned algebra are ordered by increasing dimension of the corresponding simple modules of kG.

`BasicAlgebraOfExtAlgebra(A)`

The function returns the basic algebra from a computed ext-algebra which is $\mathrm{Ext}^*_A(S,S)$, where S is the direct sum of the irreducible A-modules, of the basic algebra A. If no ext-algebra for A has been computed or if the exalgebra is not verified to be finite dimensional then an error is returned.

`BasicAlgebraOfExtAlgebra(A)`

The function returns the basic algebra for the ext-algebra, which is $\mathrm{Ext}^*_A(S,S)$, where S is the direct sum of the irreducible A-modules, of A computed to n steps. If no ext-algebra for A to n steps has been computed then it will be computed. If the ext-algebra is not verified to be finite dimensional by the computation, then an error is returned.

`BasicAlgebraOfExtAlgebra(A)`

The function creates the basic algebra from a computed ext-algebra. The input *ext* is the output of the `ExtAlgebra` function. If the ext-algebra is not verified to be finite dimensional by the computation, then an error is returned.

`OppositeAlgebra(B)`

The opposite algebra of the basic algebra B. The opposite algebra of B is the algebra with the same set of elements and the same addition but with multiplication $*$ given by $a * b = ba$ for a and b in A.

Example H85E1

We form the basic algebra of the group algebra of the alternating group on 6 letters in characteristic 2.

```
> G := AlternatingGroup(6);
> A := BasicAlgebraOfGroupAlgebra(G, GF(2));
> A;
Basic algebra of dimension 36 over GF(2^2)
Number of projective modules: 5
Number of generators: 9
```

Note that the field of coefficients has been extended in order to split the irreducible G-modules. A great deal of information on the nature of the group algebra and its basic algebra can be obtained from analysis such as the following.

```
> [Dimension(ProjectiveModule(A,i)): i in [1 .. 5]];
[ 9, 9, 16, 1, 1 ]
> prj := CompactProjectiveResolutionsOfAllSimpleModules(A,8);
> [x`BettiNumbers:x in prj];
[
    [
        [ 1, 0, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 1, 0, 0, 0, 0 ],
        [ 1, 0, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 1, 0, 0, 0, 0 ],
        [ 1, 0, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 1, 0, 0, 0, 0 ]
    ],
    [
        [ 0, 1, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 0, 1, 0, 0, 0 ],
        [ 0, 1, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 0, 1, 0, 0, 0 ],
        [ 0, 1, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ],
        [ 0, 1, 0, 0, 0 ]
    ],
    [
        [ 0, 0, 3, 0, 0 ],
        [ 1, 1, 2, 0, 0 ],
        [ 0, 0, 3, 0, 0 ],
        [ 0, 0, 2, 0, 0 ],
        [ 1, 1, 1, 0, 0 ],
        [ 0, 0, 2, 0, 0 ],
```

```
        [ 0, 0, 1, 0, 0 ],
        [ 1, 1, 0, 0, 0 ],
        [ 0, 0, 1, 0, 0 ]
    ],
    [
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 1, 0 ]
    ],
    [
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 0 ],
        [ 0, 0, 0, 0, 1 ]
    ]
]
```

So we see that the last two simple modules are projective and hence in the group algebra FG, they represent blocks of defect 0. From the information on the Betti numbers we observe that the first two simple modules have periodic projective resolutions. Thus the third simple module for the basic algebra corresponds to the trivial FG-module, which we know is neither projective nor periodic.

Example H85E2

We construct the Schur algebra $S(3,7)$ with coefficients in a field of characteristic 2.

```
> A := BasicAlgebraOfSchurAlgebra(3,6,GF(2));
> A;
Basic algebra of dimension 58 over GF(2)
Number of projective modules: 7
Number of generators: 21
```

It is known that A has finite global dimension, hence its ext-algebra has finite dimension.

```
> B := BasicAlgebraOfExtAlgebra(A,10);
> B;
Basic algebra of dimension 56 over GF(2)
Number of projective modules: 7
```

```
Number of generators: 25
```

We check to see if the ext-algebra of B might have finite dimension.

```
> SumOfBettiNumbersOfSimpleModules(B,5);
600
> SumOfBettiNumbersOfSimpleModules(B,6);
1334
> SumOfBettiNumbersOfSimpleModules(B,7);
3008
```

The sum of the Betti number would be the dimension of the ext-algebra computed to the indicated degree. It would appear that the ext-algebra is infinite dimensional. Just to check, we look at a particular simple module, chosen randomly.

```
> CompactProjectiveResolution(SimpleModule(B,4),10)‘BettiNumbers;
[
    [ 8, 0, 81, 3, 61, 69, 55 ],
    [ 3, 0, 36, 1, 26, 30, 24 ],
    [ 1, 0, 16, 1, 11, 13, 10 ],
    [ 1, 0, 7, 1, 5, 5, 4 ],
    [ 1, 0, 3, 1, 2, 2, 1 ],
    [ 1, 0, 1, 0, 1, 1, 0 ],
    [ 0, 0, 0, 0, 1, 1, 0 ],
    [ 0, 0, 0, 0, 1, 0, 1 ],
    [ 0, 0, 0, 1, 0, 1, 0 ],
    [ 1, 0, 0, 0, 0, 0, 1 ],
    [ 0, 0, 0, 1, 0, 0, 0 ]
]
```

Thus we have strong evidence that the fourth simple module has infinite projective dimension. In that case, the ext-algebra of B is not finite dimensional.
Now we consider the same example except in characteristic 3.

```
> A := BasicAlgebraOfSchurAlgebra(3,6,GF(3));
> A;
Basic algebra of dimension 48 over GF(3)
Number of projective modules: 7
Number of generators: 21
> B := BasicAlgebraOfExtAlgebra(A,10);
> B;
Basic algebra of dimension 98 over GF(3)
Number of projective modules: 7
Number of generators: 21
> SumOfBettiNumbersOfSimpleModules(B,5);
48
> SumOfBettiNumbersOfSimpleModules(B,6);
48
```

So we see that the algebra B has global dimension at most 5. We can compute its ext-algebra.

```
> C := BasicAlgebraOfExtAlgebra(B,10);
```

```
> C;
Basic algebra of dimension 48 over GF(3)
Number of projective modules: 7
Number of generators: 21
> D := BasicAlgebraOfExtAlgebra(C,10);
> D;
Basic algebra of dimension 98 over GF(3)
Number of projective modules: 7
Number of generators: 21
```

This provides evidence that A is isomorphic to its double ext-algebra. This would suggest that A might be a Koszul algebra.

85.2.3 Access Functions

These functions return basic information, underlying structures and elements of the given basic algebras.

`B . i`

The i^{th} element in the standard basis for the underlying vector space of the algebra B.

`BaseRing(B)`

`CoefficientRing(B)`

Given an algebra B over a field k the function returns k.

`VectorSpace(B)`

`KSpace(B)`

The underlying k-vector space of the algebra B. The space is the direct sum of the underlying vector space of the indecomposable projective modules.

`Dimension(B)`

The dimension of the underlying vector space of the algebra B.

`Basis(B)`

A basis of the underlying vector space of the algebra B.

`Generators(B)`

The generators of the algebra B as a sequence of elements in the underlying vector space of the algebra B.

`IdempotentGenerators(B)`

The sequence of mutually orthogonal idempotent generators of the basic algebra B as elements in the underlying vector space of B.

`IdempotentPositions(B)`

The sequence $N = [n_1, \ldots, n_s]$ such that $B.n_1, \ldots, B.n_s$ are the mutually orthogonal idempotent generators of the algebra B.

`NonIdempotentGenerators(B)`

The sequence of nonidempotent generators of the basic algebra B as elements in the underlying vector space of the algebra B.

`Random(B)`

A random element of the algebra B as an element of the underlying vector space of B.

`NumberOfProjectives(B)`

The number of nonisomorphic indecomposable projective modules in the basic algebra B.

`NumberOfGenerators(B)`

`Ngens(B)`

The number of generators (idempotent and nonidempotent) of the basic algebra B.

`DimensionsOfProjectiveModules(B)`

The sequence of the dimensions of the projective modules of the basic algebra B.

`DimensionsOfInjectiveModules(B)`

The sequence of the dimensions of the injective modules of the basic algebra B.

85.2.4 Elementary Operations

`a + b`

The sum of the two elements a and b.

`a * b`

The product of the two elements a and b.

`a ^ n`

The n^{th} power of the element a.

Example H85E3

We create the basic algebra of the quiver with three nodes and three arrows over the field with 7 elements. The first arrow (a) goes from node 1 to node 2, the second (b) from node 2 to node 1, and (c) from node 2 to node 3. The arrows satisfy the relation that $(\mathtt{a} * \mathtt{b})^3 = 0$.

```
> ff := GF(7);
> FA<e1,e2,e3,a,b,c> := FreeAlgebra(ff,6);
> rrr := [a*b*a*b*a*b];
> D := BasicAlgebra(FA,rrr,3,[<1,2>,<2,1>,<2,3>]);
> D;
Basic algebra of dimension 21 over GF(7)
Number of projective modules: 3
Number of generators: 6
> DimensionsOfProjectiveModules(D);
[ 9, 11, 1 ]
> DimensionsOfInjectiveModules(D);
[ 6, 7, 8 ]
```

So we can see that the algebra is not self-injective.
Now we can check the nilpotence degree of the radical of D. The radical of D is generated by the nonidempotent generators.

```
> S := NonIdempotentGenerators(D);
> S;
[ (0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0), (0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0
0 0 0 0 0), (0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0) ]
> S2 := [x*y:x in S, y in S|x*y ne 0];
> #S2;
3
> S3 := [x*y:x in S2, y in S|x*y ne 0];
> #S3;
3
> S4 := [x*y:x in S3, y in S|x*y ne 0];
> #S4;
3
> S5 := [x*y:x in S4, y in S|x*y ne 0];
> #S5;
3
> S6 := [x*y:x in S5, y in S|x*y ne 0];
> #S6;
2
> S7 := [x*y:x in S6, y in S|x*y ne 0];
> #S7;
1
> S8 := [x*y:x in S7, y in S|x*y ne 0];
> #S8;
0
```

Example H85E4

First we create the basic algebra for the symmetric group S_3 over the field $GF(3)$

```
> FA<e1,e2,a,b> := FreeAlgebra(GF(3),4);
> MM:= [a*b*a, b*a*b];
> BS3 := BasicAlgebra(FA, MM, 2, [<1,2>,<2,1>]);
> BS3;
Basic algebra of dimension 6 over GF(3)
Number of projective modules: 2
Number of generators: 4
> DimensionsOfProjectiveModules(BS3);
[ 3, 3 ]
```

Next we create the basic algebra for the cyclic group of order 3.

```
> gg := CyclicGroup(3);
> BC3 := BasicAlgebra(gg,GF(3));
> BC3;
Basic algebra of dimension 3 over GF(3)
Number of projective modules: 1
Number of generators: 2
```

We create the basic algebra for the direct product $C_3 \times S_3$.

```
> A := TensorProduct(BS3,BC3);
> A;
Basic algebra of dimension 18 over GF(3)
Number of projective modules: 2
Number of generators: 6
> DimensionsOfProjectiveModules(A);
[ 9, 9 ]
```

Example H85E5

We create the basic algebra for A_4 over a field with 2 elements. The group algebra has two nonisomorphic projective modules. We define the basic algebra by constructing the matrix algebra for the projective modules and the path trees and entering this data into the `BasicAlgebra` function.
Note that the matrices are sparse so we will define them by specifying the nonzero rows.

```
> ff := GF(2);
> MM6 := MatrixAlgebra(ff,6);
> e11 := MM6!0;
> e12 := MM6!0;
> VV6 := VectorSpace(GF(2),6);
> BB6 := Basis(VV6);
> e11[1]  := BB6[1];
> e11[3]  := BB6[3];
> e11[4]  := BB6[4];
> e11[6]  := BB6[6];
```

```
> e12[2]  := BB6[2];
> e12[5]  := BB6[5];
> a1 := MM6!0;
> b1 := MM6!0;
> c1 := MM6!0;
> d1 := MM6!0;
> a1[1] := BB6[2];
> b1[1] := BB6[3];
> c1[2] := BB6[4];
> a1[3] := BB6[5];
> b1[4] := BB6[6];
> c1[5] := BB6[6];
> A1 := sub< MM6 | [e11, e12, a1, b1, c1, d1] >;
> T1 := [ <1,1>, <1,3>, <1,4>, <2,5>, <3,3>, <4,4>];
>
> VV5 := VectorSpace(ff,5);
> BB5 := Basis(VV5);
> MM5 := MatrixAlgebra(ff,5);
> e21 := MM5!0;
> e22 := MM5!0;
> e22[1]  := BB5[1];
> e22[3]  := BB5[3];
> e22[5]  := BB5[5];
> e21[2]  := BB5[2];
> e21[4]  := BB5[4];
> a2 := MM5!0;
> b2 := MM5!0;
> c2 := MM5!0;
> d2 := MM5!0;
> f2 := MM5!0;
> g2 := MM5!0;
> c2[1] := BB5[2];
> d2[1] := BB5[3];
> b2[2] := BB5[4];
> d2[3] := BB5[5];
> a2[4] := BB5[5];
> A2 := sub< MM5 | [e21, e22, a2, b2, c2, d2] >;
> T2 := [<1,2>, <1,5>, <1,6>, <2,4>, <3,6>];
>
> C := BasicAlgebra( [<A1, T1>, <A2, T2>] );
> C;
Basic algebra of dimension 11 over GF(2)
Number of projective modules: 2
Number of generators: 6
> DimensionsOfProjectiveModules(C);
[ 6, 5 ]
> DimensionsOfInjectiveModules(C);
```

```
[ 6, 5 ]
```

85.2.5 Boolean Functions

A basic algebra in MAGMA is a sequence of matrix algebras, each with a path tree. When a basic algebra is created by entering such a sequence, MAGMA does not check to see if all of the properties of a basic algebra are satisfied, as this is an expensive operation. The following two function check to see if the properties of a basic algebra are satisfied.

`IsDimensionCompatible(B)`

Returns `true` if the dimension of a basic algebra is the same as the dimension of the matrix algebra of its action on itself. If false then the algebra is not a basic algebra.

`IsPathTree(B)`

Returns `true` if the basis elements of the projective modules in the basic algebra are determined by the path tree. If false, then the algebra is not a true basic algebra.

Two other functions check commutativity.

`IsCommutative(A)`

Returns `true` if the basic algebra A is commutative.

`IsCentral(A,x)`

Returns `true` if the element x is in the center of the basic algebra A.

85.3 Homomorphisms

MAGMA has the capability of creating homomorphisms of basic algebras. A homomorphism of a basic algebra has the type Map. The matrix of the homomorphism ϕ is accessed by entering `Matrix(phi)`. The kernel of a homomorphism is returned as a subspace of the vector space of the domain of the algebra. This is a two-sided ideal. There is no special type for ideals. They are subspaces of the underlying vector space of the algebra. They can be generated from any given set of elements of the algebra

The image of a homomorphism is returned as a basic algebra, together with the embedding homomorphism.

A homomorphism from a basic algebra A to a basic algebra B is normally created from a matrix having dimension of A rows and dimension of B columns. Note that MAGMA does not automatically check to see if the created map is an algebra homomorphism.

`hom< A - >`

The algebra homomorphism from basic algebra A to basic algebra B, whose matrix is the matrix S. Given a map ϕ, a homomorphism of basic algebra, the matrix of that map is recalled with the command `Matrix(phi)`.

`Kernel(phi)`

The kernel of the map ϕ.

`Image(phi)`

The image of the homomorphism ϕ together with the embedding homomorphism of the image into the codomain of ϕ.

`IsAlgebraHomomorphism(A, B, psi)`

Return `true` if the matrix ψ represents a homomorphism from basic algebra A to basic algebra B.

`X * Y`

The composition of the maps X and Y.

`IsAlgebraHomomorphism(A, B, psi)`
`IsAlgebraHomomorphism(A, B, psi)`
`IsAlgebraHomomorphism(A, B, psi)`
`IsAlgebraHomomorphism(A, B, psi)`

Returns `true`, if the map ψ is a homomorphism of basic algebras

`IsAlgebraHomomorphism(psi)`

Returns `true` if the map ψ is a homomorphism of basic algebras.

85.4 Subalgebras and Quotient Algebras

A subalgebra is also returned with the embedding homomorphism, and a quotient algebra is returned with the natural quotient map. These are needed for creating some standard subalgebras such as the centre of the algebra.

85.4.1 Subalgebras and their Constructions

`sub< A | S >`

The subalgebra of A generated by the elements of the sequence S, together with the inclusion map of the subalgebra into A. The subalgebra contains the idempotent of minimal rank in A that acts as a multiplicative identity on the elements of S.

`SubalgebraFromBasis(A, V)`

Given a basic algebra A and the basis V of a subspace of A, the function returns the basic algebra which is the subalgebra spanned by the subspace and the inclusion matrix of the homomorphism embedding the subalgebra into A. Note that the space V might not contain the identity element of V and in that case the minimal possible identity element is added to the returned subalgebra.

`MaximalIdempotent(A, S)`

Given a basic algebra A, a subspace S of the vector space of A that is closed under multiplication, this function returns an idempotent in A which has maximal rank among all idempotents contained in S.

`MinimalIdentity(A, S)`

Returns the idempotent of smallest rank that is a two sided identity for the elements in the set S.

`Centre(A)`

The centre of the basic algebra as a basic algebra together with the inclusion homomorphism.

`Centralizer(A,S)`

Returns the centralizer in the basic algebra A of the elements in the sequence S, along with the homomorphism embedding the centralizer into A.

`MaximalCommutativeSubalgebra(A,S)`

Returns a maximal commutative subalgebra of the basic algebra A that contains the elements of the sequence S. An error occurs if the elements of S do not commute.

85.4.2 Ideals and their Construction

`ideal< A | S >`
`ideal< A | S >`

Returns the subspace of the vector space of the algebra A that is the ideal of the A generated by the given sequence of elements S.

`LeftAnnihilator(A, S)`

Returns a basis for the left annihilator of the sequence S of elements in the basic algebra A.

`RightAnnihilator(A, S)`

Returns a basis for the right annihilator of the sequence S of elements in the basic algebra A.

`Annihilator(A,S)`

Returns a basis for the two-sided annihilator of the sequence of elements S of the basic algebra A.

`IsIdeal(A, S)`

Returns `true` if the subspace spanned by the elements of S is a two-sided ideal of the basic algebra A.

`IsLeftIdeal(A,S)`

Returns `true` if the subspace spanned by the elements of S is a left ideal of the basic algebra A.

`IsRightIdeal(A, S)`

Returns `true` if the subspace spanned by the elements of S is a two-sided ideal of the basic algebra A.

`RandomIdealGeneratedBy(A, n)`

Returns the ideal generated by n randomly selected elements in the Jacobson radical of the basic algebra A.

85.4.3 Quotient Algebras

`quo< A | S >`

Returns the quotient algebra of A by the ideal S, which is a subspace of the vector space of A, together with the quotient map.

`CoverAlgebra(A)`

Constructs the maximal extension B as in $[0 \to K \to B \to A \to 0]$ such that B acts trivially on K and B is an algebra with exactly the same minimal number of generators as A. Returns B and the algebra homomorphism of B onto A.

`GradedCoverAlgebra(A)`

This assumes that we are given the truncated algebra of a graded algebra. It creates the basic algebra of the natural cover of A and also returns the matrix of the cover onto A.

`TruncatedAlgebra(A,n)`

The quotient of the algebra by the n^{th} power of the radical of A. Returns also the quotient map.

85.5 Minimal Forms and Gradings

There are some standard ways of rewriting an algebra to an isomorphic form. We can also constructed the associated graded algebra of a basic algebra. Also included here is a function for rearranging the orders of idempotents in a basic algebra.

The first intrinsic is used extensively in the programs for computing automorphisms and isomorphisms.

`MinimalGeneratorForm(A)`

Returns a record consisting of an isomorphic basic algebra having the property that it is generated by a minimal number of elements and the projective modules are filtered by radical layers. The record consists of the following fields:

(a) The algebra in minimal form (field `algebra`).

(b) The map from the minimal generator form algebra to A (field `Homomorphism`).

(c) The inverse map from A to the minimal generator form algebra (field `InverseHomomorphism`).

(d) The dimensions of the radical layer (field `RadicalDimensions`).

(e) The dimensions of the filtration of the top radical layer by the socle layer (field `FilterDimensions`).

`MinimalGeneratorFormAlgebra(A)`

Returns an isomorphic algebra having minimal generator form.

`AssociatedGradedAlgebra(A)`

Returns the basic algebra that is isomorphic to the associated graded algebra of A.

`GradedCapHomomorphism(A)`

Returns the matrix of the map from $A/Rad(A)$ to $X/Rad(X)$ where X is the associated graded algebra of A.

`GradedCapHomomorphism(A, B, mu)`

Given an algebra homomorphism $mu : A \to B$, returns the induced homomorphism $A/\operatorname{Rad}^2(A) \to B/\operatorname{Rad}^2(B)$, where Rad^2 is the second power of the Jacobson radical.

`BuildHomomorphismFromGradedCap(A, B, phi)`

Returns the graded homomorphism from the associated graded algebra X of A to the associated graded algebra Y of B, whose cap is ϕ. That is phi is the matrix of the induced homomorphism of $X/Rad^2(X)$ to $Y/Rad^2(Y)$.

`ChangeIdempotents(A, S)`

`ChangeIdempotents(A, S)`

Returns the basic algebra isomorphic to A, obtained by permuting the order of the idempotents by the permutation S. The permutation S can be given as an element of the symmetric group or as the sequence of images of the permutation.

Example H85E6

In this examples we investigate properties of the basic algebra of a Schur algebra.

```
> A := BasicAlgebraOfSchurAlgebra(3,6,GF(3));
> A;
Basic algebra of dimension 48 over GF(3)
Number of projective modules: 7
Number of generators: 21
> B := BasicAlgebraOfExtAlgebra(A,10);
> B;
Basic algebra of dimension 98 over GF(3)
Number of projective modules: 7
Number of generators: 21
> C := BasicAlgebraOfExtAlgebra(B,10);
> C;
Basic algebra of dimension 48 over GF(3)
Number of projective modules: 7
Number of generators: 21
> boo,mat := IsIsomorphic(A,C);
> boo;
true
> IsAlgebraHomomorphism(mat);
true
```

So we see that A is isomorphic to its double ext-algebra, and it is graded since the double ext-algebra is graded. Thus we know that the basic algebra A is a Koszul algebra.

Example H85E7

Here we see how to rearrange an algebra by changing the ordering on the primitive idempotents.

```
> A := BasicAlgebraOfSchurAlgebra(3,5,GF(3));
> A;
Basic algebra of dimension 11 over GF(3)
Number of projective modules: 5
Number of generators: 9
> B, uu  := ChangeIdempotents(A,[2,4,5,1,3]);
> B;
Basic algebra of dimension 11 over GF(3)
Number of projective modules: 5
Number of generators: 9
> DimensionsOfProjectiveModules(A);
[ 2, 3, 2, 1, 3 ]
> DimensionsOfProjectiveModules(B);
[ 3, 1, 3, 2, 2 ]
> IsAlgebraHomomorphism(A,B,uu);
true
> uu;
[0 0 0 0 0 0 0 1 0 0 0]
```

```
[0 0 0 0 0 0 0 0 1 0 0]
[1 0 0 0 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 0 0 0 1]
[0 0 0 1 0 0 0 0 0 0 0]
[0 0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0 0]
```

We see that uu is a permutation matrix.

85.6 Automorphisms and Isomorphisms

MAGMA has the capability of computing automorphisms and isomorphisms of basic algebras. Because the automorphism groups tend to be rather large, the functions work best on small examples.

`GradedAutomorphismGroupMatchingIdempotents(A)`

Returns the group of graded automorphisms of the basic algebra A that preserve the idempotents of A. Returns also the graded caps (matrices of homomorphisms from $X/Rad^2(X)$ to itself, where X is the Associated Graded algebra of A) of the generators of the automorphism group in two sequenced, nonunipotent generators and unipotent generators.

`GradedAutomorphismGroup(A)`

Returns the group of graded automorphisms of the associated graded algebra X of the basic algebra A. The function returns also the graded caps of the generators of the graded automorphism group. These are the induced automorphisms of $X/Rad^2(X)$ to itself, and they are returned as two lists of nonunipotent and unipotent generators that preserve the idempotents of X and a list of generators that permute the idempotents.

`IsGradedIsomorphic(A, B)`

Returns `true` if the associated graded algebras of A and B are isomorphic, in which case the isomorphism is returned.

`AutomorphismGroupMatchingIdempotents(A)`

Returns the group of all automorphism of the basic algebra A that preserve the basic idempotent structure. That is, any element of this group induces the identity automorphism on the quotient $A/Rad(A)$ of A by its Jacobson radical.

`AutomorphismGroup(A)`

Returns the automorphism group of the basic Algebra A, together with the sequences of nonnilpotent generators preserving idempotents, nilpotent generators preserving idempotents and generators that permute the idempotents.

`IsIsomorphic(A, B)`

Returns `true` if the basic algebra A is isomorphic to the basic algebra B and, if so, the function also returns an isomorphism.

Example H85E8

We compute the automorphism group of a group algebra.

```
> A := BasicAlgebra(SmallGroup(81, 7));
> time ba := AutomorphismGroup(A);
Time: 6.260
> #ba;
34358501382134088735764075317708084846807168 1334
> Factorization(#ba);
[ <2, 1>, <3, 99> ]
```

As expected the automorphism group has a very large unipotent 3-subgroup.

Example H85E9

We can see if small changes in the presentation of an algebra affect the isomorphism type. We define the algebras by generators and relations.

```
> F<e1,e2,z,y,x> := FreeAlgebra(GF(5),5);
> RR:= [(y*z)^3,x^4,x*y*z];
> A := BasicAlgebra(F,RR,2,[<1,2>,<2,1>,<2,2>]);
> A;
Basic algebra of dimension 49 over GF(5)
Number of projective modules: 2
Number of generators: 5
> RS:= [(y*z)^3-x^4,x^5,x*y*z,(z*y)^3];
> B := BasicAlgebra(F,RS,2,[<1,2>,<2,1>,<2,2>]);
> B;
Basic algebra of dimension 49 over GF(5)
Number of projective modules: 2
Number of generators: 5
> RT:= [(y*z)^3-2*x^4,x^5,x*y*z,(z*y)^3];
> C := BasicAlgebra(F,RS,2,[<1,2>,<2,1>,<2,2>]);
> C;
Basic algebra of dimension 49 over GF(5)
Number of projective modules: 2
Number of generators: 5
> time ab, x := IsIsomorphic(A,B);
Time: 0.100
```

```
> ab;
false
> time ac, x := IsIsomorphic(A,C);
Time: 0.050
> print ac;
false
> time bc,x := IsIsomorphic(B,C);
Time: 2.350
> print bc;
true
```

Example H85E10

We can see which groups of order 32 have mod 2 group algebras that are graded. The algebra is graded if and only if it is isomorphic to its associated graded algebra. So we make a list of those algebras whose group algebras are graded. Note that there are 51 isomorphism classes of groups of order 32. The last one (number 51) is elementary abelian and we know that its group algebra is graded.

```
> graded := [];
> for i := 1 to 50 do
>     A := BasicAlgebra(SmallGroup(32,i));
>     B := AssociatedGradedAlgebra(A);
>     boo, map := IsIsomorphic(A, B);
>     if boo then Append(~graded, i); end if;
> end for;
> graded;
[ 1, 2, 3, 5, 9, 12, 14, 16, 18, 21, 22, 25, 36, 39, 45, 46 ]
```

85.7 Modules over Basic Algebras

A module M over a basic algebra B is presented as a sequence of matrices, one for each generator of the algebra.

85.7.1 Indecomposable Projective Modules

The indecomposable projective modules are defined from the structure of the algebra and have associated path trees that solve the homomorphism lifting problem.

`ProjectiveModule(B, i)`

The i^{th} projective module of the basic algebra B.

`PathTree(B, i)`

The path tree of the i^{th} projective module of the basic algebra B.

`ActionGenerator(B, i)`

The sequence of matrices for the generators of the basic algebra B acting on the i^{th} projective module of B.

`IdempotentActionGenerators(B, i)`

The sequence of matrices for the idempotent generators of the basic algebra B acting on the i^{th} projective module of B.

`NonIdempotentActionGenerators(B, i)`

The sequence of matrices for the nonidempotent generators of the basic algebra B acting on the i^{th} projective module of B.

`Injection(B, i, v)`

Given a vector v in in the i^{th} projective module of the basic algebra B, the function returns the image of inclusion of v into B.

85.7.2 Creation

`AModule(B, Q)`

Given a basic algebra B and a sequence Q of elements in a matrix algebra the function returns the B-module M on which the generators of B act by multiplication by the corresponding elements of Q.

`ProjectiveModule(B, S)`

Given a sequence $S = [s_1, s_2, ...]$, the function returns a projective module which is the direct sum of s_1 copies of the first projective of the algebra B, s_2 copies of the second, etc. It also returns the sequence of inclusions and projections from and to the indecomposable projective modules.

`IrreducibleModule(B, i)`
`SimpleModule(B, i)`

The i^{th} irreducible module of the algebra B. The module is the quotient of the i^{th} projective module by its radical.

`ZeroModule(B)`

The zero B-module.

`RightRegularModule(B)`

The algebra B as a right module over itself. The module is the direct sum of the projectives modules of B.

`RegularRepresentation(v)`

If v is an element of a basic algebra given as a vector in the underlying space, then the function computes the matrix of the action by right multiplication of the element on the algebra.

`Restriction(M, B, xi)`

If B is a subalgebra of the basic algebra A, ξ is the embedding of B into A, and M is an A-module, then the function returns the restriction of M to a B-module.

`ChangeAlgebra(M, B, xi)`

`ChangeAlgebra(M, B, xi)`

Given a module M over an algebra A and an algebra homomorphism ξ from B to A, the function returns the module M as a B-module.

`JacobsonRadical(M)`

The Jacobson radical of the module M.

`Socle(M)`

The socle of the module M. The sum of the simple submodules of M.

85.7.3 Access Functions

`Algebra(M)`

Given a module M over a basic algebra B, the function returns B.

`Dimension(M)`

The dimension of the module M over its base ring.

`Action(M)`

The matrix algebra of the action of the algebra of M on M.

`IsomorphismTypesOfRadicalLayers(M)`

Given a module M over a basic algebra, returns the sequence of isomorphism types of simple composition factors in each layer of the radical filtration of M.

`IsomorphismTypesOfSocleLayers(M)`

Given a module M over a basic algebra, returns a sequence of isomorphism types of simple composition factors in each socle layer with reversed order, *i. e.* isomorphism types of the socle of M will appear last.

`IsomorphismTypesOfBasicAlgebraSequence(S)`

Given a sequence of irreducible modules S for a basic algebra A, return a sequence of isomorphism types comparing with the simple modules of A.

Example H85E11

We show the restriction of a module over an algebra A to a subalgebra of A.

```
> G := SmallGroup(32,7);
> A := BasicAlgebra(G);
> C, mu := Center(A);
> X := RightRegularModule(A);
> Z := JacobsonRadical(X);
> L := Restriction(Z,C,mu);
> L;
AModule L of dimension 31 over GF(2)
> A eq Algebra(L);
True
> IndecomposableSummands(L);
[
    AModule of dimension 1 over GF(2),
    AModule of dimension 30 over GF(2)
]
> Dimension(Socle(L));
16
```

Next we show how to pull back modules along a quotient map. We use the same algebra A.

```
> U := ideal<A|[A.13 +A.17]>;
> Q, theta := quo<A|U>;
> X := ProjectiveModule(Q,1);
> Y := ChangeAlgebras(X,A,theta);
> Y;
AModule Y of dimension 16 over GF(2)
```

Example H85E12

Here is another example of pulling back a module along a quotient map. This one involves algebras with more than one idempotent.

```
> load m11;
Loading "/usr/local/dmagma/libs/pergps/m11"
M11 - Mathieu group on 11 letters - degree 11
Order 7 920 = 2^4 * 3^2 * 5 * 11;  Base 1,2,3,4
Group: G
> A:= BasicAlgebraOfPrincipalBlock(G,GF(2));
> A;
Basic algebra of dimension 22 over GF(2)
Number of projective modules: 3
Number of generators: 9
> DimensionsOfProjectiveModules(A);
[ 8, 8, 6 ]
> I := ideal<A|[A.9]>;
> B, mu := quo<A|I>;
```

```
> B;
Basic algebra of dimension 6 over GF(2)
Number of projective modules: 2
Number of generators: 5
> P := ProjectiveModule(B,1);
> P;
AModule P of dimension 3 over GF(2)
> Q := ChangeAlgebras(P,A,mu);
> Algebra(Q) eq A;
true
```

Example H85E13

In this example, we investigate the structure of the projective modules of a basic algebra.

```
> G := PSL(3,3);
> N := Normalizer(G,Sylow(G,2));
> A := BasicAlgebraOfHeckeAlgebra(G,N,GF(2));
> DimensionsOfProjectiveModules(A);
[ 1, 2, 3, 9, 9, 1, 1, 1, 1 ]
> IsomorphismTypesOfRadicalLayers(ProjectiveModule(A,4));
[
    [ 4 ],
    [ 2, 3, 4, 5 ],
    [ 4, 4, 5 ],
    [ 5 ]
]
> IsomorphismTypesOfSocleLayers(ProjectiveModule(A,4));
[
    [ 4 ],
    [ 3, 4, 5 ],
    [ 2, 4, 5 ],
    [ 4, 5 ]
]
```

So we see that, unlike a group algebra, a Hecke algebra can have indecomposable projective modules whose socles are not simple.

85.7.4 Predicates

The following functions return a boolean value.

`IsSemisimple(M)`

Returns `true` if the module M is a semisimple module and `false` otherwise. If `true`, then the function also returns a list of the ranks of the primitive idempotents of the algebra. This is also a list of the multiplicities of the simple modules of the algebra as composition factors in a composition series for the module.

`IsProjective(M)`

Returns `true` if the module M is projective. The function also returns a sequence of multiplicities of the standard projective modules as direct summands of the projective cover of M.

`IsInjective(M)`

Returns `true` if the module M is injective. The function also returns a sequence of multiplicities of the standard injective modules as direct summands of the injective hull of M.

85.7.5 Elementary Operations

`m * b`

Given an element b in a basic algebra B and an element m in a module M over B, $m * b$ is the product.

Example H85E14

We obtain the dimensions of the radical layers of the group algebra of an extra special group of order 243 over a field of characteristic 3.

```
> G := ExtraSpecialGroup(3,2);
> G;
Permutation group G acting on a set of cardinality 243
> ff := GF(3);
> A := BasicAlgebra(G,ff);
> A;
Basic algebra of dimension 243 over GF(3)
Number of projective modules: 1
Number of generators: 6
> P := ProjectiveModule(A,1);
> P;
AModule P of dimension 243 over GF(3)
> R := JacobsonRadical(P);
> R;
AModule R of dimension 242 over GF(3)
> while Dimension(R) ne 0 do
>     T := JacobsonRadical(R);
>     print Dimension(R) - Dimension(T);
>     R := T;
> end while;
4
11
20
30
36
39
```

```
36
30
20
11
4
1
```

Example H85E15

We consider the mod-2 group algebra of an extraspecial group of order 128, and construct the module induced from the trivial module on the subgroups of order 4 generated by the first generator of the group.

```
> G := ExtraSpecialGroup(2,3);
> G;
Permutation group G acting on a set of cardinality 128
> F := GF(2);
> A := BasicAlgebra(G,F);
> A;
Basic algebra of dimension 128 over GF(2)
Number of projective modules: 1
Number of generators: 8
> A.1;
(1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0)
```

Note that `A.1` is the unique idempotent (identity element) in the group algebra, whereas `A.2` is `G.1-1` where `G.1` is the first generator of the group.

```
> A.2;
(0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0)
> g := A.1+A.2;
```

Now we check the order of `g`.

```
> g^2;
(1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0)
> g^4;
(1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0)
```

```
> g^4 eq A!1;
true
```

So g has order 4.

```
> P := ProjectiveModule(A,1);
> P;
AModule P of dimension 128 over GF(2)
```

Note that P is generated by P.1 which corresponds to the identity element of A if we think of P as the algebra A as a module over itself. Now we create the induced module as the submodule generated by $(\mathtt{g}-1)^3$, since $(\mathtt{g}-1)^4 = 0$.

```
> U := sub<P|P.1*A.6>;
> U;
AModule U of dimension 32 over GF(2)
```

Because the dimension is a quarter of the order of the group we can be sure that we have the right thing by just checking that U is generated by a g fixed point.

```
> U.1*g eq U.1;
true
```

85.8 Homomorphisms of Modules

A homomorphism from module M to module N is simply a matrix that commutes with the action of the algebra on M and N.

85.8.1 Creation

`AHom(M, N)`

The space of homomorphisms from module M to module N.

`PHom(M,N)`

The space of projective homomorphisms from module M to module N. That is, the space of all homomorphisms that factor through a projective module.

`ZeroMap(M, N)`

The zero homomorphism from module M to module N.

`LiftHomomorphism(x, n)`

Given an element x in a module over a basic algebra and a natural number n, the function returns the homomorphism from the n^{th} projective module for the algebra to the module with the property that the idempotent e of the projective module maps to $x * e$.

`LiftHomomorphism(X, N)`

Given a sequence $X = [x_1, \ldots, x_t]$ of elements in a module M over a basic algebra and a sequence $N = [n_1, \ldots, n_s]$ of nonnegative integers, such that $n_1 + \ldots + n_s = t$, the function returns the homomorphism $P \to M$ from the projective module $P = \sum_{j=1}^{s} P_j^{n_i}$ to M that takes the idempotent e for the i^{th} summand in P to the element $x_i * e$ in M. Here P_j denotes the j^{th} projective module for the algebra.

`Pushout(M, f1, N1, f2, N2)`

The pushout of the diagram

$$\begin{array}{ccc} M & \xrightarrow{f_1} & N_1 \\ \downarrow{\scriptstyle f_2} & & \\ N_2 & & \end{array}$$

The function returns the module $L = (N_1 \oplus N_2)/\{(f_1(m), -f_2(m)) | m \in M\}$ and the homomorphisms $g_1 : N_1 \longrightarrow L$ and $g_2 : N_2 \longrightarrow L$ such that $f_1 g_1 = f_2 g_2$.

`Pullback(f1, M1, f2, M2, N)`

The pullback of the diagram

$$\begin{array}{ccc} & & M_2 \\ & & \downarrow{\scriptstyle f_2} \\ M_1 & \xrightarrow{f_1} & N \end{array}$$

The function returns the module $L = \{(m_1, m_2) \in M_1 \oplus M_2 | f_1(m_1) = f_2(m_2)\}$ and the homomorphisms $g_1 : L \longrightarrow M_1$ and $g_2 : L \longrightarrow M_2$ such that $g_1 f_1 = g_2 f_2$.

85.8.2 Access Functions

`IsModuleHomomorphism(f)`

Returns `true` if the map f is a homomorphism of modules over the algebra.

`Domain(f)`

The domain of f.

`Codomain(f)`

The codomain of f.

`Kernel(f)`

The kernel of f and the inclusion of the kernel in `Domain(f)`.

`Cokernel(f)`

The cokernel of f and the quotient map from `Codomain(f)` onto the cokernel.

85.8.3 Projective Covers and Resolutions

A projective cover of a module M is a projective module P and a surjective homomorphism $\phi : P \longrightarrow M$ such that P is minimal with respect to the property of having such a surjective homomorphism to M. A projective resolution to n steps of an A-module M is a pair consisting of a complex

$$P_n \xrightarrow{\partial_n} P_{n-1} \longrightarrow \ldots \longrightarrow P_1 \xrightarrow{\partial_1} P_0$$

which is exact except at the ends, and an augmentation homomorphism $\epsilon : P_0 \to M$ that is a projective cover of M. In addition, the image of ∂_1 must equal the kernel of ϵ. The resolution is minimal if each P_i is a projective cover of its image in P_{i-1}. In this case the i^{th} syzygy module is the image of ∂_i.

In the implementation the main function is `CompactProjectiveResolution.` This function computes a minimal projective resolution of a given module and stores the minimal amount of information that is necessary to create the boundary maps and the terms of the resolution. It runs relatively fast because it avoids the computation of the terms of the projective resolution as modules over the algebra. Instead the terms in the compact resolution are only vector spaces together with a sequence of types for the projective modules. The other information that is recorded is the sequence of images of the generators for the indecomposable projective modules. That is, for the boundary map

$$P_n \xrightarrow{\partial_n} P_{n-1}$$

the module $P_n \cong \oplus_{i=1}^{m} Q_i$ where each Q_i is an indecomposable projective module generated by an element a_i corresponding to the appropriate idempotent in the basic algebra. The function records the images $\partial_n(a_i)$ as a sequence of vectors in the vector space of the module P_{n-1}.

`ProjectiveCover(M)`

The projective cover of the module M given as the projective module P, the surjective homomorphism of P onto M, the sequences of inclusion and projection homomorphism of P from and to its indecomposable direct summands and the isomorphism type of P in the form of a list of the number of copies of the projective modules of the algebra of each type that make up P.

`ProjectiveResolution(M, n)`

The complex giving the minimal projective resolution of the module M out to n steps together with the augmentation homomorphism from the projective cover of M into M. Note that homomorphisms go from left to right so that last term of the complex (in degree 0) is the projective cover of M and the cokernel of the last homomorphism in the complex is M. The complex is constructed from the compact projective resolution of M. The function creates the compact projective resolution if it has not already been computed.

`CompactProjectiveResolution(M, n)`

Returns a minimal projective resolution for the module M out to n steps in compact form together with the augmentation map ($P_0 \to M$). The compact form of the resolution is a list of the minimal pieces of information needed to reconstruct the boundary maps in the resolution. That is the boundary map ($P_i \xrightarrow{\partial_i} P_{i-1}$) is recorded as a matrix whose entries are the images of the generators for indecomposable projective modules making up P_i in the indecomposable projective modules making up P_{i-1}. If a compact projective resolution has been previously computed to degree m and $m < n$ then the function extends that resolution by $n - m$ steps. If $m \geq n$ the function returns the previously computed compact projective resolution. The function returns a record with the fields:

(a) The list of isomorphism types of the projective modules in the resolution, each given as a sequence of integers giving the number of direct summands of each indecomposable projective in the module (field name `BettiNumbers`).

(b) The record of the boundary maps (field name `ResolutionRecord`).

(c) The module M (field name `Module`).

(d) The augmentation map (field name `AugmentationMap`).

(e) The type of the resolution, whether projective or injective (field name `Typ`).

`CompactProjectiveResolutionsOfSimpleModules(A,n)`

Returns a sequence of the compact projective resolutions of the simple A-modules computed to degree n.

`SyzygyModule(M, n)`

The n^{th} syzygy module of the module M. The module is constructed from the compact projective resolution of M. The compact resolution is constructed if it does not already exist.

`SimpleHomologyDimensions(M)`

The sequence of sequences of dimensions of the homology groups $\mathrm{Tor}_j(S_i, M)$ for simple modules S_i and module M, to the extent that they have been computed.

Example H85E16

We consider the basic algebra of a quiver with relation. The quiver has four nodes and 5 non-idempotent generators (a, b, c, d, e). The first goes from node 1 to node 2, the second from 2 to 3, the third from 3 to 4, the fourth from 3 to 2 and the last from 4 to 1. They satisfy the relations $bcfadbd = (abcf)^5ab = (bd)^2b = 0$.

```
> ff := GF(8);
> FA<e1,e2,e3,e4,a,b,c,d,f> := FreeAlgebra(ff,9);
> rrr := [b*c*f*a*b*d*b,a*b*c*f*a*b*c*f*a*b*c*f*a*b*c*f*a*b*c*f*a*b,
>     b*d*b*d*b];
> BA := BasicAlgebra(FA,rrr,4,[<1,2>,<2,3>,<3,4>,<3,2>,<4,1>]);
```

```
> BA;
Basic algebra of dimension 296 over GF(2^3)
Number of projective modules: 4
Number of generators: 9
```

Now we take the projective resolutions of the simple modules out to 5 steps. We print the type of the projective module at each stage.

```
> for i := 1 to 4 do
>     S := SimpleModule(BA,i);
>     prj := CompactProjectiveResolution(S, 5);
>     SimpleHomologyDimensions(S);
> end for;
[
    [ 0, 0, 10, 0 ],
    [ 0, 0, 5, 0 ],
    [ 0, 0, 2, 0 ],
    [ 0, 0, 1, 0 ],
    [ 0, 1, 0, 0 ],
    [ 1, 0, 0, 0 ]
]
[
    [ 0, 0, 16, 0 ],
    [ 0, 0, 8, 0 ],
    [ 0, 0, 4, 0 ],
    [ 0, 0, 2, 0 ],
    [ 0, 0, 1, 0 ],
    [ 0, 1, 0, 0 ]
]
[
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 1, 0, 1 ],
    [ 0, 0, 1, 0 ]
]
[
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 1, 0, 0, 0 ],
    [ 0, 0, 0, 1 ]
]
```

So we see that the third and fourth simple modules have finite projective dimension. The projective resolutions of the first and second simple modules appear to have exponential rates of growth but

the terms after the second term are all direct sums of copies of the third projective module.

```
> for i := 1 to 4 do
>     Dimension(Socle(ProjectiveModule(BA,i)));
> end for;
12
13
25
12
```

Notice that the socles of the projective modules have very large dimensions so the injective resolutions are probably going to grow at a very rapid rate.

Example H85E17

We create the quotient of the group algebra of a p-group by the ideal generated by a central element. In particular, we choose the group algebra of an extra special 3-group and factor out the ideal generated by $(z-1)^2$ where z is a central element of order 3. Then we compare the size of the projective resolution of the trivial module for the new algebra with that of the antecedent group algebra.

```
> G := ExtraSpecialGroup(3,1);
> F := GF(3);
> B := BasicAlgebra(G,F);
> B;
Basic algebra of dimension 27 over GF(3)
Number of projective modules: 1
Number of generators: 4
> s := NonIdempotentGenerators(B)[3];
```

Now check that `s` is in the center.

```
> [s*x eq x*s: x in Generators(B)];
[ true, true, true, true ]
> P := ProjectiveModule(B,1);
> Q := quo<P|P.1*s^2>;
> Q;
AModule Q of dimension 18 over GF(3)
```

We need to create the path tree for the projective module of the matrix algebra of the action on `Q`. In this case it is an easy exercise because the last 9 element of the basis of the projective module for `B` span the submodule that we are factoring out. This can actually be seen from the path tree for the projective module of `B`.

```
> PathTree(B,1);
[ <1, 1>, <1, 2>, <2, 2>, <1, 3>, <2, 3>, <3, 3>, <4, 3>,
<5, 3>, <6, 3>, <1, 4>, <2, 4>, <3, 4>, <4, 4>, <5, 4>,
<6, 4>, <7, 4>, <8, 4>, <9, 4>, <10, 4>, <11, 4>, <12, 4>,
<13, 4>, <14, 4>, <15, 4>, <16, 4>, <17, 4>, <18, 4> ]
```

So we get the path tree for the new module by truncation.

```
> PT := [PathTree(B,1)[j]: j in [1 .. 18]];
```

```
> PT;
[ <1, 1>, <1, 2>, <2, 2>, <1, 3>, <2, 3>, <3, 3>,
<4, 3>, <5, 3>, <6, 3>, <1, 4>, <2, 4>, <3, 4>,
<4, 4>, <5, 4>, <6, 4>, <7, 4>, <8, 4>, <9, 4> ]
```

Now form the new basic algebra.

```
> C := BasicAlgebra([<Action(Q),PT>]);
> C;
Basic algebra of dimension 18 over GF(3)
Number of projective modules: 1
Number of generators: 4
> S := SimpleModule(C,1);
> prj := CompactProjectiveResolution(S, 15);
> SimpleHomologyDimensions(S);
[ 92, 77, 70, 57, 51, 40, 35, 26, 22, 15, 12, 7, 5, 2, 1 ]
```

Now compare this with the projective resolution for the group algebra.

```
> T := SimpleModule(B,1);
> pj2 := CompactProjectiveResolution(T,15);
> SimpleHomologyDimensions(T);
[ 20, 18, 17, 16, 15, 14, 12, 10, 9, 8, 7, 6, 4, 2, 1 ]
```

85.9 Duals and Injectives

If k is the base ring for the algebra A then the k-dual $\mathrm{Hom}_k(M, k)$ for a right module M over A is a right module over the opposite algebra OA of A. Furthermore, the dual of a projective OA-module is an injective A-module and the dual of a projective OA-resolution of a module M is an A-injective resolution of the dual of M.

`Dual(M)`

Given a module M defined over a basic algebra M, this function returns the dual of M as a module over the opposite of the algebra of M. Note that the opposite of the algebra of M is created if it does not already exist.

`BaseChangeMatrix(A)`

Given a basic algebra A that has opposite algebra O, the function creates the change of basis matrix B from the vector space of A to the vector space of O, so that if x, y are in A then $(xy)B$ is the same as $(yB)(xB) \in O$.

85.9.1 Injective Modules

Injective hulls, and injective resolutions of a module are computed by taking the projective cover or projective resolution of the dual module over the opposite algebra and then again taking the dual to retrieve modules or complexes over the original algebra. If the opposite algebra of the module has not been computed then it will be created in the evaluation of any of the injective module functions.

`InjectiveModule(B, i)`

The i^{th} injective module of the algebra B.

`InjectiveHull(M)`

The injective hull of the module M is the injective module I of minimal dimension such that there is an inclusion $\iota : M \to I$. The function returns I, ι, the sequences of inclusions and projections from and to the indecomposable injective summands of I, and the type of I as a sequence $T := [t_1 \ldots, t_s]$ where I has t_1 summands of type 1, t_2 of type 2, etc.

`InjectiveResolution(M, n)`

The complex giving the minimal injective resolution of the module M together with the inclusion homomorphism from M into its injective hull. Note that homomorphisms go from left to right so that the kernel of the first homomorphism in the complex is M. The function computes the compact injective resolution and creates the complex of the injective resolution from that.

`CompactInjectiveResolution(M, n)`

A minimal injective resolution for the module M out to n steps in compact form together with the coaugmentation map ($M \to I_0$). The compact form of the resolution is a list of the minimal pieces of information needed to reconstruct the boundary maps in the resolution. That is, the boundary map ($I_{i-1} \xrightarrow{\partial_i} I_i$) is recorded as a matrix whose entries are the images of the generators for indecomposable injective modules making up I_{i-1} in the indecomposable projective modules making up I_i. The actual return of the function is the compact projective resolution of the dual module of M over the opposite algebra of the algebra of M. The return is a record with the fields:

(a) The list of isomorphism types of the injective modules in the resolution, each given as a sequence of integers giving the number of direct summands of each indecomposable injective in the module (field name `BettiNumbers`).

(b) The record of the boundary maps (field name `ResolutionRecord`).

(c) The module M (field name `Module`).

(d) The coaugmentation map (field name `CoaugmentationMap`).

(e) The type of the resolution, whether projective or injective (field name `Typ`).

`InjectiveSyzygyModule(M, n)`

The n^{th} injective-syzygy module of M. The module is constructed from the compact injective resolution of M. The compact resolution is constructed if it does not already exist.

`SimpleCohomologyDimensions(M)`

The sequence of sequences of dimensions of the cohomology groups $\mathrm{Ext}^j(S_i, M)$ for simple modules S_i and module M, to the extent that they have been computed.

Example H85E18

We create the basic algebra of a quiver over a field with 8 elements. The quiver has two nodes and three arrows, going from node 1 to node 2, from 2 to 1 and from 1 to 1. The relations are given in the sequence `rrr`.

```
> ff := GF(8);
> FA<e1,e2,a,b,c> := FreeAlgebra(ff,5);
> rrr := [a*b*a*b*a, c*c*c*c, a*b*c - c*a*b];
> B := BasicAlgebra(FA,rrr,2,[<1,2>,<2,1>,<1,1>]);
> B;
Basic algebra of dimension 41 over GF(2^3)
Number of projective modules: 2
Number of generators: 5
> DimensionsOfProjectiveModules(B);
[ 20, 21 ]
> DimensionsOfInjectiveModules(B);
[ 24, 17 ]
> P1 := ProjectiveModule(B,1);
> Socle(P1);
AModule of dimension 1 over GF(2^3)
```

We consider the injective resolution of the first projective module.

```
> time in1 := CompactInjectiveResolution(P1,10);
reverse trees
Time: 3.850
```

Note that part of the time was required to create the opposite algebra of `B`.

```
> SimpleCohomologyDimensions(P1);
[
    [ 1, 0 ],
    [ 0, 4 ],
    [ 4, 0 ],
    [ 4, 0 ],
    [ 4, 0 ],
    [ 4, 0 ],
    [ 4, 0 ],
    [ 4, 0 ],
```

```
    [ 4, 0 ],
    [ 4, 0 ]
]
```

The injective resolution appears to be periodic. Now we look at a module constructed from the resolution.

```
> M := InjectiveSyzygyModule(P1,6);
> M;
AModule M of dimension 64 over GF(2^3)
```

Consider the space of endomorphisms of M.

```
> hh := AHom(M,M);
> hh;
KMatrixSpace of 64 by 64 matrices and dimension 128 over GF(2^3)
> [Rank(hh.i): i in [1 .. Dimension(hh)]];
[ 16, 16, 16, 16, 12, 12, 12, 12, 8, 8, 8, 8, 8, 8, 8, 8, 6, 6, 6, 6, 4, 4, 4,
4, 4, 4, 4, 4, 2, 2, 2, 2, 4, 8, 12, 16, 16, 12, 8, 4, 8, 4, 12, 16, 4, 8, 12,
16, 16, 16, 16, 16, 2, 4, 6, 8, 8, 6, 4, 2, 4, 2, 6, 8, 2, 4, 6, 8, 12, 12, 12,
12, 8, 8, 8, 8, 8, 8, 8, 8, 6, 6, 6, 6, 4, 4, 4, 4, 4, 4, 4, 4, 2, 2, 2, 2, 16,
16, 16, 16, 12, 12, 12, 12, 8, 8, 8, 8, 8, 8, 8, 8, 6, 6, 6, 6, 4, 4, 4, 4, 4,
4, 4, 4, 2, 2, 2, 2 ]
```

Note that no generator of the endomorphism ring has rank more than 16. This would indicate that the module is decomposable since the identity map must be a sum of homomorphisms of smaller rank.
How can we produce a decomposition? One method is the following.

```
> vv := Random(hh);
> Rank(vv);
64
> vv*vv eq vv;
false
> [Rank(vv*vv-u*vv):u in ff];
[ 60, 64, 64, 64, 64, 64, 64, 64 ]
> [u:u in ff];
[ 1, ff.1, ff.1^2, ff.1^3, ff.1^4, ff.1^5, ff.1^6, 0 ]
> Rank(vv*vv - vv);
60
> U := vv*vv - vv;
> Rank(U);
60
> Rank(U*U);
56
> Rank(U*U*U);
52
> Rank(U*U*U*U);
48
> Rank(U*U*U*U*U);
48
```

```
> Rank(U*U*U*U*U*U);
48
> T := U*U*U*U;
> N1 := Kernel(T);
> N2 := Image(T);
> Dimension(N1);
16
> Dimension(N2);
48
> Dimension(N1+N2);
64
```

So the sum of `N1` and `N2` must be all of `M` and by counting dimensions, it must be a direct sum.

85.10 Cohomology

`CohomologyRingGenerators(P)`

Given a compact projective resolution P for a simple module S over a basic algebra A, the function returns the chain maps in compact form of a minimal set of generators for the cohomology $\mathrm{Ext}^*_A(S,S)$, as well as some other information. The record that is returned has the following fields:

(a) The list of maps in compact form for the chain map of the generators (field name `ChainMapRecord`).

(b) The sequence of degrees of cohomology generators (field name `ChainDegrees`).

(c) The tops of the chain maps (maps on modules modulo radicals) for the purposes of computing products (field name `TopsOfCohomologyGenerators`).

(d) The tops of the chain maps representing monomials in the generators (field name `TopsOfCohomologyChainMaps`).

(e) The original compact projective resolution (field name `ProjectiveResolution`).

`CohomologyRightModuleGenerators(P, Q, CQ)`

Given projective resolutions P and Q for simple modules S and T over a basic algebra A and the cohomology generators CQ for T associated to the resolution Q, the function returns the chain maps in compact form of the minimal generators for the cohomology $\mathrm{Ext}^*_A(S,T)$ as a right module over the cohomology ring $\mathrm{Ext}^*_A(T,T)$. The function returns a record consisting of the following fields.

(a) The list of maps in compact form for the chain map of each cohomology generator (field name `ChainMapRecord`).

(b) The sequence of degrees of cohomology generators (field name `ChainDegrees`).

(c) The tops of the chain maps (maps on modules module radicals) for the purposes of computing products (field name `TopsOfCohomologyGenerators`).

`CohomologyLeftModuleGenerators(P, CP, Q)`

Given projective resolutions P and Q for simple modules S and T over a basic algebra A and the cohomology generators CP for T associated to the resolution Q, the function returns the chain maps in compact form of the minimal generators for the cohomology $\mathrm{Ext}^*_A(S,T)$ as a left module over the cohomology ring $\mathrm{Ext}^*_A(S,S)$. The function returns a record consisting of the following fields.

(a) The list of maps in compact form for the chain map of each cohomology generator (field name `ChainMapRecord`).

(b) The sequence of degrees of cohomology generators (field name `ChainDegrees`).

(c) The tops of the chain maps (maps on modules module radicals) for the purposes of computing products (field name `TopsOfCohomologyGenerators`).

`DegreesOfCohomologyGenerators(C)`

Given the generators C for cohomology, as either module generators or as ring generators, the function returns the list of degrees of the minimal generators.

`CohomologyGeneratorToChainMap(P, Q, C, n)`

Given the projective resolutions P and Q of two modules M and N and the cohomology generators C of the cohomology module, $\mathrm{Ext}^*_B(M,N)$, the function returns the chain map from P to Q that lifts the n^{th} generator of the cohomology module and has degree equal to the degree of that generator.

`CohomologyGeneratorToChainMap(P, C, n)`

Given the projective resolution P of a module and the cohomology generators C of the cohomology ring of that module, the function returns the chain map from P to P that lifts the n^{th} generator of the cohomology ring and has degree equal to the degree of that generator.

Example H85E19

We create the Basic algebra for the principal block of the sporadic simple group M_{11} in characteristic 2. The block algebra has three simple modules of dimension 1, 44, and 10. The basic algebra has dimension 22.

```
> ff := GF(2);
> VV8 := VectorSpace(ff,8);
> BB8 := Basis(VV8);
> MM8 := MatrixAlgebra(ff,8);
> e11 := MM8!0;
> e12 := MM8!0;
> e13 := MM8!0;
> e11[1]  := BB8[1];
> e11[4]  := BB8[4];
> e11[5]  := BB8[5];
> e11[8]  := BB8[8];
```

```
> e12[2]  := BB8[2];
> e12[7]  := BB8[7];
> e13[3]  := BB8[3];
> e13[6]  := BB8[6];
> a1 := MM8!0;
> b1 := MM8!0;
> c1 := MM8!0;
> d1 := MM8!0;
> e1 := MM8!0;
> f1 := MM8!0;
> a1[1] :=  BB8[2];
> a1[5] :=  BB8[7];
> b1[1] :=  BB8[3];
> b1[4] :=  BB8[6];
> c1[2] :=  BB8[4];
> c1[7] :=  BB8[8];
> e1[3] :=  BB8[5];
> e1[6] :=  BB8[8];
> f1[3] :=  BB8[6];
> A1 := sub< MM8 | [e11, e12, e13, a1, b1, c1, d1, e1, f1] >;
> T1 := [ <1,1>,<1,4>,<1,5>,<2,6>,<3,8>,<4,5>,<5,4>,<6,8>];
> VV6 := VectorSpace(ff,6);
> BB6 := Basis(VV6);
> MM6 := MatrixAlgebra(ff,6);
> e21 := MM6!0;
> e22 := MM6!0;
> e23 := MM6!0;
> e22[1]  := BB6[1];
> e22[5]  := BB6[5];
> e22[6]  := BB6[6];
> e21[2]  := BB6[2];
> e21[4]  := BB6[4];
> e23[3]  := BB6[3];
> a2 := MM6!0;
> b2 := MM6!0;
> c2 := MM6!0;
> d2 := MM6!0;
> e2 := MM6!0;
> f2 := MM6!0;
> a2[4] := BB6[6];
> b2[2] := BB6[3];
> c2[1] := BB6[2];
> d2[1] := BB6[5];
> d2[5] := BB6[6];
> e2[3] := BB6[4];
> A2 := sub< MM6 | [e21, e22, e23, a2, b2, c2, d2, e2, f2]>;
> T2 := [ <1,2>, <1,6>, <2,5>, <3,8>, <1,7>, <5,7> ];
> VV8 := VectorSpace(ff,8);
```

```
> BB8 := Basis(VV8);
> MM8 := MatrixAlgebra(ff,8);
> e31 := MM8!0;
> e32 := MM8!0;
> e33 := MM8!0;
> e31[2]  := BB8[2];
> e31[6]  := BB8[6];
> e32[4]  := BB8[4];
> e33[1]  := BB8[1];
> e33[3]  := BB8[3];
> e33[5]  := BB8[5];
> e33[7]  := BB8[7];
> e33[8]  := BB8[8];
> a3 := MM8!0;
> b3 := MM8!0;
> c3 := MM8!0;
> d3 := MM8!0;
> e3 := MM8!0;
> f3 := MM8!0;a3[2] :=  BB8[4];
> b3[6] :=  BB8[8];
> b3[2] :=  BB8[7];
> c3[4] :=  BB8[6];
> e3[1] :=  BB8[2];
> e3[3] :=  BB8[6];
> f3[1] :=  BB8[3];
> f3[3] :=  BB8[5];
> f3[5] :=  BB8[7];
> f3[7] :=  BB8[8];
> A3 := sub< MM8 | [e31, e32, e33, a3, b3, c3, d3, e3, f3] >;
> T3 := [ <1,3>,<1,8>,<1,9>,<2,4>,<3,9>,<4,6>,<5,9>,<6,5>];
>
> m11 := BasicAlgebra( [<A1, T1>, <A2, T2>, <A3, T3>] );
> m11;
Basic algebra of dimension 22 over GF(2)
Number of projective modules: 3
Number of generators: 9
> s1 := SimpleModule(m11,1);
> s2 := SimpleModule(m11,2);
```

Now we compute the projective resolutions of the first and second simple modules. Then we find the degrees of their cohomology ring generators.

```
> prj1 := CompactProjectiveResolution(s1,20);
> prj2 := CompactProjectiveResolution(s2,20);
> CR1 := CohomologyRingGenerators(prj1);
> CR2 := CohomologyRingGenerators(prj2);
> DegreesOfCohomologyGenerators(CR1);
[ 3, 4, 5 ]
> DegreesOfCohomologyGenerators(CR2);
```

```
[ 1, 2 ]
```

Finally we look at the cohomology Ext(`s2`, `s1`) as a left module over the cohomology ring of `s1` and as a right module over the cohomology ring of `s2`.

```
> CR12 := CohomologyLeftModuleGenerators(prj1,CR1,prj2);
> DegreesOfCohomologyGenerators(CR12);
[ 1, 2, 3, 4 ]
> CR12 := CohomologyRightModuleGenerators(prj1,prj2,CR2);
> DegreesOfCohomologyGenerators(CR12);
[ 1 ]
```

So as a module over the cohomology ring of `s1` it is generated by 4 elements. But as a module over the cohomology ring of `s2` it is generated by a single element.
Next we get the chain complex for the projective resolution of the first simple module and the chain map for the third generator of the cohomology ring of the first simple module.

```
> pj1 := ProjectiveResolution(s1,20);
> pj1;
Basic algebra complex with terms of degree 20 down to 0
Dimensions of terms: 74 66 68 68 60 54 54 54 48 40 40 42 34 26 28 28 20 14 14
   14 8
> gen113 := CohomologyGeneratorToChainMap(pj1,CR1,3);
> gen113;
Basic algebra chain map of degree -5
```

We can compose this with itself.

```
> gen113*gen113;
Basic algebra chain map of degree -10
```

Now compute the kernel and the dimensions of the homology of the kernel.

```
> Ker, phi := Kernel(gen113);
> Ker, phi;
Basic algebra complex with terms of degree 20 down to 0
Dimensions of terms: 20 15 19 20 20 17 17 20 22 15 17 22 20 15 19 20 20 14 14
14 8
Basic algebra chain map of degree 0
> DimensionsOfHomology(Ker);
[ 0, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0, 3, 0, 0, 0 ]
```

We apply the same procedure in the case of the cokernel.

```
> Cok, mu := Cokernel(gen113);
> Cok, mu;
Basic algebra complex with terms of degree 20 down to 0
Dimensions of terms: 74 66 68 68 60 0 3 5 0 0 3 5 0 0 3 5 0 0 3 5 0
Basic algebra chain map of degree 0
> DimensionsOfHomology(Cok);
```

```
[ 0, 0, 0, 27, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0, 2 ]
```

We can also check the image.

```
> Imm, theta, gamma := Image(gen113);
> Imm;
Basic algebra complex with terms of degree 20 down to 0
Dimensions of terms: 0 0 0 0 0 54 51 49 48 40 37 37 34 26 25 23 20 14 11 9 8
> DimensionsOfHomology(Imm);
[ 0, 0, 0, 0, 27, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0, 2, 0, 0, 0 ]
```

We can check that certain things make sense.

```
> IsChainMap(theta);
true
> IsChainMap(gamma);
true
```

85.10.1 Ext-Algebras

The ext-algebra of an algebra B is the algebra $Ext^*_B(S,S)$ for $S = S_1 \oplus \ldots \oplus S_n$ where $S_1, \ldots, S_n$ are all of the simple B-modules. In the event that the algebra B had finite global dimension, this is a finite dimensional algebra and we can form its basic algebra.

`ExtAlgebra(A, n)`

The function computes the information on the ext-algebra B of the basic algebra A where the projecive resolutions and cohomology have been computed to degree n. The function returns a record carrying the data:

(i) A free algebra F,

(ii) A list of relations in the elements of F, such that the ext-algebra is the quotient F/I where I is the ideal generated by the relations,

(iii) The sequence of chain maps of the generators. Each chain map goes from the projective resolution of one simple module to that of another.

(iv) The seqence of degrees of the generators.

(v) A sequence of sequences of sequences of basis element such the j^{th} element of the i^{th} sequence is a basis of in $Ext^*_A(S_i, S_j)$ where S_i is the i^{th} simple module.

(vi) A basis of the entire ext-algebra, the concatenation of the previous sequences.

(vii) The number of steps of the cohomology that were computed.

(viii) The global dimension that has been computed. This number is smaller than the number of steps only in the case that the global dimension of A is less than n, meaning that the n^{th} step in the projective resolution of any simple module is the zero module.

`BasicAlgebraOfExtAlgebra(ext)`

The function creates the basic algebra from a computed ext-algebra. The input is the output of the `ExtAlgebra` function. If the ext-algebra is not verified to be finite dimensional by the computation, then an error is returned.

`BasicAlgebraOfExtAlgebra(A)`

The function forms the basic algebra from a computed ext-algebra of the basic algebra A. If no ext-algebra for A has been computed or if the ext-algebra is not verified to be finite dimensional then an error is returned.

`BasicAlgebraOfExtAlgebra(A, n)`

The function creates the basic algebra for the ext-algebra of A computed to n steps. If no ext-algebra for A to n steps has been computed then it computes one. If the ext-algebra is not verified to be finite dimensional by the computation, then an error is returned.

`SumOfBettiNumbersOfSimpleModules(A, n)`

This function computes the Betti numbers of all of simple A-modules out to degree n. This is the dimension of the ext-algebra of A computed to degree n.

Example H85E20

We construct the basic algebra of the algebra B of lower triangular matrices over the field with 5 elements. Note that because the identity element of B is the sum of primitive idempotents of rank 1, B is actually isomorphic to its basic algebra.

```
> A := MatrixAlgebra(GF(5),10);
> U := A!0;
> ElementaryMatrix := function(i,j);
>     W := U;
>     W[i,j] := 1;
>     return W;
> end function;
> S := &cat[[ElementaryMatrix(i,j): i in [j .. 10]]:j in [1 .. 10]];
> B := sub<A|S>;
> B;
Matrix Algebra of degree 10 with 55 generators over GF(5)
> C := BasicAlgebra(B);
> C;
Basic algebra of dimension 55 over GF(5)
Number of projective modules: 10
Number of generators: 19
```

Note that C has the same dimension as B. The two are isomorphic, though they have different types.

```
> SumOfBettiNumbersOfSimpleModules(C,9);
19
```

```
> SumOfBettiNumbersOfSimpleModules(C,10);
19
```

From the above we see that C has global dimension at most 9. Consequently, we can compute the basic algebra of its ext-algebra.

```
> D:= ExtAlgebra(C,10);
> E := BasicAlgebraOfExtAlgebra(D);
> E;
Basic algebra of dimension 19 over GF(5)
Number of projective modules: 10
Number of generators: 19
> SumOfBettiNumbersOfSimpleModules(E,8);
54
> SumOfBettiNumbersOfSimpleModules(E,9);
55
> SumOfBettiNumbersOfSimpleModules(E,10);
55
```

Here we see that E has global dimension 9. So we compute the basic algebra of its ext-algebra.

```
> F := BasicAlgebraOfExtAlgebra(E,10);
> F;
Basic algebra of dimension 55 over GF(5)
Number of projective modules: 10
Number of generators: 19
> G := BasicAlgebraOfExtAlgebra(F,10);
> G;
Basic algebra of dimension 19 over GF(5)
Number of projective modules: 10
Number of generators: 19
```

So it would appear that C and F are isomorphic as well as E and G.

85.11 Group Algebras of p-groups

There is a special type for the basic algebras which are the modular group algebras of p-groups for p a prime. If G is a finite p and k is a field of characteristic p, then the commands `BasicAlgebra(`G, k`)` and `BasicAlgebra(`G`)` automatically create a basic algebra of type `AlgBasGrpP`. The type is optimized for the computation of cohomology rings. Included for this type are restriction and inflation maps. Most of the functions for modules and complexes are the same as for general basic algebras.

85.11.1 Access Functions

`Group(A)`

The group which defines the algebra A.

`PCGroup(A)`

The internal PC group of the algebra A.

`PCMap(A)`

The map from `Group(A)` to `PCGroup(A)` for an algebra A.

`AModule(M)`

Converts a `GModule` M over a p-group to a module over the basic algebra of that group.

`GModule(M)`

Returns the standard module of the algebra A as a module over `Group(A)` and as a module over `PCGroup(A)`.

`GModule(M)`

Converts a module M for the basic algebra of a p-group into a module over the p-group.

85.11.2 Projective Resolutions

`ResolutionData(A)`

Returns the data needed to compute the projective resolution of an A-module for an algebra A. The data is given as a record with the fields:

(a) The matrices of the `PCGenerators` of the p-group on the standard indecomposable projective module for the algebra (field name `PCgenMats`).

(b) The matrices of the minimal generators of the p-group on the standard indecomposable projective module for the algebra (field name `MingenMats`).

(c) The algebra A (field name `Algebra`).

`CompactProjectiveResolutionPGroup(M, n)`

`CompactProjectiveResolution(M, n)`

Computes the projective resolution of the module M out to n steps. The function returns a record with the fields:

(a) The list of the ranks of the projective modules in the resolution (field name `BettiNumbers`).

(b) The record of the boundary maps (field name `ResolutionRecord`).

(c) The module M (field name `Module`).

(d) The augmentation map (field name `AugmentationMap`).

(e) The type of the resolution, whether projective or injective (field name `Typ`).

`ProjectiveResolutionPGroup(PR)`

The projective resolution as a complex of modules over the basic algebra of the group algebra, computed from the compact projective resolution PR.

`ProjectiveResolution(M, n)`

The projective resolution of the module M computed as a complex out to n steps. The function also returns the augmentation map.

`ProjectiveResolution(PR)`

The projective resolution computed from a compact projective resolution PR as a complex. The function also returns the augmentation map.

85.11.3 Cohomology Generators

`AllCompactChainMaps(PR)`

Creates the data on the chain maps for all generators of the cohomology of the simple module k in degrees within the limits of the compact projective resolution PR of the simple module. The function returns a record having the following information.

(a) The record of the chain maps of the generators of cohomology (field name `ChainMapRecord`).

(b) The sequence of sizes of the chain map record (field name `ChainSizes`).

(c) The degrees of the chain maps (field name `ChainDegrees`).

(d) The list of cocycles representing the generators (field name `Cocycles`).

(e) The record of the products of the generators (field name `ProductRecord`).

(f) The locations of the products of the generators (field name `ProductLocations`). Much of the information is for use in the computation of the cohomology ring.

`CohomologyElementToChainMap(P, d, n)`

Creates a chain map from the projective resolution P to itself for the element number n in degree d of cohomology.

`CohomologyElementToCompactChainMap(PR, d, n)`

Creates a chain map in compact form from the compact projective resolution PR to itself for the element number n in degree d of cohomology.

85.11.4 Cohomology Rings

`CohomologyRing(k, n)`

`CohomologyRing(PR, AC)`

The cohomology ring of the unique simple module k for the basic algebra of the group algebra of a p-group. The input can be given either as the module k and the number of steps n or as the compact projective resolution PR of k together with AC, the calculation of the chain map generators of the cohomology. In the former case the compact resolution and the chain map of the generators are computed in the process. The ring is returned as a record having the following fields:

(a) The polynomial ring or free graded-commutative k-algebra R generated by the cohomology generators (field name `PolRing`).

(b) The ideal of relations in R satisfied by the cohomology generators (field name `RelationsIdeal`).

(c) The list of relations that have been computed (field name `ComputedRelations`).

(d) The chain maps giving the tops of the monomial in the cohomology generators (field name `MonomialData`).

(e) The number of computed steps in the resolution (field name `NumberOfSteps`).

`MinimalRelations(R)`

A minimal set of relations generating the relations ideal of a cohomology ring R.

85.11.5 Restrictions and Inflations

`RestrictionData(A,B)`

Assuming that A is the basic algebra of a p-group G and that B is the basic algebra of a subgroup of G, the function returns the change of basis matrix that make the standard free module for A into a direct sum of standard free modules for B. It also returns the inverse of the matrix and a set of coset representatives of the `PCGroup(B)` in `PCGroup(A)`.

`RestrictResolution(PR, RD)`

Takes the compact projective resolution PR for the trivial module of G and the resolution data RD for the basic algebra of a subgroup H and returns the restriction of the resolution to a complex of modules over the basic algebra for H.

`RestrictionChainMap(P1,P2)`

Computes the chain map from the resolution $P2$ of the simple module for the basic algebra of a subgroup H of a group G to the restriction to H of the resolution $P1$ of the simple module for the basic algebra of G. The inputs $P1$ and $P2$ must be in compact form.

`RestrictionOfGenerators(PR1, PR2, AC1, AC2, REL2)`

Computes the sequence of images of the generators of the cohomology ring of G restricted to a subgroup H. The input is the projective resolutions and cohomology generators for the basic algebra of G ($PR1$ and $AC1$) and for the basic algebra of the subgroup ($PR2$ and $AC2$), as well as the cohomology relations for the subgroup, $REL2$.

`InflationMap(PR2, PR1, AC2, AC1, REL1, theta)`

Returns the images of the generators of the cohomology ring of a quotient group Q in the cohomology ring of a group G. The input θ is the quotient map $G \to Q$. Other input is the projective resolutions and cohomology generators for the basic algebra of G ($PR1$ and $AC1$) and for the quotient group Q ($PR2$ and $AC2$) as well as the cohomology relations for G, $REL1$.

Example H85E21

We create the cohomology ring of a group G of order 64 and find a cyclic subgroup Z of the center of G. We compute the restriction of the cohomology of G to the cohomology of Z and also the inflation of the cohomology of G/Z to the cohomology ring of G.

```
> SetSeed(1);
> G := SmallGroup(64,7);
> Z := sub<G| Random(Center(G))>;
> G;
GrpPC : G of order 64 = 2^6
PC-Relations:
    G.1^2 = G.4,
    G.2^2 = G.5,
    G.3^2 = G.5,
    G.4^2 = G.6,
    G.2^G.1 = G.2 * G.3,
    G.3^G.1 = G.3 * G.5,
    G.3^G.2 = G.3 * G.5
> #Z, [G!Z.i: i in [1 .. Ngens(Z)]];
4 [ G.4 ]
```

So we see that Z has order 4 and is generated by the element $G.4$. Now construct the quotient and the basic Algebras.

```
> Q, mu := quo<G|Z>;
> A := BasicAlgebra(G);
> B := BasicAlgebra(Q);
> C := BasicAlgebra(Z);
```

Next we want the simple modules and the cohomology rings. We compute the cohomology out to 17 steps which should be more than enough to get the generators and relations.

```
> k := SimpleModule(A,1);
> kk := SimpleModule(B,1);
```

```
> kkk := SimpleModule(C,1);
> time R := CohomologyRing(k,17);
Time: 2.060
> time S := CohomologyRing(kk,17);
Time: 0.140
> time T := CohomologyRing(kkk,17);
Time: 0.060
```

The structure of the cohomology rings can be read from the following outputs.

```
> R`RelationsIdeal,S`RelationsIdeal,T`RelationsIdeal;
First the cohomology ring for $G$.
Ideal of Graded Polynomial ring of rank 6 over GF(2)
Lexicographical Order
Variables: $.1, $.2, $.3, $.4, $.5, $.6
Variable weights: 1 1 2 2 3 4
Basis:
[
    $.1^2,
    $.1*$.2,
    $.2^3,
    $.1*$.3,
    $.2*$.5,
    $.3^2,
    $.1*$.5 + $.2^2*$.3,
    $.3*$.5,
    $.5^2
]
```

Now the cohomology ring for Q.

```
Ideal of Graded Polynomial ring of rank 4 over GF(2)
Lexicographical Order
Variables: $.1, $.2, $.3, $.4
Variable weights: 1 1 3 4
Basis:
[
    $.1*$.2,
    $.1^3,
    $.1*$.3,
    $.2^2*$.4 + $.3^2
]
```

And finally the cohomology ring for Z.

```
Ideal of Graded Polynomial ring of rank 2 over GF(2)
Lexicographical Order
Variables: $.1, $.2
Variable weights: 1 2
Basis:
[
```

```
    $.1^2
]
```

Next we require the inputs for the restriction and inflation maps.

```
> Pr1 := k‘CompactProjectiveResolution;
> Pr2 := kk‘CompactProjectiveResolution;
> Pr3 := kkk‘CompactProjectiveResolution;
> Ac1 := k‘AllCompactChainMaps;
> Ac2 := kk‘AllCompactChainMaps;
> Ac3 := kkk‘AllCompactChainMaps;
```

Now the inflation map from Q to G sends the generators of the cohomology of Q to the given list of elements in the cohomology ring of G.

```
> inf := InflationMap(Pr2,Pr1,Ac2,Ac1,R,mu);
> inf;
[
    $.2,
    $.1,
    $.5,
    $.6
]
```

The restriction map from the cohomology ring of G to the cohomology ring of Z sends the generators of R to the corresponding elements in the computed sequence.

```
> res := RestrictionOfGenerators(Pr1,Pr3,Ac1,Ac3,T);
> res;
[
    0,
    0,
    0,
    $.2,
    0,
    0
]
```

Finally, a set of minimal relations is determined for the cohomology ring R.

```
> MinimalRelations(R);
[
    $.1^2,
    $.1*$.2,
    $.2^3,
    $.1*$.3,
    $.2*$.5,
    $.3^2,
    $.1*$.5 + $.2^2*$.3,
    $.3*$.5,
    $.5^2
```

]

85.12 A-infinity Algebra Structures on Group Cohomology

As described in [Kel01, **????**], an $A\infty$-algebra structure can be induced on H^*A for any differential graded algebra A. Consider $\mathrm{Ext}^*_R(S,S)$, for R a quiver algebra quotient and S the direct sum of all simple R-modules. Regarded as the homology of the endomorphism algebra of a projective resolution of S, Keller further demonstrates how this additional algebraic structure allows recovery of R from $\mathrm{Ext}^*_R(S,S)$.

An $A\infty$-algebra structure on a vector space V consists of higher structural operations $m_1,\ldots$ defined as $m_i : V^{\otimes i} \to V$ fulfilling the Stasheff axioms for all n:

$$\sum_{i+j-1=n, 0\le k\le n-j} \pm m_i(a_1,\ldots,a_{k-1},m_j(a_k,\ldots,a_{k+j}),a_{k+j+1},\ldots,a_n) = 0$$

An $A\infty$-algebra homomorphism from an $A\infty$-algebra A to an $A\infty$-algebra B is a family f_i of maps $A^{\otimes i} \to B$ such that the homomorphism axioms hold for all n:

$$\sum_{i+j-1=n, 0\le k\le n-j} \pm f_i(a_1,\ldots,a_{k-1},m_j(a_k,\ldots,a_{k+j}),a_{k+j+1},\ldots,a_n) =$$

$$\sum_{i_1+\ldots+i_r=n} \pm m_r(f_{i_1}(a_1,\ldots,a_{i_1}),\ldots,f_{i_r}(a_{n-i_r+1},\ldots,a_n))$$

According to a theorem fundamental to the algebraic uses of $A\infty$-techniques, for a differential graded algebra A, there is an $A\infty$-structure on H^*A and an $A\infty$-algebra homomorphism $f : H^*A \to A$ such that f_1 is a quasiisomorphism of differential graded algebras, and induced by the identity map on H^*A.

A blackbox method of calculation can be based on Kadeishvilis' proof of this statement, using the homomorphism axioms to recursively calculate any specific values that are needed, and choosing the m_i and f_i in such a way as not to violate the axioms. The following package implements this method for the special case of $\mathrm{Ext}^*_{kG}(k,k)$ for G a p-group, k a prime field of characteristic p and also the one-dimensional unique simple kG-module.

`AInfinityRecord(G,n)`

Constructs a record carrying all relevant information to calculate $A\infty$-operations on a group cohomology ring. Among the data carried can be found the cohomology ring in `R`, the cohomology ring quotient in `S`, the projective resolution used in `P`, the simple module resolved in `k` and the basic algebra in `A`.

`MasseyProduct(Aoo,terms)`

`HighProduct(Aoo,terms)`

Given an $A\infty$ object *Aoo* corresponding to a group cohomology ring, this intrinsic calculates the structure map $m_i(t_1 \otimes \ldots \otimes t_i)$, where the i give the length of terms, and $t_1, \ldots, t_i$ are the elements of terms.

`HighMap(Aoo,terms)`

Given an $A\infty$ object *Aoo* corresponding to a group cohomology ring, this intrinsic calculates the value of an $A\infty$-quasiisomorphism f at the point $t_1 \otimes \ldots \otimes t_i$, where the i gives the length of terms, and $t_1, \ldots, t_i$ are the elements of terms.

Example H85E22

The $A\infty$-structures on the cohomology rings of cyclic p-groups are well known examples in the literature: the $A\infty$-structure on $H^*(C_n, F_2)$ has one single higher structure nontrivial operation, namely m_n, which takes any n-tuple of odd coclasses to the even coclass of appropriate degree. In order to verify this for a specific example, we start by constructing an $A\infty$ record that contains all relevant information for the cohomology ring.

```
> Aoo := AInfinityRecord(CyclicGroup(4),10);
> S<x,y> := Aoo`S;
> HighProduct(Aoo,[x,x,x,x]);
y
> HighMap(Aoo,[x,x,x,x]);
Basic algebra chain map of degree -1
```

Example H85E23

The code as written handles odd characteristics well, with the sign choices featured in Kadeishvilis article [Kad80] embedded in the code.

```
> Aoo := AInfinityRecord(CyclicGroup(3),10);
> S<x,y> := Aoo`S;
> HighProduct(Aoo,[x,x,x]);
y
> HighMap(Aoo,[x,x,x]);
Basic algebra chain map of degree -1
```

85.12.1 Homological Algebra Toolkit

For the computation of $A\infty$-structures, several methods are used that would invite a wider use in a generic homological algebra toolkit.

`ActionMatrix(A,x)`

Produces a matrix of the right action of the Basic algebra element described by x in the Basic algebra A.

`CohomologyRingQuotient(CR)`

Computes the actual cohomology ring as a quotient ring of a multivariate polynomial ring from a cohomology ring record.

`LiftToChainmap(P,f,d)`

Lifts the function described by f to a chain map from P to P of degree d.

`NullHomotopy(f)`

Constructs a null homotopy of the null homotopic chain map f. If f is not null homotopic, the function will throw an error message, since in that case some of the equations encountered on the way are not solvable.

`IsNullHomotopy(f,H)`

Confirms that H is a null homotopy of f, in other words that $f = dH - Hd$, with d the differential of the corresponding chain complexes.

`ChainmapToCohomology(f,CR)`

Takes a chain map f and returns the element in the cohomology quotient ring to which the chain map corresponds.

`CohomologyToChainmap(xi,CR,P)`

Takes an element xi of a cohomology quotient ring of the cohomology ring record CR and a projective resolution corresponding to that cohomology ring, and returns a chain map in the coclass represented by xi.

Example H85E24

To illustrate the code that generates null homotopies, we consider the cohomology ring of a cyclic group, and pick out chain map representatives for the degree 1 coclass. Although this squares to zero, the corresponding chainmaps do not compose to the zero chainmap.

```
> A := BasicAlgebra(CyclicGroup(4));
> k := SimpleModule(A,1);
> P := ProjectiveResolution(k,5);
> R := CohomologyRing(k,5);
> S<x,y> := CohomologyRingQuotient(R);
> xi := CohomologyToChainmap(x,R,P);
> x*x;
```

```
0
> IsZero(xi*xi);
false
> ModuleMaps(xi*xi);

86 QUATERNION ALGEBRAS

Chapter 86
QUATERNION ALGEBRAS

86.1 Introduction

A quaternion algebra A over a field K is a central simple algebra of dimension four over K, or equivalently when K does not have characteristic 2, an algebra generated by elements i, j which satisfy

$$i^2 = a,\ j^2 = b,\ ji = -ij$$

with $a, b \in K^*$. A quaternion algebra in MAGMA is a specialized type `AlgQuat`, which is a subtype of associative algebra `AlgAss` defined over a field. MAGMA can recognize if an associative algebra A is a quaternion algebra and will return a standard representation for A with a, b as above.

Examples of quaternion algebras include the ring $M_2(K)$ of 2×2-matrices over K with $a = b = 1$, as well as the division ring of Hamiltonians over $K = \mathbf{R}$ with $a = b = -1$. Every quaternion algebra over a finite field or an algebraically closed field is isomorphic to $M_2(K)$. Over a local field, there is a unique quaternion algebra (up to isomorphism) which is a division ring.

Every quaternion algebra A over K not isomorphic to $M_2(K)$ is a division algebra. Finding a zerodivisor in A is computationally equivalent to the problem of finding a K-rational point on a conic. Given a zerodivisor in A, MAGMA will compute an explicit isomorphism $A \to M_2(K)$. If L is an extension field of K, then $A_L = A \otimes_K L$ is a quaternion algebra over L, and we say L is a *splitting field* if $A_L \cong M_2(L)$. If $[L : K] = 2$, then L is a splitting field if and only if there exists a K-embedding $L \hookrightarrow A$, and such an embedding can be computed in MAGMA.

Further functionality is available for quaternion algebras A defined over number fields K. Such an algebra is said to be *unramified* at a noncomplex place v of K if K_v is a splitting field for A, otherwise A is *ramified* at v. Testing if an algebra is ramified at a place is encoded in the *Hilbert symbol*, which can be computed for any such algebra. The set S of ramified places of an algebra is finite and of even cardinality, and conversely, given such a set S there exists a quaternion algebra which is ramified only at S. One may compute the set of ramified places of A as well as constructing an algebra given its ramification set.

In MAGMA, there are algorithms for quaternion algebras which are analogous to those for number fields—computation of the ring of integers, class group, and unit group. One may compute a maximal order $O \subset A$, a p-maximal order for a prime p of K, and orders with given index in a maximal order. Secondly, a representative set of (right) ideal classes in O can be enumerated, and one can test if two ideals are isomorphic (hence if a given ideal is principal). Finally, for a definite quaternion algebra (defined over a totally real field), one may compute the group of units of norm 1 in O. Over $\mathbf{Q}$, these functions tie into machinery for constructing the Brandt module, with applications to modular forms.

Orders for quaternion algebras over the rational numbers and over rational function fields in MAGMA have type `AlgQuatOrd` and ideals have type `AlgQuatOrdIdl`. Over other number rings, orders have the general type `AlgAssVOrd` and ideals `AlgAssVOrdIdl` which is also the type for used for associative orders. The types `AlgQuatOrd`, `AlgQuatOrdElt` and `AlgQuatOrdIdl` inherit from the types `AlgAssVOrd`, `AlgAssVOrdElt` and `AlgAssVOrdIdl` respectively.

The main reference for material in this chapter is the book of Vignéras [Vig80]. Most nontrivial algorithms for quaternion algebras over the rationals and over number fields are described in [KV10].

IMPORTANT WARNING.

In MAGMA, the rationals are *not* considered to be a number field (the type `FldRat` is not a subtype of `FldNum`). Much of the functionality for quaternion algebras, and particularly for orders in quaternion algebras, is implemented only for algebras whose base field is a `FldNum` (while some, but not all, also works for algebras over the `FldRat`). To compute with algebras over $\mathbf{Q}$, in many cases the best solution is to create $\mathbf{Q}$ as a number field at the outset, using `RationalsAsNumberField()`, and create the algebra over this field instead of `Rationals()`.

86.2 Creation of Quaternion Algebras

A general constructor for a quaternion algebra over any field K creates a model in terms of two generators x and y and three relations

$$x^2 = a, \quad y^2 = b, \quad yx = -xy$$

with $a, b \in K^*$ if K has characteristic different from 2, and

$$x^2 + x = a, \quad y^2 = b, \quad yx = (x+1)y$$

if K has characteristic 2. The printing names i, j, and k are assigned to the generators x, y, and xy by default, unless the user assigns alternatives (see the function `AssignNames` below, or the example which follows).

Special constructors are provided for quaternion algebras over $\mathbf{Q}$, which return an algebra with a more general set of three defining quadratic relations. In general, the third generator need not be the product of the first two. This allows the creation of a quaternion algebra A such that the default generators $\{1, i, j, k\}$ form a basis for a maximal order.

`QuaternionAlgebra< K | a, b >`

For $a, b \in K^*$, this function creates the quaternion algebra A over the field K on generators i and j with relations $i^2 = a$, $j^2 = b$, and $ji = -ij$ or $ji = (i+1)j$, as $\mathrm{char}(K) \neq 2$ or $\mathrm{char}(K) = 2$, respectively. A third generator is set to $k = ij$. The field K may be of any MAGMA field type; for inexact fields, such as local fields, one should expect unstable results since one cannot test deterministically for element equality.

`AssignNames(~A, S)`

Given a quaternion algebra A and sequence S of strings of length 3, this function assigns the strings to the generators of A, i.e. the basis elements not equal to 1. This function is called by the bracket operators `< >` at the time of creation of a quaternion algebra.

Example H86E1

A general quaternion algebra can be created as follows. Note that the brackets `< >` can be used to give any convenient names to the generators of the ring.

```
> A<x,y,z> := QuaternionAlgebra< RationalField() | -1, -7 >;
> x^2;
-1
> y^2;
-7
> x*y;
z
```

In the case of this constructor the algebra generators are of trace zero and are pairwise anticommuting. This contrasts with some of the special constructors for quaternion algebras over the rationals described below.

Example H86E2

Similarly, we have the following for characteristic 2.

```
> A<i,j> := QuaternionAlgebra< GF(2) | 1, 1 >;
> i^2;
1 + i
> j^2;
1
```

`QuaternionAlgebra(N)`

`Al`	MonStgElt	*Default :* "*TraceValues*"
`Optimized`	BoolElt	*Default :* `true`

Given a positive squarefree integer N, this function returns a rational quaternion algebra of discriminant N. If the optional parameter `Al` is set to `"Random"`, or N is the product of an even number of primes (i.e. the algebra is indefinite), then a faster, probabilistic algorithm is used. If `Al` is set to `"TraceValues"` and N is a product of an odd number of primes, then an algebra basis is computed which also gives a basis for a maximal order (of discriminant N). If `Optimized` is `true` then an optimized representation of the algebra is returned.

`QuaternionAlgebra(N)`

Given a squarefree polynomial $N \in \mathbf{F}_q[x]$ for some odd q, this function returns a quaternion algebra over $\mathbf{F}_q(x)$ of discriminant N.

`QuaternionAlgebra(I)`

`Optimized` BoolElt *Default :* `true`

Given an ideal I of a number field F with an even number of prime ideal factors, the function returns the quaternion algebra A over F which is ramified exactly at the primes dividing I. The ideal I is not required to be squarefree, so A will be ramified at the radical of I. If `Optimized` is `true` then an optimized representation of the algebra is returned.

`QuaternionAlgebra(I, S)`

`Optimized` BoolElt *Default :* `true`

Given an ideal I and a subset S of real places of a number field F such that the number of prime ideal divisors of I has the same parity as S, the function returns the quaternion algebra which is ramified exactly at the primes dividing I and at the real places specified by the set S. If `Optimized` is `true` then an optimized representation of the algebra is returned.

`QuaternionAlgebra(S)`

`Optimized` BoolElt *Default :* `true`

Given an even set S of noncomplex places of a number field F, this function returns the quaternion algebra which is ramified exactly at S. If `Optimized` is `true` then an optimized representation of the algebra is returned.

Example H86E3

We illustrate the above constructors in the case of a general number field.

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Foo := InfinitePlaces(F);
> Z_F := MaximalOrder(F);
> I := ideal<Z_F | 6>;
> A := QuaternionAlgebra(I);
> FactoredDiscriminant(A);
[
    Prime Ideal of Z_F
    Two element generators:
        [3, 0, 0]
        [2, 1, 0],
    Principal Prime Ideal of Z_F
    Generator:
        [2, 0, 0]
```

```
]
[]
> A := QuaternionAlgebra(ideal<Z_F | 1>, Foo[1..2]);
> FactoredDiscriminant(A);
[]
[ 1st place at infinity, 2nd place at infinity ]
```

`QuaternionAlgebra(D1, D2, T)`

This intrinsic creates the rational quaternion algebra $\mathbf{Q}\langle i, j\rangle$, where $\mathbf{Z}[i]$ and $\mathbf{Z}[j]$ are quadratic suborders of discriminant D_1 and D_2, respectively, and $\mathbf{Z}[ij - ji]$ is a quadratic suborder of discriminant $D_3 = D_1D_2 - T^2$. The values D_1D_2 and T must have the same parity and D_1, D_2 and D_3 must each be the discriminant of some quadratic order, i.e. nonsquare integers congruent to 0 or 1 modulo 4.

Example H86E4

The above constructor is quite powerful for constructing quaternion algebras with given ramification. For any i and j, a commutator element such as $ij - ji$ has trace zero, so in the above constructor, the minimal polynomial of this element is $x^2 + n$, where $n = (D_1D_2 - T^2)/4$.
In the following example we construct such a ring, and demonstrate some of the relations satisfied in this algebra. Note that the minimal polynomial is an element of the commutative polynomial ring over the base field of the algebra.
In particular, we note that the algebra is not in standard form.

```
> A<i,j,k> := QuaternionAlgebra(-7,-47,1);
> PQ<x> := PolynomialRing(RationalField());
> MinimalPolynomial(i);
x^2 - x + 2
> MinimalPolynomial(j);
x^2 - x + 12
> MinimalPolynomial(k);
x^2 - x + 24
> i*j;
k
> i*j eq -j*i;
false
```

From their minimal polynomials, we see that the algebra generators i, j, and k generate commutative subfields of discriminants -7, -47, and -95. The value $82 = (D_1D_2 - T^2)/4$, however, is a more important invariant of the ring. We give a preview of the later material by demonstrating the functionality for computing the determinant and ramified primes of an algebra over $\mathbf{Q}$.

```
> MinimalPolynomial(i*j-j*i);
x^2 + 82
> Discriminant(A);
41
> RamifiedPrimes(A);
```

```
[ 41 ]
```

A ramified prime must be inert or ramified in every subfield and must divide the norm of any commutator element $xy - yx$.

```
> x := i;
> y := j;
> Norm(x*y-y*x);
82
> Factorization(82);
[ <2, 1>, <41, 1> ]
> x := i-k;
> y := i+j+k;
> Norm(x*y-y*x);
1640
> Factorization(1640);
[ <2, 3>, <5, 1>, <41, 1> ]
> KroneckerSymbol(-7,2), KroneckerSymbol(-47,2), KroneckerSymbol(-95,2);
1 1 1
> KroneckerSymbol(-7,41), KroneckerSymbol(-47,41), KroneckerSymbol(-95,41);
-1 -1 -1
```

The fact that the latter Kronecker symbols are -1, indicating that 41 is inert in the quadratic fields of discriminants -7, -47, and -95, proves that 41 is a ramified prime, and 2 is not.

86.3 Creation of Quaternion Orders

Let R be a ring with field of fractions K, and let A be a quaternion algebra over K. An *R-order* in A is a subring $O \subset A$ which is a R-submodule of A with $O \cdot K = A$. An order is *maximal* if it is not properly contained in any other order.

One can create orders for number rings R, for $R = \mathbf{Z}$ or for $R = k[x]$ with k a field. Unlike commutative orders, it is important to note that maximal orders O of quaternion algebras are no longer unique: for any $x \in A$ not in the normalizer of O, we have another maximal order given by $O' = x^{-1}Ox \neq O$.

When $R = \mathbf{Z}$ or $R = k[x]$, the order O has type `AlgQuatOrd`. When R inherits from type `RngOrd` (a number ring), the order O has type `AlgAssVOrd`; see Section 81.4 for more information on constructors and general procedures for these orders.

See above (86.1) for an important warning regarding quaternion algebras over the rationals.

86.3.1 Creation of Orders from Elements

The creation of orders from elements of number rings is covered in Section 81.4. The creation of quaternion orders over the integers and univariate polynomial rings is covered in this section.

`QuaternionOrder(S)`

`IsBasis` BoolElt *Default :* `false`

Given S a sequence of elements in a quaternion algebra defined over $\mathbf{Q}$ or $\mathbf{F}_q(X)$, this function returns the order generated by S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$. If the set S does not generate an order, an error will be returned. If the parameter `IsBasis` is set to `true` then S will be used as the basis of the order returned.

`QuaternionOrder(R, S)`

`Order(R, S)`

`Check` BoolElt *Default :* `true`

Given a ring R and a sequence S of elements of a quaternion algebra over $\mathbf{Q}$ or $\mathbf{F}_q(X)$, this function returns the R-order with basis S. The sequence must have length four.

Example H86E5

First we construct an order over a polynomial ring.

```
> K<t> := FunctionField(FiniteField(7));
> A<i,j,k> := QuaternionAlgebra< K | t, t^2+t+1 >;
> O := QuaternionOrder( [i,j] );
> Basis(O);
[1, i, j, k ]
```

Next we demonstrate how to construct orders in quaternion algebras generated by a given sequence of elements. When provided with a sequence of elements of a quaternion algebra over $\mathbf{Q}$, Magma reduces the sequence so as to form a basis. When provided with the ring over which these elements are to be interpreted, the sequence must be a basis with initial element 1, and the order having this basis is constructed.

```
> A<i,j,k> := QuaternionAlgebra< RationalField() | -1, -3 >;
> B := [ 1, 1/2 + 1/2*j, i, 1/2*i + 1/2*k ];
> O := QuaternionOrder(B);
> Basis(O);
[ 1, 1/2*i + 1/2*k, 1/2 - 1/2*j, -1/2*i + 1/2*k ]
> S := QuaternionOrder(Integers(),B);
> Basis(S);
[ 1, 1/2 + 1/2*j, i, 1/2*i + 1/2*k ]
```

86.3.2 Creation of Maximal Orders

`MaximalOrder(A)`

A maximal order is constructed in the quaternion algebra A. The algebra A must be defined over a field K where K is either a number field, $\mathbf{Q}$, $\mathbf{F}_q(X)$ with q odd, or the field of fractions of a number ring. Over $\mathbf{F}_q(X)$ we use the standard algorithm [Fri97, IR93]. Over the rationals or over a number field, we use a variation of this algorithm optimized for the case of quaternion algebras. First, a factorization of the discriminant of a tame order (see below) is computed. Then, for each prime p dividing the discriminant, a p-maximal order compatible with the existing order is computed. The method used corresponds to Algorithm 4.3.8 in [Voi05]. See also [Voi11].

Example H86E6

The following is an example of a quaternion algebra which is unramified at all finite primes.

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> A<alpha,beta,alphabeta> := QuaternionAlgebra<F | -3,b>;
> O := MaximalOrder(A);
> Factorization(Discriminant(O));
[]
```

Hence the algebra A has a maximal order of discriminant 1, or equivalently, A is unramified at all finite places of F.
Since we are working over a general order of a number field, we can no longer guarantee that an order will have a free basis, so it must be represented by a pseudomatrix. For more on pseudomatrices, see Section 55.10.

```
> Z_F := BaseRing(O);
> PseudoBasis(O);
[
    <Principal Ideal of Z_F
    Generator:
        Z_F.1, Z_F.1>,
    <Fractional Ideal of Z_F
    Two element generators:
        Z_F.1
        2/3*Z_F.1 + 1/6*Z_F.2 + 1/6*Z_F.3, 3/1*Z_F.1 + i>,
    <Principal Ideal of Z_F
    Generator:
        Z_F.1, j>,
    <Fractional Ideal of Z_F
    Two element generators:
        Z_F.1
        11/2*Z_F.1 + 1/6*Z_F.2 + 35/6*Z_F.3, 3/1*Z_F.1 - i + 3/1*Z_F.1*j + k>
```

```
]
```

The wide applicability of the above algorithm, is demonstrated by examining a "random" quaternion algebra over a "random" quadratic number field.

```
> for c := 1 to 10 do
>   D := Random([d : d in [-100..100] | not IsSquare(d)]);
>   K<w> := NumberField(x^2-D);
>   Z_K := MaximalOrder(K);
>   K<K1,w> := FieldOfFractions(Z_K);
>   a := Random([i : i in [-50..50] | i ne 0]) + Random([-50..50])*w;
>   b := Random([i : i in [-50..50] | i ne 0]) + Random([-50..50])*w;
>   printf "D = %o, a = %o, b = %o\n", D, a, b;
>   A := QuaternionAlgebra<K | a,b>;
>   O := MaximalOrder(A);
>   ds := [<pp[1],pp[2],HilbertSymbol(A,pp[1])> :
>           pp in Factorization(Discriminant(O))];
>   print ds;
>   for d in ds do
>     if d[3] eq 1 then
>       break c;
>     end if;
>   end for;
> end for;
D = 5, a = -46/1*K1 + 25/1*w, b = -10/1*K1 - 7/1*w
[
    <Prime Ideal of Z_K
    Two element generators:
        [31, 0]
        [5, 2], 2, -1>,
    <Prime Ideal of Z_K
    Two element generators:
        [11, 0]
        [6, 2], 2, -1>
]
...
```

For each such "random" quaternion algebra, we verify that the Hilbert symbol evaluated at each prime dividing the discriminant of the maximal order is -1, indicating that the algebra is indeed ramified at the prime.

`MaximalOrder(O)`

For O a quaternion order defined over $\mathbf{Z}$, $\mathbf{F}_q[X]$ with q odd or a number ring, this function returns a maximal order containing O.

`pMaximalOrder(O, p)`

For O a quaternion order defined over $\mathbf{Z}$, $\mathbf{F}_q[X]$ with q odd or a number ring and a prime (ideal) p, this function returns a p-maximal order O' containing the order O. The p-adic valuation of the discriminant of O' (which is either 0 or 1) is returned as a second return value.

`TameOrder(A)`

Given a quaternion algebra A, this function returns an order O having the property that the odd reduced discriminant of O is squarefree. The algebra A must be defined over a number field or field of fractions of a number ring. The algorithm ignores even primes and does not test the remaining odd primes for maximality.

86.3.3 Creation of Orders with given Discriminant

The following two functions together with the maximal order algorithms of the previous subsection allow the construction of arbitrary Eichler orders.

`Order(O, N)`

Given an order O in a quaternion algebra A over the rationals or $\mathbf{F}_q(x)$ with q odd, and some element N in the base ring of O, this function returns a suborder O' of O having index N. Currently, N and the level of O must be coprime and N must have valuation at most 1 at each ramified prime of A. The order O' is locally Eichler at all prime divisors of N that are not ramified in A. In particular, if O is Eichler and N is coprime to the discriminant of A, so is O'.

`Order(O, N)`

Given a maximal quaternion order O over a number ring, this function returns an Eichler order of level N inside O.

`GorensteinClosure(O)`

Given a quaternion order O over the integers, $\mathbf{F}_q[x]$ with q odd or a number ring, this function returns the smallest Gorenstein order containing O.

Example H86E7

First we construct a quaternion algebra A over $\mathbf{F}_5(x)$ ramified at x^2+x+1, then a maximal order M in A and finally an Eichler O order of discriminant $(x^2+x+1)(x^3+x+1)^5$.

```
> P<x> := PolynomialRing(GF(5));
> A := QuaternionAlgebra(x^2+x+1);
> M := MaximalOrder(A);
> O := Order(M, (x^3+x+1)^5);
> FactoredDiscriminant(O);
[
    <x^2 + x + 1, 1>,
    <x^3 + x + 1, 5>
]
```

86.3.4 Creation of Orders with given Discriminant over the Integers

When constructing quaternion orders over the integers, several shortcuts are available.

`QuaternionOrder(A, M)`

Given a quaternion algebra A and a positive integer M, this function returns an order of index M in a maximal order of the quaternion algebra A defined over $\mathbf{Q}$. The second argument M can have at most valuation 1 at any ramified prime of A.

`QuaternionOrder(N)`

`QuaternionOrder(N, M)`

Given positive integers N and M, this function returns an order of index M in a maximal order of the rational quaternion algebra A of discriminant N. The discriminant N must be a product of an odd number of distinct primes, and the argument M can be at most of valuation 1 at any prime dividing N. If M is omitted, the integer M defaults to 1, i.e., the function will return a maximal order.

`QuaternionOrder(D1, D2, T)`

This intrinsic constructs the quaternion order $\mathbf{Z}\langle x, y\rangle$, where $\mathbf{Z}[x]$ and $\mathbf{Z}[y]$ are quadratic subrings of discriminant D_1 and D_2, respectively, and $\mathbf{Z}[xy - yx]$ is a quadratic subring of discriminant $D_1 D_2 - T^2$.

Note that the container algebra of such a quaternion order is **not** usually in standard form (see the example below).

Example H86E8

The above constructors permit the construction of Eichler orders over $\mathbf{Z}$, if the discriminant N and the index M are coprime. More generally they allow the construction of an order whose index in an Eichler order divides the discriminant.

```
> A := QuaternionOrder(103,2);
> Discriminant(A);
206
> Factorization($1);
[ <2, 1>, <103, 1> ]
> _<x> := PolynomialRing(Rationals());
> [MinimalPolynomial(A.i) : i in [1..4]];
[
    x - 1,
    x^2 + 1,
    x^2 - x + 52,
    x^2 + 104
]
```

The constructor `QuaternionOrder(D1, D2, T)` may return an order whose container algebra is not in standard form.

```
> A := QuaternionOrder(-4, 5, 2);
```

```
> B := Algebra(A);
> B.1 * B.2 eq - B.2 * B.1;
false
```

86.4 Elements of Quaternion Algebras

For more information about elements of orders of associative algebras, see Section 81.4.

86.4.1 Creation of Elements

`A ! 0`
`Zero(A)`

The zero element of the quaternion algebra A.

`A ! 1`
`One(A)`

The identity element of the quaternion algebra A.

`A . i`
`Name(A, i)`

Given a quaternion algebra A and an integer $1 \leq i \leq 3$, returns the ith generator of A as an algebra over the base ring. Note that the element 1 is always the first element of a basis, and is never returned as a generating element.

`A ! x`

Return an element of the quaternion algebra A described by x, where x may be an algebra element, a module element, a sequence, an element of an order of an associative algebra or be coercible into the coefficient ring of A.

86.4.2 Arithmetic of Elements

`x + y`

The sum of x and y.

`x - y`

The difference of x and y.

`x * y`

The product of x and y.

`x / y`

The quotient of x by the unit y in the quaternion algebra.

`x eq y`

Returns `true` if the elements x and y are equal; otherwise `false`.

`x ne y`

Returns `true` if and only if the elements x and y are not equal.

`x in A`

Returns `true` if and only if x is in the algebra A.

`x notin A`

Returns `true` if and only if x is not in the algebra A.

`Conjugate(x)`

The conjugate $\bar{x}$ of the element x of a quaternion algebra, defined so that the reduced trace and reduced norm are $\bar{x} + x$ and $\bar{x}x$, respectively.

`ElementToSequence(x)`

`Eltseq(x)`

`Coordinates(x)`

Given an element x of a quaternion algebra or order, this function returns the sequence of coordinates of x in terms of the basis of its parent.

`Norm(x)`

The reduced norm $\mathrm{N}(x)$ of the element x of a quaternion algebra, defined so that the characteristic polynomial for x is $x^2 - \mathrm{Tr}(x)x + \mathrm{N}(x) = 0$, where $\mathrm{Tr}(x)$ is the reduced trace.

`Trace(x)`

The reduced trace $\mathrm{Tr}(x)$ of the element x of a quaternion algebra, defined so that the characteristic polynomial for x is $x^2 - \mathrm{Tr}(x)x + \mathrm{N}(x) = 0$, where $\mathrm{N}(x)$ is the reduced norm.

`CharacteristicPolynomial(x)`

The characteristic polynomial of degree 2 for the element x of a quaternion algebra over the base ring of its parent.

`MinimalPolynomial(x)`

The minimal polynomial of degree 1 or 2 for the element x of a quaternion algebra over the base ring of its parent.

Example H86E9

We demonstrate the relation between characteristic polynomial, and reduced trace and norm in the following example.

```
> A := QuaternionAlgebra< RationalField() | -17, -271 >;
> x := A![1,-2,3,0];
> Trace(x);
2
> Norm(x);
2508
> x^2 - Trace(x)*x + Norm(x);
0
```

Note that trace and norm of an element x of any algebra can be defined as the trace and norm of the linear operator corresponding to right-multiplication by x. The reduced trace and norm in a quaternion algebra A are taken instead to be the corresponding trace and determinant in any two-dimensional matrix representation of A, or equivalently, the sum and product of an element with its conjugate. The definition of norm and trace used for a general algebra can be realised in a quaternion algebra by the following code.

```
> P<X> := PolynomialRing(RationalField());
> M := RepresentationMatrix(x, A);
> M;
[   1   -2    3    0]
[  34    1    0    3]
[-813    0    1    2]
[   0 -813  -34    1]
> Trace(M);
4
> Factorization(CharacteristicPolynomial(M));
[
    <X^2 - 2*X + 2508, 2>
]
```

The general definition of trace (for the algebra) is twice the reduced trace, and the general definition of norm is the square of the reduced norm.

86.5 Attributes of Quaternion Algebras

`BaseField(A)`

`BaseRing(A)`

The base field of the quaternion algebra A.

`Basis(A)`

The basis of the algebra A.

`RamifiedPrimes(A)`

Given a quaternion algebra A over $\mathbf{Q}$ or $\mathbf{F}_q(X)$ with q odd, this function returns a list of primes or normalized irreducible polynomials corresponding to the finite ramified places of A.

Example H86E10

The sequence of ramified primes of a quaternion algebra A over $\mathbf{Q}$ determines the isomorphism class of the algebra.

```
> A := QuaternionAlgebra(-436,-503,22);
> RamifiedPrimes(A);
[ 17 ]
```

Provided the discriminant is of a size which can be factored, the ramified primes are determined efficiently using Hilbert symbols.

`RamifiedPlaces(A)`

`FactoredDiscriminant(A)`

Given a quaternion algebra A over $\mathbf{Q}$ or $\mathbf{F}_q(X)$ with q odd or a number field, this function returns the finite as well as infinite places where A is ramified.

Note: The first return value of these functions is always a list of ideals, even if the algebra is given over $\mathbf{Q}$ or $\mathbf{F}_q(X)$.

Example H86E11

This example shows the (minor) difference between `RamifiedPrimes` and `RamifiedPlaces`.

```
> F<x> := RationalFunctionField( GF(5) );
> A := QuaternionAlgebra< F | 2, x >;
> R<x>:= Integers(F);
> RamifiedPrimes(A);
[ x ]
> RamifiedPlaces(A);
[
    Ideal of Univariate Polynomial Ring in x over GF(5) generated by x
]
[ Infinity ]
```

`Discriminant(A)`

The reduced discriminant of a quaternion algebra A over $\mathbf{Q}$, $\mathbf{F}_q(X)$ with q odd or a number field. In the first two cases, the functions return the product of the ramified primes. Over number fields, they return the product of the ramified prime ideals as well as the sequence of ramified infinite places.

`StandardForm(A)`

Returns integers a and b in the base field F of the given quaternion algebra A such that there exists elements $i, j \in A$ where $i^2 = a$, $j^2 = b$, and $ji = -ij$. The third object returned is the standard quaternion algebra $B =$ `QuaternionAlgebra<F|a,b>`, and the fourth object is the homomorphism from A to B.

86.6 Hilbert Symbols and Embeddings

Let A be a quaternion algebra over Q, $\mathbf{F}_q(X)$ (with q odd) or a number field F with defining elements a, b, and let v be a place of F. If v is unramified in A (i.e. $A \otimes_F F_v \cong M_2(F_v)$, we define the *Hilbert symbol* $(a, b)_v$ to be 1, and otherwise we define $(a, b)_v = -1$.

`HilbertSymbol(a, b, p)`

`HilbertSymbol(A, p)`

`Al` MonStgElt *Default :* "*NormResidueSymbol*"

Computes the Hilbert symbol for the quaternion algebra A over F, namely $(a, b)_p$, where $a, b \in F$ and p is either a prime (if $a, b \in \mathbf{Q}$ or $\mathbf{F}_q(X)$) or a prime ideal. If $a, b \in \mathbf{Q}$, by default table-lookup is used to compute the Hilbert symbol; one can optionally insist on using the full algorithm by setting the parameter `Al` to the value `"Evaluate"`.

`IsRamified(p, A)`

`IsUnramified(p, A)`

Returns `true` if and only if the prime or prime ideal p is ramified (unramified) in the quaternion algebra A.

Example H86E12

We first verify the correctness of all Hilbert symbols over the rationals.

```
> QQ := Rationals();
> for a,b in [1..8] do
>   bl := HilbertSymbol(QQ ! a, QQ ! b,2 : Al := "Evaluate")
>                 eq NormResidueSymbol(a,b,2);
>   print <a,b,bl>;
>   if not bl then
>     break a;
>   end if;
> end for;
<1, 1, true>
<1, 2, true>
<1, 3, true>
...
```

For a second test, we input a quaternion algebra which is unramified at all finite places.

```
> P<x> := PolynomialRing(Rationals());
```

```
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> A := QuaternionAlgebra<F | -3,b>;
> symbols := [];
> for p in [p : p in [2..100] | IsPrime(p)] do
>   pps := Decomposition(Z_F,p);
>   for pp in pps do
>     Append(~symbols,HilbertSymbol(A,pp[1]));
>   end for;
> end for;
> symbols;
[ 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1 ]
```

Finally, we test "random" quaternion algebras over quadratic extensions at even primes, the hardest case. We use the fact that the quaternion algebra (a, b) is ramified at a prime ideal p if and only if b is a norm from the extension $F(\sqrt{a})$, so we can test this condition using `IsLocalNorm`. Note that this takes substantially more time.

```
> for c in [2,-2,6,-6,-1,3,-3] do
>   K<s> := NumberField(x^2-c);
>   Z_K := MaximalOrder(K);
>   Z_Kmod8, f8 := quo<Z_K | 8>;
>   PPK<xK> := PolynomialRing(K);
>   for i := 1 to 10 do
>     S := [x+y*Z_K.2 : x,y in [0..7] | x*y ne 0];
>     a := Random(S);
>     b := Random(S);
>     A := QuaternionAlgebra<K | a,b>;
>     for pp in Decomposition(Z_K,2) do
>       hsym := HilbertSymbol(A,pp[1]);
>       if not IsIrreducible(xK^2-a) then
>         print <c, a, b, hsym eq 1>;
>         if hsym ne 1 then
>           break c;
>         end if;
>       else
>         lclsym := IsLocalNorm(AbelianExtension(ext<K | xK^2-a>),Z_K ! b,pp[1]);
>         bl := (hsym eq 1) eq lclsym;
>         print <c, a, b, bl>;
>         if not bl then
>           break c;
>         end if;
>       end if;
>     end for;
>   end for;
> end for;
<2, 5/1*Z_K.1 + 3/1*Z_K.2, Z_K.1 + 7/1*Z_K.2, true>
<2, 6/1*Z_K.1 + 4/1*Z_K.2, 4/1*Z_K.1 + Z_K.2, true>
```

```
<2, 7/1*Z_K.1 + Z_K.2, 2/1*Z_K.1 + 2/1*Z_K.2, true>
...
```

`pMatrixRing(A, p)`

`pMatrixRing(O, p)`

`Precision` RngIntElt *Default :*

Let A be a quaternion algebra A over a field F where F is the rationals, a number field of $\mathbf{F}_q(x)$ with q odd. Given A and a prime (ideal) p of the ring of integers R of F such that p is unramified in A, this function returns the matrix ring over the completion F_p of F at p, a map from $A \to M_2(F_p)$ and the embedding $F \to F_p$.

Given a p-maximal order O in A, the map from $A \to M_2(F_p)$ induces a map from $O \to \mathrm{M}_2(R_p)$.

`IsSplittingField(K, A)`

`HasEmbedding(K, A)`

`ComputeEmbedding` BoolElt *Default :* `false`

Given a quaternion algebra A defined over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field F and K a quadratic extension of F, the function returns `true` if and only if there exists an embedding $K \to A$ over F. This is done by comparison of ramified places in K and A (see [Vig80, Cor. III.3.5]). If no embedding exists, the second return value will be a witness place. If an embedding exists and the optional argument `ComputeEmbedding` is set to `true`, the second and third return values contain the result of a call to `Embed` as described below.

`Embed(K, A)`

`Al` MonStgElt *Default :* "*NormEquation*"

Given a quaternion algebra A defined over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field F and K a quadratic extension of F, returns an embedding $K \to A$ over F, given as an element of A, the image of the primitive generator of K, and the map $K \to A$.

The algorithm by default involves solving a relative norm equation. Alternatively, a naive search algorithm may be selected by setting the optional parameter `Al:="Search"`.

If there is no embedding, a runtime error occurs (or the `"Search"` runs forever). To check whether an embedding exists, use `HasEmbedding` (see immediately above).

`Embed(Oc, O)`

`Al` MonStgElt *Default :* "*NormEquation*"

Given a quadratic order O_c with base number ring R and a quaternion order O with base ring R, the function computes an embedding $O_c \hookrightarrow O$ over R. It returns the image of the second generator `Oc.2` of `Oc`; secondly it returns the embedding map $O_c \to O$.

The algorithm by default involves solving a relative norm equation. Alternatively, a naive search algorithm may be selected by setting the optional parameter `Al:="Search"`.

Notes. Let K be the number field containing Oc.

(i) `Oc.1, Oc.2` are the generators of Oc as a module, and `Oc.2` is unrelated to `K.1`, where K is the number field containing Oc.

(ii) To check whether an embedding of K into the algebra exists, one can use `HasEmbedding(K, Algebra(O) : ComputeEmbedding:=false)`.

Example H86E13

```
> F<b> := NumberField(Polynomial([1,-3,0,1]));
> A := QuaternionAlgebra<F | -3, b>;
> K := ext<F | Polynomial([2,-1,1])>;
> mu, iota := Embed(K, A);
> mu;
1/2 + 1/6*(-2*b^2 + 2*b + 7)*i + 1/2*(2*b^2 + b - 6)*j + 1/6*(-2*b^2 - b + 4)*k
> MinimalPolynomial(mu);
$.1^2 - $.1 + 2
> iota(K.1) eq mu;
true
```

86.7 Predicates on Algebras

A quaternion algebra A over a number field F with $[F : \mathbf{Q}] = h$ is *definite* (or *totally definite*) if F is totally real and $A \otimes_{\mathbf{Q}} \mathbf{R} \cong H^h$, where H is the division ring of real Hamiltonians, otherwise A is *indefinite*.

A quaternion algebra A over $\mathbf{F}_q(X)$ is called *definite* if the place corresponding to the degree valuation is ramified.

`IsDefinite(A)`

`IsIndefinite(A)`

Given a quaternion algebra A over a number field, $\mathbf{Q}$ or $\mathbf{F}_q(X)$ with q odd, returns `true` if and only if A is a (totally) definite or indefinite quaternion algebra, respectively.

86.8 Recognition Functions

A quaternion algebra A over a field K is isomorphic to the matrix ring $M_2(K)$ if and only if there exists a zerodivisor ϵ in A. Given such an ϵ, we can exhibit an explicit isomorphism; otherwise a zerodivisor will be computed first by finding a point on a conic (see [Vig80, Cor. I.2.4]).

Given an associative algebra, we also have an algorithm to recognize if the algebra is a quaternion algebra, and, if so, return an isomorphism to a quaternion algebra in standard form.

`IsMatrixRing(A)`

`Isomorphism` BoolElt *Default :* `false`

Returns `true` if and only if the quaternion algebra A with base field F is isomorphic to $M_2(F)$, or equivalently if A has no ramified places. The field F has to be $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field.

If A is isomorphic to $M_2(F)$ and `Isomorphism` is set to `true`, then $M_2(F)$ and an isomorphism $A \to M_2(F)$ are also returned.

`MatrixRing(A, eps)`

`MatrixAlgebra(A, eps)`

Given a quaternion algebra A and a zerodivisor $\epsilon \in A$, the function returns the matrix algebra $M_2(F)$ and an isomorphism $A \to M_2(F)$.

Example H86E14

```
> A := QuaternionAlgebra<Rationals() | -1, 1>;
> eps := A.3-1;
> MinimalPolynomial(eps), Norm(eps);
x^2 + 2*x
0
```

Thus, since ϵ has reduced norm 0, it is a zerodivisor: indeed, $\epsilon(\epsilon + 2) = 0$.

```
> M2F, phi := MatrixRing(A,eps);
> [<MinimalPolynomial(A.i), MinimalPolynomial(phi(A.i))> : i in [1..3]];
[
    <x^2 + 1, x^2 + 1>,
    <x^2 - 1, x^2 - 1>,
    <x^2 - 1, x^2 - 1>
]
```

`IsQuaternionAlgebra(B)`

Returns `true` if and only if the associative algebra B is a quaternion algebra; if true, it returns the associated quaternion algebra A in standard form and an algebra homomorphism from B to A. The algorithm used is [Voi05, Algorithm 4.2.9].

Example H86E15

We create an associative algebra which is known to be a quaternion algebra A and then recover A (or an isomorphic algebra).

```
> A := AssociativeAlgebra(QuaternionAlgebra<Rationals() | -1,1>);
> vecs := [&+[Random(10)*A.i : i in [1..4]] : j in [1..4]];
> Mchange := Matrix(Rationals(),4,4,&cat[Eltseq(vecs[i]) : i in [1..4]]);
> Mchange := Mchange^(-1);
> seq := [<i,j,k,((vecs[i]*vecs[j])*Mchange)[k]> : i,j,k in [1..4]];
> A := AssociativeAlgebra<Rationals(),4 | seq>;
> bl, Aquat, phi := IsQuaternionAlgebra(A);
> bl;
true
> Aquat;
Quaternion Algebra with base ring Rational Field
> Aquat.1^2, Aquat.2^2;
25 -3924/25
> phi;
Mapping from: AlgAss: A to AlgQuat: Aquat given by a rule
```

We now verify the functionality when a zerodivisor is encountered.

```
> A := Algebra(MatrixAlgebra(Rationals(),2));
> IsQuaternionAlgebra(A);
true Quaternion Algebra with base ring Rational Field
Mapping from: AlgAss: A to Quaternion Algebra with base ring Rational Field
given by a rule
```

The algebra $k < x, y >$ with $x^2 = y^2 = xy + yx = 0$ is not semisimple; the ideal generated by x, y is a nontrivial two-sided ideal. Similarly, a commutative algebra is not a quaternion algebra.

```
> A := Algebra(FPAlgebra<Rationals(), x,y | x^2, y^2, x*y+y*x>);
> IsQuaternionAlgebra(A);
false
> A := Algebra(FPAlgebra<Rationals(), x | x^4+x^2+1>);
> IsQuaternionAlgebra(A);
false
```

In characteristic 2, the algorithm also performs correctly, both for an associative but non-quaternion algebra and for the "universal" example of a quaternion algebra.

```
> A := Algebra(FPAlgebra<GF(2), x,y | x^2, y^2, x*y+y*x+1>);
> IsQuaternionAlgebra(A);
false
> F<a,b,x,y,z,w> := FieldOfFractions(PolynomialRing(GF(2),6));
> M := [[1,0,0,0],[0,1,0,0],[0,0,1,0],[0,0,0,1],
>       [0,1,0,0],[a,1,0,0],[0,0,0,1],[0,0,a,1],
>       [0,0,1,0],[0,0,1,1],[b,0,0,0],[b,b,0,0],
>       [0,0,0,1],[0,0,a,0],[0,b,0,0],[a*b,0,0,0]];
> A<alpha,beta> := AssociativeAlgebra<F,4 | M>;
```

```
> alpha^2+alpha+a;
(0 0 0 0)
> beta^2+b;
(0 0 0 0)
>
> bl, Aquat, phi := IsQuaternionAlgebra(A);
> bl;
true
> Aquat;
Quaternion Algebra with base ring Multivariate rational function field of
rank 6 over GF(2)
> theta := phi(x+y*alpha+z*beta+w*alpha*beta);
> Trace(theta);
y
> Norm(theta);
a*b*w^2 + a*y^2 + b*z^2 + b*z*w + x^2 + x*y
```

`MatrixRepresentation(A)`

`MatrixRepresentation(R)`

Given a quaternion algebra A over $\mathbf{Q}$ or a quaternion order R over $\mathbf{Z}$, this function returns a 2×2-matrix representation of A, defined over a quadratic extension.

86.9 Attributes of Orders

For further information about orders of associative algebras, see Section 81.4.

For a quaternion order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, MAGMA additionally defines the following functions.

`Algebra(S)`

`QuaternionAlgebra(S)`

The quaternion algebra for which S is an order.

`BasisMatrix(S)`

`EmbeddingMatrix(S)`

Returns the basis matrix of the quaternion order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$. The rows of the matrix give the basis elements of S with respect to the basis of the container algebra.

`Discriminant(S)`

Given an order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, this function returns the reduced discriminant of S as a positive integer or a normalized polynomial.

`FactoredDiscriminant(S)`

Given a quaternion order S, this function returns the factorisation of the reduced discriminant of S (that is, `Factorization(Discriminant(S))`).

`Conductor(S)`

`Level(S)`

Given an order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ in a quaternion algebra A, this function returns the reduced index of S in a maximal order of A containing it. Together with the reduced discriminant of the order, this serves to classify the local isomorphism class of an Eichler order.

`Normalizer(S)`

Let S be an order in a definite quaternion algebra A over a field F where F is the rationals, $\mathbf{F}_q(t)$ or a number field. This function returns a matrix group G isomorphic to the normalizer of S in A^* modulo F^*. A homomorphism from G to A^* is also returned.

86.10 Predicates of Orders

Let O be a quaternion order with base ring $\mathbf{Z}$, $\mathbf{F}_q[X]$ with q odd, or a number ring. Then MAGMA can test the following predicates.

`IsMaximal(O)`

Returns `true` if and only if the order O is maximal.

`IspMaximal(O, p)`

Returns `true` if and only if the order O is maximal at the prime or prime ideal p.

`IsEichler(O)`

`MaximalOrders` BOOLELT *Default :* `false`

Returns `true` if and only if the order O is *Eichler*, that is an intersection of two (not necessarily distinct) maximal orders. The function calls the `EichlerInvariant` intrinsic explained below.

If the optional argument `MaximalOrders` is set to `true`, the algorithm also returns two maximal orders such that O is their intersection.

`IsEichler(O, p)`

`MaximalOrders` BOOLELT *Default :* `false`

Returns `true` if and only if the completion of the order O at the prime (ideal) p is *Eichler*.

If the optional argument `MaximalOrders` is set to `true`, the algorithm also returns two p-maximal orders such that O is their intersection.

`EichlerInvariant(O, p)`

Returns the local Eichler invariant of O at some prime (ideal) p which divides the discriminant of O. Let R be the base ring of O and let J be the Jacobson radical of the R/p-algebra O/pO. If J has dimension 3 then the Eichler invariant is defined to be 0. Otherwise the quotient of O/pO by J is either isomorphic to a direct sum of two copies of R/p or a quadratic field extension of R/p. In the first case the Eichler invariant is 1, in the latter it is -1.

`IsHereditary(O)`

Returns `true` if and only if the order O is a hereditary order in a quaternion algebra A. That is, every lattice in A of full rank such that O is contained in its left order is a projective left O-module. The hereditary orders are precisely those with squarefree discriminant.

`IsHereditary(O, p)`

Returns `true` if and only if the completion of the order O at the prime (ideal) p is *hereditary*.

`IsGorenstein(O)`

Returns `true` if and only if the order O is a Gorenstein order. That is, the dual of O with respect to the trace bilinear form is a projective O-module.

`IsGorenstein(O, p)`

Returns `true` if and only if the completion of the order O at the prime (ideal) p is *Gorenstein*.

86.11 Operations with Orders

`O1 meet O2`

This returns the order obtained by intersecting the quaternion orders O_1 and O_2.

`O ^ x`

This returns the conjugate of the order O by an element x in the associative algebra A for which O is an order (in other words the order $x^{-1}Ox$).

86.12 Ideal Theory of Orders

The right (or left) ideals of an R-order O in a quaternion algebra A defined over a number field fall into finitely many isomorphism classes. Already, for the case of number rings, it is a computationally difficult problem to compute the class group, and due to the noncommutativity of quaternion algebras, the problem of enumerating ideal classes of quaternion orders is even more difficult because this set does not have the structure of a group.

All orders in this section are required to be *Eichler*. The reader should recall that this includes the maximal orders.

The algorithms underpinning the intrinsics described in this section, in particular, those for determining ideal classes, are described in [KV10]. The methods depend on whether A is definite or indefinite. For a definite algebra, we use a variation of Kneser's neighbouring method together with Eichler's mass formula (see [Vig80, Chapter 5] and [DG88]) to construct sufficient ideals to represent all ideal classes. We then test if two right (or left) ideals I, J are isomorphic (Section 86.14.3).

For an indefinite quaternion algebra, we use a theorem of Eichler [Rei03, Th. 35.14] which states that the reduced norm gives rise to an bijection of sets between the class groups of the order and the number ring. (Over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, therefore, every ideal of an indefinite quaternion order is principal.) We may compute representative ideals I of O whose reduced norm is in a specified ideal class. We then reduce the problem of testing for an isomorphism $I \cong J$ between two ideals to the similar problem over R. Here, the problem of explicitly computing such an isomorphism is much less difficult, as an order (or ideal) will have infinitely many elements of bounded norm, and in most cases a search amongst reduced bases will find a desired element.

Ideals of quaternion orders belong to the types `AlgQuatOrdIdl` and `AlgAssVOrdIdl` according as to whether the order O is defined over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ (both of type `AlgQuatOrd`) or over a number ring (of type `AlgAssVOrd`). For more on the constructions and functions for ideals of the latter type, see Section 81.4.

86.12.1 Creation and Access Functions

`LeftIdeal(S, X)`
`lideal< S | X >`
`RightIdeal(S, X)`
`rideal< S | X >`
`ideal< S | X >`

These intrinsics construct a left, right or two-sided ideal of the order S generated by the sequence X, which should contain elements that are coercible into the algebra of S.

In the case of the constructors `lideal< | >` and `rideal< | >`, the right hand side may also be a matrix or pseudo-matrix giving the basis of the ideal with respect to the basis of S.

`PrimeIdeal(S, p)`

Given a quaternion order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, the function returns the unique two-sided (integral) prime ideal P of S over the prime p of $\mathbf{Z}$ or $\mathbf{F}_q[X]$. If p exactly divides the discriminant of S, then P properly contains pS and need not be principal, and otherwise P is equal to pS.

`CommutatorIdeal(S)`

The two-sided ideal of the quaternion order S generated by elements of the form $xy - yx$.

`MaximalLeftIdeals(O, p)`

`MaximalRightIdeals(O, p)`

The integral ideals of norm p with left or right order O.

Example H86E16

We demonstrate the construction of the 2-sided prime ideals and their relationship with the commutator ideal.

```
> S := QuaternionOrder(2*5*11);
> P := PrimeIdeal(S, 2);
> I := ideal< S | [2] cat [ x*y-y*x : x, y in Basis(S) ] >;
> P eq I;
true
> Q := PrimeIdeal(S, 5);
> R := PrimeIdeal(S, 11);
> P*Q*R eq CommutatorIdeal(S);
true
```

By way of explanation, we note that the composition of ideals is well-defined, since each of these ideals is a 2-sided ideal for S, that is, a left ideal whose right order is also S. The collection of all prime ideals over the ramified primes of a maximal order forms an elementary 2-abelian class group, and the commutator ideal is the product of these prime ideals.

Example H86E17

First we create an integral ideal I of norm 2.

```
> QQ:= Rationals();
> A<i,j> := QuaternionAlgebra< QQ | -1, -11 >;
> S := MaximalOrder(A);
> P<x> := PolynomialRing(QQ);
> P ! MinimalPolynomial(i);
x^2 + 1
> I := lideal< S | 2, 1+i >;
> Norm(I);
2
> I in MaximalLeftIdeals(S, 2);
```

```
true
```

We now examine the basis of the ideal I.

```
> Basis(I);
[ 2, 1 + i, i + k, 3/2 + 1/2*i + 1/2*j + 1/2*k ]
> [ Eltseq(x) : x in Basis(I) ];
[
    [ 2, 0, 0, 0 ],
    [ 1, 1, 0, 0 ],
    [ 0, 1, 0, 1 ],
    [ 3/2, 1/2, 1/2, 1/2 ]
]
> BasisMatrix(I, A);
[  2   0   0   0]
[  1   1   0   0]
[  0   1   0   1]
[3/2 1/2 1/2 1/2]
```

If the ideal I is printed, the rational coordinates with respect to the basis of the quaternion order S will be shown, We can get this base change matrix if we call `BasisMatrix` with no additional parameters.

```
> I;
Left Ideal with basis Pseudo-matrix over Integer Ring
[2 0 0 0]
[1 1 0 0]
[0 0 2 0]
[1 0 1 1]
> BasisMatrix(I);
[2 0 0 0]
[1 1 0 0]
[0 0 2 0]
[1 0 1 1]
```

`LeftOrder(I)`

Given an ideal I of a quaternion order defined over $\mathbf{Z}$, $\mathbf{F}_q[X]$ or a number ring, this function returns the left order of I, defined as the ring of all elements of the quaternion algebra of I mapping I to itself under left multiplication.

`RightOrder(I)`

Given an ideal I of a quaternion order defined over $\mathbf{Z}$, $\mathbf{F}_q[X]$ or a number ring, this function returns the right order of I, defined as the ring of all elements of the quaternion algebra of I mapping I to itself under right multiplication.

Example H86E18

```
> K := NumberField(Polynomial([5,0,1]));
> K;
Number Field with defining polynomial $.1^2 + 5 over the Rational Field
> A := QuaternionAlgebra<K | 3, K.1>;
> O := MaximalOrder(A);
> I := lideal<O | O.2, Norm(O.2)>;
> Norm(I);
Principal Ideal
Generator:
    2/1*$.1
> LeftOrder(I) eq O;
true
> RightOrder(I) eq O;
true
```

86.12.2 Enumeration of Ideal Classes

The tools provided for calculating ideal classes in the case of a maximal or, more generally, an Eichler order S in a quaternion algebra over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field are described in this section.

`Mass(S)`

Given a definite order S of level N over R, this function returns the mass

$$\sum_i h_i/[S_i^* : R^*]$$

where $S_1, \ldots, S_t$ represent the conjugacy classes of Eichler orders of level N and h_i denotes the number of two-sided ideal classes of S_i.

`LeftIdealClasses(S)`

`RightIdealClasses(S)`

`Support` [RngOrdIdl] *Default :*

These intrinsics find representatives for the left or right locally free ideal classes of S, where S is an order in a quaternion algebra A defined over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field. The algorithms are guaranteed to work correctly only when S is a maximal order or an Eichler order.

For definite algebras, the support of the returned ideals may be specified using parameter `Support`; this should be a sequence of primes or prime ideals in the base ring which generate the narrow class group and which do not ramify in A. In this case, the routine will find ideal class representatives whose norms are divisible only by primes in the specified support. The algorithm usually runs faster if the support

is either not specified or if the support includes the prime divisors of the discriminant of S.

For indefinite algebras, the representatives are obtained from a ray class group of the base field.

`TwoSidedIdealClasses(S)`

`Support` [RngOrdIdl] *Default :*

Given an order S in a quaternion algebra, this function returns a sequence containing representatives for the two-sided locally free ideal classes of S. The algorithm is only guaranteed to work when S is a maximal order or an Eichler order.

If the optional argument `Support` is specified, Magma tries to construct representatives that have norm divisible by primes or prime ideals in the specified support. If this is not possible, the set specified using parameter `Support` will be enlarged by the prime divisors of the discriminant of S. If this enlarged set is still not large enough (which can only happen if the set does not generate the class of group of the base ring of S) an error will be raised.

`TwoSidedIdealClassGroup(S : Support)`

`Support` [RngOrdIdl] *Default :*

Given an order S in a quaternion algebra, this returns the two-sided ideal class group of S as an abstract abelian group, together with a map from the group to the set of two-sided ideal classes of S. Inverses with respect to this map can be calculated in a very efficient way and thus may be used to compute discrete logarithms. The algorithm is only guaranteed to work when S is a maximal order or an Eichler order.

The optional parameter `Support` may be used to specify a support: this should be a sequence of primes or prime ideals in the base ring which generate the narrow class group and which do not ramify in the parent algebra.

`ConjugacyClasses(S)`

Given a maximal order (or an Eichler order S of level N) in a quaternion algebra A, this function returns representatives for the conjugacy classes of maximal orders (or orders of level N) in A.

For definite algebras, the algorithm involves computing the right ideal classes (in fact, the two problems are computationally equivalent in practice).

Example H86E19

In the following example we construct a maximal order in the quaternion algebra ramified at 37, and enumerate its left ideal classes.

```
> S := QuaternionOrder(37);
> ideals := LeftIdealClasses(S);
> [ Basis(I) : I in ideals ];
[
  [ 1, i, j, k ],
```

```
  [ 2, 2*i, 1 + i + j, i + k ],
  [ 2, 2*i, i + j, k ]
]
```

We now compute the right orders of the two nontrivial left ideal classes.

```
> _, I, J := Explode(ideals);
> R1 := RightOrder(I);
> R2 := RightOrder(J);
> IsIsomorphic(R1,R2);
true
```

Although the ideals I and J are non-isomorphic left ideals over S, they have isomorphic right orders. In the example following the next section we explore this phenomenon further.

Example H86E20

In this example, we enumerate ideal classes for a definite quaternion algebra (over a totally real field).

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> Foo := InfinitePlaces(F);
> pp := Decomposition(Z_F, 17)[1][1];
> A := QuaternionAlgebra(pp, Foo);
> O := MaximalOrder(A);
> time Rideals := RightIdealClasses(O);
Time: 0.870
> #Rideals;
2
```

Example H86E21

In this example the classgroup of the base field is not trivial and there are some ramified prime ideals in the algebra. Hence we expect nontrival two-sided ideal classes.

```
> K:= QuadraticField(401);
> A:= QuaternionAlgebra< K | -1, -1>;
> RamifiedPlaces(A);
[
    Prime Ideal
    Two element generators:
        2
        $.2 + 1,
    Prime Ideal
    Two element generators:
        2
        $.2 + 2
]
```

```
[ 1st place at infinity, 2nd place at infinity ]
> M:= MaximalOrder(A);
> #TwoSidedIdealClasses(M);
10
> time #RightIdealClasses(M);
140
Time: 6.470
```

86.12.3 Operations on Ideals

In addition to operations on ideals of orders over more general rings (see Section 81.4), the following operations are defined for ideals of quaternion orders over $\mathbf{Z}$, $\mathbf{F}_q[X]$ and number rings.

`I * J`

The composite of I and J, where the right order of I equals the left order of J.

`I meet J`

Given ideals or orders I and J, this function returns the intersection $I \cap J$.

`Conjugate(I)`

Given an ideal I (of a quaternion algebra), this function returns the conjugate ideal.

`Norm(I)`

Given an ideal I over $\mathbf{Z}$, this function returns the reduced norm of the ideal, defined as the positive generator of the image of the reduced norm map in $\mathbf{Q}$.

Given an ideal I over $\mathbf{F}_q[X]$, this function returns the reduced norm of the ideal, defined as the normalized generator of the image of the reduced norm map in $\mathbf{F}_q(X)$.

Given an ideal I over a commutative order, this function returns the reduced norm of I as a fractional ideal of the order.

`Factorization(I)`

Given a two-sided ideal I of an hereditary order O, this function returns the unique factorization of I into two-sided O-ideals. The result is a sequence of tuples. The first entry of each tuple is a two-sided ideal of O, the second is its exponent. (If the base ring of I is $\mathbf{F}_q[X]$, then q is currently required to be odd.)

86.13 Norm Spaces and Basis Reduction

For definite quaternion orders or ideals one can compute reduced bases and Gram matrices.

If the base ring of the order or ideal is $\mathbf{Z}$ or $\mathbf{F}_q[X]$ with q odd, the Gram matrices can be made unique up to isomorphism. In fact, in these cases, the isomorphism testing of ideals and orders is based on this reduction.

`NormSpace(A)`

Given a quaternion algebra A over any field F not of characteristic 2, this function returns the underlying F-space with inner product the norm form. A map from A into the structure is returned as second value.

`NormSpace(S)`

Given a quaternion order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ (with q odd), this function returns the underlying module over its base ring, with inner product respect to the norm. A map from O into the structure is returned as second value.

`GramMatrix(S)`
`GramMatrix(I)`

The Gram matrix of the quaternion order S or ideal I over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ with respect to the norm on the basis for S.

`ReducedGramMatrix(S)`

Given an order or ideal S over $\mathbf{Z}$ in a definite quaternion algebra, this function returns the Gram matrix G of the corresponding lattice.

The quaternion ideal machinery makes use of a Minkowski basis reduction algorithm which returns a unique normalized reduced Gram matrix G for any definite quaternion ideal. This forms the core of the isomorphism testing for quaternion ideals.

`ReducedBasis(S)`

Given an order or ideal S over $\mathbf{Z}$ in a definite quaternion algebra, this function returns some basis B of S the Gram matrix G of the corresponding lattice associated with S. Note that while there exists a unique Minkowski-reduced Gram matrix G, the basis B is not unique.

Example H86E22

Recall that Minkowski basis reduction is used which returns a unique normalized reduced Gram matrix G for any definite quaternion ideal. This forms the core of the isomorphism testing for quaternion ideals. We illustrate this by applying it to representatives of the set of left ideal classes of an order.

```
> A := QuaternionOrder(19,2);
> ideals := LeftIdealClasses(A);
> #ideals;
5
```

```
> [ (1/Norm(I))*ReducedGramMatrix(I) : I in ideals ];
[
    [ 2  0  1  1]
    [ 0  2  1  1]
    [ 1  1 20  1]
    [ 1  1  1 20],

    [6 0 1 3]
    [0 6 3 1]
    [1 3 8 1]
    [3 1 1 8],

    [6 0 1 3]
    [0 6 3 1]
    [1 3 8 1]
    [3 1 1 8],

    [ 4  0  1 -1]
    [ 0  4  1  1]
    [ 1  1 10  0]
    [-1  1  0 10],

    [ 4  0  1 -1]
    [ 0  4  1  1]
    [ 1  1 10  0]
    [-1  1  0 10]
]
```

`ReducedGramMatrix(S)`

`ReducedBasis(S)`

`Canonical` BoolElt *Default :* `false`

Given an order or ideal S over $\mathbf{F}_q[X]$ in a quaternion algebra A, this function returns a Gram matrix and/or a basis of S whose Gram matrix is in dominant diagonal form (see the function `DominantDiagonalForm` in Section 31.2.1). The Gram matrix will not be unique unless A is definite and `Canonical` is set to `true`.

`ReducedBasis(O)`

`ReducedBasis(I)`

Returns a "reduced" basis for the order O or the ideal I over some number ring. If O or I arise from a definite quaternion algebra, then this basis is LLL-reduced with respect to the norm form; otherwise, the basis is reduced with respect to a Minkowski-like embedding (see [KV10, Section 4]).

`OptimizedRepresentation(O)`

`OptimisedRepresentation(O)`

Given an order O contained in a quaternion algebra A over $\mathbf{Q}$ or a number field F, this function returns a new quaternion algebra A' such that $A' = ((a, b)/F)$ where a and b are small (with respect to O), and, as second return value, an isomorphism $A \to A'$.

`OptimizedRepresentation(A)`

`OptimisedRepresentation(A)`

Given a quaternion algebra A over $\mathbf{Q}$ or a number field F, this function returns a new quaternion algebra A' such that $A' = ((a, b)/F)$ where a and b are small. An isomorphism $A \to A'$ is returned as second value.

`Enumerate(O, A, B)`

The sequence of all elements x (up to sign) in the definite quaternion order O or ideal I over $\mathbf{Z}$ such that the reduced norm of x lies in the interval $[A, \ldots B]$ or $[0, \ldots B]$, respectively.

`Enumerate(O, A, B)`

`Enumerate(O, B)`

The sequence of elements x (up to sign) in the definite quaternion order O or ideal I over a number ring such that the absolute trace of the norm of x lies in the interval $[A, \ldots B]$ or $[0, \ldots B]$, respectively.

86.14 Isomorphisms

86.14.1 Isomorphisms of Algebras

Two quaternion algebras A, B over a common field F are isomorphic algebras if and only if they share the same ramified places. Finding an explicit isomorphism is much harder. Currently MAGMA embeds the first standard generator of A into B and then finds another element perpendicular to that image having the correct minimal polynomial. In particular, this requires the construction of two points on a conic (or equivalently, the solution of two norm equations) over quadratic extensions of F.

`IsIsomorphic(A, B)`

`Isomorphism` BOOLELT *Default :* `false`

Given two quaternion algebras A, B over $\mathbf{Q}$, $\mathbf{F}_q(X)$ with q odd or a number field, this function returns `true` if and only if they are isomorphic.

If the algebras are isomorphic and `Isomorphism` is set to true, an isomorphism $A \to B$ is also returned.

86.14.2 Isomorphisms of Orders

Two orders S, T in a quaternion algebra A are isomorphic if and only if they are conjugate in A.

In a definite algebra, we use the fact that this conjugation induces an isometry of the quadratic $\mathbf{Z}$- or $\mathbf{F}_q[X]$-modules S and T equipped with the (absolute) norm form. Over an indefinite algebra, we use the fact that any connecting ideal I having left order S and right order T must be isomorphic to a right ideal of T. See [KV10] for details.

`IsIsomorphic(S, T)`

`IsConjugate(S, T)`

`FindElement`	BoolElt	*Default :* `false`
`ConnectingIdeal`	AlgAssVOrdIdl	*Default :*

Given orders S and T in a quaternion algebra A over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field, this function returns `true` if and only if S and T are isomorphic.

For indefinite algebras, the orders are currently required to be maximal.

If `FindElement` is set, the second return value is an isomorphism from S to T and the third return value is an element a with $T = a^{-1}Sa$, inducing the isomorphism. For indefinite algebras, this search is expensive and may sometimes fail (as in `IsIsomorphic` for ideals, see below).

For indefinite algebras defined over number fields, part of the computation may be faster when a connecting ideal is specified using the parameter `ConnectingIdeal`; this should be an ideal with left order S and right order T.

`Isomorphism(S, T)`

Given two isomorphic definite quaternion orders S, T over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ (with q odd), this function returns an algebra isomorphism. For orders over number rings the intrinsic `IsIsomorphic` should be used with the optional argument `FindElement` set.

86.14.3 Isomorphisms of Ideals

Two right (left) ideals I, J of an order O in a quaternion algebra A are isomorphic O-modules if and only if $xI = J$ ($Ix = J$) for some $x \in A^*$.

To decide whether I and J are isomorphic, we test whether the *colon ideal* $(J : I) = \{x \in A : xI \subset J\}$ (similarly defined if I, J are left ideals) is principal, or not.

Over $\mathbf{Z}$, to accomplish this task we compute a Minkowski-reduced Gram matrix of $(J : I)$ which produces an element of smallest norm. Over $\mathbf{F}_q[X]$ we compute a Gram matrix which has dominant diagonal form (see [Ger03]) which also produces a suitable element. Over other number rings R, we search $(J : I)$ for an element of the required norm by computing a reduced basis. This method runs very quickly for "reasonably small" input. (See [KV10, DD08] for further details.)

`IsIsomorphic(I, J)`

Given ideals I and J of the same order O in a quaternion algebra A over $\mathbf{Q}$, $\mathbf{F}_q(X)$ (with q odd) or a number field, this function returns `true` if and only if the quaternion ideals I and J are isomorphic (left or right) O-ideals. If I and J are isomorphic, there exists some $x \in A$ such that $xI = J$ (in the case of right O-ideals) or $Ix = J$ (for left ideals). For definite algebras, such an element x is always returned. For indefinite algebras over $\mathbf{Z}$ or a number ring, a search for such an element is made, and if one is found then it is returned.

`IsPrincipal(I)`

Given a left (or right) ideal I over $\mathbf{Z}, \mathbf{F}_q[X]$ or a number ring, this function returns `true` if and only if I is a principal ideal; if so, a generator is returned as the second value.

`IsLeftIsomorphic(I, J)`

`IsRightIsomorphic(I, J)`

Given two definite ideals over $\mathbf{Z}$ or $\mathbf{F}_q[X]$ (with q odd) with the same left (or right) order S, this function returns `true` if and only if they are isomorphic as S-modules. The isomorphism and the transforming scalar in the quaternion algebra are returned as second and third values if `true`.

`IsLeftIsomorphic(I, J)`

`IsRightIsomorphic(I, J)`

Given two left (or right) ideals I and J over a number ring, with the same left order O, this function returns `true` if and only if they are isomorphic as O-modules. The isomorphism is given by multiplication as a second return value.

`LeftIsomorphism(I, J)`

Given two isomorphic left ideals over a definite order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, this function returns the S-module isomorphism between them, followed by the quaternion algebra element which defines the isomorphism by right-multiplication.

`RightIsomorphism(I, J)`

Given two isomorphic right ideals over a definite order S over $\mathbf{Z}$ or $\mathbf{F}_q[X]$, this function returns the S-module isomorphism between them, followed by the quaternion algebra element which defines the isomorphism by left-multiplication.

86.14.4 Examples

Example H86E23

In this example, we create two quaternion algebras over $\mathbf{F}_7$, show that they are isomorphic and find an isomorphism between them.

```
> F<x> := RationalFunctionField( GF(7) );
> Q1 := QuaternionAlgebra< F | (x^2+x-1)*(x+1), x >;
> a := x^3 + x^2 + 3;
> b := x^13 + 4*x^11 + 2*x^10 + x^9 + 6*x^8 + 4*x^5 + 3*x^4 + x;
> Q2:= QuaternionAlgebra< F | a, b >;
> ok, phi:= IsIsomorphic(Q1, Q2 : Isomorphism);
> ok;
true
> forall{ <x,y> : x,y in Basis(Q1) |  phi(x*y) eq phi(x)*phi(y) };
true
```

Example H86E24

In this example, we create two ideals, show that they have isomorphic right orders, and then explicitly exhibit the isomorphism.

```
> A := QuaternionAlgebra(37);
> S := MaximalOrder(A);
> ideals := LeftIdealClasses(S);
> _, I, J := Explode(ideals);
> R := RightOrder(I);
> Q := RightOrder(J);
> IsIsomorphic(R,Q);
true
> // Get the x which conjugates R to Q:
> _, pi := Isomorphism(R,Q);
> Norm(pi);
37
> J := lideal< S | [ x*pi : x in Basis(J) ] >;
> RightOrder(J) eq R;
true
```

Example H86E25

We construct two non-isomorphic left ideals with the same left and right orders, then investigate their isomorphisms as right ideals.

```
> S := QuaternionOrder(37);
> ideals := LeftIdealClasses(S);
> _, I, J := Explode(ideals);
> R := RightOrder(I);
> _, pi := Isomorphism(R,RightOrder(J));
```

```
> J := lideal< S | [ x*pi : x in Basis(J) ] >;
> IsLeftIsomorphic(I,J);
false
> IsRightIsomorphic(I,J);
true Mapping from: AlgQuatOrd: I to AlgQuatOrd: J given by a rule [no inverse]
1 + i - 2*k
> h, x := RightIsomorphism(I,J);
> y := [1,2,-1,3];
> y := &+[y[i]*b[i] : i in [1 .. 4]] where b is Basis(I);
> h(y);
[-73  15  31   4]
> x*y;
-73 + 15*i + 31*j + 4*k
```

The existence of an isomorphism as a right ideal is due to the fact that the two-sided ideals of R do not have non-isomorphic counterparts in S.

```
> TwoSidedIdealClasses(R);
[ Ideal with basis Pseudo-matrix over Integer Ring
1 * [1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
, Ideal with basis Pseudo-matrix over Integer Ring
1 * [37  0 32 18]
[ 0 37 10  2]
[ 0  0  1  0]
[ 0  0  0  1]
 ]
> TwoSidedIdealClasses(S);
[ Ideal with basis Pseudo-matrix over Integer Ring
1 * [1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
 ]
```

Thus while `Conjugate(I)*J` is in the non-principal R-ideal class, the ideal `I*Conjugate(J)` represents the unique principal ideal class of S.

Example H86E26

We exhibit isomorphism testing for ideals of orders over number rings.

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> F := FieldOfFractions(Z_F);
> A<alpha,beta,alphabeta> := QuaternionAlgebra<F | -3, b>;
> O := Order([alpha,beta,alphabeta]);
```

```
> O;
Order of Quaternion Algebra with base ring F
with coefficient ring Maximal Equation Order with defining polynomial x^3 - 3*x
    - 1 over its ground order
> I := ideal<O | 2>;
> I eq (I + ideal<O | 2>);
true
> I eq (I + ideal<O | 3>);
false
>
> Foo := InfinitePlaces(F);
> A := QuaternionAlgebra(ideal<Z_F | 2*3*5>, Foo);
> IsDefinite(A);
true
> O := MaximalOrder(A);
> I := rideal<O | Norm(O.2), O.2>;
> J := rideal<O | Norm(O.3), O.3>;
> IsIsomorphic(I, J);
true (F.2 + F.3) + (27/9190*F.1 - 143/9190*F.2 - 73/9190*F.3)*i +
(-251/27570*F.1 + 7/2757*F.2 + 10/2757*F.3)*k
```

86.15 Units and Unit Groups

Let S be a definite quaternion order over $\mathbf{Z}$, $\mathbf{F}_q[X]$ with q odd, or a number ring. In the first two cases, the unit group of S is finite and can be read off any reduced Gram matrix of S. If the base ring of S is some number ring R, then an explicit description of the finite quotient S^*/R^* is given in [Vig76].

`NormOneGroup(S)`

`ModScalars` BoolElt *Default :* `false`

Returns a group G isomorphic to the group S_1 of elements in S with reduced norm 1 (unless `ModScalars` is set, in which case G is isomorphic to S_1 modulo $\{\pm 1\}$).

The second object returned is a map from G to S expressing the isomorphism.

`Units(S)`

This intrinsic computes the set of units S^* for the definite order S. When the base ring of S is Z or $\mathbf{F}_q[X]$, the returned sequence contains all units of S; when the base field is a number field, the returned sequence contains representatives modulo the unit group of the base ring (since the unit group is infinite in general).

`MultiplicativeGroup(S)`

`UnitGroup(S)`

This intrinsic computes the unit group S^* of the definite quaternion order S. The function returns an abstract group G, and a map from G to S. When the base ring of S is Z or $\mathbf{F}_q[X]$, G represents the full group of units of S; when the base field is a number field, G represents the unit group of S modulo the unit group of the base ring (since the unit group is infinite in general).

Example H86E27

The following example illustrates the unit group computation for an order in a definite quaternion algebra over $\mathbf{Q}$.

```
> A := QuaternionAlgebra< RationalField() | -1, -1 >;
> S1 := MaximalOrder(A);
> S2 := QuaternionOrder(A,2);
> G1, h1 := UnitGroup(S1);
> #G1;
24
> [ A | h1(g) : g in G1 ];
[ 1, -1, -j, -k, i, -1/2 + 1/2*i - 1/2*j - 1/2*k, 1/2 + 1/2*i - 1/2*j + 1/2*k,
-1/2 - 1/2*i - 1/2*j + 1/2*k, -1/2 + 1/2*i + 1/2*j + 1/2*k, 1/2 - 1/2*i - 1/2*j
- 1/2*k, 1/2 + 1/2*i + 1/2*j - 1/2*k, 1/2 - 1/2*i + 1/2*j + 1/2*k, -1/2 - 1/2*i
+ 1/2*j - 1/2*k, 1/2 - 1/2*i + 1/2*j - 1/2*k, -1/2 + 1/2*i + 1/2*j - 1/2*k, 1/2
+ 1/2*i - 1/2*j - 1/2*k, -1/2 - 1/2*i - 1/2*j - 1/2*k, 1/2 + 1/2*i + 1/2*j +
1/2*k, -1/2 - 1/2*i + 1/2*j + 1/2*k, -1/2 + 1/2*i - 1/2*j + 1/2*k, 1/2 - 1/2*i -
1/2*j + 1/2*k, k, -i, j ]
> G2, h2 := UnitGroup(S2);
> #G2;
8
> [ A | h2(g) : g in G2 ];
[ 1, -1, -j, j, k, -k, -i, i ]
```

The unit groups of orders in indefinite quaternion algebras A are infinite arithmetic groups, which are twisted analogues of the groups $\mathrm{SL}_2(\mathbf{Z})$ and their families of subgroups. These are studied in relation to their actions on the upper half complex plane, via an embedding in $\mathrm{GL}_2(\mathbf{R})$ provided by some isomorphism $A \otimes \mathbf{R} \cong M_2(\mathbf{R})$.

Example H86E28

Now we exhibit unit group computations over a number ring.

```
> P<x> := PolynomialRing(Rationals());
> F := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> Foo := InfinitePlaces(F);
```

We use `SetSeed` since the following line makes random choices.

```
> SetSeed(1);
```

```
> A := QuaternionAlgebra(ideal<Z_F | 2>, Foo);
> IsDefinite(A);
true
> O := MaximalOrder(A);
> U, h := UnitGroup(O);
> U;
Permutation group U acting on a set of cardinality 12
Order = 12 = 2^2 * 3
    Id(U)
    (1, 2, 4)(3, 6, 7)(5, 9, 10)(8, 12, 11)
    (1, 3)(2, 5)(4, 8)(6, 11)(7, 9)(10, 12)
> #Units(O);
12
```

87 ALGEBRAS WITH INVOLUTION

Chapter 87
ALGEBRAS WITH INVOLUTION

87.1 Introduction

In this chapter we describe techniques for computing with $*$-*algebras*, namely algebras equipped with an anti-automorphism $x \mapsto x^*$ of order at most 2 (an *involution* or *star*). For further information on involutions and the structure of $*$-algebras see [Alb61] and [KMRT98].

The principal application of these techniques is currently to isometry groups of systems of reflexive forms (and the intimately related study of intersections of classical groups). However, it is also possible to use the techniques to compute with group algebras of moderate dimension.

To any set of reflexive forms defined on a common vector space (a *system of forms*) one may associate a matrix $*$-algebra called the *adjoint algebra* of the system. The group of units of this adjoint algebra contains a natural subgroup of *unitary elements*, namely those elements x satisfying the condition $x^* = x^{-1}$. The group of unitary elements coincides with the group of isometries of the system of forms, which is also the intersection of the general classical groups associated with these forms.

The StarAlgebras package provides functions that enable the user to investigate the structure of $*$-algebras. It also provides functions to compute and determine the structure of the group of isometries of a system of reflexive forms, and to compute intersections of arbitrary collections of classical groups defined on a common vector space.

The algorithms are mainly due to Peter Brooksbank and James Wilson [BW11a, BW11b].

87.2 Algebras with Involution

This section introduces two general constructions for $*$-algebras:

(i) The algebra of adjoints of a system of reflexive (alternating, reflexive, or Hermitian) forms $[\phi_1, \ldots, \phi_e]$ defined on a common vector space V.

(ii) The group algebra $K[G]$, where K is any ring and G is a finite group.

We also provide a constructor function for simple $*$-algebras.

87.2.1 Reflexive Forms

A *reflexive form* on a K-vector space V is a bilinear function $\phi : V \times V \to K$ such that, whenever $\phi(u, v) = 0$ for $u, v \in V$, we also have $\phi(v, u) = 0$. Reflexive forms ϕ and ψ on V are *isometric* if $\phi(u, v) = \psi(u, v)$ for all $u, v \in V$; they are *similar* if there exists $a \in K$ such that ϕ and $a\psi$ are isometric. The *radical* of a reflexive form ϕ is the subspace $\mathrm{rad}\phi = \{u \in V : \phi(u, V) = 0\}$, and ϕ is *nondegenerate* if $\mathrm{rad}\phi = 0$.

A fundamental result of Birkhoff and von Neumann states that there are three similarity classes of reflexive forms: *alternating*, *symmetric*, and *Hermitian*. Each such form ϕ is represented by a matrix and an automorphism of K. Specifically, regarding V as the space of row vectors, we specify F and α such that $\phi(u, v) = u^\alpha F v^{\mathrm{tr}}$, where α is the identity if ϕ is bilinear, or the automorphism $x \mapsto \overline{x}$ of order 2 if ϕ is Hermitian. Thus a matrix $g \in \mathrm{GL}(d, K)$ is an *isometry* (respectively *similarity*) of the reflexive form if $g^\alpha F g^{\mathrm{tr}} = F$ (respectively $g^\alpha F g^{\mathrm{tr}} = aF$).

`IsometryGroup(F : parameters)`

`Auto` RngIntElt *Default :* 0

The group of isometries of the (possibly degenerate) reflexive form represented by the matrix F with entries in a finite field $\mathbf{F}_{p^e}$. The field automorphism associated with F is specified by the parameter `Auto`, which represents the exponent f in the map $x \mapsto x^{p^f}$. The default is that F is bilinear on its base ring.

`SimilarityGroup(F : parameters)`

`Auto` RngIntElt *Default :* 0

The group of similarities of the (possibly degenerate) reflexive form represented by the matrix F with entries in a finite field $\mathbf{F}_{p^e}$. The field automorphism associated with F is specified by the parameter `Auto`, which represents the exponent f in the map $x \mapsto x^{p^f}$. The default is that F is bilinear on its base ring.

87.2.2 Systems of Reflexive Forms

A *system of forms* is a sequence $[\phi_1, \ldots, \phi_e]$, where each ϕ_i is a reflexive form on a common K-vector space V. The radical of a system of forms is the intersection of the radicals of the individual forms in the system; A system is *nondegenerate* if its radical is zero.

A classical group on a K-vector space V preserves a reflexive form on V that is unique up to similarity. Hence systems of forms arise naturally from sets of classical groups having V as their common defining module.

Systems of forms also arise naturally from the study of p-groups. Let G be a finite p-group. Let $G = \gamma_1(G) > \gamma_2(G) > \ldots > \gamma_m(G) = 1$ denote the lower central series of G, and let $1 = \zeta_1(G) < \zeta_2(G) < \ldots < \zeta_n(G) = G$ denote its upper central series. Let $\Phi(G)$ be the Frattini subgroup of G, and put $N := \langle \Phi(G), \zeta_{n-1}(G) \rangle$. Then $V = G/N$ and $W = \gamma_2(G)/\gamma_3(G)$ are $\mathrm{GF}(p)$-vector spaces and commutation in G induces a bilinear map $V \times V \to W$. One now obtains a system of forms associated to G by choosing bases for V and W.

Just as matrices are useful representations of bilinear forms, so are systems of forms convenient computational models for *bilinear maps*.

PGroupToForms(G)

PGroupToForms(G)

Return a system of forms associated to the p-group G. For matrix groups, the input must be a class 2 p-group.

Example H87E1

We construct a system of forms associated to a Sylow 7-subgroup of $\mathrm{GL}(3,7)$.

```
> S := ClassicalSylow(GL (3, 7), 7);
> G := PCGroup(S);
> Forms := PGroupToForms(G);
> Forms;
[
    [0 1]
    [6 0]
]
```

Now we apply the same construction working directly with the matrix group as a p-group of class 2.

```
> Forms := PGroupToForms(S);
> Forms;
[
    [0 1]
    [6 0]
]
```

It is preferable to input a PC-group if such a representation can readily be obtained. The option to use a matrix group for p-groups of class 2 enables the user to construct an associated system of forms in situations where it requires considerably more time to first construct a PC-representation.

87.2.3 Basic Attributes of $*$-Algebras

Using the following functions one can ascertain whether or not a given algebra has an assigned involution, and also access the map if it has.

IsStarAlgebra(A)

IsStarAlgebra(A)

Return `true` if and only if A has an assigned involution.

Star(A)

Star(A)

Return the involution associated to the $*$-algebra A.

87.2.4 Adjoint Algebras

Let $S = [\phi_1, \ldots, \phi_e]$ be a system of reflexive forms on a K-vector space V. Let R denote the algebra $\mathrm{End}_K(V)$ and R^{op} denote its opposite ring. Then the *algebra of adjoints* of S is defined as follows:

$$\mathrm{Adj}(S) = \{(x, y) \in R \times R^{\mathrm{op}} : \phi_i(ux, v) = \phi_i(u, yv)\ \forall u, v \in V,\ \forall i \in \{1, \ldots, e\}\}.$$

As the ϕ_i are reflexive forms, $(x, y) \in \mathrm{Adj}(S)$ if and only if $(y, x) \in \mathrm{Adj}(S)$. If S is nondegenerate, then y is uniquely determined by x; thus we identify $\mathrm{Adj}(S)$ with its projection onto R and the assignment $x^* := y$ equips $\mathrm{Adj}(S)$ with an involution.

The function to compute $\mathrm{Adj}(S)$ is an implementation of the algorithms in [BW11a, Proposition 5.1] and [BW11b, Section 5].

`AdjointAlgebra(S : parameters)`

`Autos` SeqEnum *Default :* $[0, .., 0]$

Given a sequence S containing a nondegenerate system of reflexive forms, this function returns the $*$-algebra of adjoints of the forms in S. The parameter `Autos` is used to specify a list of Frobenius exponents associated with the given forms. By default all forms are considered to be bilinear over their common base ring, which must be a finite field. Note that the individual forms in the system are allowed to be degenerate.

Example H87E2

We construct the algebra of adjoints of a particular pair of forms on a vector space of dimension 3 over GF(5^2). The matrices have entries in GF(5) but we regard them as forms over the larger field, and define the first (symmetric) form to be Hermitian over the larger field.

```
> MA := MatrixAlgebra(GF (25), 3);
> F := MA![1,2,0,2,3,4,0,4,1];
> G := MA![0,1,0,4,0,0,0,0,0];
> A := AdjointAlgebra([F, G] : Autos := [1, 0]);
> IsStarAlgebra(A);
true
> Degree(A);
6
> BaseRing(A);
Finite field of size 5
```

Observe that the function has converted the given system of forms to a new system over GF(5) and returned an algebra of degree 6 over the subfield. Now we access the involution on A and apply it to a generator of A.

```
> star := Star(A);
> A.3;
[1 0 2 0 2 0]
[0 1 0 2 0 2]
```

```
[1 0 4 0 4 0]
[0 1 0 4 0 4]
[0 0 0 0 0 0]
[0 0 0 0 0 0]
> A.3@star;
[4 0 3 0 3 0]
[0 4 0 3 0 3]
[4 0 1 0 1 0]
[0 4 0 1 0 1]
[0 0 0 0 0 0]
[0 0 0 0 0 0]
```

87.2.5 Group Algebras

If G is a finite group and R is any ring, then the group algebra $A = R[G]$ possesses a natural involution. Thus each group algebra may be regarded as a $*$-algebra.

`StarOnGroupAlgebra(A)`

The natural involution on the group algebra A induced by inversion on the underlying group. Specifically, if $a = \sum_{g \in G} \alpha_g g \in A$, then $a^* = \sum_{g \in G} \alpha_g g^{-1}$.

`GroupAlgebraAsStarAlgebra(R, G)`

Construct the group algebra $R[G]$ equipped with the natural involution afforded by inversion in G.

Example H87E3

We construct the group algebra $Z[S_3]$ as a $*$-algebra.

```
> G := SymmetricGroup(3);
> K := Integers();
> A := GroupAlgebraAsStarAlgebra(K, G);
> IsStarAlgebra(A);
true;
```

Now access the involution on A and apply it to an element of A.

```
> star := Star(A);
> a := A![0,0,1,0,3,0];
> a;
(1, 3, 2) + 3*(1, 2)
> a@star;
(1, 2, 3) + 3*(1, 2)
```

Alternatively, $Z[S_3]$ can be constructed using the standard constructor and the involution can be attached later.

```
> A := GroupAlgebra(K, G);
```

```
> IsStarAlgebra(A);
false
> StarOnGroupAlgebra(A);
Mapping from: AlgGrp: A to AlgGrp: A given by a rule [no inverse]
> IsStarAlgebra(A);
true
```

87.2.6 Simple $*$-Algebras

The Artinian *simple $*$-algebras* – those having no proper $*$-invariant ideals – were classified by Albert [Alb61]. They come in two basic flavours: *classical* and *exchange*. The classical types are simple as algebras and arise as adjoints of nondegenerate reflexive forms. A simple $*$-algebra of exchange type is a direct sum of two isomorphic simple algebras where the involution interchanges the two factors. Naturally extending the MAGMA classification of reflexive forms (see the manual entry for the function `ClassicalForms`) a simple $*$-algebra S is assigned a `name` as follows:

`"symplectic"` if S is defined by an alternating form;

`"orthogonalcircle"` if S is defined by a symmetric form in odd dimension;

`"orthogonalplus"` if S is defined by a symmetric form of maximal Witt index;

`"orthogonalminus"` if S is defined by a symmetric form of non-maximal Witt index;

`"unitary"` if S is defined by an Hermitian form; and

`"exchange"` if S has exchange type.

Every simple $*$-algebra is isomorphic to a standard simple $*$-algebra having one of these six names defined naturally on a suitable vector space.

We note that involutions on simple $*$-algebras are often classified as being "of the first kind" or "of the second kind" according to whether or not they induce the identity on the center of the algebra. Thus, involutions of the second kind are unitary and exchange, and the others are all involutions of the first kind [KMRT98].

`SimpleStarAlgebra(name, d, K)`

Given a `name`, a positive integer d, and a field K, this function constructs the standard copy of the simple $*$-algebra of type `name` defined naturally on a K-vector space of dimension d.

Example H87E4

We construct the standard copy of the simple $*$-algebra of exchange type on the vector space of dimension 4 over GF(16).

```
> K := GF(16);
> S := SimpleStarAlgebra("exchange", 4, K);
> Dimension(S);
8
> IsStarAlgebra(S);
```

```
true;
> w := K.1;
> s := S.1 * S.2 + w * S.1;
> s;
[   K.1      1      0      0]
[     0      0      0      0]
[     0      0      0      0]
[     0      0      0      0]
> star := Star(S);
> s@star;
[     0      0      0      0]
[     0      0      0      0]
[     0      0    K.1      0]
[     0      0      1      0]
```

87.3 Decompositions of $*$-Algebras

Every finite-dimensional K-algebra A has a decomposition $A = J \oplus W$, where J is the Jacobson radical of A and W is a semisimple subring of A. We refer to such decompositions as *Wedderburn decompositions*. The procedure that computes Wedderburn decompositions is adapted from an analogous MAGMA function written by W. de Graaf for algebras defined by structure constants.

If A is a $*$-algebra and the characteristic of K is not 2, then it follows from a result of Taft [Taf57] that A has a Wedderburn decomposition of the form $A = J \oplus T$ in which T is invariant under the involution of A. We refer to such decompositions as *Taft decompositions*. The procedure that computes Taft decompositions is based on Taft's original proof, and is described in [BW11a, Proposition 4.3].

`WedderburnDecomposition(A)`

`WedderburnDecomposition(A)`

A Wedderburn decomposition is constructed for the $*$-algebra A. Specifically, the Jacobson radical, J, of A, and a semisimple complement, W, to J in A are computed. Here A may be either a matrix algebra or a group algebra over any field.

`TaftDecomposition(A)`

`TaftDecomposition(A)`

A Taft decomposition is constructed for the $*$-algebra A. Specifically, the Jacobson radical, J, of A and a $*$-invariant Wedderburn complement to J in A are computed. This function requires that the base ring of A has characteristic different from 2. Here A may be either a matrix $*$-algebra or a group algebra.

Example H87E5

We compute a Wedderburn decomposition of the group algebra GF(5)[A_5] equipped with its natural involution.

```
> K := GF(5);
> G := AlternatingGroup(5);
> A := GroupAlgebraAsStarAlgebra(K, G);
> J, W := WedderburnDecomposition(A);
```

We check dimensions and the $*$-invariance of T.

```
> Dimension(J); Dimension(W);
25
35
> forall { i : i in [1..Ngens (W)] | W.i@Star(A) in W };
false
```

Now find a $*$-invariant decomposition.

```
> J, T := TaftDecomposition(A);
> Dimension(J); Dimension(W);
25
35
> forall { i : i in [1..Ngens(T)] | T.i@Star(A) in T };
true
```

87.4 Recognition of $*$-Algebras

In this section we describe methods that facilitate structural examinations of $*$-algebras. *All of the functions in this section require that the base ring of the given algebra is a finite field of odd order.* The functions are implementations of the methods described in [BW11a, Sections 4.2 and 4.3].

87.4.1 Recognition of Simple $*$-Algebras

If A is a simple $*$-algebra, then we *constructively recognise* A by finding an explicit inverse isomorphisms between A and the standard copy of the simple $*$-algebra which is isomorphic to A. The latter is the output of the function `SimpleStarAlgebra` with the appropriate input parameters.

`RecogniseClassicalSSA(A)`

Given a matrix $*$-algebra A, this function first decides whether or not A is a simple $*$-algebra of classical type. If it is, the standard $*$-algebra, T, corresponding to A, a $*$-isomorphism from A to T, and its inverse from T to A are returned.

`RecogniseExchangeSSA(A)`

Given a matrix $*$-algebra A, this function first decides whether or not A is a simple $*$-algebra of exchange type. If it is, the standard $*$-algebra, T, corresponding to A, a $*$-isomorphism from A to T, and its inverse from T to A are returned.

Example H87E6

We build a particular simple $*$-algebra of symplectic type and recognise it constructively.

```
> MA := MatrixAlgebra(GF(7), 4);
> F := MA![0,1,3,4,6,0,0,1,4,0,0,2,3,6,5,0];
> F;
[0 1 3 4]
[6 0 0 1]
[4 0 0 2]
[3 6 5 0]
> A := AdjointAlgebra([F]);
> isit, T, f, g := RecogniseClassicalSSA(A);
> isit;
true;
```

A quick check that f is, as claimed, a $*$-isomorphism.

```
> (A.1 + A.2)@f eq (A.1@f) + (A.2@f);
true
> (A.1 * A.2)@f eq (A.1@f) * (A.2@f);
true
> (A.2@Star(A))@f eq (A.2@f)@Star(T);
true
```

87.4.2 Recognition of Arbitrary $*$-Algebras

If A is an arbitrary $*$-algebra, then we constructively recognise A as follows:

(i) Find a decomposition $A = J \oplus T$, where J is the Jacobson radical of A and T is a $*$-invariant semisimple complement to J in A;

(ii) Find a decomposition $T = I_1 \oplus \ldots \oplus I_t$ of T into minimal $*$-ideals; and

(iii) For each $j \in \{1, \ldots, t\}$ constructively recognise the simple $*$-algebra I_j.

`RecogniseStarAlgebra(A)`

`RecogniseStarAlgebra(A)`

Constructively recognise the $*$-algebra A given as a matrix $*$-algebra or a group algebra.

There are several functions available that permit easy access to structural information about a $*$-algebra that has been constructively recognised. (In fact all of these functions also initiate a constructive recognition of the input $*$-algebra if the recognition has not already been carried out.) For all of the access functions A can be either a matrix $*$-algebra or a group algebra.

`IsSimpleStarAlgebra(A)`

`IsSimpleStarAlgebra(A)`

Return `true` if and only if A is a simple $*$-algebra.

`SimpleParameters(A)`

`SimpleParameters(A)`

Given a $*$-algebra A, this function returns the parameters that determine (up to $*$-isomorphism) the minimal $*$-ideals of the semisimple quotient A/J, where J is the Jacobson radical of A. The parameters are returned in the form of a sequence.

`NormGroup(A)`

Given a $*$-algebra A, this function returns the group of unitary elements of A, namely the group consisting of all units in A satisfying the condition $x^* = x^{-1}$. The function is based on methods described in [BW11a, Section 5].

Example H87E7

Our first example illustrates how the $*$-algebra machinery may be used to distinguish between group algebras over GF(5) for the dihedral and quaternion groups of order 8. Those group algebras are isomorphic as algebras, but the example shows that they are nonisomorphic as $*$-algebras.

```
> K := GF(5);
> G1 := SmallGroup(8, 3);
> G2 := SmallGroup(8, 4);
> A1 := GroupAlgebraAsStarAlgebra(K, G1);
> A2 := GroupAlgebraAsStarAlgebra(K, G2);
> J1, T1 := TaftDecomposition(A1);
> J2, T2 := TaftDecomposition(A2);
> Dimension(J1); Dimension(J2);
0
0
```

Thus (as we know from Maschke's theorem) both GF(5)$[D_8]$ and GF(5)$[Q_8]$ are semisimple. We now recognise them as $*$-algebras and examine their minimal $*$-ideals.

```
> RecogniseStarAlgebra(A1);
true
> RecogniseStarAlgebra(A2);
true
> SimpleParameters(A1);
[ <"orthogonalcircle", 1, 5>, <"orthogonalcircle", 1, 5>,
<"orthogonalcircle", 1, 5>, <"orthogonalcircle", 1, 5>,
<"orthogonalplus", 2, 5> ]
> SimpleParameters(A2);
[ <"orthogonalcircle", 1, 5>, <"orthogonalcircle", 1, 5>,
<"orthogonalcircle", 1, 5>, <"orthogonalcircle", 1, 5>,
<"symplectic", 2, 5>
]
```

Both group algebras decompose into four 1-dimensional $*$-ideals, and one 4-dimensional $*$-ideal. However, the latter has type `"orthogonalplus"` for GF(5)$[D_8]$, but type `"symplectic"` for GF(5)$[Q_8]$.

Example H87E8

Our second example shows how to use $*$-algebra functions to distinguish between two p-groups of class 2 and order 43^6. The first group is a Sylow 43-subgroup of $\mathrm{GL}(3, 43^2)$.

```
> P1 := ClassicalSylow(GL(3, 43^2), 43);
> Forms1 := PGroupToForms(P1);
> A1 := AdjointAlgebra(Forms1);
> RecogniseStarAlgebra(A1);
true
> SimpleParameters(A1);
[ <"symplectic", 2, 1849> ]
```

The second group is constructed as a subgroup of $\mathrm{GL}(3, \mathrm{GF}(43)[x]/(x^2))$.

```
> R<x> := PolynomialRing(GF(43));
> S, f := quo< R | x^2 >;
> G := GL(3, S);
> Ua := G![1,1,0,0,1,0,0,0,1];
> Wa := G![1,0,0,0,1,1,0,0,1];
> Ub := G![1,x@f,0,0,1,0,0,0,1];
> Wb := G![1,0,0,0,1,x@f,0,0,1];
> P2 := sub< G | [ Ua, Wa, Ub, Wb ] >;
> Forms2 := PGroupToForms(P2);
> A2 := AdjointAlgebra(Forms2);
> RecogniseStarAlgebra(A2);
true
> SimpleParameters(A2);
[ <"symplectic", 2, 43> ]
```

Since A_1 and A_2 are non-isomorphic $*$-algebras, it follows that P_1 and P_2 are non-isomorphic groups.

87.5 Intersections of Classical Groups

The main application of the $*$-algebra machinery is to the study of the group preserving each form in a system of forms; the so-called *isometry group* of the system. An essentially equivalent (but perhaps more familiar) problem is that of computing the intersection of a set of classical groups defined on a common vector space. The main functions are implementations of the algorithms presented in [BW11a, Theorem 1.2] and [BW11b, Theorem 1.1].

`IsometryGroup(S : parameters)`

`Autos`	SeqEnum	*Default :* $[0, .., 0]$
`DisplayStructure`	BoolElt	*Default :* `false`

Given a sequence S containing a system of reflexive forms, this function returns the group of isometries of the system. In addition to allowing the individual forms to be degenerate, the function handles degenerate systems.

The field automorphisms associated to the individual forms are specified using the parameter `Autos`; the default is that all forms in the system are bilinear over their common base ring. As well as finding generators for the isometry group, the procedure determines the structure of this group. The parameter `DisplayStructure` may be used to display this structure.

Example H87E9

We compute the isometry group of the system of forms associated to a particular p-group.

```
> G := ClassicalSylow(Sp (4, 5^2), 5);
> S := PGroupToForms(G);
> Parent(S[1]);
Full Matrix Algebra of degree 6 over GF(5)
> I := IsometryGroup(S : DisplayStructure := true);
   G
   |   GL ( 1 , 5 ^ 1 )
   *
   |   5 ^ 4    (unipotent radical)
   1
> #I;
2500
```

`ClassicalIntersection(S)`

Given a sequence S containing a number of classical groups, each one of which preserves (up to similarity) a unique nondegenerate reflexive form on a common finite vector space V, this function returns the intersection of the groups. It is not required that a classical group G in S be the full group of isometries.

Example H87E10

In our final example we intersect two quasisimple classical groups. First we construct a symplectic group $\mathrm{Sp}(F_1)$ for a particular skew-symmetric matrix F_1.

```
> K := GF(3);
> M := UpperTriangularMatrix
>        (K,[0,2,1,0,1,2,1,1,1,2,0,0,1,2,1,0,1,0,1,2,2]);
> F1 := M - Transpose(M);
```

```
> G1 := IsometryGroup(F1);
```

First check that G1 is a group of isometries.

```
> forall{ g : g in Generators(G1) | g*F1*Transpose(g) eq F1 };
true
```

Next we construct a quasisimple orthogonal group $\Omega^-(F_2)$ for a particular symmetric matrix F_2.

```
> F2 := SymmetricMatrix
>         (K, [1,2,0,1,2,2,1,0,2,2,1,0,0,0,1,2,1,1,0,1,0]);
> C := TransformForm(F2, "orthogonalminus");
> G := OmegaMinus(6, 3);
> G2 := G^(C^-1);
```

First check that G2 is a group of isometries.

```
> forall { g : g in Generators(G2) | g*F2*Transpose(g) eq F2 };
true
```

Finally compute the intersection of G_1 and G_2 and ask for the order of this intersection group.

```
> I := ClassicalIntersection([G1, G2]);
> #I;
14
```

88 CLIFFORD ALGEBRAS

Chapter 88
CLIFFORD ALGEBRAS

88.1 Introduction

Given a quadratic form Q defined on a vector space V over a field F, the Clifford algebra of Q is an associative F-algebra C with a vector space homomorphism $f : V \to C$ such that $f(v)^2 = Q(v)$ for all $v \in V$. Furthermore, the triple (C, V, f) has the universal property that if A is any associative algebra with a homomorphism $g : V \to A$ such that $g(v)^2 = Q(v)$ for all $v \in V$, then there is a unique algebra homomorphism $h : C \to A$ such that $hf = g$. It can be shown that f is injective and therefore we may identify V with its image in C. If the dimension of V is n, then the dimension of C is 2^n.

The primary references for quadratic forms and Clifford algebras are [Che97] and [Art57].

88.2 Clifford Algebras and their Elements

Clifford algebras are represented in MAGMA as structure constant algebras and so many of the functions described in Chapter 79 apply to Clifford algebras. The MAGMA type of a Clifford algebra is `AlgClff` and all Clifford algebras have the attributes

space: the quadratic space from which the Clifford is derived;

embedding: the standard embedding of the quadratic space into the Clifford algebra;

mainInvolutionMatrix: the matrix of the antiautomorphism of the Clifford algebra that reverses the multiplication.

Let C be the Clifford algebra of the quadratic form Q defined on the vector space V. If e_1, e_2, ..., e_n is a basis for V, a basis for C is the set of all products $e_1^{i_1} e_2^{i_2} \cdots v_n^{i_n}$, where i_k is 0 or 1 for all k. The function $k \mapsto i_k$ is the characteristic function of a subset of $\{1, 2, \ldots, n\}$, namely $S = \{k \mid i_k eq 1\}$. The map $S \mapsto 1 + \sum_{k \in S} 2^{k-1}$ is a bijection between the subsets of $\{1, 2, \ldots, n\}$ and the integers in the interval $[1 \ldots 2^n]$.

Thus the elements of C can be represented by a sequence of pairs $\langle S, a \rangle$ where S is a subset of $\{1, 2, \ldots, n\}$ and a is a field element. Multiplication is determined by the fact that for all $u, v \in V$ we have

$$v^2 = Q(v) \cdot 1 \quad \text{and} \quad uv + vu = \beta(u, v) \cdot 1,$$

where β is the polar form of Q.

`CliffordAlgebra(Q)`

This function returns a triple C, V, f, where C is the Clifford algebra of the quadratic form Q, V is the quadratic space of Q, and f is the standard embedding of V into C.

`CliffordAlgebra(V)`

If V is a quadratic space with quadratic form Q, this function returns the pair C, f, where C is the Clifford algebra of Q and f is the standard embedding of V into C.

88.2.1 Elements of a Clifford Algebra

`elt< C | `$r_1, r_2, \ldots, r_m$` >`

Given a Clifford algebra C of dimension $m = 2^n$ over a field F, and field elements r_1, r_2, ..., $r_m \in F$ construct the element $r_1 * C.1 + r_2 * C.2 + \cdots + r_m * C.m$ of C.

`C ! L`

Given a Clifford algebra C of dimension $m = 2^n$ and a sequence $L = [r_1, r_2, \ldots, r_m]$ of elements of the base ring R of C, construct the element $r_1 * C.1 + r_2 * C.2 + \cdots + r_m * C.m$ of C.

`BasisProduct(A, i, j)`

Return the product of the i-th and j-th basis element of the Clifford algebra C.

`BasisElement(C, L)`

The basis element $C.j$ of the Clifford algebra C corresponding to the subset L of $\{1, 2, \ldots, n\}$ where $j = 1 + \sum_{k \in L} 2^{k-1}$. If e_1, e_2, ..., e_n is the standard basis for the vector space on which C is based, this corresponds to the product $e_{i_1} * e_{i_2} * \cdots * e_{i_h}$, where $L = \{i_1, i_2, \ldots, i_h\}$ and $i_1 < i_2 < \cdots < i_h$.

PART XII
REPRESENTATION THEORY

89 MODULES OVER AN ALGEBRA

Chapter 89
MODULES OVER AN ALGEBRA

89.1 Introduction

Let A be an algebra over a field K and let M be a vector space over K. We say that M is a *(right) A-module* if for each $a \in A$ and $m \in M$, a product $ma \in M$ is defined such that

$$(m+n)a = ma + na, m(a+b) = ma + mb,$$
$$m(ab) = (ma)b, m1 = m,$$
$$m(ka) = (ma)k = (mk)a,$$

for all $a, b \in A, m, n \in M, k \in K$.

Recall that a *representation* of an algebra A over a field K is an algebra homomorphism of A into $\mathrm{Hom}_K(M, M)$, for some K-module M. Taking M to be an A-module, and defining a mapping $\rho : M \to M$ by

$$\rho(m) := ma \quad (a \in A, m \in M)$$

then it is an easy exercise to show that ρ is a representation of A. A *matrix representation of degree n* of the algebra A is an algebra homomorphism of A into $M_n(K)$, the complete matrix algebra of degree n over K. Suppose M has finite K-dimension n and choose a basis for M. If, for each $a \in A$, we associate the matrix corresponding to the action of a on the basis elements, we obtain a matrix representation of A. Thus, each A-module of finite K-dimension *affords* a matrix representation of the algebra A. An important special case occurs when $A = K[G]$, the group algebra of a group G. In this case the theory of A-modules coincides with the theory of group representations.

Throughout this chapter we shall use the term *A-module* when referring to modules as defined above. For Magma V2.19, A-modules are restricted to one of the following cases:

(i) A matrix algebra A defined over a field.

(ii) A matrix algebra A defined over a field corresponding to a representation of a group G of finite degree. In this case the user is (implicitly) computing with the group algebra $K[G]$.

(iii) A matrix algebra A defined over an Euclidean Domain R. However, as currently the action of A may be used only in the construction of submodules, discussion will be limited to the case in which the coefficient ring is a field.

Note that in all of the above cases A has finite K-dimension.

Magma provides a range of facilities for defining and computing with A-modules. In particular, extensive machinery is provided for creating $K[G]$-modules which is described in the following chapter. It should be noted however, that many advanced functions only apply when A is an algebra over a finite field. Since the R-module of n-tuples, $R^{(n)}$, underlies an A-module, the operations for $R^{(n)}$ are also applicable.

89.2 Modules over a Matrix Algebra

This section describes function dealing with modules over a matrix algebra, for which there are the most number of operations available.

89.2.1 Construction of an A-Module

89.2.1.1 General Constructions

`RModule(A)`

Given a subalgebra A of $M_n(K)$, create the right A-module M with underlying vector space $K^{(n)}$, where the action of $a \in A$ is given by $m * a$, $m \in M$.

`RModule(Q)`

Given the subalgebra A of $M_n(K)$ generated by the terms of the sequence Q, create the right A-module M with underlying vector space $K^{(n)}$, where the action of $a \in A$ is given by $m * a$, $m \in M$.

Example H89E1

We construct the 6-dimensional module over $\mathbf{F}_2$ with an action given by the matrices

$$\begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 0 \end{pmatrix} \qquad \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

```
> A := MatrixAlgebra<GF(2), 6 |
>   [ 1,0,0,1,0,1,
>     0,1,0,0,1,1,
>     0,1,1,1,1,0,
>     0,0,0,1,1,0,
>     0,0,0,1,0,1,
>     0,1,0,1,0,0 ],
>   [ 0,1,1,0,1,0,
>     0,0,1,1,1,1,
>     1,0,0,1,0,1,
>     0,0,0,1,0,0,
>     0,0,0,0,1,0,
>     0,0,0,0,0,1 ] >;
> M := RModule(A);
> M;
RModule M of dimension 6 over GF(2)
```

89.2.1.2 Constructions for $K[G]$-Modules

Although $K[G]$-modules are discussed in the next chapter, it is convenient to use them as examples in this chapter and so we give two basic constructions here. The reader is referred to the $K[G]$-module chapter for many other techniques for constructing these modules.

`GModule(G, Q)`

`Check` BoolElt *Default :* `true`

Let G be a group defined on r generators and let Q be a sequence of r invertible elements of $M_n(K)$ or $GL(n, K)$. It is assumed that the mapping from G to Q defined by $\phi(G.i) \mapsto Q[i]$, for $i = 1, \ldots, r$, is a group homomorphism from G into $GL(n, K)$. The function constructs a $K[G]$-module M of dimension n, where the action of the generators of G is given by the terms of Q.

`PermutationModule(G, K)`

Given a permutation group G and a field K, create the natural permutation module for G over K.

89.2.2 Accessing Module Information

This section deals with the underlying vector space of a module M, which is a module over the algebra A.

89.2.2.1 The Underlying Vector Space

`M . i`

Given an A-module M and a positive integer i, return the i-th generator of M.

`CoefficientRing(M)`

`BaseRing(M)`

Given an A-module M, where A is an algebra over the field K, return K.

`Generators(M)`

The generators for the A-module M, returned as a set.

`Parent(u)`

Given an element u belonging to the A-module M, return M.

89.2.2.2 The Algebra

`Action(M)`

`RightAction(M)`

Given an A-module M, return the matrix algebra A giving the action of A on M.

`MatrixGroup(M)`

`Check` BoolElt *Default :* `true`

Given an $R[G]$-module M, return the matrix group whose generators are the (invertible) generators of the acting algebra of M.

`ActionGenerator(M, i)`

The i-th generator of the (right) acting matrix algebra for the module M.

`NumberOfActionGenerators(M)`

`Ngens(M)`

The number of action generators (the number of generators of the algebra) for the A-module M.

`Group(M)`

Given an $R[G]$-module M, return the group G.

Example H89E2

We illustrate the use of several of these access functions by applying them to the 6-dimensional representation of a matrix algebra defined over $\mathbf{F}_2$.

```
> F2 := GF(2);
> F := MatrixAlgebra(F2, 6);
> A := sub< F |
>   [ 1,0,0,1,0,1,
>     0,1,0,0,1,1,
>     0,1,1,1,1,0,
>     0,0,0,1,1,0,
>     0,0,0,1,0,1,
>     0,1,0,1,0,0 ],
>   [ 0,1,1,0,1,0,
>     0,0,1,1,1,1,
>     1,0,0,1,0,1,
>     0,0,0,1,0,0,
>     0,0,0,0,1,0,
>     0,0,0,0,0,1 ] >;
> T := RModule(F2, 6);
> M := RModule(T, A);
> Dimension(M);
6
```

```
> BaseRing(M);
Finite field of size 2
```

We set R to be the name of the matrix ring associated with M. Using the generator subscript notation, we can access the matrices giving the (right) action of A.

```
> R := RightAction(M);
> R.1;
[1 0 0 1 0 1]
[0 1 0 0 1 1]
[0 1 1 1 1 0]
[0 0 0 1 1 0]
[0 0 0 1 0 1]
[0 1 0 1 0 0]
> R.2;
[0 1 1 0 1 0]
[0 0 1 1 1 1]
[1 0 0 1 0 1]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
```

We display full details of the module.

```
> M: Maximal;
Module M of dimension 6 with base ring GF(2)
Generators of acting algebra:

[1 0 0 1 0 1]
[0 1 0 0 1 1]
[0 1 1 1 1 0]
[0 0 0 1 1 0]
[0 0 0 1 0 1]
[0 1 0 1 0 0]

[0 1 1 0 1 0]
[0 0 1 1 1 1]
[1 0 0 1 0 1]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
```

89.2.3 Standard Constructions

Given one or more existing modules, various standard constructions are available to construct new modules.

89.2.3.1 Changing the Coefficient Ring

`ChangeRing(M, S)`

Given an A-module M with base ring R, together with a ring S, such that there is a natural homomorphism from R to S, construct the module N with base ring S where N is obtained from M by coercing the components of the vectors of M into N. The corresponding homomorphism from M to N is returned as a second value.

`ChangeRing(M, S, f)`

Given a module M with base ring R, together with a ring S, and a homomorphism $f : R \to S$, construct the module N with base ring S, where N is obtained from M by applying f to the components of the vectors of M. The corresponding homomorphism from M to N is returned as a second value.

89.2.3.2 Direct Sum

`DirectSum(M, N)`

Given R-modules M and N, construct the direct sum D of M and N as an R-module. The embedding maps from M into D and from N into D respectively and the projection maps from D onto M and from D onto N respectively are also returned.

`DirectSum(Q)`

Given a sequence Q of R-modules, construct the direct sum D of these modules. The embedding maps from each of the elements of Q into D and the projection maps from D onto each of the elements of Q are also returned.

89.2.3.3 Changing Basis

`M ^ T`

Given a $K[G]$-module M of dimension n over the field K, and a nonsingular $n \times n$ matrix T over K, construct the $K[G]$-module N which corresponds to taking the rows of T as a basis for M.

89.2.4 Element Construction and Operations

89.2.4.1 Construction of Module Elements

`elt< M | a`$_1$`, ..., a`$_n$ `>`

Given a module M with underlying vector space $K^{(n)}$, and elements $a_1, \ldots, a_n$ belonging to K, construct the element $m = (a_1, \ldots, a_n)$ of M. Note that if m is not an element of M, an error will result.

`M ! Q`

Given the module M with underlying vector space K^n, and a sequence $Q = [a_1, \ldots, a_n]$ with universe K, construct the element $m = (a_1, \ldots, a_n)$ of M. Note that if m is not an element of M, an error will result.

`Zero(M)`

`M ! 0`

The zero element for the A-module M.

`Random(M)`

Given a module M defined over a finite ring or field, return a random vector.

89.2.4.2 Deconstruction of Module Elements

`ElementToSequence(u)`

`Eltseq(u)`

Given an element u belonging to the A-module M, return u in the form of a sequence Q of elements of K.

89.2.4.3 Action of the Algebra on the Module

`u * a`

Given a vector u belonging to an A-module M, and an element $a \in A$ return the image of u under the action of a.

`u * g`

Given a vector u belonging to an $K[G]$-module M, and an element g belonging to the group G, return the image of u under the action of $K[G]$ on the module M.

89.2.4.4 Arithmetic with Module Elements

`u + v`

Sum of the elements u and v, where u and v lie in the same A-module M.

`-u`

Additive inverse of the element u.

`u - v`

Difference of the elements u and v, where u and v lie in the same A-module M.

`k * u`

Given an element u in an A-module M, where A is a K-algebra and an element $k \in K$, return the scalar product $k * u$ as an element of M.

`u * k`

Given an element u in an A-module M, where A is a K-algebra and an element $k \in K$, return the scalar product $u * k$ as an element of M.

`u / k`

Given an element u in an A-module M, where A is a K-algebra and a non-zero element $k \in K$, return the scalar product $u * (1/k)$ as an element of M.

89.2.4.5 Indexing

`u[i]`

Given an element u belonging to a submodule M of the R-module $R^{(n)}$ and a positive integer i, $1 \leq i \leq n$, return the i-th component of u (as an element of the ring R).

`u[i] := x`

Given an element u belonging to a submodule M of the R-module $T = R^{(n)}$, a positive integer i, $1 \leq i \leq n$, and an element x of the ring R, redefine the i-th component of u to be x. The parent of u is changed to T (since the modified element u need not lie in M).

89.2.4.6 Properties of Module Elements

`IsZero(u)`

Returns `true` if the element u of the A-module M is the zero element.

`Support(u)`

A set of integers giving the positions of the non-zero components of the vector u.

89.2.5 Submodules

89.2.5.1 Construction

`sub< M | L >`

Given an A-module M, construct the submodule N generated by the elements of M specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of R defining an element of M;

(b) A set or sequence whose terms are elements of M;

(c) A submodule of M;

(d) A set or sequence whose terms are submodules of M.

The generators stored for N consist of the elements specified by terms L_i together with the stored generators for submodules specified by terms of L_i. Repetitions of an element and occurrences of the zero element are removed (unless N is trivial).

The constructor returns the submodule N as an A-module together with the inclusion homomorphism $f : N \to M$.

`ImageWithBasis(X, M)`

`Check` BoolElt *Default :* `true`

Given a basis matrix X for a A-submodule of the A-module M, return the submodule N of M such that the morphism of N into M is X.

`Morphism(M, N)`

If the A-module M was created as a submodule of the module N, return the inclusion homomorphism $\phi : M \to N$ as an element of $\mathrm{Hom}_A(M, N)$. Thus, ϕ gives the correspondence between elements of M (represented with respect to the standard basis of M) and elements for N.

Example H89E3

We construct a submodule of the permutation module for $L(3, 4)$ in its representation of degree 21.

```
> G := PSL(3, 4);
> M := PermutationModule(G, GF(2));
> x := M![0,0,0,1,0,1,0,0,0,1,1,0,0,0,1,0,1,1,0,0,1];
> N := sub< M | x >;
> N:Maximal;
GModule N of dimension 9 over GF(2)
Generators of acting algebra:

[1 0 0 0 1 0 1 0 1]
[0 1 0 1 1 1 0 0 0]
[0 0 1 1 1 1 1 0 1]
[0 0 0 0 0 1 1 0 0]
[0 0 0 1 0 0 1 0 0]
[0 0 0 0 1 0 1 0 0]
[0 0 0 1 1 1 0 0 0]
[0 0 0 0 1 1 0 0 1]
[0 0 0 1 0 1 0 1 1]

[0 0 0 0 0 1 0 1 1]
[1 0 0 0 0 0 0 0 1]
[0 1 1 0 0 1 0 0 1]
[0 0 0 0 0 1 0 0 0]
[0 0 1 0 0 1 0 0 0]
[0 0 1 0 1 1 0 0 1]
[0 0 1 1 0 0 0 0 1]
[0 0 1 0 0 0 0 0 1]
[0 0 0 0 0 0 1 0 0]
```

Note that as a $\mathbf{F}_2$-module V has dimension 1, while as a $K[G]$-module it has dimension 9. The submodule N is defined on a reduced basis so we use `Morphism` to see N embedded in M.

```
> phi := Morphism(N, M);
```

```
> [ phi(x) : x in Basis(N) ];
[
    M: (1 0 0 0 0 0 0 0 0 1 1 1 1 0 0 0 1 0 1 0 1),
    M: (0 1 0 0 0 0 0 0 0 1 0 0 0 1 0 0 1 1 1 1 1),
    M: (0 0 1 0 0 0 0 0 0 1 0 1 1 0 1 0 1 1 0 1 0),
    M: (0 0 0 1 0 0 0 0 0 0 1 0 1 1 0 1 0 1 1 0 1),
    M: (0 0 0 0 1 0 0 0 0 1 1 0 1 1 1 0 0 0 0 1 1),
    M: (0 0 0 0 0 1 0 0 0 1 0 0 1 1 1 1 1 0 1 0 0),
    M: (0 0 0 0 0 0 1 0 0 0 1 0 0 1 1 1 1 1 0 1 0),
    M: (0 0 0 0 0 0 0 1 0 0 0 1 0 0 1 1 1 1 1 0 1),
    M: (0 0 0 0 0 0 0 0 1 1 1 1 0 0 0 1 0 1 0 1 1)
]
```

89.2.5.2 Membership and Equality

The operators described below refer to the underlying vector space.

`u in M`

Returns `true` if the element u lies in the A-module M.

`N subset M`

Returns `true` if the A-module N is contained in the A-module M.

`N eq M`

Returns `true` if the A-modules N and M are equal, where N and M are contained in a common A-module.

89.2.5.3 Operations on Submodules

`M + N`

Sum of the submodules M and N, where M and N belong to a a common A-module.

`M meet N`

Intersection of the submodules M and N, where M and N belong to a common A-module.

89.2.6 Quotient Modules

`quo< M | L >`

Given an A-module M, construct the quotient module $P = M/N$ as an A-module, where N is the submodule generated by the elements of M specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of R defining an element of M;

(b) A set or sequence whose terms are elements of M;

(c) A submodule of M;

(d) A set or sequence whose terms are submodules of M.

The generators constructed for N consist of the elements specified by terms L_i together with the stored generators for submodules specified by terms of L_i. The constructor returns the quotient module P as an A-module together with the natural homomorphism $f : M \to P$.

`Morphism(M, N)`

If the A-module N was created as a quotient module of the module M, return the natural homomorphism $\phi : M \to N$ as an element of $\mathrm{Hom}_R(M, N)$. Thus ϕ gives the correspondence between elements of M and elements of N (represented with respect to the standard basis for N).

Example H89E4

We construct a quotient module of the permutation module for $L(3, 4)$ considered above.

```
> G := PSL(3, 4);
> M := PermutationModule(G, GF(2));
> x := M![0,0,0,1,0,1,0,0,0,1,1,0,0,0,1,0,1,1,0,0,1];
> N := sub< M | x >;
> N;
GModule N of dimension 9 over GF(2)
> Q, phi := quo< M | x >;
> Q;
GModule Q of dimension 12 over GF(2)
```

We locate the kernel of the epimorphism ϕ and check that it is the same as N.

```
> K :=  Kernel(phi);
GModule Ker of dimension 9 over GF(2)
> K eq N;
true
```

Given an element x in the codomain Q of the epimorphism ϕ, the value returned as the preimage of x is a representative element of the coset of the kernel that is the actual preimage of x. Since

we are working in a module over a finite field, we can explicitly construct the full preimage `PreIm` of x.

```
> x := Q![0,0,0,1,1,0,0,0,0,1,0,0];
> PreIm := { x@@phi + k : k in K };
> #PreIm;
512
```

89.2.7 Structure of a Module

Most of the functions described in this section assume that the base ring is a **finite field**.

89.2.7.1 Reducibility

`Meataxe(M)`

Given an A-module M with base ring a finite field attempt to find a proper submodule N of M or else prove that M is irreducible. If a splitting of M is found, three values are returned:

(a) An A-module N corresponding to the induced action of A on S;

(b) An A-module P corresponding to the induced action of A on the quotient space M/N;

(c) Let ρ, ν and π denote the representations of A afforded by modules M, N and P, respectively. The third value returned is an invertible matrix T which conjugates the matrices of $\rho(A)$ into reduced form. Specifically, if $a \in A$, then

$$T * \rho(a) * T^{-1} = \begin{pmatrix} \nu(a) & 0 \\ * & \pi(a) \end{pmatrix}$$

If M is proved to be irreducible, the function simply returns M. The fact that M is irreducible is recorded as part of the data structure for M.

`IsIrreducible(M)`

Returns `true` if and only if the A-module M is irreducible. If M is reducible, a proper submodule S of M together with the corresponding quotient module $Q = M/S$, are also returned.

`IsAbsolutelyIrreducible(M)`

Returns `true` if and only if the A-module M is absolutely irreducible. Return also a matrix algebra generator for the endomorphism algebra E of M (a field), as well as the dimension of E.

`AbsolutelyIrreducibleModule(M)`

Let A be an algebra over a field K. Given an irreducible A-module M that is not absolutely irreducible over K, return an irreducible module N that is a constituent of the module M considered as a module over the splitting field for M. Note that the module N, while not unique, is absolutely irreducible.

Example H89E5

Consider the group $O_5(3)$ given as a permutation group of degree 45. We construct the permutation module, and we apply the Meataxe manually to find an irreducible constituent.

```
> SetSeed(3);
> O53 := PermutationGroup<45 |
>     (2,3)(4,6)(7,9)(8,11)(12,16)(13,14)(15,19)(18,22)(20,25)(21,26)(27,33)
>       (28,35) (29,34)(31,38)(36,43)(39,41),
>     (1,2,4,7,10,14,16,3,5)(6,8,12,17,21,27,34,41,44)(9,13,18,23,29,37,33,40,43)
>       (11,15,20)(19,24,30,25,31,22,28,36,38)(26,32,39)(35,42,45)>;
>
> P := PermutationModule(O53, GF(2));
> A, B := Meataxe(P); A; B;
GModule A of dimension 20 over GF(2)
GModule B of dimension 25 over GF(2)
> A, B := Meataxe(A); A; B;
GModule A of dimension 14 over GF(2)
GModule B of dimension 6 over GF(2)
> IsIrreducible(A);
true
```

`MinimalField(M)`

Let A be an algebra over a finite field K. Given an A-module M over K, return the smallest subfield of K, over which M can be realised.

`IsPermutationModule(M)`

Returns `true` if and only if the generators of the matrix algebra A are permutation matrices, for a given A-module M.

89.2.7.2 Composition Series

`CompositionSeries(M)`

Given an A-module M, construct a composition series by repeatedly applying the meataxe. The function returns three values:

(a) The composition series as a sequence of A-modules;

(b) The composition factors as a sequence of A-modules in the order determined by the composition series (a);

(c) A transformation matrix t such that for each $a \in A$, $t * a * t^{-1}$ is in reduced form.

`CompositionFactors(M)`

Given an A-module M, construct the composition factors by repeatedly applying the meataxe. The composition factors are returned in the form of a sequence of R-modules in the order determined by a composition series for M. If M is irreducible, the function returns a sequence containing M alone.

`Constituents(M)`

Given an A-module M, construct the constituents C of M, i.e., a sequence of representatives for the isomorphism classes of composition factors of M. A sequence I of indices is also returned, so that that i-th element of C is the $I[i]$-th composition factor of M.

`ConstituentsWithMultiplicities(M)`

Given an A-module M, return the constituents of M, together with their multiplicities. A sequence I of indices is also returned, so that that i-th element of C is the $I[i]$-th composition factor of M.

Example H89E6

We continue with the $O_5(3)$ example from the previous section. We notice that the constituent of dimension of 8 is not absolutely irreducible, so we lift it to over an extension field.

```
> O53 := PermutationGroup<45 |
>     (2,3)(4,6)(7,9)(8,11)(12,16)(13,14)(15,19)(18,22)(20,25)(21,26)(27,33)
>       (28,35) (29,34)(31,38)(36,43)(39,41),
>     (1,2,4,7,10,14,16,3,5)(6,8,12,17,21,27,34,41,44)(9,13,18,23,29,37,33,40,43)
>       (11,15,20)(19,24,30,25,31,22,28,36,38)(26,32,39)(35,42,45)>;
>
> P := PermutationModule(O53, GaloisField(2));
> Constituents(P);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 8 over GF(2),
    GModule of dimension 14 over GF(2)
]
> ConstituentsWithMultiplicities(P);
[
    <GModule of dimension 1 over GF(2), 3>,
    <GModule of dimension 6 over GF(2), 1>,
    <GModule of dimension 8 over GF(2), 1>,
    <GModule of dimension 14 over GF(2), 2>
]
> S, F := CompositionSeries(P);
> S, F;
[
    GModule of dimension 14 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 21 over GF(2),
    GModule of dimension 29 over GF(2),
    GModule of dimension 30 over GF(2),
    GModule of dimension 31 over GF(2),
    GModule P of dimension 45 over GF(2)
]
```

```
[
    GModule of dimension 14 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 8 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2)
]
> IndecomposableSummands(P);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 44 over GF(2)
]
> C := Constituents(P);
> C;
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 8 over GF(2),
    GModule of dimension 14 over GF(2)
]
> [IsAbsolutelyIrreducible(M): M in C];
[ true, true, false, true ]
> DimensionOfEndomorphismRing(C[3]);
2
> L := GF(2^2);
> E := ChangeRing(C[3], L);
> E;
GModule E of dimension 8 over GF(2^2)
> CE := CompositionFactors(E);
> CE;
[
    GModule of dimension 4 over GF(2^2),
    GModule of dimension 4 over GF(2^2)
]
> IsAbsolutelyIrreducible(CE[1]);
true
> IsIsomorphic(CE[1], CE[2]);
false
```

89.2.7.3 Socle Series

`IsSemisimple(M)`

Given an A-module M, which is a $K[G]$-module (`ModGrp`) for a field K, return whether M is semisimple.

If M is a semisimple module defined over a matrix algebra, the function returns as second return value a list of the ranks of the primitive idempotents of the algebra. This is also a list of the multiplicities of the simple modules of the algebra as composition factors in a composition series for the module.

`MaximalSubmodules(M)`

Given an A-module M, return a sequence containing the maximal submodules of M.

`Limit` RngIntElt *Default :* 0

If a limit L is provided, only up L submodules are calculated, and the second return value indicates whether all of the submodules are returned.

`JacobsonRadical(M)`

The Jacobson radical of the A-module M.

`MinimalSubmodules(M)`

Given an A-module M, return a sequence containing the minimal submodules of M.

`Limit` RngIntElt *Default :* 0

If a limit L is provided, only up L submodules are calculated, and the second return value indicates whether all of the submodules are returned.

`MinimalSubmodules(M, F)`

Given an A-module M and an irreducible module F, return a sequence containing those minimal submodules of M, each of which is isomorphic to F.

`Limit` RngIntElt *Default :* 0

If a limit L is provided, only up L submodules are calculated, and the second return value indicates whether all of the submodules are returned.

`MinimalSubmodule(M)`

Given an A-module M, return a single minimal (or irreducible) submodule of M; if M is itself irreducible, M is returned.

`Socle(M)`

Given a A-module M, return its socle, i.e. the sum of the minimal submodules of M.

`SocleSeries(M)`

A socle series S for the A-module M, together with the socle factors corresponding to the terms of S and a matrix T giving the transformation of M into (semi-simple) reduced form. The socle series, as returned, does not include the trivial module but does include M.

`SocleFactors(M)`

The factors corresponding to the terms of a socle series for the A-module M. The factors are returned in the form of a sequence of A-modules in the order determined by a socle series for M. If M is irreducible, the function returns a sequence containing M alone.

Example H89E7

We continue with the $O_5(3)$ example from the previous section.

```
> O53 := PermutationGroup<45 |
>   (2,3)(4,6)(7,9)(8,11)(12,16)(13,14)(15,19)(18,22)(20,25)(21,26)(27,33)
>     (28,35) (29,34)(31,38)(36,43)(39,41),
>   (1,2,4,7,10,14,16,3,5)(6,8,12,17,21,27,34,41,44)(9,13,18,23,29,37,33,40,43)
>     (11,15,20)(19,24,30,25,31,22,28,36,38)(26,32,39)(35,42,45)>;
>
> P := PermutationModule(O53, FiniteField(2));
> MaximalSubmodules(P);
[
    GModule of dimension 31 over GF(2),
    GModule of dimension 44 over GF(2)
]
> JacobsonRadical(P);
GModule of dimension 30 over GF(2)
> MinimalSubmodules(P);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2)
]
> Soc := Socle(P);
> Soc;
GModule Soc of dimension 15 over GF(2)
> SocleSeries(P);
[
    GModule of dimension 15 over GF(2),
    GModule of dimension 22 over GF(2),
    GModule of dimension 30 over GF(2),
    GModule of dimension 31 over GF(2),
    GModule P of dimension 45 over GF(2)
]
> SocleFactors(P);
[
```

```
    GModule of dimension 15 over GF(2),
    GModule of dimension 7 over GF(2),
    GModule of dimension 8 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2)
]
```

89.2.8 Decomposability and Complements

The functions in this section currently apply only in the case in which A is an algebra over a finite field.

`IsDecomposable(M)`

Given an A-module M, return `true` iff M is decomposable. If M is decomposable and defined over a finite field, the function also returns proper submodules S and T of M such that $M = S \oplus T$.

`DirectSumDecomposition(M)`

`IndecomposableSummands(M)`

`Decomposition(M)`

Given an A-module M, return a sequence Q of indecomposable summands of M. Each element of Q is an indecomposable submodule of M and M is equal to the (direct) sum of the terms of Q. If M is indecomposable, the sequence Q consists of M alone.

`HasComplement(M, S)`

`IsDirectSummand(M, S)`

Given an A-module M and a submodule S of M, determine whether S has a A-invariant complement in M. If this is the case, the value `true` is returned together with a submodule T of M such that $M = S \oplus T$; otherwise the value `false` is returned.

`Complements(M, S)`

Given an A-module M and a submodule S of M, return all A-invariant complements of S in M.

Example H89E8

```
> A := MatrixAlgebra<GF(2), 6 |
>   [ 1,0,0,1,0,1,
>     0,1,0,0,1,1,
>     0,1,1,1,1,0,
>     0,0,0,1,1,0,
>     0,0,0,1,0,1,
>     0,1,0,1,0,0 ],
>   [ 0,1,1,0,1,0,
>     0,0,1,1,1,1,
>     1,0,0,1,0,1,
>     0,0,0,1,0,0,
>     0,0,0,0,1,0,
>     0,0,0,0,0,1 ] >;
> M := RModule(RSpace(GF(2), 6), A);
> M;
RModule M of dimension 6 over GF(2)
> IsDecomposable(M);
false
> MM := DirectSum(M, M);
> MM;
RModule MM of dimension 12 over GF(2)
> l, S, T := IsDecomposable(MM);
> l;
true;
> S;
RModule S of dimension 6 over GF(2)
> HasComplement(MM, S);
true
> Complements(MM, S);
[
    RModule of dimension 6 over GF(2),
    RModule of dimension 6 over GF(2)
]
> IndecomposableSummands(MM);
[
    RModule of dimension 6 over GF(2),
    RModule of dimension 6 over GF(2)
]
> Q := IndecomposableSummands(MM);
> Q;
[
    RModule of dimension 6 over GF(2),
    RModule of dimension 6 over GF(2)
]
> Q[1] meet Q[2];
RModule of dimension 0 over GF(2)
```

```
> Q[1] + Q[2];
RModule MM of dimension 12 over GF(2)
```

89.2.9 Lattice of Submodules

Let M be an A-module. MAGMA can construct the lattice L of all submodules of M if this is not too large. Various properties of the lattice L may then be examined. The elements of L are called *submodule-lattice elements* and are numbered from 1 to n where n is the cardinality of L. Once the lattice has been constructed, the result of various lattice operations, such as meet and intersection, are available without the need for any module-theoretic calculation. Certain information about M and its submodules may then be obtained by analyzing L. Given an element of L, one can easily create the submodule N of M corresponding to it and one can also create the element of L corresponding to any submodule of M.

The functions is this section currently apply only in the case in which A is an algebra over a finite field.

89.2.9.1 Creating Lattices

`SubmoduleLattice(M)`

`Limit`	RNGINTELT	*Default :* 0
`CodimensionLimit`	RNGINTELT	*Default :* -1

Given an A-module M, construct the lattice L of submodules of M. If a limit n is provided, at most n submodules are calculated, and the second return value indicates whether the returned lattice L is the full lattice of submodules of M.

`SubmoduleLatticeAbort(M, n)`

Given an A-module M and a positive integer n, construct the lattice L of submodules of M, provided that the number of submodule does not exceed n. In this case the value `true` and the lattice L are returned. If M has more than n submodules, the function aborts and returns the value `false`.

`SetVerbose("SubmoduleLattice", i)`

Control verbose printing for the submodule lattice algorithm. The level i can be 2 for maximal printing or 1 for moderate printing. The algorithm works down a composition series of the module and a summary is printed for each level.

`Submodules(M)`

`CodimensionLimit`	RNGINTELT	*Default :* `Dimension(M)`

Given an A-module M, return a sequence containing all submodules of M sorted by dimension.

Example H89E9

We create the lattice of submodules for the A-module $\mathbf{F}_3[\mathbf{Z}_6]$ with level 1 verbose printing turned on.

```
> M := PermutationModule(CyclicGroup(6), GF(3));
> SetVerbose("SubmoduleLattice", 1);
> L := SubmoduleLattice(M);
Submodule Lattice; Dimension: 6, Composition length: 6
Starting level 4; Current number of modules: 2
Starting level 3; Current number of modules: 3
Starting level 2; Current number of modules: 6
Starting level 1; Current number of modules: 9
Starting level 0; Current number of modules: 12
Change basis time: 0.010
Jacobson radical time: 0.060
Complement time: 0.070
Total time: 0.250
> #L;
16
```

89.2.9.2 Operations on Lattices

In the following, L is the lattice of submodules for a module M.

`#L`

The cardinality of L, i.e. the number of submodules of M.

`L ! i`

Create the i-th element of the lattice L. The number i is insignificant (i.e. the elements of L are not numbered in any special way), but this allows one to uniquely identify each element of the lattice L.

`L ! S`

Create the element of the lattice L corresponding to the submodule S of M.

`Bottom(L)`

Create the bottom of the lattice L, i.e. the element of L corresponding to the zero-submodule of M. If the lattice was created with a limit on the number of submodules and the lattice is partial, the bottom of the lattice may not be the zero submodule.

`Random(L)`

Create a random element of L.

`Top(L)`

Create the top of the lattice L, i.e. the element of L corresponding to M.

89.2.9.3 Operations on Lattice Elements

In the following, L is the lattice of submodules for a module M. Elements of L are identified with the integers $[1..\#L]$ but not in any particular order.

`IntegerRing() ! e`

The integer corresponding to lattice element e.

`e + f`

The sum of lattice elements e and f, i.e. the lattice element corresponding to the sum of the modules corresponding to e and f.

`e meet f`

The intersection of lattice elements e and f.

`e eq f`

Returns `true` if and only if lattice elements e and f are equal.

`e subset f`

Returns `true` if and only if e is under f in the lattice L, i.e. the submodule corresponding to e is a submodule of the submodule corresponding to f.

`MaximalSubmodules(e)`

The maximal submodules of e, returned as a set of lattice elements.

`MinimalSupermodules(e)`

The minimal supermodules of e, returned as a set of lattice elements.

`Module(e)`

The submodule of M corresponding to the element e of the lattice L.

89.2.9.4 Properties of Lattice Elements

`Dimension(e)`

The dimension of the submodule of M corresponding to e.

`JacobsonRadical(e)`

The Jacobson radical of e, i.e. the lattice element corresponding to the Jacobson radical of the submodule corresponding to e.

`Morphism(e)`

The morphism from the module corresponding to e to M.

Example H89E10

We create the lattice of submodules for the A-module $\mathbf{F}_3[\mathbf{Z}_6]$.

```
> SetSeed(1);
> M := PermutationModule(CyclicGroup(6), GF(3));
> L := SubmoduleLattice(M);
> #L;
16
> T := Top(L);
> B := Bottom(L);
> T;
16
> B;
1
> // Check that element of L corresponding to M is T
> L ! M;
1
> (L ! M) eq T;
true
> // Check that module corresponding to B is zero-submodule of M
> Module(B);
GModule of dimension 0 with base ring GF(3)
```

We next find the minimal supermodules (immediate parents) of B in L and then determine the actual A-submodules to which they correspond.

```
> S := MinimalSupermodules(B);
> S;
{ 2, 3 }
> Module(L ! 2);
GModule of dimension 1 with base ring GF(3)
> Module(L ! 3);
GModule of dimension 1 with base ring GF(3)
> Dimension(L ! 2);
1
> Morphism(L ! 2);
[1 1 1 1 1 1]
> Morphism(L ! 3);
[1 2 1 2 1 2]
> // Set A to the sum of these elements
> A := L!2 + L!3;
> A;
5;
> // Note that A has dimension 2 and its morphism is the sum of the previous
> Dimension(A);
2
> Morphism(A);
[1 0 1 0 1 0]
[0 1 0 1 0 1]
```

```
> MaximalSubmodules(A);
{ 2, 3}
> S!2 subset A;
true
```

We now find the maximal submodules of L, and examine one, S, in detail.

```
> MaximalSubmodules(T);
{ 14, 15 }
> A := L ! 14;
> Dimension(A);
5
> Morphism(A);
[1 0 0 0 0 1]
[0 1 0 0 0 2]
[0 0 1 0 0 1]
[0 0 0 1 0 2]
[0 0 0 0 1 1]
> S := Module(A);
> S;
GModule S of dimension 5 with base ring GF(3)
```

Finally, we compute the Jacobson radical of S directly, and also obtain it from the lattice, checking that the two methods match.

```
> J := JacobsonRadical(S);
> J;
GModule J of dimension 3 with base ring GF(3)
> L ! J;
8
> JacobsonRadical(A);
8
```

89.2.10 Homomorphisms

Let M and N be A-modules where A is an algebra defined over a field K. Then $\mathrm{Hom}_A(M, N)$ consists of all K-homomorphisms from M to N which commute with the action of A. The type of such (matrix) homomorphisms, called *A-homs*, is `ModMatGrpElt`.

The functions is this section currently apply only in the case in which A is an algebra over a finite field.

89.2.10.1 Creating Homomorphisms

`hom< M -> N | X >`

Given A-modules M and N, create the (map) homomorphism from M to N given by matrix X.

`H ! f`

Given matrix space H, which is $\mathrm{Hom}_A(M, N)$ for A-modules M and N, together with a homomorphism f from M to N, create the matrix corresponding to the map f.

`IsModuleHomomorphism(X)`

Given a matrix X belonging to $\mathrm{Hom}_K(M, N)$, where M and N are A-modules, return `true` if X is an A-homomorphism.

89.2.10.2 $\mathrm{Hom}(M, N)$

`Hom(M, N)`

Given A-modules M and N, construct the vector space of homomorphisms, $\mathrm{Hom}_K(M, N)$, where K is the field over which A is defined.

`AHom(M, N)`

Given A-modules M and N, construct the vector space of homomorphisms, $\mathrm{Hom}_A(M, N)$, as a submodule of $\mathrm{Hom}_K(M, N)$.

`GHomOverCentralizingField(M, N)`

Given A-modules M and N, construct $\mathrm{Hom}_{L[G]}(M, N)$ as a subspace of $\mathrm{Hom}_K(M, N)$ where L is the centralizing field of M.

Example H89E11

We construct a 12-dimensional module M and a 9-dimensional submodule P of M for a soluble group of order 648 over $\mathbf{F}_3$. We then construct $H = \mathrm{Hom}_A(M, N)$ and perform map operations on elements of H.

```
> G := PermutationGroup< 12 |
>         (1,6,7)(2,5,8,3,4,9)(11,12),
>         (1,3)(4,9,12)(5,8,10,6,7,11) >;
> K := GF(3);
> P := PermutationModule(G, K);
> M := sub< P | [1,0,0,0,0,1,0,0,1,0,0,1] >;
> M;
GModule M of dimension 9 over GF(3)
> H := AHom(P, M);
> H: Maximal;
KMatrixSpace of 12 by 9 GHom matrices and dimension 2 over GF(3)

```

89.2.10.3 Endo– and Automorphisms

`EndomorphismAlgebra(M)`

`EndomorphismRing(M)`

`Direct` BoolElt *Default :* `false`

Given a A-module M with base ring K, construct $E = \mathrm{End}_A(M)$ as a subring E of the complete matrix ring $K^{(n\times n)}$.

`CentreOfEndomorphismRing(M)`

Given a A-module M with base ring K, construct the centre of $\mathrm{End}_A(M)$ as a subring Z of the complete matrix ring $K^{(n\times n)}$. This is equivalent to `Centre(EndomorphismRing(M))` but will often be much faster.

`AutomorphismGroup(M)`

Given a A-module M with base ring K, construct $\mathrm{Aut}(M)$ as a subgroup G of the general linear group $GL(n, K)$. Thus, G is the group of units of $\mathrm{End}(M)$.

`IsIsomorphic(M, N)`

Returns `true` if the A-modules M and N are isomorphic, `false` otherwise. If M and N are isomorphic, the function also returns a matrix T such that $M^T = N$. Note that the action generators of M and N must match, so the function effectively determines whether there is an invertible matrix T such that `T^-1*ActionGenerator(M, i)*T` equals `ActionGenerator(N, i)` for each i.

Example H89E13

We construct the endomorphism ring for a permutation module over $\mathbf{F}_3$ for a soluble group of order 648.

```
> G := PermutationGroup< 12 |
>         (1,6,7)(2,5,8,3,4,9)(11,12),
>         (1,3)(4,9,12)(5,8,10,6,7,11) >;
> P := PermutationModule(G, GF(3));
> time End := EndomorphismAlgebra(P);
Time: 0.000
> End;
Matrix Algebra of degree 12 and dimension 3 over GF(3)
```

Thus, the permutation module P has 27 endomorphisms.

```
> time Aut := AutomorphismGroup(P);
Time: 0.010
> Aut;
MatrixGroup(12, GF(3))
Generators:
    [1 0 0 1 1 1 1 1 1 1 1 1]
    [0 1 0 1 1 1 1 1 1 1 1 1]
    [0 0 1 1 1 1 1 1 1 1 1 1]
    [1 1 1 1 0 0 1 1 1 1 1 1]
    [1 1 1 0 1 0 1 1 1 1 1 1]
    [1 1 1 0 0 1 1 1 1 1 1 1]
    [1 1 1 1 1 1 1 0 0 1 1 1]
    [1 1 1 1 1 1 0 1 0 1 1 1]
    [1 1 1 1 1 1 0 0 1 1 1 1]
    [1 1 1 1 1 1 1 1 1 1 0 0]
    [1 1 1 1 1 1 1 1 1 0 1 0]
    [1 1 1 1 1 1 1 1 1 0 0 1]

    [2 1 1 0 0 0 0 0 0 0 0 0]
    [1 2 1 0 0 0 0 0 0 0 0 0]
    [1 1 2 0 0 0 0 0 0 0 0 0]
    [0 0 0 2 1 1 0 0 0 0 0 0]
    [0 0 0 1 2 1 0 0 0 0 0 0]
    [0 0 0 1 1 2 0 0 0 0 0 0]
    [0 0 0 0 0 0 2 1 1 0 0 0]
    [0 0 0 0 0 0 1 2 1 0 0 0]
    [0 0 0 0 0 0 1 1 2 0 0 0]
    [0 0 0 0 0 0 0 0 0 2 1 1]
    [0 0 0 0 0 0 0 0 0 1 2 1]
    [0 0 0 0 0 0 0 0 0 1 1 2]

    [0 1 1 0 0 0 0 0 0 0 0 0]
    [1 0 1 0 0 0 0 0 0 0 0 0]
    [1 1 0 0 0 0 0 0 0 0 0 0]
```

```
    [0 0 0 0 1 1 0 0 0 0 0 0]
    [0 0 0 1 0 1 0 0 0 0 0 0]
    [0 0 0 1 1 0 0 0 0 0 0 0]
    [0 0 0 0 0 0 0 1 1 0 0 0]
    [0 0 0 0 0 0 1 0 1 0 0 0]
    [0 0 0 0 0 0 1 1 0 0 0 0]
    [0 0 0 0 0 0 0 0 0 0 1 1]
    [0 0 0 0 0 0 0 0 0 0 1 0 1]
    [0 0 0 0 0 0 0 0 0 0 1 1 0]
> #Aut;
18
> IsAbelian(Aut);
true
> AbelianInvariants(Aut);
[ 3, 6 ]
```

The module has 18 automorphisms. The automorphism group is isomorphic to the abelian group $\mathbf{Z}_2 \times \mathbf{Z}_3 \times \mathbf{Z}_3$.

89.3 Modules over a General Algebra

89.3.1 Introduction

This section describes the functionality for modules over general algebras in MAGMA. A left-module over an algebra A is a module M together with a bilinear map $A \times M \to M$. A right-module over A is a module M together with a bilinear map $M \times A \to M$. MAGMA provides functionality for both kinds of modules.

89.3.2 Construction of Algebra Modules

`Module(A, m)`

For an algebra A this function creates a module over A. If the module will be a left-module then m is a map from the Cartesian product $A \times M$ to M. If the module will be a right-module then m is a map from $M \times A$ to M. Here M has to be an R-module, where R is the coefficient field of A.

Example H89E14

We create the right-module over the full matrix algebra of 3×3 - matrices acting on its natural module.

```
> A:= MatrixAlgebra(Rationals(), 3);
> V:= RModule(Rationals(), 3);
> m:= map< CartesianProduct(V, A) -> V | t :-> t[1]*t[2] >;
> Module(A, m);
Right Module of Full Matrix Algebra of degree 3 over Rational Field
```

89.3.3 The Action of an Algebra Element

`a ^ v`

Given an element v of a left-module over an algebra A, and an element a of A computes the result of letting a act on v.

`v ^ a`

Given an element v of a right-module over an algebra A and an element a of A computes the result of letting a act on v.

`ActionMatrix(M, a)`

Given a module M over an algebra A and an element a of A returns the matrix of the action of a on M. If M is a left-module then the i-th column of this matrix contains the coordinates of the image of a acting on the i-th basis element of M. If A is a right-module then the rows contain these coordinates.

Example H89E15

```
> A:= MatrixAlgebra(Rationals(), 3);
> V:= RModule(Rationals(), 3);
> m:= map< CartesianProduct(V, A) -> V | t :-> t[1]*t[2] >;
> M:=Module(A, m);
> M.1^A.1;
M: (1 0 0)
> ActionMatrix(M, A.2);
[0 1 0]
[0 0 1]
[1 0 0]
```

89.3.4 Related Structures of an Algebra Module

`Algebra(M)`

This returns the algebra over which the algebra module M is defined.

`CoefficientRing(M)`

Returns the ground field of the algebra module M.

`Basis(M)`

Returns a sequence containing the basis vectors of the algebra module M.

89.3.5 Properties of an Algebra Module

`IsLeftModule(M)`

This returns `true` if the algebra module M is a left-module, and `false` if it is a right module.

`IsRightModule(M)`

This returns `true` if the algebra module M is a right-module, and `false` if it is a left module.

`Dimension(M)`

The dimension of the algebra module M.

89.3.6 Creation of Algebra Modules from other Algebra Modules

`DirectSum(Q)`

Given a sequence Q of algebra modules (all defined over the same algebra, and all left (respectively right) modules), returns the module M that is the direct sum of the modules in Q. Furthermore, two sequences of mappings are returned. The i-th element of the first sequence is the embedding of the i-th element of Q into M. The i-th element of the second sequence is the projection of M onto the i-th element of Q.

`SubalgebraModule(B, M)`

Given an algebra module M over the algebra A, and a subalgebra B of A, return M as a B-module.

`ModuleWithBasis(Q)`

Given a sequence Q containing the elements of a particular basis of an algebra module M, create an algebra module that is isomorphic to M, but with basis Q. (Or, more precisely, the basis vectors of the module V that is returned are in bijection with Q. The action of an algebra element on the i-th basis vector of V is computed by computing it on the i-th vector in Q and expressing the result as a linear combination of the elements of Q. The resulting coordinates are used to form the corresponding element of V.) This can be used to compute the action of algebra elements with respect to a given basis of M.

Example H89E16

```
> A:= MatrixAlgebra(Rationals(), 3);
> V:= RModule(Rationals(), 3);
> m:= map< CartesianProduct(V, A) -> V | t :-> t[1]*t[2] >;
> M:=Module(A, m);
> N:=DirectSum([ M, M ]);
> ActionMatrix(N, A.1);
[1 0 0 0 0 0]
[0 0 0 0 0 0]
[0 0 0 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 0 0]
[0 0 0 0 0 0]
> W:= ModuleWithBasis([ M.1+M.2+M.3, M.2+M.3, M.3 ]);
> ActionMatrix(W, A.1);
[ 1 -1  0]
[ 0  0  0]
[ 0  0  0]
```

`sub< M | S >`

`sub< M | e1, ..., en >`

Return the submodule of M containing the elements in the sequence S or the elements $e1$, ..., en.

`quo< M | S >`

`quo< M | e1, ..., en >`

Construct the quotient module of M by the submodule S of M, the submodule containing the elements in the sequence S or the elements $e1, ..., en$.

90 $K[G]$-MODULES AND GROUP REPRESENTATIONS

Chapter 90
$K[G]$-MODULES AND GROUP REPRESENTATIONS

90.1 Introduction

A module over a group algebra, $K[G]$, where K is a field and G is a group, is an important special case of modules over an algebra. This case coincides with the theory of group representations. MAGMA provides extensive machinery for constructing $K[G]$-modules. It should be noted however, that some advanced functions apply only when K is a finite field.

In this chapter the machinery for constructions peculiar to $K[G]$-modules will be described. In addition, a number of operations that apply only to $K[G]$-modules are described. All of the operations for A-modules also apply to $K[G]$-modules and are not repeated in this chapter.

90.2 Construction of $K[G]$-Modules

The following functions provide for the construction of finite-dimensional $K[G]$-modules for a group G, where the action of G is given in terms of a matrix representation of G. Note that an Euclidean Domain may appear in place of the field K.

90.2.1 General $K[G]$-Modules

`GModule(G, A)`

Let G be a group defined on r generators and let A be a subalgebra of the matrix algebra $M_n(K)$, also defined by r non-singular matrices. It is assumed that the mapping from G to A defined by $\phi(G.i) \mapsto A.i$, for $i = 1, \ldots, r$, is a group homomorphism. Let M be an n-dimensional vector space over K. The function constructs a $K[G]$-module M of dimension n, where the action of the i-th generator of G on M is given by the i-th generator of A.

`GModule(G, Q)`

Let G be a group defined on r generators and let Q be a sequence of r invertible elements of $M_n(K)$ or $GL(n, K)$. It is assumed that the mapping from G to Q defined by $\phi(G.i) \mapsto Q[i]$, for $i = 1, \ldots, r$, is a group homomorphism from G into the matrix algebra A defined by the terms of Q. The function constructs a $K[G]$-module M of dimension n, where the action of G is defined by the matrix algebra A.

`TrivialModule(G, K)`

Create the trivial $K[G]$-module for the group G.

Example H90E1

We construct a 3-dimensional module for PSL(2, 7) over $\mathbf{F}_2$. The action of the group on M is described in terms of two elements, x and y, belonging to the ring of 3×3 matrices over $\mathbf{F}_2$.

```
> PSL27 := PermutationGroup< 8 | (2,3,5)(6,7,8), (1,2,4)(3,5,6) >;
> S := MatrixAlgebra< FiniteField(2), 3 |
>        [ 0,1,0,  1,1,1,  0,0,1 ], [ 1,1,1,  0,1,1,  0,1,0 ] >;
> M := GModule(PSL27, S);
> M: Maximal;
GModule M of dimension 3 with base ring GF(2)
Generators of acting algebra:

[0 1 0]
[1 1 1]
[0 0 1]

[1 1 1]
[0 1 1]
[0 1 0]
```

Example H90E2

We write a function which, given a matrix algebra A, together with a matrix group G acting on A by conjugation (so A is closed under action by G), computes the G-module M representing the action of G on A. We then construct a particular (nilpotent) upper-triangular matrix algebra A, a group $G = 1 + A$ which acts on A, and finally construct the appropriate G-module M.

```
> MakeMod := function(A, G)
>     // Make G-module M of G acting on A by conjugation
>     k := CoefficientRing(A);
>     d := Dimension(A);
>     S := RMatrixSpace(A, k);
>     return GModule(
>         G,
>         [
>             MatrixAlgebra(k, d) |
>             &cat[
>                 Coordinates(S, S.j^g): j in [1 .. d]
>             ] where g is G.i: i in [1 .. Ngens(G)]
>         ]
>     );
> end function;
>
> MakeGroup := function(A)
>     // Make group G from upper-triangular matrix algebra A
>     k := CoefficientRing(A);
>     n := Degree(A);
>     return MatrixGroup<n, k | [Eltseq(1 + A.i): i in [1 .. Ngens(A)]]>;
```

```
> end function;
>
> k := GF(3);
> n := 4;
> M := MatrixAlgebra(k, n);
> A := sub<M |
>      [0,2,1,1, 0,0,1,1, 0,0,0,1, 0,0,0,0],
>      [0,1,0,0, 0,0,2,2, 0,0,0,1, 0,0,0,0]>;
> G := MakeGroup(A);
> G;
MatrixGroup(4, GF(3)) of order 3^4
Generators:
    [1 2 1 1]
    [0 1 1 1]
    [0 0 1 1]
    [0 0 0 1]

    [1 1 0 0]
    [0 1 2 2]
    [0 0 1 1]
    [0 0 0 1]
> M := MakeMod(A, G);
> M: Maximal;
GModule M of dimension 5 over GF(3)
Generators of acting algebra:

[1 1 1 2 0]
[0 1 1 0 0]
[0 0 1 0 0]
[0 0 0 1 0]
[0 0 0 0 1]

[1 2 2 2 0]
[0 1 1 0 0]
[0 0 1 0 0]
[0 0 0 1 0]
[0 0 0 0 1]
```

90.2.2 Natural $K[G]$-Modules

The following functions provide for the construction of $K[G]$-modules for a group G in one of its natural actions. Note that an Euclidean Domain may be used in place of the field K.

`GModule(G, K)`

Given a finite permutation group G and a ring K, create the natural permutation module for G over K.

GModule(G)

Given a matrix group G defined as a subgroup of the group of units of the ring $Mat_n(K)$, where K is a field, create the natural $K[G]$-module for G.

Example H90E3

Given the Mathieu group M_{11} presented as a group of 5×5 matrices over $\mathbf{F}_3$, we construct the natural $K[G]$-module associated with this representation.

```
> G := MatrixGroup<5, FiniteField(3) |
>      [ 2,1,2,1,2,  2,0,0,0,2,  0,2,0,0,0,  0,1,2,0,1,  1,0,2,2,1],
>      [ 2,1,0,2,1,  1,2,0,2,2,  1,1,2,1,1,  0,2,0,1,1,  1,1,2,2,2] >;
> Order(G);
7920
>
> M := GModule(G);
> M : Maximal;
GModule M of dimension 5 with base ring GF(3)
Generators of acting algebra:

[2 1 2 1 2]
[2 0 0 0 2]
[0 2 0 0 0]
[0 1 2 0 1]
[1 0 2 2 1]

[2 1 0 2 1]
[1 2 0 2 2]
[1 1 2 1 1]
[0 2 0 1 1]
[1 1 2 2 2]
```

90.2.3 Action on an Elementary Abelian Section

GModule(G, A, B)

GModule(G, A)

Given a group G, a normal subgroup A of G and a normal subgroup B of A such that the section A/B is elementary abelian of order p^n, create the $K[G]$-module M corresponding to the action of G on A/B, where K is the field $\mathbf{F}_p$. If B is trivial, it may be omitted. The function returns

(a) the module M; and

(b) the homomorphism $\phi : A/B \to M$.

Example H90E4

We construct a module M for the wreath product G of the alternating group of degree 4 with the cyclic group of degree 3. The module is given by the action of G on an elementary abelian normal subgroup H of order 64.

```
> G := WreathProduct(AlternatingGroup(4), CyclicGroup(3));
> G := PCGroup(G);
> A := pCore(G, 2);
> A;
GrpPC of order 64 = 2^6
Relations:
A.1^2 = Id(A),
A.2^2 = Id(A),
A.3^2 = Id(A),
A.4^2 = Id(A),
A.5^2 = Id(A),
A.6^2 = Id(A)
> M := GModule(G, A, sub<G|>);
> M;
GModule of dimension 6 with base ring GF(2)
```

90.2.4 Permutation Modules

The following functions provide for the construction of permutation modules for a group G. Note that an Euclidean Domain may be used in place of the field K.

`PermutationModule(G, H, K)`

Given a group G, a subgroup H of finite index in G and a field K, create the $K[G]$-module for G corresponding to the permutation action of G on the cosets of H.

`PermutationModule(G, K)`

Given a permutation group G and a field K, create the natural permutation module for G over K.

`PermutationModule(G, V)`

Given a permutation group G of degree n and an n-dimensional vector space V, create the natural permutation module for G over K.

`PermutationModule(G, u)`

Given a permutation group G of degree n, and a vector u belonging to the vector space $V = K^{(n)}$, construct the $K[G]$-module corresponding to the action of G on the K-subspace of V generated by the set of vectors obtained by applying the permutations of G to the vector u.

Example H90E5

We construct the permutation module for the Mathieu group M_{12} over the field $\mathbf{F}_2$.

```
> M12 := PermutationGroup<12 |
>       (1,2,3,4,5,6,7,8,9,10,11),
>       (1,12,5,2,9,4,3,7)(6,10,11,8) >;
> M := PermutationModule(M12, FiniteField(2));
> M : Maximal;
GModule M of dimension 12 with base ring GF(2)
Generators of acting algebra:

[0 1 0 0 0 0 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0]
[0 0 0 0 1 0 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0]
[0 0 0 0 0 0 0 1 0 0 0 0]
[0 0 0 0 0 0 0 0 1 0 0 0]
[0 0 0 0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 0 0 0 1 0]
[1 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 0 1]

[0 0 0 0 0 0 0 0 0 0 0 1]
[0 0 0 0 0 0 0 0 1 0 0 0]

[0 0 1 0 0 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 1 0 0]
[1 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 1 0 0 0 0]
[0 0 0 0 1 0 0 0 0 0 0 0]
```

Example H90E6

We construct the constituent of the permutation module for the alternating group of degree 7 that contains the vector $(1, 0, 1, 0, 1, 0, 1)$.

```
> A7 := AlternatingGroup(7);
> V  := VectorSpace(FiniteField(2), 7);
> x  := V![1,0,1,0,1,0,1];
> M  := PermutationModule(A7, x);
> M : Maximal;
GModule of dimension 6 with base ring GF(2)
```

```
Generators of acting algebra:

[1 0 1 0 0 0]
[0 0 1 0 1 0]
[0 1 1 0 0 0]
[0 0 1 0 0 0]
[0 0 1 1 0 0]
[0 0 1 0 0 1]

[0 0 0 0 0 1]
[0 1 0 0 0 0]
[1 0 0 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 1 0 0 0]
```

90.2.5 Action on a Polynomial Ring

`GModule(G, P, d)`

Let G be a permutation group of degree n or a or matrix group of degree n over a finite field, $P = K[x_1, \ldots, x_n]$ a polynomial ring over a field K in n variables, and d a non-negative integer. This function creates the $K[G]$-module M corresponding to the action of G on the space of homogeneous polynomials of degree d of the polynomial ring P. The function also returns the isomorphism f between the space of homogeneous polynomials of degree d of P and M, together with an indexed set of monomials of degree d of P which correspond to the columns of M.

`GModule(G, I, J)`

Let G be a permutation group of degree n or a or matrix group of degree n over a finite field, I an ideal of a multivariate polynomial ring $P = K[x_1, \ldots, x_n]$ in n variables over a field K, and J a zero-dimensional subideal of I. This function creates the $K[G]$-module M corresponding to the action of G on the finite-dimensional quotient I/J. The function also returns the isomorphism f between the quotient space I/J and M, together with an indexed set of monomials of P, forming a (vector space) basis of I/J, and which correspond to the columns of M.

`GModule(G, Q)`

Let G be a permutation group of degree n or a or matrix group of degree n over a finite field and $Q = I/J$ a finite-dimensional quotient ring of a multivariate polynomial ring $P = K[x_1, \ldots, x_n]$ in n variables over a field K. This function creates the $K[G]$-module M corresponding to the action of G on the finite-dimensional quotient Q. The function also returns the isomorphism f between the quotient ring Q and M, together with an indexed set of monomials of P, forming a (vector space) basis of Q, and which correspond to the columns of M.

Example H90E7

Let T be the polynomial ring in five indeterminates over $GF(5)$. We create the representation of the alternating group of degree 5 that corresponds to its action on the space H_4 of homogeneous polynomials of degree 4 of T.

```
> G := Alt(5);
> R<[x]> := PolynomialRing(GF(5), 5);
> M, f := GModule(G, R, 4);
> M;
GModule M of dimension 70 over GF(5)
```

Thus, the action of $Alt(5)$ on H_4 yields a 70-dimensional module. We find its irreducible constituents.

```
> Constituents(M);
[
    GModule of dimension 1 over GF(5),
    GModule of dimension 3 over GF(5),
    GModule of dimension 5 over GF(5)
]
> t := x[1]^4 + x[2]^4 + x[3]^4 + x[4]^4 + x[5]^4;
> v := f(t); v;
M: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 1 0 0 0 1)
> v@@f;
x[1]^4 + x[2]^4 + x[3]^4 + x[4]^4 + x[5]^4
```

90.3 The Representation Afforded by a $K[G]$-module

```
GModuleAction(M)
```

Given a $K[G]$-module M, return the action of G on M as homomorphism f of G into the matrix group $GL_n(K)$.

```
Representation(M)
```

Given a $K[G]$-module M, return the action of G on M as homomorphism f of G into the matrix algebra $M_n(K)$.

Example H90E8

The function `Representation` allows the easy calculation of group characters. We illustrate this with the 6-dimension module for the group A_7 constructed above.

```
> A7 := AlternatingGroup(7);
> M  := PermutationModule(A7, Vector(GF(11), [1,0,1,0,1,0,1]));
> phi := Representation(M);
> [ Trace(phi(c[3])) : c in Classes(A7) ];
[ 7, 3, 4, 1, 1, 2, 0, 0, 0 ]
```

Example H90E9

We present a procedure which, given a $K[G]$-module M, constructs its dual D.

```
> DualModule := function(M)
>       G := Group(M);
>       f := Representation(M);
>       return GModule(G, [ Transpose(f(G.i))^-1 : i in [1 .. Ngens(G)] ]);
> end function;
```

`ActionGenerator(M, i)`

`RightActionGenerator(M, i)`

The i-th generator of the (right) acting matrix algebra for the module M. That is, the image of the i-th group generator in the corresponding representation.

`ActionGenerators(M)`

Return the matrices giving the action on the module M as a sequence. These are the images of the generators of the group in the corresponding representation.

`NumberOfActionGenerators(M)`

`Nagens(M)`

The number of action generators (the number of generators of the algebra) for the $R[G]$-module M.

`ActionGroup(M)`

The matrix group generated by the action generators of M.

`Sections (G)`

Given a matrix group G defined over a finite field K, return the action of G on each composition factor of the natural K[G]-module for G.

Example H90E10

We construct the tensor square T of the natural module M of the matrix group $G = SL(3, 5)$ and then determine the action of G on each composition factor of T.

```
> G := SL(3, 5);
> M := GModule(G);
> T := TensorProduct(M, M);
> A := ActionGroup(T);
> S := Sections(A);
> #S;
2
```

There are just two composition factors of T, the symmetric square and the exterior square of M.

```
> S[2];
MatrixGroup(3, GF(5))
Generators:

    [1 0 0]
    [0 2 0]
    [0 0 3]

    [0 1 0]
    [1 0 1]
    [1 0 0]
```

90.4 Standard Constructions

Given one or more existing modules, various standard constructions are available to construct new modules.

90.4.1 Changing the Coefficient Ring

In this collection of functions will be found utilities for changing the base ring of the module. Note that several of the functions for rewriting over a minimal field are restricted to rings $K[G]$ where K is a finite field.

`ChangeRing(M, S)`

Given an A-module M with base ring R, together with a ring S, such that there is a natural homomorphism from R to S, construct the module N with base ring S where N is obtained from M by coercing the components of the vectors of M into N. The corresponding homomorphism from M to N is returned as a second value.

`ChangeRing(M, S, f)`

Given a module M with base ring R, together with a ring S, and a homomorphism $f : R \to S$, construct the module N with base ring S, where N is obtained from M by applying f to the components of the vectors of M. The corresponding homomorphism from M to N is returned as a second value.

90.4.2 Writing a Module over a Smaller Field

The functions in this section currently only apply to $K[G]$-modules defined over a finite field K.

`IsRealisableOverSmallerField(M)`

Given a $K[G]$-module M, where K is a finite field, return true if M can be realised over a proper subfield F of K. The equivalent $F[G]$-module is also returned. The Glasby-Howlett algorithm is used to determine the smallest field over which M can be realised.

`IsRealisableOverSubfield(M, F)`

Let M be a $K[G]$-module, where K is a finite field of characteristic p, and let F be a finite field also of characteristic p. If it is possible to realise M over the subfield F of K, return true and the equivalent $F[G]$-module.

`WriteOverSmallerField(M, F)`

Given a module M of dimension d over a finite field E having degree e and a subfield F of E having degree f, write the action of M as $d * e/f$ by $d * e/f$ matrices over F and return the module and the isomorphism.

`AbsoluteModuleOverMinimalField(M, F)`

Let M be a $K[G]$-module, where K is a finite field of characteristic p, and let F be a finite field also of characteristic p. This function returns the module obtained by writing M over the smallest possible field containing F subject to the condition that the dimension of M does not increase. The Glasby-Howlett algorithm is used to determine the smallest field over which M can be realised.

`AbsoluteModuleOverMinimalField(M)`

Verbose	`Reduce`	*Maximum :* 2
Verbose	`Cohomology`	*Maximum :* 2
Verbose	`GrunwaldWang`	*Maximum :* 2

Let M be a $K[G]$-module, where K is a finite field of characteristic p or a number field. This function returns the module obtained by writing M over a field of smallest possible degree subject to the condition that the dimension of M does not increase. For modules over finite fields, a field of smallest degree is always a subfield of K, in this case, the Glasby-Howlet algorithm is used. For number fields, a different field might be necessary and a combination of Plesken's method and a constructive version of the Grunwald-Wang theorem is used.

`Minimize(R)`

`All`	BoolElt	*Default :* `false`
`Char`	AlgChtrElt	*Default :* `false`
`FindSmallest`	BoolElt	*Default :* `false`
Verbose	`Reduce`	*Maximum :* 2
Verbose	`Cohomology`	*Maximum :* 2
Verbose	`GrunwaldWang`	*Maximum :* 2

Let $R : G \to \mathrm{Gl}(n, K)$ be an absolutely irreducible representation over some number field K. This function tries to find minimal subfields k of K that afford R, ie. it tries to write the representation over a smaller field. In general however, there might be number field k not contained in K of smaller degree that afford R. If `All` is given, then instead of a single representation over a minimal degree subfield of K, a list of representations over all minimal subfields of K is returned instead. If `Char` is given, it should be set to the character of the representation. If `FindSmallest` is given, the field K will be extended by some auxiliary field A such that KA will contain a minimal degree field affording R. This involves a constructive version of the Grunwald-Wang theorem and can be computationally expensive if the degree of KA is too large.

`AbsoluteModulesOverMinimalField(Q, F)`

Let Q be a sequence of $K[G]$-modules, where K is a finite field of characteristic p, and let F be a finite field also of characteristic p. This function returns the sequence of modules obtained by writing each module M of Q over the smallest possible field containing F subject to the condition that the dimension of M does not increase. Thus, the effect of the function is to apply the function `AbsoluteModuleOverMinimalField` to each module of Q. The Glasby-Howlett algorithm is used to determine the smallest field over which the modules M of Q can be realised.

`ModuleOverSmallerField(M, F)`

Let M be a $K[G]$-module of dimension d, where K is a finite field of characteristic p, and let F be a subfield of K of index n. This function returns the $F[G]$-module N obtained by writing the action of M as $dn \times dn$ matrices over F.

`ModulesOverSmallerField(Q, F)`

Let Q be a sequence of $K[G]$-modules, where K is a finite field of characteristic p, and let F be a subfield of K of index n. This function returns the sequence R of $F[G]$-modules obtained by applying the function `ModuleOverSmallerField` to each term of Q. That is, each term N of R is formed by writing the action of the corresponding term of Q as $dn \times dn$ matrices over F.

`ModulesOverCommonField(M, N)`

Given $K[G]$-modules M and N, change their base fields to K, where K is the smallest field containing the base fields of M and N.

`WriteGModuleOver(M, K)`

`Char`	AlgChtrElt	*Default :* `false`
`Subfield`	BoolElt	*Default :* `false`
Verbose	`Reduce`	*Maximum :* 2
Verbose	`Cohomology`	*Maximum :* 2
Verbose	`GrunwaldWang`	*Maximum :* 2

Given a $L[G]$ module M and some number field K, try to write M over K. If `Char` is specified, it should be set to the character of this module. If `Subfield` is given, the module will be rewritten over a minimal degree subfield of K.

`WriteRepresentationOver(R, K)`

`Char`	AlgChtrElt	*Default :* `false`
`Subfield`	BoolElt	*Default :* `false`
Verbose	`Reduce`	*Maximum :* 2
Verbose	`Cohomology`	*Maximum :* 2
Verbose	`GrunwaldWang`	*Maximum :* 2

Given an absolutely irreducible representation $R : G \to \mathrm{Gl}(n, L)$ and some normal number field K, try to write R over K. If `Char` is specified, it should be set to the character of this representation. If `Subfield` is given, the representation will be rewritten over a minimal degree subfield of K.

Example H90E11

We will work with the G-module and character of the unique 2-dimensional character of Q_8. It is well known that, while the character is defined over Q, the corresponding representation can only be defined over fields where -1 is the sum of 2 squares.

```
> G := TransitiveGroup(8, 5);
> TransitiveGroupDescription(G);
Q_8(8);
> R := AbsolutelyIrreducibleModules(G, Rationals());
> R;
[
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 2 over Cyclotomic Field
    of order 4 and degree 2
]
```

```
> R := R[5];
> WriteGModuleOver(R, CyclotomicField(5));
GModule of dimension 2 over Cyclotomic Field
of order 5 and degree 4
```

So $Q(\zeta_5)$ is an example of a field affording the module but having no minimal degree subfield (of degree 2 here) affording R!.

```
> AbsoluteModuleOverMinimalField($1);
GModule of dimension 2 over Number Field with
defining polynomial Qx.1^2 - Qx.1 + 1 over the
Rational Field
```

Note that the base field returned here is $Q(\zeta_3)$ which is of degree 2 but different from $Q(\zeta_4)$ that was found initially. In general there are infinetely many minimal degree splitting fields.
If we try to realize R over a field where -1 cannot be written as a sums of two squares we get an error:

```
>  WriteGModuleOver(R, QuadraticField(3));
>> WriteGModuleOver(R, QuadraticField(3));
                    ^
Runtime error in 'WriteGModuleOver': The G-module
cannot be realised over K
```

We can try to find a minimal field containing $Q(\sqrt{3})$ by computing the local Schur-indices and then obtain a splitting field:

```
> k := QuadraticField(3);
> SchurIndices(Character(R), k);
[ <1st place at infinity, 2>, <2nd place at
infinity, 2> ]
> A := SplittingField($1);
> A;
FldAb, defined by (<3>, [1      2])
of structure: Z/2
```

So the splitting field is returned as an abelian extension. We can see that A is of degree 2 over k and will be ramified at most at 3 and both infinite places. In order to use it to rewrite the module, we need to convert to a number field over Q first:

```
> A := NumberField(A);
> A;
Number Field with defining polynomial $.1^2 + 1
over k
> A := AbsoluteField(A);
> A;
Number Field with defining polynomial Qx.1^4 -
    4*Qx.1^2 + 16 over the Rational Field
> WriteGModuleOver(R, A);
GModule of dimension 2 over A
> WriteGModuleOver(R, A:Subfield);
```

```
GModule of dimension 2 over Number Field with
defining polynomial Qx.1^2 - Qx.1 + 1 over the
Rational Field
```

90.4.3 Direct Sum

`DirectSum(M, N)`

Given $K[G]$-modules M and N, construct the direct sum D of M and N as an $K[G]$-module. The embedding maps from M into D and from N into D respectively and the projection maps from D onto M and from D onto N respectively are also returned.

`DirectSum(Q)`

Given a sequence Q of $K[G]$-modules, construct the direct sum D of these modules. The embedding maps from each of the elements of Q into D and the projection maps from D onto each of the elements of Q are also returned.

90.4.4 Tensor Products of $K[G]$-Modules

`TensorProduct(M, N)`

Let M and N be two $K[G]$ modules. This function constructs the tensor product, $M \otimes_A N$, with diagonal action.

`TensorPower(M, n)`

Given a $K[G]$-module M and an integer $n \geq 1$, construct the n-th tensor power of M.

`ExteriorSquare(M)`

Given a $K[G]$-module M, construct the A-submodule of $M \otimes_A M$ consisting of the skew tensors.

`SymmetricSquare(M)`

Given a $K[G]$-module M, construct the A-submodule of $M \otimes_A M$ consisting of the symmetric tensors.

90.4.5 Induction and Restriction

`Dual(M)`

Given an $K[G]$-module M, construct the $K[G]$-module which is the K-dual, $\mathrm{Hom}_K(M, K)$, of M.

`Induction(M, G)`

Given a $K[H]$-module M and a supergroup G of H, construct the $K[G]$-module obtained by inducing M up to G.

`Induction(R, G)`

Given a representation R of a subgroup of G, construct the representation of G obtained by inducing R up to G.

`Restriction(M, H)`

Given a $K[G]$-module M and a subgroup H of G, form the $K[H]$-module corresponding to the restriction of M to the subgroup H.

Example H90E12

Starting with the permutation module M over $\mathbf{F}_2$ for the Mathieu group M_{22}, we apply the induction and restriction functions to find new irreducible modules for M_{22}.

```
> SetSeed(1);
> G := PermutationGroup< 22 |
>         (1,2,4,8,16,9,18,13,3,6,12)(5,10,20,17,11,22,21,19,15,7,14),
>         (1,18,4,2,6)(5,21,20,10,7)(8,16,13,9,12)(11,19,22,14,17),
>         (1,18,2,4)(3,15)(5,9)(7,16,21,8)(10,12,20,13)(11,17,22,14) >;
> M := PermutationModule(G, GaloisField(2));
> M;
GModule M of dimension 22 with base ring GF(2)
> CM := Constituents(M);
> CM;
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 10 over GF(2),
    GModule of dimension 10 over GF(2)
]
```

We restrict the module M to the stabilizer of a point in M_{22} and then induce back up, a constituent of the restriction.

```
> L34 := Stabilizer(G, 1);
> N := Restriction(M, L34);
> N;
GModule N of dimension 22 with base ring GF(2)
> CN := Constituents(N);
> CN;
[
```

```
    GModule of dimension 1 over GF(2),
    GModule of dimension 9 over GF(2),
    GModule of dimension 9 over GF(2)
]
> Ind1 := Induction(CN[1], G);
> Ind1;
GModule Ind1 of dimension 22 over GF(2)
> Constituents(Ind1);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 10 over GF(2),
    GModule of dimension 10 over GF(2)
]
> Ind2 := Induction(CN[2], G);
> Ind2;
GModule Ind2 of dimension 198 over GF(2)
> Constituents(Ind2);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 10 over GF(2),
    GModule of dimension 10 over GF(2),
    GModule of dimension 34 over GF(2),
    GModule of dimension 98 over GF(2)
]
```

Thus, inducing up the 1-dimensional constituent of N gives us irreducible modules for G having the same dimensions as those appearing as constituents of M. However, inducing up the 9-dimensional module gives us irreducible modules of new dimensions: 34 and 98. Hence starting out with only the permutation module for M_{22} over $\mathbf{F}_2$, we have found 5 irreducible modules for the group.

90.4.6 The Fixed-point Space of a Module

`Fix(M)`

Given an $K[G]$-module M, construct the largest submodule of M on which G acts trivially, i.e. the fixed-point space of M.

90.4.7 Changing Basis

`M ^ T`

Given a $K[G]$-module M of dimension n over the field K, and a nonsingular $n \times n$ matrix T over K, construct the $K[G]$-module N which corresponds to taking the rows of T as a basis for M.

90.5 The Construction of all Irreducible Modules

The construction of all irreducible K[G]-modules for a finite group G is of major interest. If G is soluble there is a very effective method that dates back to Schur. This proceeds by working up a composition series for G and constructing the irreducibles for each subgroup by inducing or extending representations from the previous subgroup. This works equally well over finite fields and over fields of characteristic zero. If G is non-soluble the situation is more difficult. Starting with a faithful representation, by a theorem of Burnside, it is possible to construct all representations by splitting tensor powers of the faithful representation. An algorithm based on this idea developed by Cannon and Holt uses the Meataxe to split representations and works well over small finite fields. A similar algorithm for rational representations using a different method for splitting representations is under development by Steel. Methods based on the theorem of Burnside, will be referred to as *Burnside algorithms*.

90.5.1 Generic Functions for Finding Irreducible Modules

The functions described in this section construct all irreducible representations of a finite group. The choice of algorithm depends upon the type of group and the kind of field given. The individual algorithms may be invoked directly by means of intrinsic functions described in subsequent sections.

`IrreducibleModules(G, K : parameters)`

`AbsolutelyIrreducibleModules(G, K : parameters)`

Let G be a finite group and let K be a field. If G is soluble then K may be either a finite field, the rational field or a cyclotomic field whose order divides the exponent of G. If G is non-soluble, then currently K is restricted to being a finite field or the rational field. These functions construct all of the irreducible or absolutely irreducible G-modules over K. Since V2.16, if K is the rational field, then by default a new algorithm is used. Otherwise, if G is soluble, Schur's algorithm is normally used while if G is non-soluble, the Burnside method is used.

`Alg` MonStgElt *Default :*

The parameter `Alg` may be used to override the usual choice of algorithm if desired. Note that Schur's algorithm may only be applied to soluble groups, while, for the time being, Burnside's method requires that the field K is finite.

The Schur algorithm is usually very fast and is often able to find the complex representations more quickly than it is possible to compute the character table. The speed of the Burnside algorithm is determined firstly by the maximal degree of the irreducible modules and secondly by the number of irreducible modules. It will start to become quite slow if G has modules of dimension in excess of 1000. In order to prevent the Burnside method from wasting huge amounts of time, the algorithm takes a parameter which controls the degree of the largest module that will be consider for splitting.

`DimLim` RngInt *Default :* 2000

The parameter `DimLim` only affects the Burnside algorithm where it is used to limit the dimension of the modules which will be considered for splitting. If this limit prevents all irreducibles being found, a warning message is output and those irreducibles that have been found will be returned. This possibility allows the user to determine a sample of low degree modules without using excessive time.

Example H90E13

We take a group of order $416 = 2^5 13$ and compute its irreducible modules over various fields.

```
> G := SmallGroup(416, 136);
> G;
GrpPC : G of order 416 = 2^5 * 13
PC-Relations:
    G.1^2 = Id(G),
    G.2^2 = G.5,
    G.3^2 = Id(G),
    G.4^2 = G.5,
    G.5^2 = Id(G),
    G.6^13 = Id(G),
    G.3^G.1 = G.3 * G.5,
    G.3^G.2 = G.3 * G.4,
    G.4^G.2 = G.4 * G.5,
    G.4^G.3 = G.4 * G.5,
    G.6^G.1 = G.6^12
```

We first compute the $K[G]$-modules for the finite fields $K = GF(p)$, where p runs through the primes dividing the order of G.

```
> IrreducibleModules(G, GF(2));
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 12 over GF(2)
]
> IrreducibleModules(G, GF(13));
[
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 1 over GF(13),
    GModule of dimension 2 over GF(13),
    GModule of dimension 2 over GF(13),
    GModule of dimension 4 over GF(13)
```

```
]
```

We now compute the $K[G]$-modules where K is the rational field.

```
> time L := IrreducibleModules(G, Rationals());
Time: 16.170
> L;
[
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 1 over Rational Field,
    GModule of dimension 2 over Rational Field,
    GModule of dimension 2 over Rational Field,
    GModule of dimension 8 over Rational Field,
    GModule of dimension 12 over Rational Field,
    GModule of dimension 12 over Rational Field,
    GModule of dimension 12 over Rational Field,
    GModule of dimension 12 over Rational Field,
    GModule of dimension 24 over Rational Field,
    GModule of dimension 96 over Rational Field
]
```

Finally, we compute the $K[G]$-modules taking K to be the splitting field over the rationals and verify that the number of irreducibles is equal to the number of conjugacy classes of G.

```
> Exponent(G);
104
> mods := IrreducibleModules(G, CyclotomicField(104));
> #mods;
53;
> #Classes(G);
53
> [ Dimension(N) : N in mods ];
[ 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
  2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 4, 4,
  4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
> X := CharacterTable(G);
> [ Degree(x) : x in X ];
[ 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,

  4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
```

90.5.2 The Burnside Algorithm

The Burnside algorithm finds all irreducible $K[G]$-modules with a faithful $K[G]$-module P and looks for the distinct irreducibles among the tensor powers of P. Both irreducible and absolutely irreducible modules may be found. At present the algorithm is restricted to finite fields. In more detail the algorithm starts with a some faithful permutation module over the given field, splits it into irreducibles using the meataxe, and constructing further modules to split as tensor products of those already found. A warning is printed if all irreducible modules are not found.

`AbsolutelyIrreducibleModulesBurnside(G, K : parameters)`

`DimLim` RngIntElt *Default :* 2000

Given a finite group G and a finite field K, this function constructs the absolutely irreducible $K[G]$-modules over extensions of K. Currently, the group G is restricted to a permutation group. The maximum dimension of a module considered for splitting is controlled by the parameter `DimLim`, which has default value 2000.

`IrreducibleModulesBurnside(G, K : parameters)`

`DimLim` RngIntElt *Default :* 2000

Given a finite group G and a finite field K, this function constructs the irreducible $K[G]$-modules over K. Currently, the group G is restricted to a permutation group. The maximum dimension of a module considered for splitting is controlled by the parameter `DimLim`, which has default value 2000.

`AbsolutelyIrreducibleConstituents(M)`

Given an irreducible module M, return M if it is already absolutely irreducible, else return the absolutely irreducible modules obtained by finding the constituents of M after extending the base field of M to a splitting field.

Example H90E14

We find all irreducible modules for M_{11} over $GF(2)$, and all absolutely irreducible modules of characteristic 2. The Burnside algorithm is used by default.

```
> load m11;
Loading "/home/magma/libs/pergps/m11"
M11 - Mathieu group on 11 letters - degree 11
Order 7 920 = 2^4 * 3^2 * 5 * 11;  Base 1,2,3,4
Group: G
> IrreducibleModules(G, GF(2));
[
  GModule of dimension 1 over GF(2),
  GModule of dimension 10 over GF(2),
  GModule of dimension 44 over GF(2),
  GModule of dimension 32 over GF(2)
]
> AbsolutelyIrreducibleModules(G, GF(2));
```

```
[
  GModule of dimension 1 over GF(2),
  GModule of dimension 10 over GF(2),
  GModule of dimension 44 over GF(2),
  GModule of dimension 16 over GF(2^2),
  GModule of dimension 16 over GF(2^2)
]
```

90.5.3 The Schur Algorithm for Soluble Groups

This collection of functions allows the user to find all irreducible modules of a finite soluble group. The group is first replaced by an isomorphic group defined by a power-conjugate presentation. The irreducibles are then found using Schur's method of working up the composition series for G defined by the pc-presentation.

`IrreducibleModules(G, K : parameters)`

`AbsolutelyIrreducibleModulesSchur(G, K: parameters)`

Let G be a finite soluble group and let K be one the following types of field: a finite field, the rational field or a cyclotomic field. The order of a cyclotomic field must divide the exponent of G. The function constructs all absolutely irreducible representations of G over appropriate extensions or subfields of the field K. The modules returned are non-isomorphic and consist of all distinct modules, subject to the conditions imposed. In the case when K is a finite field, the Glasby-Howlett algorithm is used to determine the minimal field over which an irreducible module may be realised. If K has characteristic 0, the field over which an irreducible module is given may not be minimal.

The irreducible modules are found using Schur's method of climbing the composition series for G defined by the pc-presentation.

`Process` BoolElt *Default :* `true`

If the parameter `Process` is set true then the list is a list of pairs comprising an integer and a representation. This list or any sublist of it is a suitable value for the argument L in the last versions of the function, and in this case only the representations in L will be extended up the series. This allows the user to inspect the representations produced along the way and cull any that are uninteresting.

`GaloisAction` MonStgElt *Default :* "Yes"

Possible values are "Yes", "No" and "Relative". The default is "Yes" for intermediate levels and "No" for the whole group. The value "Yes" means that it only lists one irreducible from each orbit of the action of the absolute Galois group $Gal(K/\text{primefield}(K))$. Setting this parameter to "No" turns this reduction off (thus listing all inequivalent representations), while setting it to "Relative" uses the group $Gal(K/k)$.

`MaxDimension` RngIntElt *Default :*

Restrict the irreducible to those of dimension $\leq$ MaxDimension. Default is no restriction.

`ExactDimension` SetEnum *Default :*

If `ExactDimension` is assigned a set S of positive integers, attention is restricted to irreducible having dimensions lying in the set S. The default is equivalent to taking the set of all positive integers.

If both `MaxDimension` and `ExactDimension` are assigned values, then irreducible having dimensions that are either bounded by `MaxDimension` or contained in `ExactDimension` are produced.

`IrreducibleModulesSchur(G, K: parameters)`

Compute irreducible modules for G over the given field K. All arguments and parameters are as for the absolutely irreducible case.

The computation proceeds by first computing the absolutely irreducible representations subject to the given conditions, then rewriting over the field K, with a consequent change of dimension of the representation.

Example H90E15

We compute representations of the dihedral group of order 20.

```
> G := DihedralGroup(GrpPC, 10);
> FactoredOrder(G);
[ <2, 2>, <5, 1> ]
```

First some modular representations with characteristic 2.

```
> r := IrreducibleModulesSchur(G, GF(2));
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2)
*]
> r := AbsolutelyIrreducibleModulesSchur(G, GF(2));
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 2 over GF(2^2),
    GModule of dimension 2 over GF(2^2)
*]
> r := AbsolutelyIrreducibleModulesSchur(G, GF(2) : GaloisAction:="Yes");
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 2 over GF(2^2)
*]
```

The irreducible representation of dimension 4 is not absolutely irreducible, as over $GF(4)$ it splits into two Galois-equivalent representations.

Finding irreducible modules over the complex field is straightforward, despite not being able to use the complex field as the field argument. We could instead specify the cyclotomic field having order equal to the exponent of G, but it is preferable to ask for all absolutely irreducible modules over the rationals.

```
> r := AbsolutelyIrreducibleModulesSchur(G, Rationals());
> r;
[*
   GModule of dimension 1 over Rational Field,
   GModule of dimension 1 over Rational Field,
   GModule of dimension 1 over Rational Field,
   GModule of dimension 1 over Rational Field,
   GModule of dimension 2 over Cyclotomic Field of order 5 and degree 4,
   GModule of dimension 2 over Cyclotomic Field of order 5 and degree 4,
   GModule of dimension 2 over Cyclotomic Field of order 5 and degree 4,
   GModule of dimension 2 over Cyclotomic Field of order 5 and degree 4
*]
> Representation(r[6])(G.2);
[zeta_5^3        0]
[       0 zeta_5^2]
```

AbsolutelyIrreducibleRepresentationsInit(G, F : *parameters*)

AbsolutelyIrreducibleModulesInit(G, F : *parameters*)

IrreducibleRepresentationsInit(G, F : *parameters*)

IrreducibleModulesInit(G, F : *parameters*)

Initialize a Process for calculating all linear representations of a soluble group G over the field F. The field F is restricted to either a finite field or the rationals. The parameters are as described above.

NextRepresentation(P)

NextModule(P)

Return `true` and the next representation from the process P, if there is one, or just `false` if the process is exhausted.

AbsolutelyIrreducibleRepresentationProcessDelete(~P)

Free all data associated with the process P.

90.5.4 The Rational Algorithm

MAGMA V2.16 contains a new algorithm for constructing irreducible rational representations of an arbitrary finite group. This algorithm is now selected by default in the function `IrreducibleModules(G, K)` when the field K is $\mathbf{Q}$.

Given an irreducible complex character for a group G, the sum of its Galois orbit gives an *irreducible rational character* for G. The Schur index of an irreducible rational character χ is defined to be the Schur index of an irreducible complex character whose Galois orbit sum is χ.

We call the sequence of all possible irreducible rational characters for G (sorted by degree) the *rational character table* of G. The irreducible modules returned by `IrreducibleModules(G, RationalField())` always match the rational character table.

`IrreducibleModules(G, Q : parameters)`

Given a finite group G, this function returns a sequence L of all irreducible rational $K[G]$-modules, and also the rational character table of G as a sequence C, which matches L. The character of the i-th module $L[i]$ is always $s_i \cdot C[i]$, where s_i is the Schur index of $C[i]$. Thus the dimension of the irreducible module $L[i]$ is $s_i \cdot \mathrm{Deg}(C[i])$.

`MaxDegree` RNGINTELT *Default :* 0

Setting the parameter `MaxDegree` to a positive integer D instructs the algorithm not to spend effort on constructing irreducible modules whose corresponding irreducible rational characters have degree greater than D. Note that irreducible modules whose character degrees greater than D may be returned in any case, if they are easily constructed (often as side effects of operations used to construct smaller-dimensional modules).

`Characters` [ALGCHTRELT] *Default :*

Setting the parameter `Characters` to a set or sequence S of characters for the group G instructs the algorithm to attempt to construct only the irreducible modules whose characters are in S. Each character in S may either be an irreducible rational character, or a (complex) ordinary character χ, in which case the irreducible rational character corresponding to χ (the orbit sum of χ) is used. As for the parameter `MaxDegree`, irreducible modules whose characters are not in S may be returned in any case, if they are easily constructed or are needed as intermediate modules to construct the desired modules.

`CharacterDegrees` [RNGINTELT] *Default :*

Setting the parameter `CharacterDegrees` to a set or sequence I of positive integers instructs the algorithm to attempt to construct only the irreducible modules whose character degrees are in S. This is equivalent to setting the parameter `Characters` to `[c: c in RationalCharacterTable(G) | Degree(c) in I]`.

`UseInduction` BOOLELT *Default :* `true`

By default, as the algorithm proceeds, it automatically searches for subgroups H_i of G such that irreducible rational H_i-modules may be induced up to G to yield

G-modules from which irreducible G-modules may be computed. In general, this method is very effective (and often yields modules for G with small entries) but can be very slow for some groups (particularly when G has many subgroups). Thus setting the parameter `UseInduction` to `false` will force the algorithm not to use induction.

`RationalCharacterTable(G)`

Given a finite group G, return the rational character table of G as a sequence C of the irreducible rational characters of G (sorted by degree), and also a index sequence I, such that for each i, $C[i]$ is the sum of the Galois orbit of $T[I[i]]$, where T is the ordinary (complex) character table of G.

Example H90E16

We compute all irreducible rational modules for PSL(3, 3) and note that the characters of the resulting modules match the entries in the rational character table.

```
> G := PSL(3, 3); #G;
5616
> T := CharacterTable(G); [Degree(x): x in T];
[ 1, 12, 13, 16, 16, 16, 16, 26, 26, 26, 27, 39 ]
> C := RationalCharacterTable(G); C;
[
    ( 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1 ),
    ( 12, 4, 3, 0, 0, 1, 0, 0, -1, -1, -1, -1 ),
    ( 13, -3, 4, 1, 1, 0, -1, -1, 0, 0, 0, 0 ),
    ( 26, 2, -1, -1, 2, -1, 0, 0, 0, 0, 0, 0 ),
    ( 27, 3, 0, 0, -1, 0, -1, -1, 1, 1, 1, 1 ),
    ( 39, -1, 3, 0, -1, -1, 1, 1, 0, 0, 0, 0 ),
    ( 52, -4, -2, -2, 0, 2, 0, 0, 0, 0, 0, 0 ),
    ( 64, 0, -8, 4, 0, 0, 0, 0, -1, -1, -1, -1 )
]
> time L := IrreducibleModules(G, RationalField());
Time: 0.760
> L;
[
    GModule of dimension 1 over Rational Field,
    GModule of dimension 12 over Rational Field,
    GModule of dimension 13 over Rational Field,
    GModule of dimension 26 over Rational Field,
    GModule of dimension 27 over Rational Field,
    GModule of dimension 39 over Rational Field,
    GModule of dimension 52 over Rational Field,
    GModule of dimension 64 over Rational Field
]
> [Character(M): M in L];
[
    ( 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1 ),
```

```
    ( 12, 4, 3, 0, 0, 1, 0, 0, -1, -1, -1, -1 ),
    ( 13, -3, 4, 1, 1, 0, -1, -1, 0, 0, 0, 0 ),
    ( 26, 2, -1, -1, 2, -1, 0, 0, 0, 0, 0, 0 ),
    ( 27, 3, 0, 0, -1, 0, -1, -1, 1, 1, 1, 1 ),
    ( 39, -1, 3, 0, -1, -1, 1, 1, 0, 0, 0, 0 ),
    ( 52, -4, -2, -2, 0, 2, 0, 0, 0, 0, 0, 0 ),
    ( 64, 0, -8, 4, 0, 0, 0, 0, -1, -1, -1, -1 )
]
```

Example H90E17

For large groups, one can use the parameter `MaxDegree` to compute the irreducible modules of reasonable dimension.

```
> load m23;
Loading "/home/magma/libs/pergps/m23"
M23 - Mathieu group on 23 letters - degree 23
Order 10 200 960 = 2^7 * 3^2 * 5 * 7 * 11 * 23;  Base 1,2,3,4,5,6
Group: G
> T := CharacterTable(G); [Degree(x): x in T];
[ 1, 22, 45, 45, 230, 231, 231, 231, 253, 770, 770,
896, 896, 990, 990, 1035, 2024 ]
> C := RationalCharacterTable(G); C;
[
    ( 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1 ),
    ( 22, 6, 4, 2, 2, 0, 1, 1, 0, 0, 0, -1, -1, -1, -1, -1, -1 ),
    ( 90, -6, 0, 2, 0, 0, -1, -1, -2, 2, 2, 1, 1, 0, 0, -2, -2 ),
    ( 230, 22, 5, 2, 0, 1, -1, -1, 0, -1, -1, 1, 1, 0, 0, 0, 0 ),
    ( 231, 7, 6, -1, 1, -2, 0, 0, -1, 0, 0, 0, 0, 1, 1, 1, 1 ),
    ( 253, 13, 1, 1, -2, 1, 1, 1, -1, 0, 0, -1, -1, 1, 1, 0, 0 ),
    ( 462, 14, -6, -2, 2, 2, 0, 0, -2, 0, 0, 0, 0, -1, -1, 2, 2 ),
    ( 1035, 27, 0, -1, 0, 0, -1, -1, 1, 1, 1, -1, -1, 0, 0, 0, 0 ),
    ( 1540, -28, 10, -4, 0, 2, 0, 0, 0, 0, 0, 0, 0, 0, 0, -1, -1 ),
    ( 1792, 0, -8, 0, 2, 0, 0, 0, 0, -1, -1, 0, 0, 2, 2, -2, -2 ),
    ( 1980, -36, 0, 4, 0, 0, -1, -1, 0, 0, 0, -1, -1, 0, 0, 2, 2 ),
    ( 2024, 8, -1, 0, -1, -1, 1, 1, 0, 0, 0, 1, 1, -1, -1, 0, 0 )
]
> Q := RationalField();
> time L := IrreducibleModules(G, Q: MaxDegree := 253);
Time: 23.400
> L;
[
    GModule of dimension 1 over Rational Field,
    GModule of dimension 22 over Rational Field,
    GModule of dimension 90 over Rational Field,
    GModule of dimension 230 over Rational Field,
    GModule of dimension 231 over Rational Field,
    GModule of dimension 253 over Rational Field,
```

```
    undef,
    undef,
    undef,
    undef,
    GModule of dimension 1980 over Rational Field
]
```

Note that the module of dimension 1980 is included (it was easily constructed as the tensor product of modules of dimension 20 and 90).

90.6 Extensions of Modules

For $K[G]$-modules M and N, the K-vector $\mathrm{Ext}(M, N)$ of equivalence classes of $K[G]$-module extensions

$$0 \to N \to L \to M \to 0$$

of N by M can be computed, and corresponding extensions L constructed.

`Ext(M, N)`

Given $K[G]$-modules M and N, construct the K-vector space $\mathrm{Ext}(M, N)$ of equivalence classes of $K[G]$-module extensions of N by M.

`Extension(M, N, e)`

Construct a $K[G]$-module extension L of N by M corresponding to the element e of E, where E must be the vector space returned by a previous call of `Ext(M,N)`. The insertion $N \to L$ and projection $L \to M$ are also returned.

`MaximalExtension(M, N, E)`

Again E must be the vector space returned by a previous call of `Ext(M,N)`. Construct the largest possible $K[G]$-module extension L of a direct sum of copies of N by M, such that none of the submodules of L that are isomorphic to N has a complement in L.

Example H90E18

```
> G := Alt(5);
> I := IrreducibleModules(G, GF(2));
> I;
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 4 over GF(2)
]
> M1 := rep{M: M in I | Dimension(M) eq 1};
> M4 := rep{M: M in I | Dimension(M) eq 4 and not IsAbsolutelyIrreducible(M)};
> M4; assert not IsAbsolutelyIrreducible(M4);
```

```
GModule M of dimension 4 over GF(2)
> E, rho := Ext(M4, M1);
> E;
Full Vector space of degree 2 over GF(2)
> Extension(M4, M1, E.1, rho);
GModule of dimension 5 over GF(2)
[0 0 0 0 1]
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
[0 0 0 0]
> E := MaximalExtension(M4, M1, E, rho);
> E;
GModule E of dimension 6 over GF(2)
> CompositionFactors(E);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2)
]
```

90.7 The Construction of Projective Indecomposable Modules

For a finite group G and a finite field K, the projective indecomposable $K[G]$-modules are in one-one correspondence with the irreducible $K[G]$-modules, where the projective indecomposable module P corresponding to the irreducible module I has the property that Socle(P) and P/JacobsonRadical(P) are both isomorphic to I.

MAGMA functions for the construction of the irreducible modules were described in Subsection 90.5.1. The functions described in this section may be used to construct the corresponding projective indecomposables for finite groups of moderate order – up to around 10^6, depending on the example. Large-dimensional projective indecomposable modules can sometimes be constructed by using *condensation* techniques, which allow many of the necessary computations to be carried out in condensed modules, which may have significantly smaller dimension than their standard uncondensed equivalents. As with the computation of irreducible modules, these methods work best for permutation groups and PC-groups.

The verbose flag `"KGModule"` may be set to 1 or 2 to show details of the computations.

`ProjectiveIndecomposableDimensions(G, K)`

The K-dimensions of the projective indecomposable $K[G]$-modules corresponding to the irreducible $K[G]$-modules returned by `IrreducibleModules(G,K)`. (These can be computed quickly from the Brauer characters of the irreducible modules, using the Cartan matrix discussed below.)

`ProjectiveIndecomposableModule(I:` *parameters*`)`

Construct and return the projective indecomposable $K[G]$-module P corresponding to the irreducible $K[G]$-module I. Note that Socle(P) and P/JacobsonRadical(P) are both isomorphic to I.

`condensation` BoolElt *Default :* `false`

If set to `true`, then an attempt is made to find a subgroup of G which allows computations to be carried out in condensed versions of the modules involved.

`ProjectiveIndecomposableModules(G, K)`

Construct the complete list of projective indecomposable $K[G]$-modules corresponding to the irreducible $K[G]$-modules returned by `IrreducibleModules(G,K)`.

`condensation` BoolElt *Default :* `false`

If set to `true`, then an attempt is made to find a subgroup of G which allows computations to be carried out in condensed versions of the modules involved.

Example H90E19

We compute the projective indecomposable modules for the alternating group of degree 8 over the field of order 2.

```
> G := Alt(8);
> K := GF(2);
> IrreducibleModules(G, K);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 14 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 64 over GF(2)
]
> ProjectiveIndecomposableDimensions(G, K);
[ 448, 192, 192, 320, 320, 192, 192, 64 ]
> time proj := ProjectiveIndecomposables(G, K);
Time: 22.070
> proj;
[
```

```
    GModule of dimension 448 over GF(2),
    GModule of dimension 192 over GF(2),
    GModule of dimension 192 over GF(2),
    GModule of dimension 320 over GF(2),
    GModule of dimension 320 over GF(2),
    GModule of dimension 192 over GF(2),
    GModule of dimension 192 over GF(2),
    GModule of dimension 64 over GF(2)
]
> CompositionFactors(proj[1]);
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 14 over GF(2),
    GModule of dimension 6 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 4 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 20 over GF(2),
    GModule of dimension 1 over GF(2),
    GModule of dimension 14 over GF(2),

`CartanMatrix(G, K)`

Let k be the number of irreducible $K[G]$-modules. The Cartan Matrix C for G over K is a $k \times k$ matrix of integers, in which the entry C_{ij} is equal to the number of times that the j-th irreducible $K[G]$-module is a constituent of the i-th projective indecomposable $K[G]$-module. This can be computed quickly from the Brauer characters of the irreducible $K[G]$-modules, and is used in `ProjectiveIndecomposableDimensions`.

(Note that, unlike the absolute Cartan matrix discussed below, C need not be symmetric.)

`AbsoluteCartanMatrix(G, K)`

This is the Cartan matrix of G over an extension L of K that is large enough for all irreducible $L[G]$-modules to be absolutely irreducible. Its rows and columns correspond to the $K[G]$-modules returned by `AbsolutelyIrreducibleModules(G,K)`.

It is a symmetric matrix with integer entries, and is equal to the Cartan matrix for G in the characteristic p of K, as defined in textbooks on modular representation theory.

`DecompositionMatrix(G, K)`

The decomposition matrix D of G in the characteristic p of K, as defined in textbooks on modular representation theory. The entry D_{ij} is equal to the number of times that the j-th absolutely irreducible $K[G]$-module occurs as a constituent of the i-th ordinary irreducible G-module over the complex numbers reduced modulo p. Note that $D^{\mathrm{T}}D$ is equal to the absolute Cartan matrix.

`ProjectiveCover(M)`

Compute the projective cover P of $K[G]$-module M together with a $K[G]$-module epimorphism $P \to M$ returned as a matrix.

If P_i is the projective indecomposable $K[G]$-module corresponding to the irreducible $K[G]$-module I_i and $M/\text{JacobsonRadical}(M)$ is isomorphic to $\oplus_{j=1}^{t} I_{i_j}$ then P is isomorphic to $\oplus_{j=1}^{t} P_{i_j}$.

`CohomologicalDimension(M, n)`

For $K[G]$-module M (with K a finite field and G a finite group), compute and return the K-dimension of the cohomology group $H^n(G, M)$ for $n \geq 0$. For $n = 0$ and 1, this is carried out by using the functions described in Chapter 68. For $n \geq 2$, it is done recursively using projective covers and dimension shifting to reduce to the case $n = 1$. (In particular, for $n = 2$, the method is different from that employed by the corresponding function for a cohomology module described in Chapter 68.)

`CohomologicalDimensions(M, n)`

For $K[G]$-module M (with K a finite field and G a finite group), compute and return the sequence of K-dimensions of the cohomology groups $H^k(G, M)$ for $1 \leq k \leq n$. On account of the recursive method used, this is quicker than computing them individually.

Example H90E20

We compute the cohomology of the irreducible modules for Alt(8) over the field of order 2 computed in the previous example.

```
> G := Alt(8);
> K := GF(2);
> irr :=  IrreducibleModules(G, K);
> [ CohomologicalDimension(I, 1) : I in irr ];
[ 0, 0, 0, 1, 1, 1, 1, 0 ]
> time [ CohomologicalDimension(I, 2) : I in irr ];
[ 1, 1, 1, 0, 2, 0, 0, 0 ]
Time: 0.440
> time [ CohomologicalDimension(I, 3) : I in irr ];
[ 2, 1, 1, 1, 1, 1, 1, 0 ]
Time: 15.070
> time [ CohomologicalDimension(I, 4) : I in irr ];
[ 2, 1, 1, 2, 3, 2, 2, 0 ]
Time: 99.500
> time CohomologicalDimensions(irr[1], 6);
[ 0, 1, 2, 2, 3, 6 ]
Time: 139.270
```

91 CHARACTERS OF FINITE GROUPS

Chapter 91
CHARACTERS OF FINITE GROUPS

Assume that G is a finite group of exponent m with k conjugacy classes of elements. The operators discussed here are concerned with the ring of *class functions on* G, defined to be the ring of complex-valued functions on G that are constant on conjugacy classes. This ring is made into a $\mathbf{C}$-algebra by identifying $c \in \mathbf{C}$ with the constant function that is c everywhere. In fact we will restrict ourselves to functions with values that are elements of cyclotomic fields.

Elements of the ring, ie. objects of type `AlgChtrElt`, are represented by the k values (elements of some cyclotomic field $\mathbf{Q}(\zeta_n)$) on the classes. The numbering of those elements matches the numbering of the classes as returned by `Classes` applied to the underlying group `G`: Thus `X[i]` is the value of the character `X` on the i-th class, ie. `Classes(G)[i]`.

91.1 Creation Functions

91.1.1 Structure Creation

`ClassFunctionSpace(G)`

`CharacterRing(G)`

Given a finite group G, create the ring of complex-valued class functions. This function will trigger the computation of the conjugacy classes of G if these are not yet known. Information about the irreducible characters is stored in the ring when it is computed.

91.1.2 Element Creation

The elementary constructions for class functions are listed. Other useful ways of defining class functions and characters are defined in sections discussing the permutation character, the (de)composition functions, and the sections on the conjugating, restricting and inducing of class functions.

`elt< R | a`$_1$`, ..., a`$_k$ *:parameters* `>`

`R ! [ a`$_1$`, ..., a`$_k$ `]`

Given the ring of class functions R of a finite group G with k conjugacy classes and k elements a_i contained in some common cyclotomic field, create a class function on G for which the value on the i-th class is equal to the i-th term a_i.

`Character` BoolElt *Default :* `false`

If `Character := true`, then the resulting character is flagged to be a proper character.

`R ! a`

Define a constant class function for the ring of class functions R of the group G. Here a is allowed to be an integer, a rational field element or a cyclotomic field element.

`Id(R)`

`Identity(R)`

`One(R)`

`PrincipalCharacter(G)`

Given the finite group G or its ring of class functions R, create the principal character (which takes on the value 1 on every element of G).

`Zero(R)`

Given a ring of class functions R create its zero element (which is the class function that takes on the value 0 on every element of the group).

91.1.3 The Table of Irreducible Characters

The function `CharacterTable` can be invoked to determine the complete or a partial table of irreducible characters on a finite group G. If necessary, an existing character table can be supplemented by another call to the function. The known irreducible characters are stored in the character ring of G.

The default algorithm for character tables is Unger's Induce/Reduce algorithm, described in detail in [Ung06]. Computing character tables assumes that the classes of the group can be computed and stored, along with a class representative for each class, as well as the power map of the group. Unger's algorithm constructs elementary subgroups of the group (where elementary means direct product of cyclic group with p-group), and constructs characters of these subgroups (using Conlon's algorithm for the character table of the p-part of the group). Following Brauer's theorem on induced characters, these characters are induced to the full group and all irreducible characters of the full group are found in the integral span of the induced characters (using LLL reduction to maintain a manageable basis of the character space found). The two potentially most time-consuming parts of the algorithm are the computation of fusion in the elementary subgroups, which is necessary for induction, and repeated use of LLL to maintain a basis of the space of generalised characters found to date. Arithmetic with generalised characters is done quickly by using a finite field representation of these characters, as in Dixon's work [Dix67], but here the prime used may be twice the length of Dixon's.

The Dixon-Schneider algorithm for computing character tables [Dix67, Sch90] is also available. See below for details on how to access it. This was the previous default algorithm for character tables. As indicated above, Conlon's algorithm for the character table of a p-group [Con90] is also implemented, and may be accessed directly as indicated below.

The functions in this section return character tables, which are enumerated sequences of characters that are flagged to allow printing in a special format.

`KnownIrreducibles(G)`

Given a finite group G, or a class function space R of G, return the table of irreducible characters currently stored. Such a table is a sequence of characters with specially formatted printing.

It should be noted that characters are stored with some information about whether they are characters, generalized characters or class functions. From this information, it is often possible to deduce with little effort that a character is, in fact, irreducible. When a new irreducible is found this way, it is immediately inserted into the table of irreducible characters.

`CharacterTable(G :`*parameters*`)`

Construct the table of ordinary irreducible characters for the group G.

`Al`	MonStgElt	*Default :* "*Default*"

This parameter controls the algorithm used. The string `"DS"` forces use of the Dixon-Schneider algorithm. The string `"IR"` forces the use of Unger's Induce/Reduce algorithm [Ung06]. The string `"Conlon"` forces the use of Conlon's algorithm. This last is only valid when the group is a p-group. The `"Default"` algorithm is to use Dixon-Schneider for groups of order ≤ 5000, Conlon's algorithm for larger p-groups and Unger's algorithm for other groups. This may change in future.

`DSSizeLimit`	RngIntElt	*Default :* 0

When the algorithm selected is either "Default" or "IR", a positive value n for `DSSizeLimit` means that before using ithe Induce/Reduce algorithm, the full possible character space is split by some passes of the Dixon-Schneider algorithm, restricted to using class matrices corresponding to conjugacy classes with size at most n.

`CharacterTableDS(G :`*parameters*`)`

`ClassMatrices`	SeqEnum	*Default :* []
`ClassMatrixLimit`	RngIntElt	*Default :* ∞
`ClassSizeLimit`	RngIntElt	*Default :* ∞
`MinChars`	RngIntElt	*Default :* ∞
`Modulus`	RngIntElt	*Default :* 0

Given a finite group G, construct the table of irreducible characters of G using the Dixon-Schneider algorithm [Dix67, Sch90]. The conjugacy classes of G will be computed if necessary; if the user wishes to exert control over the computation of the classes, the function `Classes` can be invoked on G before calling `CharacterTableDS`.

There are several optional parameters for `CharacterTableDS`. Assigning a non-negative integer value m to `MinChars`, indicates that the computation is to be terminated as soon as m or more additional characters have been found. By setting `ClassMatrixLimit` to a positive integer n, the user can limit the number of class matrices used. If the calculation of all irreducible characters (or at least m of them

if `MinChars` has been set) cannot be completed by using k class matrices, an incomplete character table is returned. Setting `ClassSizeLimit` to an integer n restricts the algorithm to computing class matrices corresponding to classes of size at most n. Again, if the calculation of all irreducible characters cannot be completed using class matrices from these small classes, an incomplete character table is returned. The optional argument `ClassMatrices` (a sequence of integers in the range $1 \dots k$, where k is the number of conjugacy classes of G) can be used to specify a preference for the order in which class matrices should be used. Finally the `Modulus` argument can be used to set which prime field is used for the internal computations of the Dixon-Schneider algorithm. The value used must be a prime equivalent to 1 modulo the group exponent and greater than twice the square root of the group order.

The second return argument is the sequence of unsplit character spaces remaining at the point the algorithm terminated. This is empty when the algorithm returns a complete character table, but may be useful when an incomplete character table is returned.

`Basis(R)`

The function `Basis` takes the character ring R of G as input and performs the same computation to find the basis for R consisting of the irreducible characters.

Both `CharacterTable` and `Basis` return a character table, which is an enumerated sequence of elements of the character ring over G (if necessary, the ring is created) that only differs from arbitrary sequences of class functions with respect to printing.

`CharacterTableConlon(G)`

Compute the character table of group G using Conlon's algorithm for p-groups. The group group G must thus be a p-group for some prime p.

`LinearCharacters(G)`

Given a finite group G, determine the (partial) character table containing only the linear characters.

`CharacterDegrees(G)`

`CharacterDegrees(G)`

`CharacterDegrees(G)`

`CharacterDegrees(G)`

Returns the degrees of the ordinary irreducible characters of the finite group G. The sequence returned has form $[< d_1, c_1 >, < d_2, c_2 >, \dots]$ where c_i is the number of characters of degree d_i. For p-groups Slattery's algorithm is used, for other soluble groups Conlon's counting algorithm is used, and for insoluble groups the character table of G is computed.

`CharacterDegrees(G, z, p)`

Returns the degrees of the absolutely irreducible characters of G lying over a faithful linear character of $\langle z \rangle$, where z is a central element of G and p is zero or a prime.

`CharacterDegreesPGroup(G)`

Returns the degrees of the ordinary irreducible characters of the finite p-group G. The sequence returned has form $[c_0, c_1, c_2 \ldots]$, where c_i is the number of characters of degree p^i. Slattery's counting algorithm is used.

`RationalCharacterTable(G)`

Returns a sequence of minimal rational characters of G. These are the sums of the Galois orbits on the character table of G.

Example H91E1

We use the `CharacterTable` function and print the resulting table. Character tables have a special print format.

```
> G := Alt(5);
> CT := CharacterTable(G);
> CT;

Character Table of Group G
--------------------------

---------------------------
Class |   1  2  3    4    5
Size  |   1 15 20   12   12
Order |   1  2  3    5    5
---------------------------
p  =  2   1  1  3    5    4
p  =  3   1  2  1    5    4
p  =  5   1  2  3    1    1
---------------------------
X.1   +   1  1  1    1    1
X.2   +   3 -1  0   Z1 Z1#2
X.3   +   3 -1  0 Z1#2   Z1
X.4   +   4  0  1   -1   -1
X.5   +   5  1 -1    0    0

Explanation of Character Value Symbols
--------------------------------------

# denotes algebraic conjugation, that is,
```

```
#k indicates replacing the root of unity w by w^k

Z1     = (CyclotomicField(5: Sparse := true)) ! [
RationalField() | 1, 0, 1, 1 ]

> CT[2];
( 3, -1, 0, zeta(5)_5^3 + zeta(5)_5^2 + 1, -zeta(5)_5^3 -
  zeta(5)_5^2 )
> CT[2]:Minimal;
( 3, -1, 0, Z1, Z1#2 )
```

The character table is represented as a sequence of characters. Non-rational values in a character table are printed symbolically. This same printing can be forced on an individual character by using `Minimal` printing.

Example H91E2

The `CharacterTable` algorithm can handle quite large groups. We illustrate this by computing the character table of the almost simple group $P\Gamma U_5(4)$.

```
> G := PGammaU(5,4);
> G;
Permutation group G acting on a set of cardinality 17425
Order = 2^22 * 3^2 * 5^5 * 13 * 17 * 41
> time CT := CharacterTable(G);
Time: 205.150
> #CT;
160
> Degree(CT[160]);
5227500
```

91.2 Character Ring Operations

91.2.1 Related Structures

`Parent(R)` `Category(R)`

`Group(R)`

Given the ring R of class functions on a finite group G, return G.

`Centre(x)`

The centre of the character x of G, i.e. the subgroup of G consisting of those classes C of G for which $|x(g)|$, g in C, is equal to the degree of x.

`CoefficientField(x)`

The (minimal) coefficient field $\mathbf{Q}_m$ of the class function x.

`Kernel(x)`

The kernel of the character x of G, i.e. the normal subgroup of G consisting of those elements g for which $x(g) = x(1)$.

91.3 Element Operations

91.3.1 Arithmetic

In the list of arithmetic operations below x and y denote class functions in the same ring, and a denotes a scalar, which is any element coercible into a cyclotomic field. Also, j denotes an integer.

`+ y` `- y`

`x + y` `x - y` `x * y`

`a * x` `x ^ j`

91.3.2 Predicates and Booleans

The following Boolean-valued functions are available. Note that with the exception of `in`, `notin`, `IsReal` and `IsFaithful`, these functions use the table of irreducible characters, which will be created if it is not yet available.

`x in y`

Returns `true` if the inner product of class functions x and y is non-zero, otherwise `false`. If x is irreducible and y is a character, this tests whether or not x is a constituent of y.

`x notin y`

Returns `true` if the inner product of class functions x and y is zero, otherwise `false`. If x is irreducible and y is a character, this tests whether or not x is not a constituent of y. Returns `true` if the character x is not a constituent of the character y, otherwise `false`.

`a in F` `a notin F`

`x eq y` `x ne y`

`IsCharacter(x)`

Returns `true` if the class function x is a character, otherwise `false`. A class function is a character if and only if all inner products with the irreducible characters are non-negative integers.

`IsGeneralizedCharacter(x)`

Returns `true` if the class function x is a generalized character, otherwise `false`. A class function is a generalized character if and only if all inner products with the irreducible characters are integers.

`IsIrreducible(x)`

Returns `true` if the character x is an irreducible character, otherwise `false`.

`IsLinear(x)`

Returns `true` if the character x is a linear character, otherwise `false`.

`IsFaithful(x)`

Returns `true` if the character x is faithful, i.e. has trivial kernel, otherwise `false`.

`IsReal(x)`

Returns `true` if the character x is a real character, i.e. takes real values on all of the classes of G, otherwise `false`.

`IsOne(x)` `IsMinusOne(x)` `IsZero(x)`

91.3.3 Accessing Class Functions

In this subsection T is a character table, and x is any class function. A character table is an enumerated sequence of characters that has a special print function attached. In particular, its entries can be accessed with the ordinary sequence indexing operations.

`T[i]`

Given the table T of ordinary characters of G, return the i-th character of G, where i is an integer in the range $[1...k]$.

`T[i][j]`

The value of the i-th irreducible character (from the character table T) on the j-th conjugacy class of G.

`#T`

Given a character table T (or any sequence of characters), return the number of entries.

`x(g)`
`g @ x`

The value of the class function x on the element g of G.

`x[i]`

The value of the class function x on the i-th conjugacy class of G.

`#x`

Given a class function x on G return its length (which equals the number of conjugacy classes of the group G).

91.3.4 Conjugation of Class Functions

`x ^ g`

Given a class function x on a normal subgroup N of the group G, and an element g of G, construct the conjugate class function x^g of x which is defined as follows: $x^g(n) = x(g^{-1}ng)$, for all n in N.

`x ^ H`

Given a class function x on a normal subgroup N of the group G, and a subgroup H of G, construct the sequence of conjugates of x under the action of the subgroup H. The action of an element of H on x is that defined in the previous function.

`GaloisConjugate(x, j)`

Let $\mathbf{Q}(x)$ be the subfield of $\mathbf{Q}(\zeta_m)$ generated by $\mathbf{Q}$ and the values of the G-character x. This function returns the Galois conjugate x^j of x under the action of the element of the Galois group $\mathrm{Gal}(\mathbf{Q}(x)/\mathbf{Q})$ determined by the integer j. The integer j must be coprime to m.

`GaloisOrbit(x)`

Let $\mathbf{Q}(x)$ be the subfield of $\mathbf{Q}(\zeta_m)$ generated by $\mathbf{Q}$ and the values of the G-character x. This function returns the sequence of Galois conjugates of x under the action of the Galois group $\mathrm{Gal}(\mathbf{Q}(x)/\mathbf{Q})$.

`ClassPowerCharacter(x, j)`

Given a class function x on the group G and a positive integer j, construct the class function x^j which is defined as follows: $x^j(g) = x(g^j)$.

91.3.5 Functions Returning a Scalar

`Degree(x)`

The degree of the class function x, i.e. the value of x on the identity element of G.

`InnerProduct(x, y)`

The inner product of the class functions x and y, where x and y are class functions belonging to the same character ring.

`Order(x)`

Given a linear character of the group G, determine the order of x as an element of the group of linear characters of G.

`Norm(x)`

Norm of the class function x (which is the inner product with itself).

`Schur(x, k)`

`Indicator(x)`

Given class function x and a positive integer k, return the generalised Frobenius–Schur indicator which is defined as follows: Suppose g is some element of G, and set $T_k(g) = |\{h \in G | h^k = g\}|$. The value of `Schur(x, k)` is the coefficient a_x in the expression $T_k = \sum_{x \in \mathrm{Irr}(G)} a_x x$.

The call `Indicator(x)` is equivalent to `Schur(x,2)`.

`StructureConstant(G, i, j, k)`

The structure constant $a_{i,j,k}$ for the centre of the group algebra of the group G. If K_i is the formal sum of the elements of the i-th conjugacy class, $a_{i,j,k}$ is defined by the equation $K_i * K_j = \sum_k a_{i,j,k} * K_k$.

91.3.6 The Schur Index

MAGMA incorporates functions for computing the Schur index of an ordinary irreducible character over various number fields and local fields. The routines below are all based on the function `SchurIndices(x)`, which computes the Schur Indices of the given character over all the completions of the rationals.

The algorithm is based on calculations with characters, groups and fields, and does not compute representations.

The algorithm was devised by Gabi Nebe and Bill Unger, with code written by Bill Unger. The extension to compute a Schur index over a number field was written by Claus Fieker.

`SchurIndex(x)`

`SchurIndex(x, F)`

The Schur index of the character x over the given field. When no field is given, the Schur index over the rationals is returned. The character x must be a complex irreducible character. The field F must be an absolute number field.

`SchurIndices(x)`

`SchurIndices(x, F)`

`SchurIndices(C, s, F)`

Compute the Schur indices of the character x over the completions of the given field. The character x must be a complex irreducible character. The field F must be an absolute number field. When no field is specified the rational field is assumed. The last form takes the character field, C, and the output from `SchurIndices(x)`, s, as well as a number field. This is sufficient to compute the Schur indices over the number field without repeating group and character computations when a number of fields are being considered for one character.

The return value is a sequence of pairs. Each pair gives a completion at which the Schur index is not 1, followed by the Schur index over the complete field. For the rational field, a completion is specified by an integer. The integer zero specifies the archimedean completion (the real numbers), while a prime p specifies the p-adic field $\mathbf{Q}_p$. When a number field is given, the completions are specified by a place of the field, an object of type `PlcNumElt`.

If the character has Schur index 1 over the given field the return value will be an empty sequence. Otherwise the Schur index over the given field is the least common multiple of the second entries of the tuples returned.

Example H91E3

We first look at the faithful irreducible character of the Dihedral group of order 8. It has Schur index 1.

```
> T := CharacterTable(SmallGroup(8, 3));
> T[5];
( 2, -2, 0, 0, 0 )
> SchurIndex(T[5]);
1
> SchurIndices(T[5]);
[]
```

The corresponding character of the quaternion group of order 8 has non-trivial Schur index.

```
> T := CharacterTable(SmallGroup(8, 4));
> T[5];
( 2, -2, 0, 0, 0 )
> SchurIndex(T[5]);
2
> SchurIndices(T[5]);
[ <0, 2>, <2, 2> ]
```

The Schur index is 2 over the real numbers and Q_2. For all odd primes p, the Schur index over Q_p is 1. We look at the Schur index of this character over some number fields. First we look at some cyclotomic fields.

```
> [SchurIndex(T[5], CyclotomicField(n)):n in [3..20]];
[ 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 1 ]
> SchurIndices(T[5], CyclotomicField(7));
[ <Place at Prime Ideal
Two element generators:
  [2, 0, 0, 0, 0, 0]
  [1, 1, 0, 1, 0, 0], 2>, <Place at Prime Ideal
Two element generators:
  [2, 0, 0, 0, 0, 0]
```

```
  [1, 0, 1, 1, 0, 0], 2> ]
```

The cyclotomic field of order 7 gives Schur index 2. An archimedean completion of this field is necessarily the field of complex numbers, hence no infinite places give Schur index greater than 1. There are now two 2-adic completions which give Schur index 2.

```
> P<t> := PolynomialRing(Rationals());
> F := ext<Rationals()|t^3-2>;
> SchurIndex(T[5], F);
2
> SchurIndices(T[5], F);
[ <1st place at infinity, 2>, <Place at Prime Ideal
Two element generators:
  [2, 0, 0]
  [0, 1, 0], 2> ]
```

For the non-normal field F, one archimedean completion is real, the other complex. Thus the real field features in the output of `SchurIndices`, along with the 2-adic completion.

Example H91E4

We will use a general construction for a character with given Schur index over the rationals to construct a character with Schur index 6. Given an integer $n \geq 1$, we select a prime p such that $p = kn + 1$ where k and n are coprime. We take an integer a such that a has order n modulo p. We then consider the metacyclic group

$$G = \langle < x, y | x^{n^2}, y^p, y^x = y^a \rangle.$$

The order of G is n^2p. The subgroup of G generated by x^n and y is cyclic, normal and self-centralizing in G with order np. If λ is any faithful linear character of this subgroup, then λ^G is an irreducible character of G with Schur index n over the rational field. The correctness of this construction is proved in Lemma 3 of [Tur01].
We construct G in two stages. First as a finitely presented group as described above. Then we convert to a PC-presentation for further computations. We take $n = 6$, $p = 7$ and $a = 3$.

```
> G1 := Group<x,y|x^36, y^7, y^x = y^3>;
> G, f := SolubleQuotient(G1, 36*7);
> x := f(G1.1); y := f(G1.2);
> C := sub<G|x^6,y>;
> IsCyclic(C);
true
> IsNormal(G, C);
true
> Centralizer(G,C) eq C;
true
> exists(l){l:l in LinearCharacters(C)|IsFaithful(l)};
true;
> c := Induction(l, G);
> IsIrreducible(c);
true
> Degree(c);
```

```
6
> CharacterField(c);
Cyclotomic Field of order 3 and degree 2 in sparse
representation
> SchurIndex(c);
6
```

The construction of the previous example is used in the following two intrinsics.

`SchurIndexGroup(n: parameters)`

`Prime` RngIntElt *Default :*

Return a group having a faithful character with Schur index n over the rational field. The construction used is as in the previous example. The parameter `Prime` may be used to supply the prime p. (The necessary conditions on p are not checked. If these conditions are not met, an error is possible.) If `Prime` is not set, then the least prime meeting the conditions is used.

`CharacterWithSchurIndex(n: parameters)`

`Prime` RngIntElt *Default :*

Return a character with Schur index n over the rational field. The construction used is as in the previous example. The second return value is the group of the character, equal to `SchurIndexGroup(n)`. The parameter `Prime` is as for `SchurIndexGroup`.

91.3.7 Attribute

`AssertAttribute(x, "IsCharacter", b)`

Procedure that, given a class function x and a Boolean value b, stores with x the information that the value of the predicate `IsCharacter(x)` equals b.

91.3.8 Induction, Restriction and Lifting

`Induction(x, G)`

Given a class function x on the subgroup H of the group G, construct the class function obtained by induction of x to G. Note that if x is a character of H, then `Induction(x, G)` will return a character of G.

The `Induction` command may also be used to induce a sequence of characters of a particular subgroup (such as a character table) to the given supergroup.

`LiftCharacter(c, f, G)`

Given a class function c of the quotient group Q of the group G and the natural homomorphism $f : G \to Q$, lift c to a class function of G.

`LiftCharacters(T, f, G)`

Given a sequence T of class functions of the quotient group Q of the group G and the natural homomorphism $f : G \to Q$, lift T to a sequence of corresponding class functions of G. Since a character table is just a sequence of class functions which is printed in a special way, this intrinsic may also be applied to it.

`Restriction(x, H)`

Given a class function x on the group G and a subgroup H of G, construct the restriction of x to H (a class function). Note that if x is a character of G, then `Restriction(x, H)` will return a character of H.

91.3.9 Symmetrization

See [Mur58] or [Fra82] for more details.

`Symmetrization(x, p)`

Given a class function x and a partition p of n ($2 \leq n \leq 6$), this function returns the symmetrized character with respect to p; the partition must be specified in the form of a sequence of positive integers (adding up to n).

`OrthogonalComponent(x, p)`

Given a class function x and a partition p of n ($2 \leq n \leq 6$), this function returns the Murnaghan component of the orthogonal symmetrization of x with respect to p; the partition must be specified in the form of a sequence of positive integers (adding up to n). Here x may not be a linear character, and its Frobenius–Schur indicator must be 1.

`SymplecticComponent(x, p)`

Given a class function x and a partition p of n ($2 \leq n \leq 6$), this function returns the Murnaghan component of the symplectic symmetrization of x with respect to p; the partition must be specified in the form of a sequence of positive integers (adding up to n). Here x may not be a linear character, and its Frobenius–Schur indicator must be -1.

`SymmetricComponents(x, n)`

Given a class function x and an integer n, return the set of symmetrizations of x by all partitions of m with $2 < m \leq n \leq 5$.

`OrthogonalComponents(x, n)`

Given a class function x, return the set of Murnaghan components for orthogonal symmetrizations of x by all partitions of m with $2 < m \leq n \leq 6$. Here x may not be a linear character, and its Frobenius–Schur indicator must be 1.

`SymplecticComponents(x, n)`

Given a class function x, return the set of Murnaghan components for symplectic symmetrizations of x by all partitions of m with $2 < m \leq n \leq 5$. Here x may not be a linear character, and its Frobenius–Schur indicator must be -1.

91.3.10 Permutation Character

`PermutationCharacter(G)`

Given group G represented as a permutation group, construct the character of G afforded by the defining permutation representation of G.

`PermutationCharacter(G, H)`

Given a group G and some subgroup H of G, construct the character of G afforded by the permutation representation of G given by the action of G on the right cosets of H in G.

91.3.11 Composition and Decomposition

`Composition(T, q)`

Given a sequence or table of characters T for the group G and a sequence q of k elements of $\mathbf{Q}(\zeta_m)$ (possibly $\mathbf{Q}$), create the class function $q_1 * T_1 + \cdots + q_k * T_k$, where T_i is the i-th character in T.

`Decomposition(T, y)`

Given a sequence or table of class functions T for G of length l and a class function y on G, attempt to express y as a linear combination of the elements of T.

The function returns two values: a sequence $q = [q_1, \ldots, q_l]$ of cyclotomic field elements and a class function z. For $1 \leq i \leq l$, the i-th term of q is defined to be the ratio of inner products $(y, T_i)/(T_i, T_i)$, where T_i is the i-th entry of T. The sequence q determines a class function $x = q_1 \cdot T_1 + \cdots + q_l \cdot T_l$ which will equal y if T is the complete table of irreducible characters. The difference $z = y - x$ is the second return value. If the entries in T are mutually orthogonal, then z is the zero class function if and only if y is a linear combination of the T_i.

91.3.12 Finding Irreducibles

A common approach to finding the irreducible characters of a group is to start with an irreducible character and generate new characters by applying `SymmetricComponents`, `OrthogonalComponents` or `SymplecticComponents`. Then, by examining norms and inner products, it is often possible to identify irreducible characters or at least characters with smaller norms. There are two MAGMA intrinsics available to help with this task.

`RemoveIrreducibles(I, C)`

Remove occurrences of the irreducible characters in the sequence I from the characters in the sequence C and look for characters of norm 1 among the reduced characters. Return a sequence of new irreducibles found and the sequence of reduced characters.

`ReduceCharacters(I, C)`

Make the norms of the characters in the sequence C smaller by computing the differences of appropriate pairs. Return a sequence of new irreducibles found and a sequence of reduced characters.

Example H91E5

We conclude this section with an example, showing how the above functions can be used to construct the character table for A_5 (compare Isaacs, p64), using only characters on subgroups.

```
> A := AlternatingGroup(GrpPerm, 5);
> R := CharacterRing(A);
```

The first character will be the principal character

```
> T1 := R ! 1;
> T1;
( 1, 1, 1, 1, 1 )
```

Next construct the permutation character

```
> pc := PermutationCharacter(A);
> T2 := pc - T1;
> InnerProduct(pc, T1), InnerProduct(T2, T2);
1 1
> T2;
( 4, 0, 1, -1, -1 )
```

It follows that pc - T1 is an irreducible character

```
> B := Stabilizer(A, 5);
> r := RootOfUnity(3, CyclotomicField(3));
> S := CharacterRing(B);
> lambda := S ! [1, 1, r, r^2 ];
> IsLinear(lambda);
true
```

This defines a linear character on a subgroup of index 5 in A

```
> T3 := Induction(lambda, A);
> InnerProduct(T3, T3);
1
> T3;
```

```
( 5, 1, -1, 0, 0 )
```

Finally we use characters on the cyclic subgroup of order 5:

```
> K := sub<A |  (1,2,3,4,5) >;
> Y := CharacterTable(K);
> Y;

Character Table of Group K
--------------------------

-------------------------------
Class |   1    2    3    4    5
Size  |   1    1    1    1    1
Order |   1    5    5    5    5
-------------------------------
p  =  5   1    1    1    1    1
-------------------------------
X.1   +   1    1    1    1    1
X.2   0   1   Z1 Z1#2 Z1#3 Z1#4
X.3   0   1 Z1#2 Z1#4   Z1 Z1#3
X.4   0   1 Z1#3   Z1 Z1#4 Z1#2
X.5   0   1 Z1#4 Z1#3 Z1#2   Z1

Explanation of Symbols:
-----------------------

# denotes algebraic conjugation, that is,
# k indicates replacing the root of unity w by w^k

Z1     = -1 - zeta_5 - zeta_5^2 - zeta_5^3

> mu := Induction(Y[2], A);
```

We subtract what we already know from mu and get a new irreducible. We use decomposition with respect to a sequence.

```
> _, T4 := Decomposition([T1, T2, T3], mu);
> InnerProduct(T4, T4);
1
> T4;
( 3, -1, 0, (1 + zeta_5^2 + zeta_5^3), (-zeta_5^2 - zeta_5^3) )
> T5 := GaloisConjugate(T4, 2);
> T5;
( 3, -1, 0, (-zeta_5^2 - zeta_5^3), (1 + zeta_5^2 + zeta_5^3) )
```

Compare this to the standard character table:

```
> CharacterTable(A);

Character Table of Group A
--------------------------

--------------------------
```

```
Class |   1  2  3    4    5
Size  |   1 15 20   12   12
Order |   1  2  3    5    5
---------------------------
p  =  2   1  1  3    5    4
p  =  3   1  2  1    5    4
p  =  5   1  2  3    1    1
---------------------------
X.1   +   1  1  1    1    1
X.2   +   3 -1  0   Z1 Z1#2
X.3   +   3 -1  0 Z1#2   Z1
X.4   +   4  0  1   -1   -1
X.5   +   5  1 -1    0    0

Explanation of Symbols:
-----------------------

#  denotes algebraic conjugation, that is,
# k indicates replacing the root of unity w by w^k

Z1     =(1 + zeta_5^2 + zeta_5^3)
```

91.3.13 Brauer Characters

MAGMA has some support for the calculation of Brauer characters. These functions are noted in this section. We anticipate considerable change to the functionality described here in the near future.

A Brauer character modulo p in MAGMA is represented as a class function (that is, element of a character ring) which is zero on p-singular group elements. In this format the standard character operations of addition, multiplication, induction and restriction all apply directly to Brauer characters as they do to other class functions.

Note that problems associated with choice of lifting from finite fields to complex roots of unity have not yet been dealt with.

`BrauerCharacter(x, p)`

The Brauer character modulo the prime p obtained by setting the value of x on p-singular elements to be zero.

`Blocks(T, p)`

When T is the full ordinary character table of a group, return the partition of T into p-blocks, where p is a given prime. The partition is returned as a sequence of sets of integers which give the blocks by the positions of the characters in T. The second return value is the corresponding sequence of defects of the blocks. The blocks are ordered first by decreasing defect, second by first character in the block.

Example H91E6

We give an example of the use of these Brauer character functions. We consider the 3-modular characters of the Higman-Sims simple group.

```
> load hs176;
> T := CharacterTable(G);
> Blocks(T,3);
[
  { 1, 2, 5, 10, 18, 19, 21, 23, 24 },
  { 3, 4, 6, 7, 11, 12, 14, 15, 20 },
  { 8, 13, 16 },
  { 9 },
  { 17 },
  { 22 }
]
[ 2, 2, 1, 0, 0, 0 ]
```

The characters $T[8], T[13], T[16]$ are the ordinary irreducible characters in a 3-block of defect one. In such a small block the two ordinary irreducibles of minimal degree will restrict to modular irreducibles.

```
> [Degree(T[i]): i in [8, 13, 16]];
[ 231, 825, 1056 ]
> BrauerCharacter(T[8], 3);
( 231, 7, -9, 0, 15, -1, -1, 6, 1, 1, 0, 0, 0, -1, -1, -1,
2, 1, 0, 0, 0, 0, 0, 0 )
> BrauerCharacter(T[13], 3);
( 825, 25, 9, 0, -15, 1, 1, 0, -5, 0, 0, 0, -1, 1, 1, 1, 0,
-1, 0, 0, 0, 0, 0, 0 )
> $1 + $2 eq BrauerCharacter(T[16], 3);
true
```

The projective indecomposable characters corresponding to these Brauer irreducible characters are as follows.

```
> T[8] + T[16];
( 1287, 39, -9, 0, 15, -1, -1, 12, -3, 2, 0, 0, -1, -1, -1,
-1, 4, 1, 0, 0, 0, 0, 0, 0 )
> T[13] + T[16];
( 1881, 57, 9, 0, -15, 1, 1, 6, -9, 1, 0, 0, -2, 1, 1, 1, 2,
-1, 0, 0, 0, 0, 0, 0 )
```

92 REPRESENTATIONS OF SYMMETRIC GROUPS

Chapter 92
REPRESENTATIONS OF SYMMETRIC GROUPS

92.1 Introduction

This chapter describes functions available in MAGMA for computations concerning the non modular representation theory of the symmetric group and the alternating group. It is possible to compute different matrix representations, complete character tables using special routines, single irreducible characters or the value of an irreducible character on an element of the group.

92.2 Representations of the Symmetric Group

For the symmetric group of degree n the irreducible representations can be indexed by partitions of weight n. For more information on partitions see Section 145.2.

92.2.1 Integral Representations

It is possible to define representing matrices of the symmetric group over the integers.

`SymmetricRepresentation(pa, pe)`

`Al` MONSTGELT *Default :* "*JamesKerber*"

Given a partition *pa* of weight n and a permutation *pe* in a symmetric group of degree n, return an irreducible representing matrix for *pe*, indexed by *pa*, over the integers. If `Al` is set to the default `"JamesKerber"` then the method described in [JK81] is used. If `Al` is set to `"Boerner"` the method described in the book of Boerner [Boe67] is used. If `Al` is set to `"Specht"` then the method used is a direct implementation of that used by Specht in his paper from 1935 [Spe35].

Example H92E1

We compute a representing matrix of a permutation using two different algorithms and check whether the results have the same character.

```
> a:=SymmetricRepresentation([3,2],Sym(5)!(3,4,5) : Al := "Boerner");a;
[ 0  0  1 -1  0]
[ 1  0  0 -1  0]
[ 0  1  0 -1  0]
[ 0  0  0 -1  1]
[ 0  0  0 -1  0]
> b:=SymmetricRepresentation([3,2],Sym(5)!(3,4,5) : Al := "Specht");b;
```

```
[ 0  1  0 -1  0]
[ 0  0  1  0 -1]
[ 1  0  0  0  0]
[ 0  0  0  0 -1]
[ 0  0  0  1 -1]
> IsSimilar(Matrix(Rationals(), a), Matrix(Rationals(), b));
true
```

The matrices are similar as they should be.

92.2.2 The Seminormal and Orthogonal Representations

The seminormal and orthogonal representations involve matrices which are not necessarily integral. The method MAGMA uses to construct these matrices is described in [JK81, Section 3.3];

`SymmetricRepresentationSeminormal(pa, pe)`

Given a partition *pa* of weight n and a permutation *pe* in a symmetric group of degree n, return the matrix of the seminormal representation for *pe*, indexed by *pa*, over the rationals.

`SymmetricRepresentationOrthogonal(pa, pe)`

Given a partition *pa* of weight n and a permutation *pe* in a symmetric group of degree n, return the matrix of the orthogonal representation for *pe*, indexed by *pa*. An orthogonal basis is used to compute the matrix which may have entries in a cyclotomic field.

Example H92E2

We compare the seminormal and orthogonal representations of a permutation and note that they are similar.

```
> g:=Sym(5)!(3,4,5);
> a:=SymmetricRepresentationSeminormal([3,2],g);a;
[-1/2    0 -3/4    0    0]
[   0  1/2    0  3/4    0]
[   1    0 -1/2    0    0]
[   0  1/3    0 -1/6  8/9]
[   0    1    0 -1/2 -1/3]
> b:=SymmetricRepresentationOrthogonal([3,2],g);b;
[-1/2 0 zeta(24)_8^2*zeta(24)_3 + 1/2*zeta(24)_8^2 0 0]
[0 1/2 0 -zeta(24)_8^2*zeta(24)_3 - 1/2*zeta(24)_8^2 0]
[-zeta(24)_8^2*zeta(24)_3 - 1/2*zeta(24)_8^2 0 -1/2 0 0]
[0 -1/3*zeta(24)_8^2*zeta(24)_3 - 1/6*zeta(24)_8^2 0
 -1/6 2/3*zeta(24)_8^3 - 2/3*zeta(24)_8]
[0 2/3*zeta(24)_8^3*zeta(24)_3 + 1/3*zeta(24)_8^3
+ 2/3*zeta(24)_8*zeta(24)_3 + 1/3*zeta(24)_8 0
```

```
    -1/3*zeta(24)_8^3 + 1/3*zeta(24)_8 -1/3]
> IsSimilar(a,b);
true
```

They should both be of finite order, 3.

```
> IsOne(a^Order(g));
true
> IsOne(b^Order(g));
true
>
```

92.3 Characters of the Symmetric Group

92.3.1 Single Values

The method used to compute the value of a character on a permutation is the recursion formula of Murnaghan and Nakayama [JK81, p. 60], except when computing the value of a character on the identity permutation a formula for the dimension of the representation indexed by a partition is used, [JK81, p. 56].

`SymmetricCharacterValue(pa, pe)`

Computes the value of the irreducible character of the symmetric group of degree n indexed by the partition pa of weight n on the permutation pe. When computing the value of the character on the identity permutation, i.e. the degree of the character, the dimension (hook) formula is used on the partition pa.

92.3.2 Irreducible Characters

`SymmetricCharacter(pa)`

Return the character of the representation of the symmetric group of degree n indexed by the partition pa where pa has weight n.

92.3.3 Character Table

`SymmetricCharacterTable(d)`

Return the character table of the symmetric group of degree d.

92.4 Representations of the Alternating Group

92.5 Characters of the Alternating Group

There is a special routine which computes the character table of the alternating group, as well as routines which compute values of alternating characters and the characters themselves. These routines make use of the fact that in most cases the irreducible characters of the symmetric group, which can be computed quickly, are also irreducible in the alternating group. So the irreducible characters of the alternating group may be indexed by partitions in the same way as those of the symmetric group. As the restriction of the irreducible character indexed by the partition λ is equal to the restriction of the character indexed by the conjugate partition, we only need to take one from each of these pairs of partitions to form a full set of irreducible characters. When a partition is conjugate to itself the character of the symmetric group indexed by that partition is no longer irreducible but is the sum of two irreducibles. This method is described in [JK81].

92.5.1 Single Values

`AlternatingCharacterValue(pa, pe)`

Return the value of the character of the alternating group of degree n indexed by the partition pa of weight n on the permutation pe. The partition pa and its conjugate should be distinct.

`AlternatingCharacterValue(pa, i, pe)`

Return the value of the ith character of the alternating group of degree n indexed by the self conjugate partition pa of weight n on the permutation pe. Since there are two possible irreducible characters indexed by such partitions i must be either 1 or 2.

92.5.2 Irreducible Characters

`AlternatingCharacter(pa)`

Return the character of the alternating group of degree n indexed by the partition pa of weight n. The partition pa and its conjugate should be distinct.

`AlternatingCharacter(pa, i)`

Return the ith character of the alternating group of degree n indexed by the self conjugate partition pa of weight n. Since there are two possible irreducible characters indexed by such partitions i must be either 1 or 2.

92.5.3 Character Table

`AlternatingCharacterTable(d)`

Returns the character table of the alternating group of degree d.

93 MOD P GALOIS REPRESENTATIONS

Chapter 93
MOD P GALOIS REPRESENTATIONS

93.1 Introduction

This package provides tools to work with φ-modules over $k((u))$ where k is a finite field, and representations of the absolute Galois group of $k((u))$ with coefficients in a finite field. The main functionality of the package computes the semisimplification of a given φ-module, and the semisimplification of the Galois representation that is naturally attached to it. In particular, the slopes of the φ-module, corresponding to the tame inertia weights of the Galois representation, can be computed using this package.

93.1.1 Motivation

Let K be a p-adic field and let G_K be the absolute Galois group of K. Representations of this group naturally arise from geometry, namely from the p-adic étale cohomology of a scheme over K.

The study of these representations is a central topic in arithmetic, and a motivation for creating this package is the following: let V be a $\mathbf{Q}_p$-representation of G_K, *i.e.* a $\mathbf{Q}_p$-vector space endowed with a continuous, linear action of G_K. Now let $T \subset V$ be any $\mathbf{Z}_p$-lattice stable under the action of G_K. There always exists such a lattice. Moreover, the quotient T/pT has a natural structure of $\mathbf{F}_p$-representation of G_K. This representation depends on the choice of T, but its semisimplification $(T/pT)^{ss}$ does not, according to the Brauer-Nesbitt theorem. Recall the semisimplification of a representation is the direct sum of the composition factors appearing in any Jordan-Holder sequence of this representation. Therefore, it is an interesting question to determine properties of $(T/pT)^{ss}$ in terms of V. Although the Fontaine-Laffaille theory completely addresses this question for some V, the general case remains an open question. Some computations concerning this problem can be performed in Magma using this package.

93.1.2 Definitions

Let k be a finite field of characteristic p, and let $K = k((u))$ be the field of Laurent series with coefficients in k. Let $s \geq 0$ and $b \geq 2$ be integers. We define a "Frobenius" map σ on K by the following formula:

$$\sigma\left(\sum_{i\in\mathbf{Z}} a_i u^i\right) = \sum_{i\in\mathbf{Z}} a_i^{p^s} u^{bi}.$$

A φ-module over K is the data of a finite-dimensional K-vector space D, endowed with an endomorphism $\varphi : D \to D$ that is semilinear with respect to σ. This means that for all $\lambda \in K$, $x \in D$, we have the identity $\varphi(\lambda x) = \sigma(\lambda)\varphi(x)$.

A φ-module is said to be étale if the map φ is injective. A φ-module can be described by the matrix representing the action of φ on some basis of D, and it is étale if and only if this matrix is invertible.

93.1.3 Classification of φ-modules

Some φ-modules play a crucial role in the theory because they are the simple objects in the category of étale φ-modules over the maximal unramified extension K^{ur} of K.

Let $d \geq 1$, $h \in \mathbf{Z}$, $\lambda \in \bar{k}$. We define the φ-module $D(d, s, \lambda)$ as the φ-module of dimension d whose matrix in some basis is the companion matrix of the polynomial $T^d - u^h$. We also write $D(d, h) = D(d, h, 1)$. Note that in general there are several ways to extend the action of σ on K^{ur}, but we may only distinguish the cases where σ acts as identity on k, and the case where is does not. We say that a couple (d, h) is reduced if there is no divisor d' of d (except d) such that $\frac{b^{d'}-1}{b^d-1}$ is a divisor of h. The main classification results are the following:

If $\sigma \neq id$, the simple objects of the category of étale φ-modules over K^{ur} are the $D(d, h)$ for (d, h) reduced, and if $\sigma = id$, the simple objects of the category of étale φ-modules over K^{ur} are the $D(d, h, \lambda)$ for (d, h) reduced.

By definition, the slope of a simple φ-module isomorphic to $D(d, h, \lambda)$ is the rational number $\frac{h}{b^d-1}$, up to the equivalence relation "$x \sim y \Leftrightarrow \exists$m,n$\in$ N such that $b^m x - b^n y \in \mathbf{Z}$". With this equivalence relation, the definition does not depend on the choice of (d, h).

If D is a φ-module over K, the slopes of D are the collection of the slopes of the composition factors of $K^{ur} \otimes_K D$ (this notion does not depend on how σ is extended to K^{ur}). Note that even though the algorithms that we present can give decompositions over K, for most practical uses the knowledge of the slopes should be sufficient.

93.1.4 Connection with Galois Representations

Let us explain the link between Galois representations and φ-modules over K. In this section, we assume that σ is the classical Frobenius $x \mapsto x^p$. Let K^{sep} be a separable closure of K and let $G_K = Gal(K^{sep}/K)$ be the absolute Galois group of K.

A theorem of Katz states that there is an equivalence of categories between the étale φ-modules over K and the $\mathbf{F}_p$-representations of G_K.

Under this equivalence of categories, the φ-module $D(d, h)$ corresponds to the "fundamental character of level d" to the power h, ω_d^h, seen as a $\mathbf{F}_p$-representation. The figures of h in base p are called the tame inertia weights of the representation, because they describe the action of the tame inertia group on the representation. These weights can be recovered from the slope of the φ-module. It is worth noting that if F is a p-adic field whose residue field is k, and F_∞ is the extension of F generated by a compatible sequence of p^n-th roots of the uniformizer for all n, then G_{F_∞} is isomorphic to G_K. Moreover, the tame inertia weights of a $\mathbf{F}_p$-representation of G_F are the same as the tame inertia weights of its restriction to G_{F_∞}, seen as a representation of G_K. Hence, working with φ-modules will enable us to study representations of p-adic Galois groups.

93.2 φ-modules and Galois Representations in Magma

Let us now give an overview of the functionalities of the package.

93.2.1 φ-modules

93.2.1.1 Category

In Magma, φ-modules have type `PhiMod`. Elements of φ-modules have type `PhiModElt`.

93.2.1.2 Creation functions

`PhiModule(M)`

F SeqEnum *Default :* $[1, p]$

Create the φ-module whose matrix is given by M in some basis. The optional argument F describes the action of the Frobenius on coefficients: if $F = [s, b]$ then φ acts by $a \mapsto a^{p^s}$ on the residue field and maps the variable u to u^b. The default value is $[1, p]$ where p is the characteristic of the base field, corresponding to the absolute Frobenius.

`ElementaryPhiModule(S,d,h)`

F SeqEnum *Default :* $[1, p]$

Create the φ-module $D(d, s)$ whose matrix is the companion matrix of $T^d - u^s$.

`PhiModuleElement(x,D)`

Create the element of the φ-module D whose coordinates are given by the vector x.

93.2.1.3 Attributes of φ-modules

`Dimension(D)`

The dimension of a φ-module.

`CoefficientRing(D)`

The coefficient ring of a φ-module.

`FrobeniusMatrix(D)`

Return the matrix of the action of φ on D in the current basis.

93.2.1.4 Basic operations and properties of φ-modules

`IsEtale(D)`

Return `true` if the action of φ on D is injective. This is only possible up to the precision of the coefficient ring of D.

`ChangePrecision(~D, prec)`

Change the precision of the coefficient ring of D to `prec`.

`DirectSum(D1, D2)`

The direct sum of two φ-modules. The coefficient rings and Frobenius action on the coefficients must be the same.

`BaseChange(~D, P)`

Change the basis of D. The base change matrix is P, meaning that if G is the current matrix of φ, the new matrix will be $P^{-1}G\varphi(P)$.

`RandomBaseChange(~D)`

Randomly change the basis of D.

`Phi(D, x)`

Compute the image of $x \in D$ under the action of φ.

93.2.1.5 Reduction of φ-modules and Galois Representations

`SemisimpleDecomposition(D)`

Compute a Jordan-Holder sequence for the φ-module D. The result G, P, sl, pol is as follows: G is the matrix of φ in a basis where it is block upper triangular, with diagonal blocks corresponding to simple φ-modules. The matrix P gives the corresponding basis. The list sl is the list of the slopes of D, and the list pol is a list of polynomials. The isomorphism class of a simple block of G is determined by the corresponding slope and polynomial.

`Slopes(D)`

Compute the list of slopes of D (with multiplicities).

`SSGaloisRepresentation(D)`

Compute the semisimplification of the Galois representation corresponding to D.

93.2.2 Semisimple Galois Representations

This part is dedicated to the study of representations of absolute Galois groups of fields of the form $k((u))$ with k finite, and with coefficients in finite fields. The implementation is for semisimple representations, and these are described by their tame inertia weights and polynomials giving the action of the Frobenius on the unramified part.

93.2.2.1 Category

In Magma, semisimple Galois representations have type `SSGalRep`.

93.2.2.2 Creation functions

`SSGaloisRepresentation(E,K,w,P)`

Create the semisimple representation of the absolute Galois group of K with coefficients in E, tame inertia weights given by w, and action of the Frobenius described by the elements of the list P.

93.2.2.3 Basic operations

`CoefficientRing(V)`

The coefficient ring.

`FixedField(V)`

The fixed field of the absolute Galois group of which V is a representation.

`Weights(V)`

The tame inertia weights of V.

93.2.2.4 Representation associated to a φ-module

`SSGaloisRepresentation(D)`

If D is a φ-module over a field K of Laurent series this returns the semisimplification of the representation associated to D.

93.3 Examples

Example H93E1

We create two φ-modules D_1, D_2, build their direct sum, and compute its slopes and corresponding representation.

```
> k<e9> := GF(3,2);
> S<u> := LaurentSeriesRing(k,20);
> D1 := ElementaryPhiModule(S,3,2);
> D1;
Phi-module of dimension 3 over Laurent series field in u over GF(3^2)
with fixed relative precision 20 with matrix
[ O(u^20)         O(u^20)        u^2 + O(u^20)]
[ 1 + O(u^20)     O(u^20)             O(u^20) ]
[ O(u^20)        1 + O(u^20)          O(u^20) ] and Frobenius [1,3]
> M := Matrix(S,2,2,[0,k.1*u,1,0]);
> D2 := PhiModule(M);
> D2;
Phi-module of dimension 2 over Laurent series field in u over GF(3^2)
with fixed relative precision 20 with matrix
[ O(u^20)       e9*u^2 + O(u^20)]
[ 1 + O(u^20)            O(u^20) ] and Frobenius [1,3]
> D := DirectSum(D1,D2);
> Slopes(D);
[
  [2, 1],
  [3, 2]
]
> SSGaloisRepresentation(D);
```

```
Semisimple representation of the absolute Galois group of
Laurent series field in u over GF(3^2) with fixed relative
precision 20 with coefficients in Finite field of size 3 and
components [

PART XIII
LIE THEORY

94 INTRODUCTION TO LIE THEORY

Chapter 94
INTRODUCTION TO LIE THEORY

A number of structures from Lie theory and the theory of Coxeter groups can be handled by Magma. Specifically, facilities are provided for:

1. Coxeter matrices, Coxeter graphs, Cartan matrices, Dynkin diagrams, and Cartan's naming system for Coxeter groups;
2. Finite root systems and finite root data;
3. Coxeter groups in three different formats: as finitely presented groups, as permutation groups, and as reflection groups;
4. Complex reflection groups;
4. Lie algebras, given as structure constant algebras, matrix algebras, or finitely generated algebras;
5. Groups of Lie type (connected reductive algebraic groups);
5. Representations of Lie algebras and groups of Lie type;
6. Universal enveloping algebras and Quantum groups.

94.1 Descriptions of Coxeter Groups

A *Coxeter system* is a group G with finite generating set $S = \{s_1, \ldots, s_n\}$, defined by the power relations $s_i^2 = 1$ for $i = 1, \ldots, n$ and braid relations

$$s_i s_j s_i \cdots = s_j s_i s_j \cdots$$

for $i, j = 1, \ldots, n$ with $i < j$, where each side of this relation has length $m_{ij} \geq 2$. Although traditionally $m_{ij} = \infty$ signifies that the corresponding relation is omitted, for technical reasons, we use $m_{ij} = 0$ instead. Set $m_{ji} = m_{ij}$ and $m_{ii} = 1$. The group G is called a *Coxeter group* and S is called the set of *Coxeter generators*. Since every group in Magma has a preferred generating set, no distinction is made between a Coxeter system and its Coxeter group.

Due to the importance and ubiquity of Coxeter groups, a number of different ways of describing these groups and their reflections have been developed. Functions for manipulating these descriptions are described in Chapter 95.

Coxeter groups are usually described by a *Coxeter matrix* $M = (m_{ij})_{i,j=1}^n$, or by a *Coxeter graph* with vertices $1, \ldots, n$ and an edge connecting i and j labeled by m_{ij} whenever $m_{ij} \geq 3$.

Coxeter systems are mainly important because they provide presentations for the real reflection groups. A *Cartan matrix* describes a particular reflection representation of a

Coxeter group. In certain cases, such a representation can be described by an integer-labelled digraph, called the *Dynkin digraph* (this is equivalent to a *Dynkin diagram*, but we have modified the definition for technical reasons).

For finite and affine Coxeter groups, the naming system due to Cartan is also used. Hyperbolic Coxeter groups of degree larger than 3 are numbered.

94.2 Root Systems and Root Data

A (real) reflection is an automorphism of a real vector space that acts as negation on a one-dimensional subspace while fixing a hyperplane pointwise. The subspace is described by a vector called the *root*, while the hyperplane is described as the kernel of an element of the dual space called the *coroot*.

A root system is a collection of root/coroot pairs that is closed under the action of the corresponding reflections. Only finite root systems are supported at the present time. A root system gives a much more detailed description of a reflection representation of a finite Coxeter group.

Root systems are used to classify the *semisimple Lie algebras*. The closely related concept of a root datum is used to classify the *groups of Lie type*.

This is described in Chapters 96 and 97.

94.3 Coxeter and Reflection Groups

Three different methods are provided for computing with a Coxeter group: the Coxeter presentation, the permutation representation on roots, or a reflection representation.

For most purposes, the presentation will be the most useful of these descriptions. The standard normal form is used for elements (the lexicographically least word of minimal length). Robert Howlett has implemented his highly efficient method for normalising and multiplying elements, based on ideas from [BH93].

If the Coxeter group is finite, it is often better to use the permutation representation. Note that elements are represented as permutations on the set of roots. This is not the minimal degree representation, but is more useful in many cases.

Finally, Coxeter groups can be represented as a reflection group over the reals (in practice over a number field, since the reals are not infinite precision). Although functions are provided for creating reflection groups over an arbitrary field, fewer facilities are available for such groups. In addition, functions are provided to construct all the finite *complex* reflection groups.

Efficient functions are provided for converting between these three forms of Coxeter group.

This is described in Chapters 98 and 99.

94.4 Lie Algebras and Groups of Lie Type

Lie algebras can be constructed in three different ways in MAGMA: as structure constant algebras, as Lie matrix algebras, or as finitely presented algebras. Most of our functionality is for algebras of finite dimension over a field. Algorithms designed and implemented by de Graaf [dG00] are available for determining the structure of a Lie algebra. In particular, if the algebra is reductive, its root system and its highest-weight representations can be determined.

We provide functionality for computing with groups of Lie type (i.e. reductive algebraic groups and their split (untwisted) groups, given by the Steinberg presentation. A canonical form for words in this group, and algorithms for computing with these words are given in [CMT04, CHM08]. Twisted groups are given by a modified version of this presentation using Galois cohomology [Hal05]. Efficient algorithms have been implemented for arithmetic with the Steinberg presentation and for converting between this presentation and matrix representations over the base field. Note that these presentations are not in the category `GrpFP` since the generators are parametrised by field elements and so the groups involved are not necessarily finitely generated.

This is described in Chapter 100.

94.5 Highest Weight Representations

The representations of Lie algebras and connected reductive Lie groups are classified by *highest weights*. In addition to being able to construct these representations [dG01], we can compute the combinatorics of their weights. This includes all the functionality of the LiE system [vLCL92]. This is described in Chapter 104.

94.6 Universal Enveloping Algebras and Quantum Groups

Given a semisimple Lie algebra over a field of characteristic zero, we can construct an integral basis for its universal enveloping algebra. Functionality for computing in these algebras is described in Section 100.17. Moreover, we provide functionality for computing in their quantised versions, which are called quantum groups. This is described in Chapter 102.

95 COXETER SYSTEMS

Chapter 95
COXETER SYSTEMS

95.1 Introduction

The functions in this chapter handle basic descriptions of Coxeter systems. A *Coxeter system* is a group G with finite generating set $S = \{s_1, \ldots, s_n\}$, defined by relations $s_i^2 = 1$ for $i = 1, \ldots, n$ and

$$s_i s_j s_i \cdots = s_j s_i s_j \cdots$$

for $i, j = 1, \ldots, n$ with $i < j$, where each side of this relation has length $m_{ij} \geq 2$. Traditionally, $m_{ij} = \infty$ signifies that the corresponding relation is omitted but for technical reasons $m_{ij} = 0$ is used in MAGMA instead. The group G is called a *Coxeter group* and S is called the set of *Coxeter generators*. Since every group in MAGMA has a preferred generating set, no distinction is made between a Coxeter system and its Coxeter group. See [Bou68] for more details on the theory of Coxeter groups.

The *rank* of the Coxeter system is $n = |S|$. A Coxeter system is said to be *reducible* if there is a proper subset I of $\{1, \ldots, n\}$ such that $m_{ij} = 2$ or $m_{ji} = 2$ whenever $i \in I$ and $j \notin I$. In this case, G is an (internal) direct product of the Coxeter subgroups $W_I = \langle s_i \mid i \in I \rangle$ and $W_{I^c} = \langle s_i \mid i \notin I \rangle$. Note that an *irreducible* Coxeter group may still be a nontrivial direct product of abstract subgroups (for example, $W(G_2) \cong S_2 \times S_3$). Two Coxeter groups are *Coxeter isomorphic* if there is a group isomorphism between them which takes Coxeter generators to Coxeter generators. In other words, the two groups are the same modulo renumbering of the generators.

Coxeter groups and their representations as reflection groups have a number of useful descriptions. In this chapter, Coxeter matrices, Coxeter graphs, Cartan matrices, and Dynkin digraphs will be discussed. The classification of finite and affine Coxeter groups provides a naming system for these groups. In Chapters 96 and 97, finite root systems and root data, which provide a more detailed description of finite Coxeter groups, are discussed. Coxeter groups themselves are discussed in Chapter 98; reflection representations of Coxeter groups are discussed in Chapter 99.

95.2 Coxeter Matrices

A Coxeter system is defined by the numbers $m_{ij} \in \{2, 3, \ldots, \infty\}$ for $i, j = 1, \ldots n$ and $i < j$, as in the previous section. Setting $m_{ji} = m_{ij}$ and $m_{ii} = 1$, yields a matrix $M = (m_{ij})_{i,j=1}^n$ that is called the *Coxeter matrix*.

Since ∞ is not an integer in MAGMA, it will be represented by 0 in Coxeter matrices.

`IsCoxeterMatrix(M)`

Returns `true` if, and only if, the matrix M is the Coxeter matrix of some Coxeter group.

`CoxeterMatrix(G)`

`CoxeterMatrix(C)`

`CoxeterMatrix(D)`

The Coxeter matrix corresponding to a Coxeter graph G, Cartan matrix C, or Dynkin digraph D.

Example H95E1

```
> M := SymmetricMatrix([1, 3,1, 2,3,1]);
> M;
[1 3 2]
[3 1 3]
[2 3 1]
> IsCoxeterMatrix(M);
true
```

`IsCoxeterIsomorphic(M1, M2)`

Returns `true` if, and only if, the Coxeter matrices M_1 and M_2 give rise to Coxeter isomorphic groups. If so, a sequence giving the permutation of the underlying basis which takes M_1 to M_2 is also returned.

`CoxeterGroupOrder(M)`

`CoxeterGroupFactoredOrder(M)`

The (factored) order of the Coxeter group with Coxeter matrix M.

Example H95E2

```
> M1 := SymmetricMatrix([1, 3,1, 2,3,1]);
> M2 := SymmetricMatrix([1, 3,1, 3,2,1]);
> IsCoxeterIsomorphic(M1, M2);
true [ 2, 1, 3 ]
>
> CoxeterGroupOrder(M1);
24
```

`IsCoxeterIrreducible(M)`

Returns `true` if, and only if, the matrix M is the Coxeter matrix of an irreducible Coxeter system. If the Coxeter matrix is reducible, this function also returns a nontrivial subset I of $\{1, \ldots, n\}$ such that $m_{ij} = 2$ whenever $i \in I$, $j \notin I$.

`IsSimplyLaced(M)`

Returns `true` if, and only if, the Coxeter matrix M is simply laced, i.e. all its entries are 1, 2, or 3.

Example H95E3

```
> M := SymmetricMatrix([1, 3,1, 2,3,1]);
> IsCoxeterIrreducible(M);
true
> M := SymmetricMatrix([1, 2,1, 2,3,1]);
> IsCoxeterIrreducible(M);
false { 1 }
```

95.3 Coxeter Graphs

A *Coxeter graph* is an undirected labelled graph describing a Coxeter system. Suppose a Coxeter system has Coxeter matrix $M = (m_{ij})_{i,j=1}^{n}$. Then the Coxeter graph has vertices $1, \ldots, n$; whenever $m_{ij} > 2$ there is an edge connecting i and j labeled by the value of m_{ij}. When $m_{ij} = 3$, the label is usually omitted.

Since ∞ is not an integer, it will be represented by 0 in our Coxeter graphs. Clearly a Coxeter graph must be standard, i.e. its vertices must be the integers $1, 2, \ldots, n$ for some n. A Coxeter system is irreducible if, and only if, its Coxeter graph is connected. Two Coxeter graphs give rise to Coxeter isomorphic groups if, and only if, they are isomorphic as labelled graphs. See Chapter 149 for more information on graphs.

`IsCoxeterGraph(G)`

Returns `true` if, and only if, the graph G is the Coxeter graph of some Coxeter group.

`CoxeterGraph(M)`
`CoxeterGraph(C)`
`CoxeterGraph(D)`

The Coxeter graph corresponding to a Coxeter matrix M, Cartan matrix C, or Dynkin digraph D.

`CoxeterGroupOrder(G)`
`CoxeterGroupFactoredOrder(G)`

The (factored) order of the Coxeter group with Coxeter graph G.

Example H95E4

```
> G := PathGraph(4);
> AssignLabel(G, 1,2, 4);
> AssignLabel(G, 3,4, 4);
> IsCoxeterGraph(G);
true
> CoxeterGroupOrder(G);
Infinity
>
> M := SymmetricMatrix([1, 3,1, 2,5,1]);
> G := CoxeterGraph(M);
> Labels(EdgeSet(G));
[ undef, 5 ]
```

`IsSimplyLaced(G)`

Returns `true` if, and only if, the Coxeter graph G is simply laced, i.e. unlabelled.

Example H95E5

```
> G := PathGraph(2);
> IsSimplyLaced(G);
true
> AssignLabel(G, 1,2, 6);
> IsSimplyLaced(G);
false
```

95.4 Cartan Matrices

A *Cartan matrix* is a real valued matrix $C = (c_{ij})_{i,j=1}^{n}$ satisfying the properties:

1. $c_{ii} = 2$;
2. $c_{ij} \leq 0$ for $i \neq j$;
3. $c_{ij} = 0$ if, and only if, $c_{ji} = 0$; and
4. if $n_{ij} := c_{ij}c_{ji} < 4$, then $n_{ij} = 4\cos^2(\pi/m_{ij})$ for some integer $m_{ij} \geq 2$.

In MAGMA, Cartan matrices can be defined over the integer ring (Chapter 18), the rational field (Chapter 20), number fields (Chapter 34), and cyclotomic fields (Chapter 36). The real field (Chapter 25) is *not* allowed since it is not infinite precision. A Cartan matrix is called *crystallographic* if all its entries are integers.

Given a Cartan matrix, the corresponding Coxeter matrix $M = (m_{ij})_{i,j=1}^{n}$ is defined by $m_{ii} = 1$; m_{ij} as in (4) if $n_{ij} < 4$; $m_{ij} = \infty$ (ie, 0) if $n_{ij} \geq 4$. The significance of Cartan matrices is due to the following construction: Let X be a real inner-product space with basis $\alpha_1, \ldots, \alpha_n$. Take the unique basis $\alpha_1^\star, \ldots, \alpha_n^\star$ for X such that $(\alpha_i, \alpha_j^\star) = c_{ij}$. Let s_i be the reflection in α_i and $\alpha_i^\star$, i.e. $s_i : V \to V$ is defined by $vs_i = v - (v, \alpha_i^\star)\alpha_i$. Then the group generated by $s_1, \ldots, s_n$ is a Coxeter group with Coxeter matrix M. In other words, a Cartan matrix specifies a faithful representation of the Coxeter group as a real reflection group. For more details on reflection groups see Chapter 99.

`IsCartanMatrix(C)`

`RealInjection`	ANY	*Default :* `false`

Returns `true` if, and only if, the matrix C is a Cartan matrix.

Number field elements and cyclotomic field elements do not have a natural identification with real numbers. The `RealInjection` flag allows the user to provide one. If the base field of C is a number field, the flag should be an injection into the real field; if the base field is cyclotomic, the flag should be an injection into the complex field taking real values on the entries of C. If no real injection is given, conditions (2) and (4) of the definition are not checked.

`CartanMatrix(M)`
`CartanMatrix(G)`

`Symmetric`	BOOLELT	*Default :* `false`
`BaseField`	MONSTGELT	*Default :* `"NumberField"`

A Cartan matrix corresponding to the Coxeter matrix M or Coxeter graph G. Note that the Cartan matrix of a Coxeter system is not unique. By default this function returns the Cartan matrix with $c_{ij} = -4\cos^2(\pi/m_{ij})$, $c_{ji} = -1$ when $m_{ij} \neq 2$ and $i < j$. This matrix is crystallographic whenever there exists a crystallographic Cartan matrix corresponding to M.

If the `Symmetric` flag is set `true`, the symmetric Cartan matrix with

$$c_{ij} = c_{ji} = -2\cos(\pi/m_{ij})$$

is returned.

The BaseField flag determines the field over which the Cartan matrix is defined. If the matrix is crystallographic however, it is defined over the integers regardless of the value of this flag. The possible values are:

1. "NumberField": An algebraic number field. This is the default. See Chapter 34.
2. "Cyclotomic" or "SparseCyclotomic": A cyclotomic field with the sparse representation for elements. See Chapter 36.
3. "DenseCyclotomic": A cyclotomic field with the dense representation for elements. See Chapter 36.

CartanMatrix(D)

The crystallographic Cartan matrix corresponding to the Dynkin digraph D.

Example H95E6

```
> C := Matrix(2,2, [ 2,-3, -1,2 ]);
> C;
> IsCartanMatrix(C);
true
> CoxeterMatrix(C);
[1 6]
[6 1]
>
> G := PathGraph(4);
> AssignLabel(G, 1,2, 4);
> AssignLabel(G, 3,4, 4);
> CartanMatrix(G);
[ 2 -2  0  0]
[-1  2 -1  0]
[ 0 -1  2 -2]
[ 0  0 -1  2]
> CartanMatrix(G : Symmetric, BaseField := "Cyclotomic");
[2 zeta(8)_8^3 - zeta(8)_8 0 0]
[zeta(8)_8^3 - zeta(8)_8 2 -1 0]
[0 -1 2 zeta(8)_8^3 - zeta(8)_8]
[0 0 zeta(8)_8^3 - zeta(8)_8 2]
```

IsCoxeterIsomorphic(C1, C2)

Returns true if, and only if, the Cartan matrices C_1 and C_2 give rise to Coxeter isomorphic Coxeter groups, i.e. their Coxeter matrices are equal modulo permutation of the underlying basis. If so, a sequence giving the permutation of the underlying basis which takes the Coxeter matrix of C_1 to the Coxeter matrix of C_2 is also returned.

`IsCartanEquivalent(C1, C2)`

Returns `true` if, and only if, the crystallographic Cartan matrices C_1 and C_2 are Cartan equivalent, i.e. they are equal modulo permutation of the underlying basis. If so, a sequence giving the permutation of the underlying basis which takes C_1 to C_2 is also returned.

Example H95E7

Cartan equivalence is a stronger condition than Coxeter isomorphism.

```
> C1 := Matrix(2,2, [ 2,-2, -2,2 ]);
> C2 := Matrix(2,2, [ 2,-1, -5,2 ]);
> IsCoxeterIsomorphic(C1, C2);
true [ 1, 2 ]
> IsCartanEquivalent(C1, C2);
false
```

`NumberOfPositiveRoots(C)`

`NumPosRoots(C)`

The number of positive roots of the root system with Cartan matrix C. See Subsection 96.1.3 for the definition of positive roots.

`CoxeterGroupOrder(C)`

`CoxeterGroupFactoredOrder(C)`

The (factored) order of the Coxeter group with Cartan matrix C.

`FundamentalGroup(C)`

The fundamental group of the crystallographic Cartan matrix C, i.e. $\mathbf{Z}^n/\Gamma$ where n is the degree of C and Γ is the lattice generated by the rows of C. The natural mapping $\mathbf{Z}^n \to \mathbf{Z}^n/\Gamma$ is the second returned value.

Example H95E8

```
> C := CartanMatrix(PathGraph(4));
> FundamentalGroup(C);
Abelian Group isomorphic to Z/5
Defined on 1 generator
Relations:
    5*$.1 = 0
Mapping from: Standard Lattice of rank 4 and degree 4 to Abelian Group
isomorphic to Z/5
Defined on 1 generator
Relations:
    5*$.1 = 0
```

`IsCoxeterIrreducible(C)`

Returns `true` if, and only if, C is the Cartan matrix of an irreducible Coxeter system. If the Coxeter matrix is reducible, this function also returns a nontrivial subset I of $\{1, \ldots, n\}$ such that $m_{ij} = 2$ (i.e. $c_{ij} = 0$) whenever $i \in I$, $j \notin I$.

`IsCrystallographic(C)`

Returns `true` if, and only if, the Cartan matrix C is crystallographic, i.e. C has integral entries.

`IsSimplyLaced(C)`

Returns `true` if, and only if, the Cartan matrix C is simply laced, i.e. all the entries in its Coxeter matrix are 1, 2, or 3.

Example H95E9

```
> C := Matrix(2,2, [ 2,-2, -2,2 ]);
> IsCoxeterIrreducible(C);
true
> IsCrystallographic(C);
true
> IsSimplyLaced(C);
false
```

95.5 Dynkin Digraphs

A *Dynkin digraph* is a directed labelled graph describing a *crystallographic* Cartan matrix $C = (c_{ij})_{i,j=1}^{n}$. The Dynkin digraph has vertices $1, \ldots, n$; whenever $c_{ij} < 0$ there is an edge from i to j labeled by the value $-c_{ij}$. When $c_{ij} = -1$, the label is usually omitted.

In the literature, the term *Dynkin diagram* is used, but here this will be reserved for a printed display of the Dynkin digraph (or Coxeter graph) corresponding to a finite or affine Coxeter group (see Section 95.6 below). For convenience, Dynkin digraphs have labelled edges rather than multiple edges.

Clearly a Dynkin digraph must be standard, i.e. its vertices must be the integers $1, 2, \ldots, n$ for some n. A Dynkin digraph has an edge from i to j if, and only if, it has an edge from j to i (although the labels may be different). Hence strong and weak connectivity are equivalent for these graphs. The Coxeter system is irreducible if, and only if, the Dynkin digraph is connected. Two Dynkin digraphs give rise to Cartan equivalent Cartan matrices if they are isomorphic as labelled digraphs. See Chapter 149 for more information on digraphs.

Note that functions are not given for computing the Dynkin digraph of a Coxeter matrix or Coxeter graph, since a particular choice of crystallographic Cartan matrix is required.

`IsDynkinDigraph(D)`

Returns `true` if, and only if, the digraph D is the Dynkin digraph of some crystallographic Cartan matrix.

`DynkinDigraph(C)`

The Dynkin digraph of the crystallographic Cartan matrix C.

`CoxeterGroupOrder(D)`

`CoxeterGroupFactoredOrder(D)`

The (factored) order of the Coxeter group with Dynkin digraph D.

`FundamentalGroup(D)`

The fundamental group of the Dynkin digraph D, i.e. $\mathbf{Z}^n/\Gamma$ where n is the degree of D and Γ is the lattice generated by the rows of the corresponding Cartan matrix. The natural mapping $\mathbf{Z}^n \to \mathbf{Z}^n/\Gamma$ is the second returned value.

`IsSimplyLaced(D)`

Returns `true` if, and only if, the Dynkin digraph D is simply laced, i.e. unlabelled.

Example H95E10

```
> D := Digraph< 4 | <1,{2,3,4}>, <2,{1}>, <3,{1}>, <4,{1}> >;
> AssignLabel(D, 1,2, 2);
> AssignLabel(D, 1,3, 5);
> IsDynkinDigraph(D);
true
> CartanMatrix(D);
[ 2 -2 -5 -1]
[-1  2  0  0]
[-1  0  2  0]
[-1  0  0  2]
> FundamentalGroup(D);
Abelian Group isomorphic to Z/2 + Z/8
Defined on 2 generators
Relations:
    2*$.1 = 0
    8*$.2 = 0
Mapping from: Standard Lattice of rank 4 and degree 4 to Abelian Group
isomorphic to Z/2 + Z/8
Defined on 2 generators
Relations:
    2*$.1 = 0
    8*$.2 = 0
```

95.6 Finite and Affine Coxeter Groups

Functions related to the classification of finite and affine Coxeter groups are described in this section. This classification is due to Cartan [Car52] and Coxeter [Cox34].

An affine reflection group is a group generated by reflections in affine space (in other words, real reflections in a hyperplane that does not necessarily pass through the origin). A Coxeter group is called *affine* if it is infinite and it has a representation as a discrete, properly acting, affine reflection group (see [Bou68] for more details on discreteness and proper action). Note that a Coxeter group is finite if, and only if, it has a representation as a discrete, properly acting group of reflections of the sphere; hence finite Coxeter groups are sometimes called *spherical*.

A Coxeter group is finite if, and only if, all its irreducible components are finite; a Coxeter group is affine if, and only if, all its irreducible components are finite or affine, and at least one component is affine. So it suffices to classify irreducible Coxeter groups.

The Dynkin diagrams of the irreducible finite crystallographic Coxeter groups are:

```
An  1---2---3- ... -n        Bn  1---2- ... -(n-1)=>=n

                                                  (n-1)
                                                 /
Cn  1---2- ... -(n-1)=<=n    Dn  1---1- ... -(n-2)
                                                 \
                                                  n

E6  1---3---4---5---6        E7  1---3---4---5---6---7
            |                            |
            2                            2

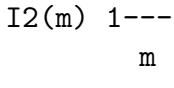
E8  1---3---4---5---6---7---8
            |
            2

F4  1---2=>=3---4            G2  1=<=2
                                     3
```

Due to the difficulty of drawing a triple bond with text characters, the edge for G_2 is labelled.

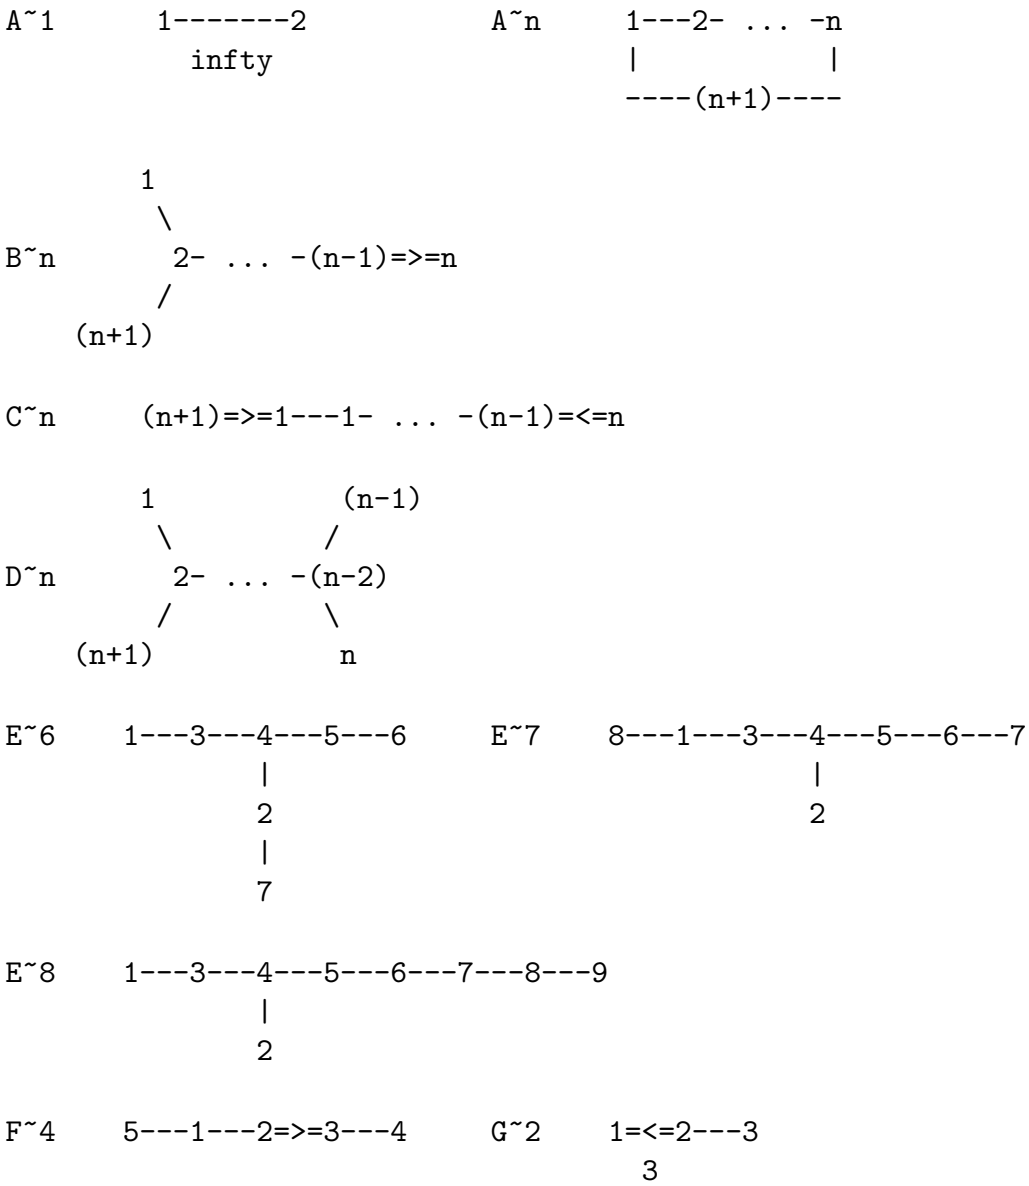
The only irreducible noncrystallographic finite Coxeter groups are H_3, H_4 and $I_2(m)$ for $m = 5$ and $m > 6$. The Coxeter graphs of these groups are:

```
H3  1---2---3                H4  1---2---3---4
      5                            5
```



Note that there is some redundancy in this classification; specifically $A_1 = B_1 = C_1 = D_1$, $A_2 = I_2(3)$, $B_2 = C_2 = I_2(4)$, $D_2 = A_1 + A_1$, $D_3 = A_3$, $G_2 = I_2(6)$. Furthermore, for $n \geq 3$, types B_n and C_n have identical Coxeter matrices but inequivalent crystallographic Cartan matrices for $n > 2$.

All irreducible affine groups are crystallographic. There is one corresponding to each irreducible crystallographic finite group. Their Dynkin diagrams are:



The labels on the vertices of these diagrams show the standard vertex order used in MAGMA, which is consistent with the order used in [Bou68].

`IsCoxeterFinite(M)`
`IsCoxeterFinite(G)`
`IsCoxeterFinite(C)`
`IsCoxeterFinite(D)`
`IsCoxeterFinite(N)`

Returns `true` if, and only if, the corresponding Coxeter group is finite. The input variable can be a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N.

`IsCoxeterAffine(M)`
`IsCoxeterAffine(G)`
`IsCoxeterAffine(C)`
`IsCoxeterAffine(D)`
`IsCoxeterAffine(N)`

Returns `true` if, and only if, the corresponding Coxeter group is affine. The input variable can be a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N.

Example H95E11

```
> IsCoxeterAffine("A~2");
true
> IsCoxeterAffine("A~2B2");
true
> IsCoxeterAffine("A2B2");
false
> IsCoxeterFinite("A2B2");
true
```

`CoxeterMatrix(N)`

The Coxeter matrix with Cartan name given by the string N.

`CoxeterGraph(N)`

The Coxeter graph with Cartan name given by the string N.

`CartanMatrix(N)`

`Symmetric`	BoolElt	*Default :* `false`
`BaseField`	MonStgElt	*Default :* `"NumberField"`

The Cartan matrix with Cartan name given by the string N. By default, the crystallographic matrix is returned for crystallographic types; otherwise the Cartan matrix with $c_{ij} = -4\cos^2(\pi/m_{ij})$, $c_{ji} = -1$ when $m_{ij} \neq 2$ and $i < j$ is returned.

If the `Symmetric` flag is set `true`, the symmetric Cartan matrix with $c_{ij} = c_{ji} = -2\cos(\pi/m_{ij})$ is returned.

The `BaseField` flag determines the field over which the Cartan matrix is defined. If the matrix is crystallographic however, it is defined over the integers regardless of the value of this flag. The possible values are:

1. `"NumberField"`: An algebraic number field. This is the default. See Chapter 34.
2. `"Cyclotomic"` or `"SparseCyclotomic"`: A cyclotomic field with the sparse representation for elements. See Chapter 36.
3. `"DenseCyclotomic"`: A cyclotomic field with the dense representation for elements. See Chapter 36.

`DynkinDigraph(N)`

The Dynkin digraph with Cartan name given by the string N. The Cartan name must be crystallographic, i.e. it cannot involve types H_3, H_4 and $I_2(m)$.

Example H95E12

```
> CoxeterMatrix("I2(7)");
[1 7]
[7 1]
> CoxeterGraph("A3");
Graph
Vertex  Neighbours
1       2 ;
2       1 3 ;
3       2 ;
> CartanMatrix("H3" : Symmetric);
[   2 -$.1    0]
[-$.1    2   -1]
[   0   -1    2]
> DynkinDigraph("A~2");
Digraph
Vertex  Neighbours
1       2 3 ;
2       1 3 ;
```

```
3       1 2 ;
```

The code for interpreting a string as a Cartan name is quite flexible: letters and numbers must alternate, except in type I where brackets must be used.

```
> M := CoxeterMatrix("A_5B3 c2I2 (5)");
> CartanName(M);
A5 B3 B2 I2(5)
```

`IrreducibleCoxeterMatrix(X, n)`

The irreducible Coxeter matrix with Cartan name X_n (or $I_2(n)$ if $X =$`"I"`).

`IrreducibleCoxeterGraph(X, n)`

The irreducible Coxeter graph with Cartan name X_n (or $I_2(n)$ if $X =$`"I"`).

`IrreducibleCartanMatrix(X, n)`

`Symmetric`	BoolElt	*Default :* `false`
`BaseField`	MonStgElt	*Default :* `"NumberField"`

The irreducible Cartan matrix with Cartan name X_n (or $I_2(n)$ if $X =$`"I"`).

If the `Symmetric` flag is set `true`, the symmetric Cartan matrix with $c_{ij} = c_{ji} = -2\cos(\pi/m_{ij})$ is returned.

The `BaseField` flag determines which field the Cartan matrix is defined over. If the matrix is crystallographic however, it is defined over the integers regardless of the value of this flag. The possible values are:

1. `"NumberField"`: An algebraic number field. This is the default. See Chapter 34.
2. `"Cyclotomic"` or `"SparseCyclotomic"`: A cyclotomic field with the sparse representation for elements. See Chapter 36.
3. `"DenseCyclotomic"`: A cyclotomic field with the dense representation for elements. See Chapter 36.

`IrreducibleDynkinDigraph(X, n)`

The irreducible Dynkin digraph with Cartan name X_n. The Cartan name must be crystallographic, i.e. it cannot involve types H_3, H_4 or $I_2(m)$.

Example H95E13

These functions are useful in loops.

```
> for n in [1..5] do
>     IsTree(IrreducibleCoxeterGraph("A~", n));
> end for;
true
false
false
false
false
> C := &join[ IrreducibleCoxeterGraph(t, 4) : t in ["A","B","C","D","F"] ];
```

`IsCoxeterIsomorphic(N1, N2)`

Returns `true` if, and only if, the Cartan names given by the strings N_1 and N_2 correspond to Coxeter isomorphic groups.

`IsCartanEquivalent(N1, N2)`

Returns `true` if, and only if, the Cartan names given by the strings N_1 and N_2 correspond to Cartan equivalent Cartan matrices. The Cartan names must be crystallographic, i.e. they cannot involve types H_3, H_4 and $I_2(m)$.

Example H95E14

```
> IsCoxeterIsomorphic("A1A1", "D2");
true
> IsCoxeterIsomorphic("B5", "C5");
true
> IsCartanEquivalent("B5", "C5");
false
```

`IsSimplyLaced(N)`

Returns `true` if, and only if, the Coxeter matrix with Cartan name given by the string N is simply laced, i.e. all its entries are 1, 2, or 3.

`CoxeterGroupOrder(N)`

`CoxeterGroupFactoredOrder(N)`

The (factored) order of the Coxeter group with Cartan name given by the string N.

`NumberOfPositiveRoots(N)`
`NumPosRoots(N)`

The number of positive roots of the Coxeter group with Cartan name given by the string N. See Subsection 96.1.3 for the definition of positive roots.

`FundamentalGroup(N)`

The fundamental group of the crystallographic Cartan matrix with Cartan name given by the string N, i.e. $\mathbf{Z}^n/\Gamma$ where Γ is the lattice generated by the rows of the Cartan matrix. The natural mapping $\mathbf{Z}^n \to \mathbf{Z}^n/\Gamma$ is the second returned value.

Example H95E15

```
> CoxeterGroupOrder("F4");
1152
> CoxeterGroupFactoredOrder("F4");
[ <2, 7>, <3, 2> ]
> NumPosRoots("F4");
24
> #FundamentalGroup("F4");
1
```

`CartanName(M)`
`CartanName(G)`
`CartanName(C)`
`CartanName(D)`

The Cartan name of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, or Dynkin digraph D. If the corresponding Coxeter group is neither finite nor affine, an error is flagged.

Example H95E16

```
> CartanName(SymmetricMatrix([1, 3,1, 2,3,1]));
A3
> CartanName(SymmetricMatrix([1, 3,1, 3,3,1]));
A~2
> CartanName(SymmetricMatrix([1, 3,1, 4,3,1]));
The component at rows and columns [ 1, 2, 3 ]
is not a finite or affine Coxeter matrix
> C := Matrix(4,4, [2,-2,0,0, -1,2,0,0, 0,0,2,-2, 0,0,-1,2] );
> C;
[ 2 -2  0  0]
[-1  2  0  0]
[ 0  0  2 -2]
```

```
[ 0  0 -1  2]
```

DynkinDiagram(M)
DynkinDiagram(G)
DynkinDiagram(C)
DynkinDiagram(D)
DynkinDiagram(N)

Print the Dynkin diagram of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D or Cartan name given by the string N. If the corresponding group is neither affine nor crystallographic, an error is flagged.

Example H95E17

```
> DynkinDiagram("A~5 D4 BC3");
A~5    1 - 2 - 3 - 4 - 5
       |               |
       ------- 6 -------
D4     9
      /
7 - 8
      \
       10
BC3    11 - 12 =>= 13
```

CoxeterDiagram(M)
CoxeterDiagram(G)
CoxeterDiagram(C)
CoxeterDiagram(D)
CoxeterDiagram(N)

Print the Coxeter diagram of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D or Cartan name given by the string N. If the corresponding group is not affine or is not crystallographic, an error is flagged.

Example H95E18

```
> CoxeterDiagram("A~5 D4 BC3");
A~5    1 - 2 - 3 - 4 - 5
       |               |
       ------- 6 -------
D4     9
      /
7 - 8
      \
       10
BC3    11 - 12 === 13
```

95.7 Hyperbolic Groups

A hyperbolic reflection group is a group generated by reflections in hyperbolic space. A Coxeter group is called *hyperbolic* if it is infinite, nonaffine, and it has a representation as a discrete, properly acting, hyperbolic reflection group whose Tits' cone consists entirely of vectors with negative norm (see [Bou68] for more details). A hyperbolic reflection group is *compact hyperbolic* if it is hyperbolic with a compact fundamental region.

Every infinite nonaffine Coxeter group of rank 3 is hyperbolic. There are only 72 hyperbolic groups of rank larger than 3 which, for convenience, are numbered from 1 to 72. The numbering is essentially arbitrary.

`IsCoxeterHyperbolic(M)`

`IsCoxeterCompactHyperbolic(M)`

Returns `true` if, and only if, the matrix M is the Coxeter matrix of a (compact) hyperbolic Coxeter group.

`IsCoxeterHyperbolic(G)`

`IsCoxeterCompactHyperbolic(G)`

Returns `true` if, and only if, the graph G is the Coxeter graph of a (compact) hyperbolic Coxeter group.

`HyperbolicCoxeterMatrix(i)`

The Coxeter matrix of the ith hyperbolic Coxeter group of rank larger than 3.

`HyperbolicCoxeterGraph(i)`

The Coxeter graph of the ith hyperbolic Coxeter group of rank larger than 3.

Example H95E19

```
> for i in [1..72] do
>   if IsCoxeterCompactHyperbolic(HyperbolicCoxeterMatrix(i)) then
>     printf "%o, ", i;
>   end if;
> end for;
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14,
```

95.8 Related Structures

In this section functions for creating other structures from Coxeter matrices, Coxeter graphs, Cartan matrices, Dynkin diagrams, and Cartan names are listed. The reader is referred to the appropriate sections of the Handbook for more details.

RootSystem(M)
RootSystem(G)
RootSystem(C)
RootSystem(D)
RootSystem(N)

The finite root system of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 96.

RootDatum(C)
RootDatum(M)
RootDatum(G)
RootDatum(D)
RootDatum(N)

The finite root datum of a crystallographic Cartan matrix C, Coxeter matrix M, Coxeter graph G, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 97.

```
CoxeterGroup(GrpFPCox, M)
CoxeterGroup(GrpFPCox, G)
CoxeterGroup(GrpFPCox, C)
CoxeterGroup(GrpFPCox, D)
CoxeterGroup(GrpFPCox, N)
```

The Coxeter group of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. See Chapter 98.

```
CoxeterGroup(GrpPermCox, M)
CoxeterGroup(GrpPermCox, G)
CoxeterGroup(GrpPermCox, C)
CoxeterGroup(GrpPermCox, D)
CoxeterGroup(GrpPermCox, N)
```

The permutation Coxeter group of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 98.

```
CoxeterGroup(M)
CoxeterGroup(G)
CoxeterGroup(C)
CoxeterGroup(D)
CoxeterGroup(N)
```

The Coxeter group of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is finite, it is returned as a permutation group; otherwise it is returned as a finitely presented group.

```
ReflectionGroup(M)
ReflectionGroup(G)
ReflectionGroup(C)
ReflectionGroup(D)
ReflectionGroup(N)
```

The reflection group of a Coxeter matrix M, Coxeter graph G, Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. See Chapter 99.

`LieAlgebra(C, k)`

`LieAlgebra(D, k)`

`LieAlgebra(N, k)`

The Lie algebra over the ring k of a crystallographic Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 100.

`MatrixLieAlgebra(C, k)`

`MatrixLieAlgebra(D, k)`

`MatrixLieAlgebra(N, k)`

The Lie algebra over the ring k of a crystallographic Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 100.

`GroupOfLieType(C, k)`

`GroupOfLieType(D, k)`

`GroupOfLieType(N, k)`

The group of Lie type over the ring k of a crystallographic Cartan matrix C, Dynkin digraph D, or Cartan name given by the string N. If the corresponding Coxeter group is infinite, an error is flagged. See Chapter 103.

96 ROOT SYSTEMS

Chapter 96
ROOT SYSTEMS

96.1 Introduction

This chapter describes Magma functions for computing with finite real root systems. A root system describes the reflections in a reflection group (Chapter 99). Root systems are essential in the theories of finite Coxeter groups (Chapter 98) and Lie algebras (Chapter 100). See [Bou68] for more details on the theory of root systems. The closely related concept of a root datum is discussed in Chapter 97.

96.1.1 Reflections

Let X and Y be vector spaces over a field k with bilinear pairing $\langle \circ, \circ \rangle : X \times Y \to k$ that identifies Y with the dual of X. Given nonzero $\alpha \in X$ and $\alpha^\star \in Y$, the linear map $s_\alpha : X \to X$ is defined by

$$x s_\alpha = x - \langle x, \alpha^\star \rangle \alpha$$

and the linear map $s_\alpha^\star : Y \to Y$ by

$$y s_\alpha^\star = y - \langle \alpha, y \rangle \alpha^\star.$$

These maps are called *reflections* if one of the following equivalent properties hold: $\langle \alpha, \alpha^\star \rangle = 2$; ${s_\alpha}^2 = 1$; $\langle x s_\alpha, y s_\alpha^\star \rangle = \langle x, y \rangle$ for all $x \in X$ and $y \in Y$; $\alpha s_\alpha = -\alpha$. The mapping $s_\alpha^\star$ is also called a *coreflection*: this just means it is a reflection defined on Y instead of X. MAGMA functions for computing with reflections are described in Section 99.2.

If X has an inner product, then we can take $Y = X$ and use the inner product as our pairing. In MAGMA, we generally take $X = Y$ to be a row space, with the bilinear pairing given by the standard inner product $\langle x, y \rangle = xy^T$. However, it is sometimes useful to allow X and Y to be distinct subspaces of a row space.

For the purposes of this chapter, k will always be the rational field (Chapter 20), a number field (Chapter 20), or a cyclotomic field (Chapter 36). The real field (Chapter 25) is *not* allowed since it is not infinite precision.

96.1.2 Definition of a Root System

Suppose Φ is a finite subset of $X \setminus \{0\}$. For each α in Φ, suppose a corresponding nonzero $\alpha^\star$ in Y is given; set $\Phi^\star = \{\alpha^\star \mid \alpha \in \Phi\}$. The tuple $R = (X, \Phi, Y, \Phi^\star)$ is called a *root system* if the following conditions are satisfied for every α in Φ

1. s_α and $s_\alpha^\star$ are reflections;
2. Φ is closed under the action of s_α; and
3. $\Phi^\star$ is closed under the action of $s_\alpha^\star$.

The set X is called the *root space* and Y is called the *coroot space*. The elements of Φ are called *roots* and the elements of $\Phi^\star$ are called *coroots*. A root system is said to be *crystallographic* if $\langle \alpha, \beta^\star \rangle$ is integral for every root α and coroot $\beta^\star$. A root system is *reduced*, if $\alpha, \beta \in \Phi$ with β a scalar product of α implies $\alpha = \pm\beta$. Note that it is possible for the set of roots to be empty, in which case the system is called *toral*.

96.1.3 Simple and Positive Roots

A subset Δ of Φ is called a set of *simple roots* if

1. Δ is a basis for the span of the roots $k\Phi \leq X$; and
2. $\Phi = \Phi^+ \cup \Phi^-$, where Φ^+ is the set of linear combinations of elements of Δ with nonnegative coefficients, and $\Phi^- = -\Phi^+$.

Every root system has a set of simple roots. Simple roots are frequently called fundamental roots. The elements of Φ^+ are called *positive roots* and the elements of Φ^- are called *negative roots*. The coroots corresponding to the simple (respectively, positive, negative) roots are the *simple* (respectively, *positive*, *negative*) *coroots*.

The *rank* of a root system is the size of Δ, i.e. the dimension of the subspace $k\Phi$. The rank cannot be larger than the *dimension* of the root system (i.e. the dimension of X); if the rank and dimension are equal, the root system is said to be *semisimple*.

Choose a basis $e_1, \ldots, e_d$ for X and a dual basis $f_1, \ldots, f_d$ for Y, so that $\langle e_i, f_j \rangle = \delta_{ij}$. A reduced root system is determined by a pair of real matrices A and B where the rows of A are the simple roots and the rows of B are the corresponding coroots; i.e. $A_{ij} = \langle \alpha_i, f_j \rangle$ and $B_{ij} = \langle e_j, \alpha_i^\star \rangle$.

96.1.4 The Coxeter Group

The group W generated by the reflections s_α, for α a simple root, is a finite Coxeter group. The *Cartan matrix* of a root system is

$$C = \left(\left\langle\, \alpha_i, \alpha_j^\star \,\right\rangle \right)_{i,j=1}^{n} = AB^t.$$

Note that the root system is crystallographic if, and only if, its Cartan matrix is crystallographic. As in Chapter 95, the Cartan matrix is used to define the Coxeter matrix, Coxeter graph, and Dynkin digraph of a root system.

The classification of Section 95.6 applies to reduced semisimple root systems. The isomorphism class of a reduced root system is determined by its Coxeter graph and its dimension.

A *Coxeter form* is a W-invariant bilinear form on X. If R is reduced and irreducible, then the roots can have at most two different lengths with respect to this form. We call the roots *long* or *short* accordingly. The Coxeter form is normalised so that the short roots in each component have length one. Note that, even if $X = Y$, this form will generally not be the same as the pairing $\langle \circ, \circ \rangle$; however it can be arranged for them to be the same (see `StandardRootSystem`).

96.1.5 Nonreduced Root Systems

A root system is *reduced*, if $\alpha, \beta \in \Phi$ with β a scalar product of α implies $\alpha = \pm\beta$. A root α with the property $2\alpha \notin \Phi$ is called *reduced*. A root α with the property $\frac{1}{2}\alpha \in \Phi$ is called *divisible*. If R is a root system, then the set R_0 of indivisible roots in R form the *indivisible subsystem*.

Let R be a nonreduced irreducible *crystallographic* root system of rank n. It can be shown that R_0 is irreducible of type of type B_n and every root is either in R_0, or is two times a short root of R_0. The Cartan type of R in this case is BC_n. For noncrystallographic root systems the situation is more complex.

Note that the Cartan matrix, Coxeter matrix, Coxeter diagram, Coxeter group and Dynkin diagram are the same for R and R_0. Thus, when creating a non-reduced crystallographic root system for a given Cartan matrix, Coxeter matrix, Coxeter diagram, Coxeter group or Dynkin diagram, one must specify the set of nonreduced simple roots. For example, let C be a cartan matrix of type $B_2 \times B_3$. Then the set of non-reduced fundamental roots can be one of $\emptyset$, $\{2\}$, $\{5\}$, or $\{2, 5\}$, in which cases the root system will be of types $B_2 \times B_3$, $BC_2 \times B_3$, $B_2 \times BC_3$, or $BC_2 \times BC_3$ respectively.

96.2 Constructing Root Systems

We first describe some optional parameters that are common to many functions described in this section.

`RealInjection` ANY *Default :* `false`

Number field elements and cyclotomic field elements do not have a natural identification with real numbers. The `RealInjection` flag allows the user to provide one. If the base field of the Cartan matrix C is a number field, the flag should be an injection into the real field; if the base field is cyclotomic, the flag should be an injection into the complex field taking real values on the entries of C (see more in Section 95.4).

`Nonreduced` SETENUM *Default :* {}

The optional argument `Nonreduced` is used to distinguish the reducedness of a root system in case the input doesn't uniquely determine it.

`Symmetric` BOOLELT *Default :* `false`

If the `Symmetric` flag is set `true`, the symmetric Cartan matrix is used. For types $I_2(m)$, H_3, H_4 the symmetric Cartan matrix is *always* used, since the root system is nonreduced otherwise.

`BaseField` MONSTGELT *Default :* `"NumberField"`

The `BaseField` flag determines the field over which the Cartan matrix is defined. The possible values are:

1. `"NumberField"`: An algebraic number field. This is the default. See Chapter 34.
2. `"Cyclotomic"` or `"SparseCyclotomic"`: A cyclotomic field with the sparse representation for elements. See Chapter 36.

3. `"DenseCyclotomic"`: A cyclotomic field with the dense representation for elements. See Chapter 36.

`RootSystem(N)`

`Symmetric`	BoolElt	*Default :* `false`
`BaseField`	MonStgElt	*Default :* `"NumberField"`

The root system with Cartan name given by the string N. In addition to the Cartan names in Section 95.6, we allow `"BCn"` for the irreducible nonreduced system, and `"Tn"` for the n-dimensional toral subsystem. Note that `"Tn"` is used for input only and does not appear in the string returned by `CartanName` when applied to the resulting root system (see example below). For descriptions of the parameters `Symmetric` and `BaseField` see the beginning of this section

Example H96E1

```
> RootSystem("H3 E6");
Root system of type H3 E6
> RootSystem("A2 T1 I2(5)");
Root system of type A2 I2(5)
```

`RootSystem(M)`

`RootSystem(G)`

`Nonreduced`	SetEnum	*Default :* {}
`Symmetric`	BoolElt	*Default :* `false`
`BaseField`	MonStgElt	*Default :* `"NumberField"`

The semisimple root system with Coxeter matrix M or Coxeter graph G (see Chapter 95). If the corresponding Coxeter group is infinite, an error is flagged. For descriptions of the parameters `Nonreduced`, `Symmetric`, and `BaseField` see the beginning of this section.

`RootSystem(C)`

`RealInjection`	Any	*Default :* `false`
`Nonreduced`	SetEnum	*Default :* {}

The semisimple root system with Cartan matrix C (see Chapter 95). If the corresponding Coxeter group is infinite, an error is flagged. For descriptions of the parameters `RealInjection` and `Nonreduced` see the beginning of this section.

`RootSystem(D)`

`Nonreduced` SETENUM *Default :* {}

The semisimple crystallographic root system with Cartan matrix C, or Dynkin diagram D (see Chapter 95). If the corresponding Coxeter group is infinite, an error is flagged. For a description of the parameter `Nonreduced` see the beginning of this section.

Example H96E2

```
> M := SymmetricMatrix([1, 3,1, 2,3,1]);
> RootSystem(M);
Root system of type A3
> M := SymmetricMatrix([1, 3,1, 3,3,1]);
> RootSystem(M);
>> RootSystem(M);
              ^
Runtime error in 'RootSystem': Not a finite root system in rows/columns
[ 1, 2, 3 ]
```

`RootSystem(A, B)`

`RealInjection` ANY *Default :* `false`

`Nonreduced` SETENUM *Default :* {}

The root system with simple roots given by the rows of the matrix A and simple coroots given by the rows of the matrix B. The matrices A and B must have the following properties:

1. A and B must have the same number of rows and the same number of columns; they must be defined over the same ring, which must be the integers, the rational field, a number field, or a cyclotomic field;
2. the number of columns must be at least the number of rows; and
3. AB^t must be the Cartan matrix of a finite Coxeter group.

For descriptions of the parameters `RealInjection` and `Nonreduced` see the beginning of this section.

Example H96E3

The following code creates a nonsemisimple root system of type G_2.

```
> A := Matrix(2,3, [1,-1,0, -1,1,-1]);
> B := Matrix(2,3, [1,-1,1, 0,1,-1]);
> RootSystem(A, B);
Root system of type G2
```

`IrreducibleRootSystem(X, n)`

`Symmetric`	BoolElt	*Default :* `false`
`BaseField`	MonStgElt	*Default :* `"NumberField"`

The irreducible root system with Cartan name X_n (or $I_2(n)$ if $X =$ "I") given by the string X and integer n. In addition to the Cartan names in Section 95.6, we allow `"BCn"` for the irreducible nonreduced system. For descriptions of the parameters `Symmetric` and `BaseField` see the beginning of this section.

`StandardRootSystem(X, n)`

The standard root system with Cartan name X_n (or $I_2(n)$ if $X =$ "I") given by the string X and integer n, i.e. the root system whose Coxeter form is the same as the standard inner product. In addition to the Cartan names in Section 95.6, we allow `"BCn"` for the irreducible nonreduced system. For type A_n, the standard root system is not semisimple.

Example H96E4

```
> Rs := { IrreducibleRootSystem("I", n) : n in [3..20] };
> { R : R in Rs | IsCrystallographic(R) };
{
    Root system of type I2(3) ,
    Root system of type I2(4) ,
    Root system of type I2(6)
}
```

`ToralRootSystem(n)`

The toral root system of dimension n, i.e., the n-dimensional root system with no roots or coroots.

`TrivialRootSystem()`

The trivial root system of dimension 0.

96.3 Operators on Root Systems

`R1 eq R2`

Returns `true` if, and only if, the root systems R_1 and R_2 are identical.

`IsIsomorphic(R1, R2)`

Returns `true` if, and only if, root systems R_1 and R_2 are isomorphic.

`IsCartanEquivalent(R1, R2)`

Returns `true` if, and only if, the crystallographic root systems R_1 and R_2 are Cartan equivalent, i.e. their Cartan matrices are the same modulo a permutation of the underlying basis.

Example H96E5

Note that the root systems B_n and C_n are isomorphic but not Cartan equivalent. Hence Cartan equivalence is *not* an invariant of a root system since it depends on the particular representation of the (co)roots within the (co)root space.

```
> R := RootSystem("B4");  S := RootSystem("C4");
> IsIsomorphic(R, S);
true
> IsCartanEquivalent(R, S);
false
```

`CartanName(R)`

The Cartan name of the root system R (Section 95.6).

`CoxeterDiagram(R)`

Print the Coxeter diagram of the root system R (Section 95.6).

`DynkinDiagram(R)`

Print the Dynkin diagram of the root system R (Section 95.6). If R is not crystallographic, an error is flagged.

`CoxeterMatrix(R)`

The Coxeter matrix of the root system R (Section 95.2).

`CoxeterGraph(R)`

The Coxeter graph of the root system R (Section 95.3).

`CartanMatrix(R)`

The Cartan matrix of the root system R (Section 95.4).

`DynkinDigraph(R)`

The Dynkin digraph of the root system R (Section 95.5). If R is not crystallographic, an error is flagged.

Example H96E6

```
> R := RootSystem("F4");
> DynkinDiagram(R);
F4    1 - 2 =>= 3 - 4
> CoxeterDiagram(R);
F4    1 - 2 === 3 - 4
```

`BaseField(R)`
`BaseRing(R)`

The field over which the root system R is defined.

`RealInjection(R)`

The real injection of the root system R (Section 96.2).

`Rank(R)`

The rank of the root system R, i.e. the number of simple (co)roots.

`Dimension(R)`

The dimension of the root system R, i.e. the dimension of the (co)root space. This is always at least as large as the rank, with equality when R is semisimple.

`CoxeterGroupOrder(R)`

The order of the Coxeter group of the root system R.

Example H96E7

```
> R := RootSystem("I2(7)");
> BaseField(R);
Number Field with defining polynomial x^3 - x^2 - 2*x + 1 over the
Rational Field
> Rank(R) eq Dimension(R);
true
> CoxeterGroupOrder(R);
14
```

96.4 Properties of Root Systems

`IsIrreducible(R)`

Returns `true` if, and only if, the root system R is irreducible.

`IsProjectivelyIrreducible(R)`

Returns `true` if, and only if, the root system R is a direct sum of a simple system and a toral system. This is equivalent to R having a connected Coxeter diagram.

`IsReduced(R)`

Returns `true` if, and only if, the root system R is reduced.

`IsSemisimple(R)`

Returns `true` if, and only if, the root system R is semisimple, i.e. its rank is equal to its dimension.

`IsCrystallographic(R)`

Returns `true` if, and only if, the root system R is crystallographic, i.e. its Cartan matrix is integral.

`IsSimplyLaced(R)`

Returns `true` if, and only if, the root system R is simply laced, i.e. its Coxeter graph contains no labelled edges.

Example H96E8

```
> R := RootSystem("A5 B2");
> IsIrreducible(R);
false
> IsSemisimple(R);
true
> IsCrystallographic(R);
true
> IsSimplyLaced(R);
false
```

96.5 Roots and Coroots

The roots are stored as an indexed set

$$\{@ \alpha_1, \ldots, \alpha_N, \alpha_{N+1}, \ldots, \alpha_{2N} @\},$$

where $\alpha_1, \ldots, \alpha_N$ are the positive roots (in an order compatible with height), and $\alpha_{N+1}, \ldots, \alpha_{2N}$ are the corresponding negative roots (i.e. $\alpha_{i+N} = -\alpha_i$). The simple roots are $\alpha_1, \ldots, \alpha_n$ where n is the rank.

Many of these functions have an optional argument `Basis` which may take one of the following values

1. `"Standard"`: the standard basis for the (co)root space (this is the default); or
2. `"Root"`: the basis of simple (co)roots.

96.5.1 Accessing Roots and Coroots

`RootSpace(R)`

`CorootSpace(R)`

The vector space containing the (co)roots of the root system R, i.e. X (respectively, Y).

`SimpleRoots(R)`

`SimpleCoroots(R)`

The simple (co)roots of the root system R as the rows of a matrix, i.e. A (respectively, B).

Example H96E9

```
> R := RootSystem("G2");
> RootSpace(R);
Full Vector space of degree 2 over Rational Field
> CorootSpace(R);
Full Vector space of degree 2 over Rational Field
> SimpleRoots(R);
[1 0]
[0 1]
> SimpleCoroots(R);
[ 2 -3]
[-1  2]
> CartanMatrix(R);
[ 2 -1]
[-3  2]
```

`NumberOfPositiveRoots(R)`

`NumPosRoots(R)`

The number of positive roots of the root system R. This is also the number of positive coroots. The total number of (co)roots is twice the number of positive (co)roots.

`Roots(R)`

`Coroots(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The indexed set of (co)roots of the root system R, i.e. $\{@ \alpha_1, \ldots \alpha_{2N} @\}$ (respectively, $\{@ \alpha_1^\star, \ldots \alpha_{2N}^\star @\}$).

`PositiveRoots(R)`

`PositiveCoroots(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The indexed set of positive (co)roots of the root system R, i.e. $\{@ \alpha_1, \ldots \alpha_N @\}$ (respectively, $\{@ \alpha_1^\star, \ldots \alpha_N^\star @\}$).

`Root(R, r)`

`Coroot(R, r)`

`Basis` MonStgElt *Default :* `"Standard"`

The rth (co)root α_r (respectively, $\alpha_r^\star$) of the root system R.

`RootPosition(R, v)`

`CorootPosition(R, v)`

`Basis` MonStgElt *Default :* `"Standard"`

If v is a (co)root in the root system R, return its index; otherwise return 0. These functions will try to coerce v, which can be a vector or a sequence representing a vector, into the appropriate vector space; v should be written with respect to the basis specified by the parameter `Basis`.

Example H96E10

```
> A := Matrix(2,3, [1,-1,0, -1,1,-1]);
> B := Matrix(2,3, [1,-1,1, 0,1,-1]);
> R := RootSystem(A, B);
> Roots(R);
{@
    (1 -1  0),
    (-1  1 -1),
    (0  0 -1),
    (1 -1 -1),
```

```
    (2 -2 -1),
    (1 -1 -2),
    (-1  1  0),
    (1 -1  1),
    (0 0 1),
    (-1  1  1),
    (-2  2  1),
    (-1  1  2)
@}
> PositiveCoroots(R);
{@
    (1 -1  1),
    (0  1 -1),
    (1  2 -2),
    (2  1 -1),
    (1 0 0),
    (1  1 -1)
@}
> #Roots(R) eq 2*NumPosRoots(R);
true
> Root(R, 4);
(1 -1 -1)
> Root(R, 4 : Basis := "Root");
(2 1)
> RootPosition(R, [1,-1,-1]);
4
> RootPosition(R, [2,1] : Basis := "Root");
4
```

`HighestRoot(R)`

`HighestCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique (co)root of greatest height in the irreducible root system R.

`HighestLongRoot(R)`

`HighestLongCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique long (co)root of greatest height in the irreducible root system R.

`HighestShortRoot(R)`

`HighestShortCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique short (co)root of greatest height in the irreducible root system R.

Example H96E11

```
> R := RootSystem("G2");
> HighestRoot(R);
(3 2)
> HighestLongRoot(R);
(3 2)
> HighestShortRoot(R);
(2 1)
```

`CoxeterForm(R)`

`DualCoxeterForm(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The matrix of an inner product on the (co)root space of the root system R which is invariant under the action of the (co)roots. This inner product is uniquely determined up to a constant on each irreducible component of R. The inner product is normalised so that the short roots in each crystallographic component have length one.

96.5.2 Reflections

The root α acts on the root space via the reflection s_α; the coroot $\alpha^\star$ acts on the coroot space via the coreflection $s^\star_\alpha$.

`SimpleReflectionMatrices(R)`

`SimpleCoreflectionMatrices(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The sequence of matrices giving the action of the simple (co)roots of the root system R on the (co)root space, i.e. the matrices of $s_{\alpha_1}, \ldots, s_{\alpha_n}$ (respectively, $s^\star_{\alpha_1}, \ldots, s^\star_{\alpha_n}$).

`ReflectionMatrices(R)`

`CoreflectionMatrices(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The sequence of matrices giving the action of the (co)roots of the root system R on the (co)root space, i.e. the matrices of $s_{\alpha_1}, \ldots, s_{\alpha_{2N}}$ (respectively, $s^\star_{\alpha_1}, \ldots, s^\star_{\alpha_{2N}}$).

`ReflectionMatrix(R, r)`

`CoreflectionMatrix(R, r)`

`Basis` MonStgElt *Default :* `"Standard"`

The matrix giving the action of the rth (co)root of the root system R on the (co)root space, i.e. the matrix of s_{α_r} (respectively, $s^\star_{\alpha_r}$).

`SimpleReflectionPermutations(R)`

The sequence of permutations giving the action of the simple (co)roots of the root system R on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutations(R)`

The sequence of permutations giving the action of the (co)roots of the root system R on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutation(R, r)`

The permutation giving the action of the rth (co)root of the root system R on the (co)roots. This action is the same for roots and coroots.

`ReflectionWords(R)`

The sequence of words in the simple reflections for all the reflections of the root system R. These words are given as sequences of integers. In other words, if $[a_1, \ldots, a_l] =$ `ReflectionWords(R)[r]`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

`ReflectionWord(R, r)`

The word in the simple reflections for the rth reflection of the root system R. The word is given as a sequence of integers. In other words, if $[a_1, \ldots, a_l] =$ `ReflectionWord(R,r)`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

Example H96E12

```
> R := RootSystem("B3");
> mx := ReflectionMatrix(R, 4);
> perm := ReflectionPermutation(R, 4);
> wd := ReflectionWord(R, 4);
> RootPosition(R, Root(R,2) * mx) eq 2^perm;
true
> perm eq &*[ ReflectionPermutation(R, r) : r in wd ];
true
>
> mx := CoreflectionMatrix(R, 4);
> CorootPosition(R, Coroot(R,2) * mx) eq 2^perm;
true
```

96.5.3 Operations and Properties for Roots and Coroot Indices

`Sum(R, r, s)`

The index of the sum of the rth and sth roots in the crystallographic root system R, or 0 if the sum is not a root. In other words, if $t =$ `Sum(R,`r`,`s`)` $\neq 0$ then $\alpha_t = \alpha_r + \alpha_s$. We require $\alpha_r \neq \pm\alpha_s$.

`IsPositive(R, r)`

Returns `true` if, and only if, the rth (co)root of the root system R is a positive root.

`IsNegative(R, r)`

Returns `true` if, and only if, the rth (co)root of the root system R is a negative root.

`Negative(R, r)`

The index of the negative of the rth (co)root of the root system R. In other words, if $s =$ `Negative(R,`r`)` then $\alpha_s = -\alpha_r$.

Example H96E13

```
> R := RootSystem("G2");
> Sum(R, 1, Negative(R,5));
10
> IsPositive(R, 10);
false
> Negative(R, 10);
4
> P := PositiveRoots(R);
> P[1] - P[5] eq -P[4];
true
```

`RootHeight(R, r)`

`CorootHeight(R, r)`

The height of the rth (co)root of the root system R, i.e. the sum of the coefficients of α_r (respectively, $\alpha_r^\star$) with respect to the simple (co)roots.

`RootNorms(R)`

`CorootNorms(R)`

The sequence of squares of the lengths of the (co)roots of the root system R.

`RootNorm(R, r)`

`CorootNorm(R, r)`

The square of the length of the rth (co)root of the root system R.

`IsLongRoot(R, r)`

Returns `true` if, and only if, the rth root of the root system R is long. This only makes sense for irreducible crystallographic root systems. Note that for non-reduced root systems, the roots which are not indivisible are actually longer than the long ones.

`IsShortRoot(R, r)`

Returns `true` if, and only if, the rth root of the root system R is short. This only makes sense for irreducible crystallographic root systems.

`IsIndivisibleRoot(R, r)`

Returns `true` if, and only if, the rth root of the root system R is indivisible, ie, $\alpha_r/2$ is not a root.

`LeftString(R, r, s)`

Indices in the crystallographic root system R of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s - \alpha_r, \alpha_s - 2\alpha_r, \ldots, \alpha_s - p\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_p]$ where $\alpha_{r_i} = \alpha_s - i\alpha_r$ and $\alpha_s - (p+1)\alpha_r$ is not a root. We require that $\alpha_r \neq \pm\alpha_s$.

`RightString(R, r, s)`

Indices in the crystallographic root system R of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s + \alpha_r, \alpha_s + 2\alpha_r, \ldots, \alpha_s + q\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_q]$ where $\alpha_{r_i} = \alpha_s + i\alpha_r$ and $\alpha_s + (q+1)\alpha_r$ is not a root. We require that $\alpha_r \neq \pm\alpha_s$.

`LeftStringLength(R, r, s)`

The largest p such that $\alpha_s - p\alpha_r$ is a root. We require that the root system R be crystallographic and $\alpha_s \neq \pm\alpha_r$.

`RightStringLength(R, r, s)`

The largest q such that $\alpha_s + q\alpha_r$ is a root. We require that the root system R be crystallographic and $\alpha_s \neq \pm\alpha_r$.

Example H96E14

```
> R := RootSystem("G2");
> RootHeight(R, 5);
4
> F := CoxeterForm(R);
> v := Root(R, 5);
> (v*F, v) eq RootNorm(R, 5);
true
> IsLongRoot(R, 5);
true
> LeftString(R, 1, 5);
[ 4, 3, 2 ]
> roots := Roots(R);
> for i in [1..3] do
>   RootPosition(R, roots[5]-i*roots[1]);
> end for;
4
3
2
> R := RootSystem("BC2");
> Root(R,2), IsIndivisibleRoot(R,2);
(0 1) true
> Root(R,4), IsIndivisibleRoot(R,4);
(0 2) false
```

`AdditiveOrder(R)`

An additive order on the positive roots of the root system R, ie. a sequence containing the numbers $1, \ldots, N$ in some order so that $\alpha_r + \alpha_s = \alpha_t$ implies t is between r and s. This is computed using the techniques of [Pap94].

`IsAdditiveOrder(R, Q)`

Returns `true` if, and only if, the sequence Q gives an additive order on a set of positive roots of the root system R. Q must be a sequence of integers in the range $[1..N]$, where N is the number of positive roots of R, with no gaps or repeats.

Example H96E15

```
> R := RootSystem("A5");
> a := AdditiveOrder(R);
> Position(a, 2);
6
> Position(a, 3);
10
> Position(a, Sum(R, 2, 3));
7
```

96.6 Building Root Systems

`sub< R | a >`

The root subsystem of the root system R generated by the roots $\alpha_{a_1}, \ldots, \alpha_{a_k}$ where $a = \{a_1, \ldots, a_k\}$ is a set of integers.

`sub< R | s >`

The root subsystem of the root system R generated by the roots $\alpha_{s_1}, \ldots, \alpha_{s_k}$ where $s = [s_1, \ldots, s_k]$ is a *sequence* of integers. In this version the roots must be simple in the root subsystem (i.e. none of them may be a summand of another), otherwise an error is signalled. The simple roots will appear in the subsystem in the given order.

`R1 subset R2`

Returns `true` if and only if the root system R_1 is a subset of the root system R_2. If true, returns an injection as sequence of roots as second return value.

`R1 + R2`

`DirectSum(R1, R2)`

The direct sum of the root systems R_1 and R_2. The root space of the result is the direct sum of the root spaces of R_1 and R_2.

`R1 join R2`

The union of the root systems R_1 and R_2. The root systems must have the same root space, which will also be the root space of the result.

Example H96E16

```
> R  := RootSystem("A1A1");
> R1 := sub<R|[1]>;
> R2 := sub<R|[2]>;
> R1 + R2;
Root system of dimension 4 of type A1 A1
> R1 join R2;
Root system of dimension 2 of type A1 A1

> R1 := RootSystem("A3T2B4T3");
> R2 := RootSystem("T3G2T4BC3");
> R1 + R2;
Root system of dimension 24 of type A3 B4 G2 BC3
> R1 join R2;
Root system of dimension 12 of type A3 B4 G2 BC3
```

`DirectSumDecomposition(R)`

`IndecomposableSummands(R)`

The set of irreducible direct summands of the semisimple root system R.

`Dual(R)`

The dual of the root system R, obtained by swapping the roots and coroots.

`IndivisibleSubsystem(R)`

The root system consisting of all indivisible roots of the root system R.

Example H96E17

```
> R1 := RootSystem("H4");
> R2 := RootSystem("B4");
> R1 + Dual(R2);
Root system of type H4 C4
> R := RootSystem("BC2");
> I := IndivisibleSubsystem(R); I;
I: Root system of type B2
> I subset R;
true [ 1, 2, 3, 5, 7, 8, 9, 11 ]
```

96.7 Related Structures

In this section functions for creating other structures from a root system are briefly listed. The reader is referred to the appropriate chapters of the Handbook for more details.

`RootDatum(R)`

The (split) root datum corresponding to the root system R. The coefficients of the simple roots and coroots must be integral; otherwise an error is signalled. See Chapter 97

`CoxeterGroup(GrpFPCox, R)`

The Coxeter group with root system R. See Chapter 98. The braid group and pure braid group can be computed from the Coxeter group using the commands in Section 98.12.

`CoxeterGroup(R)`

`CoxeterGroup(GrpPermCox, R)`

The permutation Coxeter group with root system R. See Chapter 98.

`ReflectionGroup(R)`

`CoxeterGroup(GrpMat, W)`

The reflection group of the root system R. See Chapter 99.

`LieAlgebra(R, k)`

The Lie algebra of the root system R over the base ring k. See Chapter 100.

`MatrixLieAlgebra(R, k)`

The matrix Lie algebra of the root system R over the base ring k. See Chapter 100.

Example H96E18

```
> R := RootSystem("b3");
> SemisimpleType(LieAlgebra(R, Rationals()));
B3
> #CoxeterGroup(R);
48
```

97 ROOT DATA

Chapter 97
ROOT DATA

97.1 Introduction

This chapter describes Magma functions for computing with (extended) root data. Root data are fundamental to Lie theory: Lie algebras (Chapter 100) and groups of Lie type (Chapter 103). Our description of split reduced root data follows [Dem65] and [Car93] except that reflections act on the right as in customary in MAGMA. Our description of extended root data follows [Sat71], [Sch69], and [Hal05]. Our description of split non-reduced root data follows [Bou68].

The closely related concept of a root system is discussed in Chapter 96. When working with Lie algebras or groups of Lie type, root data should be used. When working with Coxeter groups (Chapter 98) or reflection groups (Chapter 99), it is likely that only root systems are of interest.

97.1.1 Reflections

Let X and Y be free $\mathbf{Z}$-modules with bilinear pairing $\langle \circ, \circ \rangle : X \times Y \to \mathbf{Z}$ that identifies Y with the dual of X. Given nonzero $\alpha \in X$ and $\alpha^\star \in Y$, we define the $\mathbf{Z}$-linear map $s_\alpha : X \to X$ by

$$x s_\alpha = x - \langle x, \alpha^\star \rangle \alpha$$

and the $\mathbf{Z}$-linear map $s_\alpha^\star : Y \to Y$ by

$$y s_\alpha^\star = y - \langle \alpha, y \rangle \alpha^\star.$$

These maps are called *reflections* if one of the following equivalent properties hold: $\langle \alpha, \alpha^\star \rangle = 2$; ${s_\alpha}^2 = 1$; $\langle x s_\alpha, y s_\alpha^\star \rangle = \langle x, y \rangle$ for all $x \in X$ and $y \in Y$; $\alpha s_\alpha = -\alpha$. The map $s_\alpha^\star$ is also called a *coreflection*: this just means it is a reflection defined on Y instead of X. MAGMA functions for computing with reflections are described in Section 99.2.

If X has an inner product, then we can take $Y = X$ and use the inner product as our pairing. In MAGMA, X and Y are usually standard $\mathbf{Z}$-modules. However, it is sometimes useful to allow X and Y to be distinct sublattices of a standard lattice. The bilinear pairing is always given by the standard inner product: $\langle x, y \rangle = x y^T$.

97.1.2 Definition of a Split Root Datum

Suppose Φ is a finite subset of $X \setminus \{0\}$. For each α in Φ, suppose there is a corresponding $\alpha^\star$ in $Y \setminus \{0\}$; set $\Phi^\star = \{\alpha^\star \mid \alpha \in \Phi\}$. The datum $R = (X, \Phi, Y, \Phi^\star)$ is said to be a *(split) root datum* if the following conditions are satisfied for every α in Φ

1. s_α and $s_\alpha^\star$ are reflections;
2. Φ is closed under the action of s_α; and
3. $\Phi^\star$ is closed under the action of $s_\alpha^\star$.

The lattice X is called the *full root lattice* and Y the *full coroot lattice*. The vector space $X \otimes \mathbf{Q}$ is called the *root space* and $Y \otimes \mathbf{Q}$ the *coroot space*. The elements of Φ are called *roots* and the elements of $\Phi^\star$ are called *coroots*. A root datum is *reduced*, if $\alpha, \beta \in \Phi$ with β a scalar product of α implies $\alpha = \pm\beta$.

97.1.3 Simple and Positive Roots

A subset Δ of Φ is called a set of *simple roots* if

1. Δ is a basis for the rational span of the roots $\mathbf{Q}\Phi \leq \mathbf{Q} \otimes X$; and
2. $\Phi = \Phi^+ \cup \Phi^-$, where Φ^+ is the set of linear combinations of elements of Δ with nonnegative coefficients, and $\Phi^- = -\Phi^+$.

Every root datum has a set of simple roots. Simple roots are frequently called fundamental roots. The elements of Φ^+ are called *positive roots* and the elements of Φ^- *negative roots*. The coroots corresponding to the simple (resp. positive, negative) roots are the *simple* (respectively, *positive*, *negative*) *coroots*.

The *rank* of the root datum is the size of Δ, i.e. the dimension of the subspace $\mathbf{Q}\Phi$. The rank cannot be larger than the *dimension* of the root datum (i.e. the dimension of $\mathbf{Q} \otimes X$). If the rank and dimension are equal, the root datum is said to be *semisimple*.

Choose a basis $e_1, \ldots, e_d$ for X and a dual basis $f_1, \ldots, f_d$ for Y, so that $\langle e_i, f_j \rangle = \delta_{ij}$. A reduced root system is determined by a pair of integral matrices A and B where the rows of A are the simple roots and the rows of B are the corresponding coroots; i.e. $A_{ij} = \langle \alpha_i, f_j \rangle$ and $B_{ij} = \langle e_j, \alpha_i^\star \rangle$.

97.1.4 The Coxeter Group

The group W generated by the reflections s_α, for α a simple root, is a finite Coxeter group. The *Cartan matrix* of a root datum is

$$C = \left(\left\langle \, \alpha_i, \alpha_j^\star \, \right\rangle \right)_{i,j=1}^{n} = AB^t.$$

As in Chapter 95, the Cartan matrix is used to define the Coxeter matrix, Coxeter graph and Dynkin digraph of a root datum.

A *Coxeter form* is a W-invariant bilinear form on X. If R is reduced and irreducible, then the roots can have at most two different lengths with respect to this form. We call the roots *long* or *short* accordingly. The Coxeter form is normalised so that the short roots in each component have length one. Note that, even if $X = Y$, this form will generally not be the same as the pairing $\langle \circ, \circ \rangle$; however it can often be arranged for them to be the same (see `StandardRootSystem`).

97.1.5 Nonreduced Root Data

A root datum is *reduced*, if $\alpha, \beta \in \Phi$ with β a scalar product of α implies $\alpha = \pm\beta$. A root α with the property $2\alpha \notin \Phi$ is called *reduced*. A root α with the property $\frac{1}{2}\alpha \in \Phi$ is called *divisible*. If R is a root datum, then the set R_0 of indivisible roots in R form the *indivisible subsystem*.

Let R be a nonreduced irreducible root datum of rank n. It can be shown that R_0 is irreducible of type of type B_n and every root is either in R_0, or is two times a short root of R_0. The Cartan type of R in this case is BC_n.

Note that the Cartan matrix, Coxeter matrix, Coxeter diagram, Coxeter group and Dynkin diagram are the same for R and R_0. Thus, when creating a non-reduced root datum for a given Cartan matrix, Coxeter matrix, Coxeter diagram, Coxeter group or Dynkin diagram, one must specify the set of non-reduced fundamental roots. E.g., let C be a cartan matrix of type $B_2 \times B_3$. Then the set of nonreduced fundamental roots can be one of $\emptyset$, $\{2\}$, $\{5\}$ or $\{2, 5\}$, in which cases the root datum will be of types $B_2 \times B_3$, $BC_2 \times B_3$, $B_2 \times BC_3$ or $BC_2 \times BC_3$ respectively.

97.1.6 Isogeny of Split Reduced Root Data

The Dynkin digraph and dimension do not completely determine the isomorphism type of a split root datum, as the Coxeter graph and dimension do for a root system. Two root data with isomorphic Dynkin digraphs are said to be *Cartan equivalent*. We now describe the isomorphism classes within each Cartan equivalence class of split reduced irreducible root data. Since every semisimple reduced root datum is isogenous to a direct sum of irreducible root data, this immediately gives a classification of the split semisimple root data. Classifying nonsemisimple root data would be more complicated.

The *weights* of a root datum are the λ in $\mathbf{Q}\Phi \leq X \otimes \mathbf{Q}$ such that $\langle \lambda, \alpha^\star \rangle \in \mathbf{Z}$ for every coroot $\alpha^\star$. The weights form a lattice Λ called the *weight lattice*. We now have lattices $\mathbf{Z}\Phi \leq X \leq \Lambda$ (note that the second inclusion holds only for semisimple root data). The isomorphism class of a root datum in a fixed Cartan equivalence class is determined by the position of X between the root lattice $\mathbf{Z}\Phi$ and the weight lattice Λ. Alternatively, the isomorphism class is determined by the *isogeny group* $X/\mathbf{Z}\Phi$ within the *fundamental group* $\Lambda/\mathbf{Z}\Phi$. The fundamental group is determined by the Cartan matrix C: it is isometric to $\mathbf{Z}^n/\Theta$ where Θ is the lattice generated by the rows of C. The fundamental groups of the irreducible Cartan equivalence classes are

A_n: $\mathbf{Z}/(n+1)$;

B_n, C_n, E_7: $\mathbf{Z}/2$;

D_n: $\mathbf{Z}/4$ for n odd, $\mathbf{Z}/2 \times \mathbf{Z}/2$ for n even;

E_6: $\mathbf{Z}/3$;

E_8, F_4, G_2: trivial.

If $X = \mathbf{Z}\Phi$ the root datum is said to be *adjoint*; if $X = \Lambda$ it is said to be *simply connected*. The quotient $Y/\mathbf{Z}\Phi^\star$ is called the *coisogeny group*; in the semisimple case it is isomorphic to $\Lambda/\mathbf{Z}\Phi$.

97.1.7 Extended Root Data

An extended root datum is a split root datum $R = (X, \Phi, Y, \Phi^\star)$ and a permutation group Γ with actions on X and Y that respect the pairing $\langle \circ, \circ \rangle$.

Fix a set of simple roots Δ. Let $O(\chi)$ denote the orbit of $\chi \in X$ under the Γ-action. Then, for $\alpha \in \Phi$ either $O(\alpha)$ is contained in Φ^+, or it is contained in Φ^-, or the sum of the roots of $O(\alpha)$ is zero. We call $O(\alpha)$ a *positive*, *negative* or *zero orbit*, respectively. Put

$$X_0 := \{\chi \in X \mid \sum_{\gamma \in \Gamma} \chi^\gamma = 0\}.$$

Let $\Phi_0 := \Phi \cap X_0$ and $\Delta_0 := \Delta \cap X_0$. Then X_0 is a submodule of X, Φ_0 is a subsystem of Φ, and Δ_0 is a fundamental system of Φ_0. Note that Δ_0 is not necessarily a basis of X_0. Analogously, we define Y_0 and $\Phi_0^\star$. The subdatum $R_0 = (X_0, \Phi_0, Y_0, \Phi_0^\star)$ is called the *anisotropic subdatum* of R.

Set $\bar{X} := X/X_0$ and let $\pi : X \to \bar{X}$ be the standard projection. Then $\bar{X}$ is a free $\mathbf{Z}$-module and π is a homomorphism of modules. Let $\bar{\Phi}$ and $\bar{\Delta}$ be the images under π of $\Phi \setminus \Phi_0$ and $\Delta \setminus \Delta_0$, respectively. Then $\bar{\Phi}$ is a root system and $\bar{\Delta}$ is a fundamental system of it. We call $\bar{\Phi}$ the *relative root system* and $\bar{\Delta}$ the *relative fundamental system*. Note that $\bar{\Phi}$ need not be irreducible nor reduced even if Φ is. The rank of the relative system is $|\bar{\Delta}|$ and is called the *relative rank*, whereas the rank $|\Delta|$ of Φ is called the *absolute rank*. Let $\bar{\Phi}^+$ and $\bar{\Phi}^-$ denote the images under π of $\Phi^+ \setminus \Phi_0$ and $\Phi^- \setminus \Phi_0$. When $X_0 = X$, the relative root system is an empty set and the form is called *anisotropic*.

Each $\gamma \in \Gamma$ acts on X by $\chi \mapsto \chi^{\sigma w}$ for some unique $w \in W$ and σ a Dynkin diagram symmetry. By $\alpha \mapsto \alpha^\sigma$ for $\alpha \in \Delta$ we define the $[\Gamma]$-action on Δ. The extended root datum is called *inner* if the $[\Gamma]$-action is trivial and *outer* otherwise. The orbits of the $[\Gamma]$-action, that are not contained in X_0 are called *distinguished*.

An extended root datum is called *twisted* if the Γ-action is not trivial.

The (split) Cartan name of an extended root datum is the name of the corresponding split root datum. An extended root datum is *absolutely irreducible* if the corresponding split datum is irreducible. It is irreducible if there is no direct sum decomposition of the split datum which is preserved under the action of Γ. The *twisted Cartan name* of a root datum is the Cartan name, with extra information describing the twist. The name ${}^m X_{n,e}$ indicates a root datum with split Cartan name X_n, where the kernel of the $[\Gamma]$-action has index m in Γ, and e is the rank of the relative root system. The twisted Cartan name describes absolutely irreducible root data up to isomorphism. This is not true for simple root data however.

97.2 Constructing Root Data

We first describe some optional parameters that are common to many functions described below.

`Isogeny` ANY *Default :* `"Ad"`

The optional parameter `Isogeny` specifies the isomorphism class of the root datum within the Cartan equivalence class (see Subsection 97.1.6). For irreducible Cartan names, `Isogeny` can be one of the following:

1. A string: `"Ad"` for adjoint or `"SC"` for simply connected.
2. An integer giving the size of the isogeny subgroup within the fundamental group. The root datum must be absolutely irreducible. This does not work in type D_n with n even and `Isogeny` $= 2$, since in this case there are three distinct isomorphism classes (see the example below to create these data).
3. An injection of an abelian group into the fundamental group.

For compound Cartan names, `Isogeny` can be a string (`"Ad"` or `"SC"`); an injection into the fundamental group; or a list of strings, integers and injections (one for each direct summand).

`Signs` ANY *Default :* 1

Many of the constants associated with root data depend on the choice of the sign ϵ_{rs} for each extraspecial pair (r, s). This parameter allows the user to fix these signs for the root datum R by giving a sequence s of length `NumExtraspecialPairs(R)` consisting of integers 1 or -1. It is also possible to set `Signs` to 1 instead of a sequence of all 1 and to -1 instead of a sequence of all -1.

`Twist` ANY *Default :* 1

This optional parameter defines a Γ-action of an extended root datum and will accept the following values:

1. a homomorphism from Γ into `Sym(2*N)`, where N is the number of positive roots, specifying the action of Γ on the (co)roots. (Only for semisimple root data).
2. an integer i giving the order of Γ, e.g., $1, 2, 3, 6$ for ${}^1D_4$, ${}^2D_4$, ${}^3D_4$, ${}^6D_4$ (only if $i = 1$ or the root datum is irreducible).
3. $\langle D, i\rangle$, where D is a set of distinguished orbits as sets of integers and i (integer) is the order of the Dynkin diagram symmetry involved (only for irreducible root data).
4. $\langle \Gamma, ims\rangle$, where Γ is the acting group and ims define images either as permutations of the simple roots or as permutation of all roots (only for semisimple root data).
5. $\langle \Gamma, imsR, imsC\rangle$, where Γ is the acting group and $imsR$ ($imsC$) is a sequence of matrices defining the action of Γ on the root space (coroot space).

`Nonreduced` SETENUM *Default :* {}

The optional argument `Nonreduced` is used to give the set of indices of the nonreduced simple roots. Note that a root datum cannot be both twisted and nonreduced.

`RootDatum(N)`

`Isogeny`	ANY	*Default :* `"Ad"`
`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1

A root datum with Cartan name given by the string N (see Section 95.6). In addition to the possible Cartan names described in Section 95.6, this function will also accept `"Tn"` as a component of the Cartan name, which stands for an n-dimensional toral subdatum. Note, however, that this addition is for input only and will not appear in the string returned by `CartanName` when applied to the resulting root datum (see example below).

If the optional parameter `Isogeny` is a list, its length should be equal to the total number of components. Entries of this list corresponding to toral components will be ignored.

If the corresponding Coxeter group is infinite affine, an error is flagged.

Example H97E1

Examples of adjoint and simply connected irreducible root data.

```
> RootDatum("E6");
Adjoint root datum of type E6
> RootDatum("E6" : Isogeny := "SC");
Simply connected root datum of type E6
```

With nonirreducible root data the isogeny can be given as a list.

```
> R := RootDatum("A5 B3" : Isogeny := [* 3, "Ad" *]);
> R : Maximal;
Root datum of type A5 B3 with simple roots
[1 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0]
[0 0 0 1 0 0 0 0]
[1 2 0 1 3 0 0 0]
[0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 1]
and simple coroots
[ 2 -1  0  0  0  0  0  0]
[-1  2 -1  0 -1  0  0  0]
[ 0 -1  2 -1  1  0  0  0]
[ 0  0 -1  2 -1  0  0  0]
[ 0  0  0 -1  1  0  0  0]
[ 0  0  0  0  0  2 -1  0]
[ 0  0  0  0  0 -1  2 -1]
[ 0  0  0  0  0  0 -2  2]
>
```

```
> RootDatum("E6 A3 B4" : Isogeny := "SC");
Simply connected root datum of type E6 A3 B4
```

Nonsemisimple root data can be constructed by specifying a central torus.

```
> R := RootDatum("B3 T2 A2" : Isogeny := [* "SC", 0, "Ad" *]);
> R;
R: Root datum of type B3 A2
> Dimension(R), Rank(R);
7 5
> SimpleCoroots(R);
[ 1  0  0  0  0  0  0]
[ 0  1  0  0  0  0  0]
[ 0  0  1  0  0  0  0]
[ 0  0  0  0  0  2 -1]
[ 0  0  0  0  0 -1  2]
```

The following code creates the three root data of type D_6 with isogeny groups of size 2 using injections into the fundamental group.

```
> G< a, b > := FundamentalGroup("D6");
> G;
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*a = 0
    2*b = 0
> _, inj1 := sub< G | a >;
> R1 := RootDatum("D6" : Isogeny := inj1);
> _, inj2 := sub< G | b >;
> R2 := RootDatum("D6" : Isogeny := inj2);
> _, inj3 := sub< G | a*b >;
> R3 := RootDatum("D6" : Isogeny := inj3);
```

Example H97E2

Examples of extended root data:

```
> R := RootDatum("A5" : Twist := 2 ); R;
R: Twisted adjoint root datum of type 2A5,3
> R eq RootDatum("A5" : Twist := < Sym(2), [Sym(5)|(1,5)(2,4)] > );
true
> R eq RootDatum("A5" : Twist := < {{1,5},{2,4},{3}}, 2 > );
true
> RootDatum("D4" : Twist := 1);
Adjoint root datum of type D4
> RootDatum("D4" : Twist := 2);
Twisted adjoint root datum of type 2D4,3
> RootDatum("D4" : Twist := 3);
Twisted adjoint root datum of type 3D4,2
```

```
> RootDatum("D4" : Twist := 6);
Twisted adjoint root datum of type 6D4,2
>
> R := RootDatum("A2");
> TwistedRootDatum(R : Twist := 2);
Twisted adjoint root datum of type 2A2,1
```

`RootDatum(C)`

`Isogeny`	ANY	*Default :* `"Ad"`
`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1
`Nonreduced`	SETENUM	*Default :* {}

A semisimple root datum with crystallographic Cartan matrix C. If the corresponding Coxeter group is infinite, an error is flagged.

`RootDatum(D)`

`Isogeny`	ANY	*Default :* `"Ad"`
`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1
`Nonreduced`	SETENUM	*Default :* {}

A semisimple root datum with Dynkin digraph D. If the corresponding Coxeter group is infinite, an error is flagged.

`RootDatum(A, B)`

`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1
`Nonreduced`	SETENUM	*Default :* {}

The root datum with simple roots given by the rows of the matrix A and simple coroots given by the rows of the matrix B. The matrices A and B must have the following properties:

1. A and B must be integral matrices with the same number of rows and the same number of columns;
2. the number of columns must be at least the number of rows; and
3. AB^t must be the Cartan matrix of a finite Coxeter group.

Example H97E3

An example of a nonsemisimple root system of type G_2:

```
> A := Matrix(2,3, [1,-1,0, -1,1,-1]);
> B := Matrix(2,3, [1,-1,1, 0,1,-1]);
> RootDatum(A, B);
Root datum of type G2
```

An example of a non-reduced root datum and usage of `Nonreduced` argument:

```
> C := CoxeterMatrix("B2B2");
> RootDatum(C);
Adjoint root datum of type B2 B2
> RootDatum(C : Nonreduced:={2});
Adjoint root datum of type BC2 B2
> RootDatum(C : Nonreduced:={4});
Adjoint root datum of type B2 BC2
> RootDatum(C : Nonreduced:={2,4});
Adjoint root datum of type BC2 BC2
```

`IrreducibleRootDatum(X, n)`

`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1

The irreducible root datum with Cartan name X_n.

`StandardRootDatum(X, n)`

`Signs`	ANY	*Default :* 1
`Twist`	ANY	*Default :* 1

The standard root datum with Cartan name X_n, i.e. the root datum with the standard inner product equal to the Coxeter form up to a constant. For technical reasons, this is only possible for the classical types, i.e. X must be `"A"`, `"B"`, `"C"`, or `"D"`. Note that the standard root datum is not semisimple for type A_n.

Example H97E4

These functions are useful in loops.

```
> for X in ["A","B","G"] do
>   print NumPosRoots(IrreducibleRootDatum(X, 2));
> end for;
3
4
6
```

`ToralRootDatum(n)`

`Twist` ANY *Default :* 1

The toral root datum of dimension n, i.e., the n-dimensional root datum with no roots or coroots.

Example H97E5

Toral root datum of dimension 3 and a twisted version of it:

```
> ToralRootDatum(3);
Toral root datum of dimension 3
> M := Matrix(Rationals(),3,3,[0,1,0,1,0,0,0,0,1]);M;
[0 1 0]
[1 0 0]
[0 0 1]
> ToralRootDatum(3 : Twist := <Sym(2),[M],[M]>);
Twisted toral root datum of dimension 3
```

`TrivialRootDatum()`

The trivial root datum of dimension 0.

97.2.1 Constructing Sparse Root Data

Sparse root data differ from the usual root data only in the internal representation of the objects. The internal representation is less memory expensive and requires less time for creation. Sparse root data have type `RootDtmSprs`, which is a subcategory of `RootDtm`.

There are some limitation on the root data which can have sparse representation. First, sparse representation only makes sense for classical root data, that is of types A, B, C and D. At the moment only root data with a connected Coxeter diagram may have sparse representation and no twisted sparse root data can be constructed. T

`SparseRootDatum(N)`

`SparseRootDatum(N)`

`SparseRootDatum(C)`

`SparseRootDatum(D)`

`SparseRootDatum(R)`

`SparseRootDatum(A, B)`

`SparseIrreducibleRootDatum(X, n)`

`SparseStandardRootDatum(X, n)`

These functions have the same syntax as their counterparts without the "Sparse" in the name (see Section 97.2). The root datum returned has sparse representation. See [CHM08] for the algorithms used to construct sparse root data.

Example H97E6

```
> SparseRootDatum("A2");
Sparse adjoint root datum of dimension 2 of type A2
> SparseStandardRootDatum("A", 2);
Sparse root datum of dimension 3 of type A2
> SparseRootDatum("A2") eq RootDatum("A2");
true
```

`SparseRootDatum(R)`

Return a sparse root datum equal to the root datum R.

`RootDatum(R)`

Return a non-sparse root datum equal to the root datum R.

Example H97E7

Due to the restrictions mentioned above, some operations that create new root data, will return a non-sparse root datum even though the input was sparse.

```
> R := SparseRootDatum("A2");
> T := ToralRootDatum(3);
> R+T;
Sparse root datum of dimension 5 of type A2
> R+R;
Adjoint root datum of dimension 4 of type A2 A2
```

97.3 Operations on Root Data

`R1 eq R2`

Returns `true` if, and only if, R_1 and R_2 are identical root data.

`IsIsomorphic(R1, R2)`

Returns `true` if, and only if, R_1 and R_2 are isomorphic root data. If `true`, the second value returned is a sequence giving the simple root of R_2 corresponding to each simple root of R_1, and the third value returned is an isomorphism $R_1 \to R_2$. This function is currently only implemented for semisimple root data.

`IsCartanEquivalent(R1, R2)`

Returns `true` if, and only if, the root data R_1 and R_2 are Cartan equivalent, i.e. they have isomorphic Dynkin diagrams. If `true`, the second value returned is a sequence giving the simple root of R_2 corresponding to each simple root of R_1.

`IsIsogenous(R1, R2)`

Returns `true` if, and only if, R_1 and R_2 are isogenous root data. If `true`, the subsequent values returned are: a sequence giving the simple root of R_2 corresponding to each simple root of R_1, the corresponding adjoint root datum R_{ad}, the morphisms $R_{ad} \to R_1$ and $R_{ad} \to R2$, the corresponding simply connected root datum R_{sc}, and the morphisms $R_1 \to R_{sc}$ and $R_2 \to R_{sc}$.

Example H97E8

An example of isogenous root data:

```
> R1 := RootDatum("A3");
> R2 := RootDatum("A3" : Isogeny := "SC");
> R1 eq R2;
false
> IsIsomorphic(R1, R2);
false
> IsCartanEquivalent(R1, R2);
true [ 1, 2, 3 ]
> IsIsogenous(R1, R2);
true [ 1, 2, 3 ]
Adjoint root datum of type A3
Mapping from: RootDtm: ad to RootDtm: ad
Mapping from: RootDtm: ad to RootDtm: sc
Simply connected root datum of type A3
Mapping from: RootDtm: ad to RootDtm: sc
Mapping from: RootDtm: sc to RootDtm: sc
```

An example of distinct isomorphic root data:

```
> C := CartanMatrix("B2");
> R1 := RootDatum(C);
```

```
> R2 := RootDatum(Transpose(C));
> R1; R2;
Adjoint root datum of type B2
Adjoint root datum of type C2
> R1 eq R2;
false
> IsIsomorphic(R1, R2);
true [ 2, 1 ]
```

`CartanName(R)`

The Cartan name of the root datum R (Section 95.6).

`TwistedCartanName(R)`

The twisted Cartan name of the root datum R. E.g., `"2A_3,2"`.

`CoxeterDiagram(R)`

Print the Coxeter diagram of the root datum R (Section 95.6).

`DynkinDiagram(R)`

Print the Dynkin diagram of the root datum R (Section 95.6).

`CoxeterMatrix(R)`

The Coxeter matrix of the root datum R (Section 95.2).

`CoxeterGraph(R)`

The Coxeter graph of the root datum R (Section 95.3).

`CartanMatrix(R)`

The Cartan matrix of the root datum R (Section 95.4).

`DynkinDigraph(R)`

The Dynkin digraph of the root datum R (Section 95.5).

Example H97E9

```
> R := RootDatum("F4");
> DynkinDiagram(R);
F4    1 - 2 =>= 3 - 4
> CoxeterDiagram(R);
F4    1 - 2 === 3 - 4
```

Example H97E10

```
> R := RootDatum("G2");
> RootSpace(R);
Standard Lattice of rank 2 and degree 2
> CorootSpace(R);
Standard Lattice of rank 2 and degree 2
> // Add RootLattice, CorootLattice.
> // and maybe move (Co)RootSpace and (Co)RootLattice
> // to after introducing them
> SimpleRoots(R);
[1 0]
[0 1]
> SimpleCoroots(R);
[ 2 -3]
[-1  2]
> CartanMatrix(R);
[ 2 -1]
[-3  2]
> Rank(R) eq Dimension(R);
true
```

`GammaAction(R)`

The Γ-action of the root datum R. This is a record consisting of four elements: `gamma` is the Group Γ acting on R, `perm_ac` is the homomorphism defining the permutation action of Γ on the set of all roots of R, finally `mats_rt` and `mats_co` are sequences of matrices defining the action of Γ on the root and coroot spaces of R.

`GammaRootSpace(R)`

`GammaCorootSpace(R)`

The fixed space Γ acting on the (co)root space of R.

`GammaOrbitOnRoots(R,r)`

The orbit through the rth root of the Γ-action on the root datum R.

`GammaOrbitsOnRoots(R)`
`PositiveGammaOrbitsOnRoots(R)`
`NegativeGammaOrbitsOnRoots(R)`
`ZeroGammaOrbitsOnRoots(R)`

The sequence of all (respectively positive, negative and zero) orbits of the Γ-action on the root datum R (Section 97.1.7).

`GammaActionOnSimples(R)`

The [Γ]-action on the simple (co)roots of the root datum R. (Section 97.1.7). This function was called `GammaActionPi` in the last release.

`OrbitsOnSimples(R)`

The sequence of all orbits of the [Γ]-action on the simple (co)roots of the root datum R (Section 97.1.7). This function was called `OrbitsPi` in the last release.

`DistinguishedOrbitsOnSimples(R)`

The sequence of distinguished orbits of the [Γ]-action on the simple (co)roots of the root datum R (Section 97.1.7). This function was called `DistinguishedOrbitsPi` in the last release.

`BaseRing(R)`

The base ring of the root datum R is the field of rational numbers.

`Rank(R)`
`AbsoluteRank(R)`

The (absolute) rank of the root datum R, i.e. the number of simple (co)roots.

`RelativeRank(R)`

The relative rank of the root datum R, i.e. the number of simple (co)roots of the relative root system. This is the same as absolute rank for split root data.

`Dimension(R)`

The dimension of the root datum R, i.e. the dimension of the (co)root space. This is at least as large as the rank, with equality when R is semisimple.

`TwistingDegree(R)`

The twisting degree of the root datum R, i.e. the order of Γ divided by the kernel of the [Γ]-action.

`AnisotropicSubdatum(R)`

The anisitropic subdatum of the root datum R.

Example H97E11

Consider the twisted root datum of type ${}^2A_{3,1}$ with distinguished orbit $\{2\}$:

```
> R := RootDatum( "A3" : Twist := < {{2}}, 2 > );
```

First, print out the action of Γ on the root datum:

```
> GammaAction(R);
rec<recformat<gamma: GrpPerm, perm_ac: HomGrp, mats_rt, mats_co> |
     gamma := Permutation group acting on a set of cardinality 4
     Order = 4 = 2^2
          (1, 2, 3, 4),
     perm_ac := Homomorphism of GrpPerm: $, Degree 4, Order 2^2 into GrpPerm: $,
     Degree 12, Order 2^10 * 3^5 * 5^2 * 7 * 11 induced by
          (1, 2, 3, 4) |--> (1, 3, 7, 9)(2, 4, 6, 5)(8, 10, 12, 11),
     mats_rt := [
          [ 0  0  1]
          [ 1  1  0]
          [-1  0  0]
     ],
     mats_co := [
          [ 0  0  1]
          [ 0  1  0]
          [-1  1  0]
     ]
     >
```

Compute the orbits of the Γ-action:

```
> PositiveGammaOrbitsOnRoots(R);
[
     GSet{ 2, 4, 5, 6 }
]
> NegativeGammaOrbitsOnRoots(R);
[
     GSet{ 8, 10, 11, 12 }
]
> ZeroGammaOrbitsOnRoots(R);
[
     GSet{ 1, 3, 7, 9 }
]
> &+[ Root(R,r) : r in ZeroGammaOrbitsOnRoots(R)[1] ];
(0 0 0)
```

Compute the $[\Gamma]$-action and its orbits:

```
> GammaActionOnSimples(R);
Homomorphism of GrpPerm: $, Degree 4, Order 2^2 into GrpPerm: $,
Degree 3, Order 2 * 3 induced by
     (1, 2, 3, 4) |--> (1, 3)
```

```
> OrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 1, 3 }
]
> DistinguishedOrbitsOnSimples(R);
[
     GSet{ 2 }
]
```

Absolute and relative rank and the twisting degree, as well as their appearance in the name of the root datum:

```
> AbsoluteRank(R);
3
> RelativeRank(R);
1
> TwistingDegree(R);
2
> R;
R: Twisted adjoint root datum of type 2A3,1
```

anisotropic subdatum:

```
> A := AnisotropicSubdatum(R); A;
A: Twisted root datum of type 2(A1 A1)2,0
> GammaAction(A)‘perm_ac;
Homomorphism of GrpPerm: $, Degree 4, Order 2^2 into GrpPerm: $,
Degree 4, Order 2^2 induced by
     (1, 2, 3, 4) |--> (1, 2, 3, 4)
```

`CoxeterGroupOrder(R)`

The order of the (split) Coxeter group of the root datum R.

`GroupOfLieTypeOrder(R, q)`

The order of the group of Lie type with split root datum R over the field of cardinality q.

`GroupOfLieTypeFactoredOrder(R, q)`

The factored order of the group of Lie type with split root datum R over the field of order q.

Example H97E12

As well as accepting a specific prime power, these functions also take an indeterminate so that the generic order formula can be computed.

```
> P<q> := PolynomialRing(Integers());
> R := RootDatum("F4");
> GroupOfLieTypeFactoredOrder(R, q);
[
    <q - 1, 4>,
    <q, 24>,
    <q + 1, 4>,
    <q^2 - q + 1, 2>,
    <q^2 + 1, 2>,
    <q^2 + q + 1, 2>,
    <q^4 - q^2 + 1, 1>,
    <q^4 + 1, 1>
]
>
> R := RootDatum("B2");
> ord := GroupOfLieTypeOrder(R, q);
> forall{ q : q in [2..200] | not IsPrimePower(q) or
>   Evaluate(ord, q) eq GroupOfLieTypeOrder(R, q) };
true
```

`FundamentalGroup(R)`

The fundamental group $\Lambda/\mathbf{Z}\Phi$ of the root datum R together with the projection $\Lambda \to \Lambda/\mathbf{Z}\Phi$. See Subsection 97.1.6.

`IsogenyGroup(R)`

The isogeny group $X/\mathbf{Z}\Phi$ of the root datum R together with the projection $X \to X/\mathbf{Z}\Phi$. If R is semisimple, the injection $X/\mathbf{Z}\Phi \to \Lambda/\mathbf{Z}\Phi$ is also returned. See Subsection 97.1.6.

`CoisogenyGroup(R)`

The coisogeny group $Y/\mathbf{Z}\Phi^\star$ of the root datum R together with the projection $Y \to Y/\mathbf{Z}\Phi^\star$. If R is semisimple, the projection $Y/\mathbf{Z}\Phi^\star \to \Lambda/\mathbf{Z}\Phi$ is also returned. See Subsection 97.1.6.

Example H97E13

In the semisimple case, the fundamental group contains the isogeny group, with quotient isomorphic to the coisogeny group.

```
> R := RootDatum("A5" : Isogeny := 3);
> F := FundamentalGroup(R);
> G := IsogenyGroup(R);
> H := CoisogenyGroup(R);
> #G * #H eq #F;
true
```

Nonsemisimple root data have infinite isogeny groups.

```
> R := StandardRootDatum("A", 5);
> IsogenyGroup(R);
Abelian Group isomorphic to Z
Defined on 1 generator (free)
```

97.4 Properties of Root Data

`IsFinite(R)`

Returns `true` for any root datum R.

`IsIrreducible(R)`

Returns `true` if, and only if, the root datum R is irreducible.

`IsAbsolutelyIrreducible(R)`

Returns `true` if, and only if, the split version of the root datum R is irreducible.

`IsProjectivelyIrreducible(R)`

Returns `true` if, and only if, the quotient of the root datum R modulo its radical is irreducible. This is equivalent for R to have a connected Coxeter diagram.

`IsReduced(R)`

Returns `true` if, and only if, the root datum R is reduced.

`IsSemisimple(R)`

Returns `true` if, and only if, the root datum R is semisimple, i.e. its rank is equal to its dimension.

`IsCrystallographic(R)`

Returns `true` for any root datum R.

`IsSimplyLaced(R)`

Returns `true` if, and only if, the root datum R is simply laced, i.e. its Dynkin diagram contains no multiple bonds.

`IsAdjoint(R)`

Returns `true` if, and only if, the root datum R is adjoint, i.e. its isogeny group is trivial.

`IsWeaklyAdjoint(R)`

Returns `true` if, and only if, the root datum R is weakly adjoint, i.e. its isogeny group is isomorphic to $\mathbf{Z}^n$, where n is $\dim(R) - \mathrm{rk}(R)$. Note that if R is semisimple then this function is identical to IsAdjoint.

`IsSimplyConnected(R)`

Returns `true` if, and only if, the root datum R is simply connected, i.e. its isogeny group is equal to the fundamental group, i.e. its coisogeny group is trivial.

`IsWeaklySimplyConnected(R)`

Returns `true` if, and only if, the root datum R is weakly simply connected, i.e. its coisogeny group is isomorphic to $\mathbf{Z}^n$, where n is $\dim(R) - \mathrm{rk}(R)$. Note that if R is semisimple then this function is identical to IsSimplyConnected.

Example H97E14

```
> R := RootDatum("A5 B2" : Isogeny := "SC");
> IsIrreducible(R);
false
> IsSimplyLaced(R);
false
> IsSemisimple(R);
true
> IsAdjoint(R);
false
```

For some of the exceptional isogeny classes, there is only one isomorphism class of root data, which is both adjoint and simply connected.

```
> R := RootDatum("G2");
> IsAdjoint(R);
true
> IsSimplyConnected(R);
true
```

There exist root data that are neither adjoint nor simply connected.

```
> R := RootDatum("A3" : Isogeny := 2);
> IsAdjoint(R), IsSimplyConnected(R);
```

```
false false
```

Finally, we demonstrate a case where the root datum is not adjoint, but is weakly adjoint.

```
> R := RootDatum("A2T1");
> IsAdjoint(R), IsWeaklyAdjoint(R);
false true
> Dimension(R), Rank(R);
3 2
> G := IsogenyGroup(R); G;
Abelian Group isomorphic to Z
Defined on 1 generator (free)
```

`IsReduced(R)`

Returns `true` if, and only if, the root datum R is reduced.

`IsSplit(R)`

Returns `true` if, and only if, the root datum R is split, i.e. the Γ-action is trivial.

`IsTwisted(R)`

Returns `true` if, and only if, the root datum R is twisted, i.e. the Γ-action is not trivial.

`IsQuasisplit(R)`

Returns `true` if, and only if, the root datum R is quasisplit, i.e. the anisotropic subdatum is trivial.

`IsInner(R)`
`IsOuter(R)`

Returns `true` if, and only if, the root datum R is inner (resp. outer).

`IsAnisotropic(R)`

Returns `true` if, and only if, the root datum R is anisotropic, i.e. when $X = X_0$.

97.5 Roots, Coroots and Weights

The roots are stored as an indexed set

$$\{@\ \alpha_1, \ldots, \alpha_N, \alpha_{N+1}, \ldots, \alpha_{2N}\ @\},$$

where $\alpha_1, \ldots, \alpha_N$ are the positive roots in an order compatible with height; and $\alpha_{N+1}, \ldots, \alpha_{2N}$ are the corresponding negative roots (i.e. $\alpha_{i+N} = -\alpha_i$). The simple roots are $\alpha_1, \ldots, \alpha_n$ where n is the rank.

Many of these functions have an optional argument `Basis` which may take one of the following values

1. `"Standard"`: the standard basis for the (co)root space. This is the default.
2. `"Root"`: the basis of simple (co)roots.
3. `"Weight"`: the basis of fundamental (co)weights (see Subsection 99.8.3 below).

97.5.1 Accessing Roots and Coroots

`RootSpace(R)`

`CorootSpace(R)`

The vector space containing the (co)roots of the root datum R, i.e. $X \otimes \mathbf{Q}$ (respectively, $Y \otimes \mathbf{Q}$).

`FullRootLattice(R)`

`FullCorootLattice(R)`

The lattice containing the (co)roots of the root datum R, i.e. X (respectively, Y). An inclusion map into the (co)root space of R is returned as the second value.

`RootLattice(R)`

`CorootLattice(R)`

The lattice spanned by the (co)roots of the root datum R. An inclusion map into the (co)root space of R is returned as the second value.

Example H97E15

The root space, full root lattice and the root lattice of the standard root datum of type A_2:

```
> R := StandardRootDatum("A",2);
> V := RootSpace(R);
> FullRootLattice(R);
Standard Lattice of rank 3 and degree 3
Mapping from: Standard Lattice of rank 3 and degree 3 to ModTupFld: V
> RootLattice(R);
Lattice of rank 2 and degree 3
Basis:
( 1 -1  0)
( 0  1 -1)
Mapping from: Lattice of rank 2 and degree 3 to ModTupFld: V
```

`IsRootSpace(V)`

`IsCorootSpace(V)`

Return `true` if, and only if, V is the (co)root space of some root datum.

`IsInRootSpace(v)`

`IsCorootSpace(v)`

Return `true` if, and only if, V is an element of the (co)root space of some root datum.

`RootDatum(V)`

If V is the (co)root space of some root datum, this returns the datum.

Example H97E16

```
> R := RootDatum("a3");
> V := RootSpace(R);
> v := V.1;
> IsRootSpace(V);
true
> RootDatum(V);
R: Adjoint root datum of dimension 3 of type A3
> IsInRootSpace(v);
true
```

`ZeroRootLattice(R)`

`ZeroRootSpace(R)`

For the given root datum R, return the lattice X_0 and the vector space $X_0 \otimes \mathbf{Q}$, respectively (see Section 97.1.7).

`RelativeRootSpace(R)`

For the given root datum R, return the vector space $\bar{X} = (X \otimes \mathbf{Q})/(X_0 \otimes \mathbf{Q})$ containing the relative roots (see Section 97.1.7). The projection from $X \otimes \mathbf{Q}$ onto $\bar{X}$ is returned as second return value.

`SimpleRoots(R)`

`SimpleCoroots(R)`

The simple (co)roots of the root datum R as the rows of a matrix, i.e. A (respectively, B).

`NumberOfPositiveRoots(R)`

`NumPosRoots(R)`

The number of positive roots of the root datum R. This is also the number of positive coroots. The total number of (co)roots is twice the number of positive (co)roots.

`Roots(R)`

`Coroots(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The indexed set of (co)roots of the root datum R, i.e. $\{@\, \alpha_1, \ldots \alpha_{2N}\, @\}$ (respectively, $\{@\, \alpha_1^\star, \ldots \alpha_{2N}^\star\, @\}$).

`PositiveRoots(R)`

`PositiveCoroots(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The indexed set of positive (co)roots of the root datum R, i.e. $\{@\, \alpha_1, \ldots \alpha_N\, @\}$ (respectively, $\{@\, \alpha_1^\star, \ldots \alpha_N^\star\, @\}$).

`Root(R, r)`

`Coroot(R, r)`

`Basis` MonStgElt *Default :* `"Standard"`

The rth (co)root α_r (respectively, $\alpha_r^\star$) of the root datum R.

`RootPosition(R, v)`

`CorootPosition(R, v)`

`Basis` MonStgElt *Default :* `"Standard"`

If v is a (co)root in the root datum R, return its index; otherwise return 0. These functions will try to coerce v into the appropriate lattice; v should be written with respect to the basis specified by the parameter `Basis`.

`BasisChange(R,v)`

`InBasis` MonStgElt *Default :* `"Standard"`

`OutBasis` MonStgElt *Default :* `"Standard"`

`Coroots` BoolElt *Default :* `false`

Changes the basis of the vector v contained in the space spanned by the (co)roots of the root datum R. The vector v is considered as an element of the root space by default. If the parameter `Coroots` is set to `true`, v is considered as an element of the coroot space. The optional arguments `InBasis` and `OutBasis` may take the same values as the parameter `Basis` as described at the beginning of the current section.

Example H97E17

```
> R := RootDatum("A3" : Isogeny := 2);
> Roots(R);
{@
    (1 0 0),
    (0 1 0),
    (1 0 2),
    (1 1 0),
    (1 1 2),
    (2 1 2),
    (-1  0  0),
    (0 -1  0),
    (-1  0 -2),
    (-1 -1  0),
    (-1 -1 -2),
    (-2 -1 -2)
@}
> PositiveCoroots(R);
{@
    (2 -1 -1),
    (-1  2  0),
    (0 -1  1),
    (1  1 -1),
    (-1  1  1),
    (1 0 0)
@}
> #Roots(R) eq 2*NumPosRoots(R);
true
> Coroot(R, 4);
(1  1 -1)
> Coroot(R, 4 : Basis := "Root");
(1 1 0)
> CorootPosition(R, [1,1,-1]);
4
> CorootPosition(R, [1,1,0] : Basis := "Root");
4
> BasisChange(R, [1,0,0] : InBasis:="Root");
(1 0 0)
> BasisChange(R, [1,0,0] : InBasis:="Root", Coroots);
( 2 -1 -1)
```

`IsInRootSpace(R,v)`

`IsInCorootSpace(R,v)`

Returns `true` if and only if the vector v is contained in the (co)root space of the root datum R.

`HighestRoot(R)`

`HighestCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique (co)root of greatest height in the irreducible root datum R.

`HighestLongRoot(R)`

`HighestLongCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique long (co)root of greatest height in the irreducible root datum R.

`HighestShortRoot(R)`

`HighestShortCoroot(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique short (co)root of greatest height in the irreducible root datum R.

Example H97E18

```
> R := RootDatum("G2");
> HighestRoot(R);
(3 2)
> HighestLongRoot(R);
(3 2)
> HighestShortRoot(R);
(2 1)
```

`RelativeRoots(R)`

`PositiveRelativeRoots(R)`

`NegativeRelativeRoots(R)`

`SimpleRelativeRoots(R)`

The indexed set of all (resp. positive, negative, simple) relative roots of the root datum R. Note that the relative roots are returned in the order induced by the standard ordering on the (nonrelative) roots of R.

`RelativeRootDatum(R)`

The relative root datum of the root datum R.

`GammaOrbitsRepresentatives(R, delta)`

The preimage of a relative root δ is a disjoint union of Γ-orbits on the set of all roots of the root datum R. This intrinsic returns a sequence of representatives of these orbits.

Example H97E19

We first consider the twisted root datum of type ${}^2E_6$, which is quasisplit:

```
> DynkinDiagram(RootDatum("E6"));
E6    1 - 3 - 4 - 5 - 6
              |
              2
>
> R := RootDatum("E6" : Twist:=2 ); R;
R: Twisted adjoint root datum of type 2E6,4
> OrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 4 },
     GSet{ 1, 6 },
     GSet{ 3, 5 }
]
> DistinguishedOrbitsOnSimples(R) eq OrbitsOnSimples(R);
true
> AnisotropicSubdatum(R);
Twisted toral root datum of dimension 6
[]
> RR := RelativeRootDatum(R);RR;
RR: Adjoint root datum of type F4
> _,pi := RelativeRootSpace(R);
> DynkinDiagram(RR);
F4    1 - 2 =>= 4 - 3
> [ Position(Roots(RR), pi(Root(R,i)) ) : i in [1,6, 3,5, 4, 2]];
[ 3, 3, 4, 4, 2, 1 ]
```

now one with distinguished orbits $\{2\}$ and $\{4\}$:

```
> R := RootDatum("E6" : Twist := <{{2},{4}},2> ); R;
R: Twisted adjoint root datum of type 2E6,2
> OrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 4 },
     GSet{ 1, 6 },
     GSet{ 3, 5 }
```

```
]
> DistinguishedOrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 4 }
]
> AnisotropicSubdatum(R);
Twisted root datum of type 2(A2 A2)4,0
[ 1, 3, 5, 6, 7, 11, 37, 39, 41, 42, 43, 47 ]
> RR := RelativeRootDatum(R);RR;
RR: Adjoint root datum of type G2
> DynkinDiagram(RR);
G2    2 =<= 1
        3
> _,pi := RelativeRootSpace(R);
> [ Position(Roots(RR), pi(Root(R,i)) ) : i in [2,4]];
[ 1, 2 ]
```

and now the one with distinguished orbits $\{2\}$ and $\{1,6\}$, which has a non-reduced relative root datum:

```
> R := RootDatum("E6" : Twist := <{{2},{1,6}},2> ); R;
R: Twisted adjoint root datum of dimension 6 of type 2E6,2
> OrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 4 },
     GSet{ 1, 6 },
     GSet{ 3, 5 }
]
> DistinguishedOrbitsOnSimples(R);
[
     GSet{ 2 },
     GSet{ 1, 6 }
]
> AnisotropicSubdatum(R);
Twisted root datum of type 2A3,0
[ 3, 4, 5, 9, 10, 15, 39, 40, 41, 45, 46, 51 ]
> RR := RelativeRootDatum(R);RR;
RR: Adjoint root datum of type BC2
> DynkinDiagram(RR);
BC2    1 =>= 2
> _,pi := RelativeRootSpace(R);
> [ Position(Roots(RR), pi(Root(R,i)) ) : i in [2, 1,6]];
[ 1, 2, 2 ]
```

Finally, the twisted root Datum of type ${}^6D_{4,1}$:

```
> T := RootDatum( "D4" : Twist:=<{{2}},6> );
> T;
```

```
T: Twisted adjoint root datum of dimension 4 of type 6D4,1
> RelativeRootDatum(T);
Adjoint root datum of type BC1
> GammaOrbitsRepresentatives(T,1);
[ 11, 5 ]
> GammaOrbitsRepresentatives(T,2);
[ 12 ]
```

`CoxeterForm(R)`

`DualCoxeterForm(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The matrix of an inner product on the (co)root space of the root datum R which is invariant under the action of the (co)roots. The inner product is normalised so that the short roots in each irreducible component have length one.

97.5.2 Reflections

The root α acts on the root space via the reflection s_α; the coroot $\alpha^\star$ acts on the coroot space via the coreflection $s^\star_\alpha$.

`SimpleReflectionMatrices(R)`

`SimpleCoreflectionMatrices(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The sequence of matrices giving the action of the simple (co)roots of the root datum R on the (co)root space, i.e. the matrices of $s_{\alpha_1}, \ldots, s_{\alpha_n}$ (respectively, $s^\star_{\alpha_1}, \ldots, s^\star_{\alpha_n}$).

`ReflectionMatrices(R)`

`CoreflectionMatrices(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The sequence of matrices giving the action of the (co)roots of the root datum R on the (co)root space, i.e. the matrices of $s_{\alpha_1}, \ldots, s_{\alpha_{2N}}$ (respectively, $s^\star_{\alpha_1}, \ldots, s^\star_{\alpha_{2N}}$).

`ReflectionMatrix(R, r)`

`CoreflectionMatrix(R, r)`

`Basis` MonStgElt *Default :* `"Standard"`

The matrix giving the action of the rth (co)root of the root datum R on the (co)root space, i.e. the matrix of s_{α_r} (respectively, $s^\star_{\alpha_r}$).

`SimpleReflectionPermutations(R)`

The sequence of permutations giving the action of the simple (co)roots of the root datum R on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutations(R)`

The sequence of permutations giving the action of the (co)roots of the root datum R on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutation(R, r)`

The permutation giving the action of the rth (co)root of the root datum R on the (co)roots. This action is the same for roots and coroots.

`ReflectionWords(R)`

The sequence of words in the simple reflections for all the reflections of the root datum R. These words are given as sequences of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWords(R)[r]`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

`ReflectionWord(R, r)`

The word in the simple reflections for the rth reflection of the root datum R. The word is given as a sequence of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWord(R,r)`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

Example H97E20

```
> R := RootDatum("A3" : Isogeny := 2);
> mx := ReflectionMatrix(R, 4);
> perm := ReflectionPermutation(R, 4);
> wd := ReflectionWord(R, 4);
> RootPosition(R, Root(R,2) * mx) eq 2^perm;
true
> perm eq &*[ ReflectionPermutation(R, r) : r in wd ];
true
>
> mx := CoreflectionMatrix(R, 4);
> CorootPosition(R, Coroot(R,2) * mx) eq 2^perm;
true
```

97.5.3 Operations and Properties for Root and Coroot Indices

`Sum(R, r, s)`

The index of the sum of the rth and sth roots in the root datum R, or 0 if the sum is not a root. In other words, if $t =$ `Sum(R,`r`,`s`)` $\neq 0$ then $\alpha_t = \alpha_r + \alpha_s$. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied.

`IsPositive(R, r)`

Returns `true` if, and only if, the rth (co)root of the root datum R is a positive root.

`IsNegative(R, r)`

Returns `true` if, and only if, the rth (co)root of the root datum R is a negative root.

`Negative(R, r)`

The index of the negative of the rth (co)root of the root datum R. In other words, if $s =$ `Negative(R,`r`)` then $\alpha_s = -\alpha_r$.

`LeftString(R, r, s)`

Indices in the root datum R of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s - \alpha_r, \alpha_s - 2\alpha_r, \ldots, \alpha_s - p\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_p]$ where $\alpha_{r_i} = \alpha_s - i\alpha_r$ and $\alpha_s - (p+1)\alpha_r$ is not a root. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied.

`RightString(R, r, s)`

Indices in the root datum R of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s + \alpha_r, \alpha_s + 2\alpha_r, \ldots, \alpha_s + q\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_q]$ where $\alpha_{r_i} = \alpha_s + i\alpha_r$ and $\alpha_s + (q+1)\alpha_r$ is not a root. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied.

`LeftStringLength(R, r, s)`

The largest p such that $\alpha_s - p\alpha_r$ is a root of the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`RightStringLength(R, r, s)`

The largest q such that $\alpha_s + q\alpha_r$ is a root of the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

Example H97E21

```
> R := RootDatum("G2");
> Sum(R, 1, Negative(R,5));
10
> IsPositive(R, 10);
false
> Negative(R, 10);
4
> P := PositiveRoots(R);
> P[1] - P[5] eq -P[4];
true
```

`RootHeight(R, r)`

`CorootHeight(R, r)`

The height of the rth (co)root of the root datum R, i.e. the sum of the coefficients of α_r (respectively, $\alpha_r^\star$) with respect to the simple (co)roots.

`RootNorms(R)`

`CorootNorms(R)`

The sequence of squares of the lengths of the (co)roots of the root datum R.

`RootNorm(R, r)`

`CorootNorm(R, r)`

The square of the length of the rth (co)root of the root datum R.

`IsLongRoot(R, r)`

Returns `true` if, and only if, the rth root of the root datum R is long. This only makes sense for irreducible crystallographic root data. Note that for non-reduced root data, the roots which are not indivisible, are actually longer than the long ones.

`IsShortRoot(R, r)`

Returns `true` if, and only if, the rth root of the root datum R is short. This only makes sense for irreducible crystallographic root data.

`IsIndivisibleRoot(R, r)`

Returns `true` if, and only if, the rth root of the root system R is indivisible.

Example H97E22

Note that the Coxeter form is defined over the rationals. Since it is not possible to multiply a lattice element by a rational matrix, (co)roots must be coerced into a rational vector space first.

```
> R := RootDatum("G2");
> RootHeight(R, 5);
4
> F := CoxeterForm(R);
> v := VectorSpace(Rationals(),2) ! Root(R, 5);
> (v*F, v) eq RootNorm(R, 5);
true
> IsLongRoot(R, 5);
true
> LeftString(R, 1, 5);
[ 4, 3, 2 ]
> roots := Roots(R);
> for i in [1..3] do
>   RootPosition(R, roots[5]-i*roots[1]);
> end for;
4
3
2
```

`RootClosure(R, S)`

The closure in the root datum R of the set S of root indices. That is the indices of every root that can be written as a sum of roots with indices in S.

`AdditiveOrder(R)`

An additive order on the positive roots of the root datum R, ie. a sequence containing the numbers $1, \ldots, N$ in some order such that $\alpha_r + \alpha_s = \alpha_t$ implies t is between r and s. This is computed using the techniques of [Pap94]

`IsAdditiveOrder(R, Q)`

Returns `true` if, and only if, Q gives an additive order on a set of positive roots of R. Q must be a sequence of integers in the range $[1..N]$ with no gaps or repeats.

Example H97E23

```
> R := RootDatum("A5");
> a := AdditiveOrder(R);
> Position(a, 2);
6
> Position(a, 3);
10
> Position(a, Sum(R, 2, 3));
7
```

97.5.4 Weights

`WeightLattice(R)`

The weight lattice Λ of the root datum R. i.e. the λ in $\mathbf{Q}\Phi \leq \mathbf{Q} \otimes X$ such that $\langle \lambda, \alpha^\star \rangle \in \mathbf{Z}$ for every coroot $\alpha^\star$.

`CoweightLattice(R)`

The coweight lattice $\Lambda^\star$ of the root datum R, i.e. the $\lambda^\star$ in $\mathbf{Q}\Phi^\star \leq \mathbf{Q} \otimes Y$ such that $\langle \alpha, \lambda^\star \rangle \in \mathbf{Z}$ for every root α.

`FundamentalWeights(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The fundamental weights $\lambda_1, \ldots, \lambda_n$ of the root datum R given as the rows of a matrix. This is the basis of the weight lattice Λ dual to the simple coroots, i.e. $\langle \lambda_i, \alpha_j^\star \rangle = \delta_{ij}$.

`FundamentalCoweights(R)`

`Basis` MonStgElt *Default :* `"Standard"`

The fundamental coweights $\lambda_1^\star, \ldots, \lambda_n^\star$ of the root datum R given as the rows of a matrix. This is the basis of the coweight lattice $\Lambda^\star$ dual to the simple roots, i.e. $\langle \alpha_i, \lambda_j^\star \rangle = \delta_{ij}$.

Example H97E24

```
> R := RootDatum("E6");
> WeightLattice(R);
Lattice of rank 6 and degree 6
Basis:
(4  3  5  6  4  2)
(3  6  6  9  6  3)
(5  6 10 12  8  4)
(6  9 12 18 12  6)
(4  6  8 12 10  5)
(2  3  4  6  5  4)
Basis Denominator: 3
> FundamentalWeights(R);
[ 4/3    1  5/3    2  4/3  2/3]
[   1    2    2    3    2    1]
[ 5/3    2 10/3    4  8/3  4/3]
[   2    3    4    6    4    2]
[ 4/3    2  8/3    4 10/3  5/3]
[ 2/3    1  4/3    2  5/3  4/3]
```

`IsDominant(R, v)`

`Basis` MonStgElt *Default :* `"Standard"`

Returns `true` if, and only if, v is a dominant weight for the root datum R, ie, a nonnegative integral linear combination of the fundamental weights.

`DominantWeight(R, v)`

`Basis` MonStgElt *Default :* `"Standard"`

The unique dominant weight in the same W-orbit as the weight v, where W is the Weyl group of the root datum R. The second value returned is a Weyl group element taking v to the dominant weight. The weight v can be given either as a vector or as a sequence representing the vector and is coerced into the weight lattice first.

`WeightOrbit(R, v)`

`Basis` MonStgElt *Default :* `"Standard"`

The W-orbit of the weight v as an indexed set, where W is the Weyl group of the root datum R. The first element in the orbit is always dominant. The second value returned is a sequence of Weyl group elements taking the dominant weight to the corresponding element of the orbit. The weight v can be given either as a vector or as a sequence representing the vector and is coerced into the weight lattice first.

Example H97E25

```
> R := RootDatum("B3");
> DominantWeight(R, [1,-1,0] : Basis:="Weight");
(1 0 0)
[ 2, 3, 2, 1 ]
> #WeightOrbit(R, [1,-1,0] : Basis:="Weight");
6
```

97.6 Building Root Data

`sub< R | a >`

The root subdatum of the root datum R generated by the roots $\alpha_{a_1}, \ldots, \alpha_{a_k}$ where $a = \{a_1, \ldots, a_k\}$ is a set of integers.

`sub< R | s >`

The root subdatum of the root datum R generated by the roots $\alpha_{s_1}, \ldots, \alpha_{s_k}$ where $s = [s_1, \ldots, s_k]$ is a *sequence* of integers. In this version the roots must be simple in the root subdatum (i.e. none of them may be a summand of another) otherwise an error is signalled. The simple roots will appear in the subdatum in the given order.

Example H97E26

```
> R := RootDatum("A4");
> PositiveRoots(R);
{@
    (1 0 0 0),
    (0 1 0 0),
    (0 0 1 0),
    (0 0 0 1),
    (1 1 0 0),
    (0 1 1 0),
    (0 0 1 1),
    (1 1 1 0),
    (0 1 1 1),
    (1 1 1 1)
@}
> s := sub< R | [6,1,4] >;
> s;
Root datum of type A3
> PositiveRoots(s);
{@
    (0 1 1 0),
    (1 0 0 0),
```

```
    (0 0 0 1),
    (1 1 1 0),
    (0 1 1 1),
    (1 1 1 1)
@}
> s := sub< R | [1,5] >;
Error: The given roots are not simple in a subdatum
> s := sub< R | {1,5} >;
> s;
Root datum of type A2
> PositiveRoots(s);
{@
    (1 0 0 0),
    (0 1 0 0),
    (1 1 0 0)
@}
```

`R1 subset R2`

Returns `true` if and only if the root datum R_1 is a subset of the root datum R_2. If true, returns an injection as sequence of roots as second return value.

`R1 + R2`

`DirectSum(R1, R2)`

The external direct sum of the root data R_1 and R_2. The full (co)root space of the result is the direct sum of the full (co)root spaces of R_1 and R_2.

`R1 join R2`

The internal direct sum of the root data R_1 and R_2. The root data must have the same full (co)root space, which will also be the full (co)root space of the result. The root data must have disjoint (co)root spaces.

Example H97E27

```
> R  := RootDatum("A1A1");
> R1 := sub<R|[1]>;
> R2 := sub<R|[2]>;
> R1 + R2;
Root datum of dimension 4 of type A1 A1
> R1 join R2;
R: Adjoint root datum of dimension 2 of type A1 A1
```

`DirectSumDecomposition(R)`
`IndecomposableSummands(R)`

Returns a sequence Q of irreducible root data, a root datum S which is the direct sum of the terms of Q, and an isogeny map $\phi : S \to R$. The root datum R must be semisimple. Note that a semisimple root datum R need not be a direct sum of simple root data, but it is isogenous to a direct sum of root data S.

Example H97E28

If the root datum in adjoint or simply connected, then it is a direct sum of simples. In this case we get $S = R$.

```
> R := RootDatum("A4B5" : Isogeny:="SC");
> Q, S := DirectSumDecomposition( R );
> R eq S;
true
> R eq Q[1] join Q[2];
true
```

The join of the summands of the direct sum decomposition is the original root datum again:

```
> R eq &join DirectSumDecomposition(R);
true
> R eq &+    DirectSumDecomposition(R);
false

> R1 := RootDatum("A3T2B4T3");
> R2 := RootDatum("T3G2T4BC3");
> R1 + R2;
Adjoint root datum of dimension 24 of type A3 B4 G2 BC3
> R1 join R2;
Root datum of dimension 12 of type A3 B4 G2 BC3
```

Here is an example of a semisimple root datum which is not a direct sum of simple subdata. Note that a simple root datum of type A_1 is either simply connected or adjoint.

```
> G<a,b>:=FundamentalGroup("A1A1");
> _,inj:=sub<G|a*b>;
> R:=RootDatum("A1A1":Isogeny:=inj);
> ad := RootDatum( "A1" : Isogeny:="Ad" );
> sc := RootDatum( "A1" : Isogeny:="SC" );
> IsIsomorphic( R, DirectSum(ad,ad) );
false
> IsIsomorphic( R, DirectSum(ad,sc) );
false
> IsIsomorphic( R, DirectSum(sc,sc) );
false
> Q, S := DirectSumDecomposition( R );
> R eq S;
```

```
false
```

`Dual(R)`

The dual of the root datum R, obtained by swapping the roots and coroots. The second value returned is the dual morphism from R to its dual.

`SimplyConnectedVersion(R)`

The simply connected version of the root datum R. If R is semisimple then the injection of the simply connected version into R is returned as the second value.

`AdjointVersion(R)`

The adjoint version of the root datum R. If R is semisimple then the projection from R to its adjoint version is returned as the second value.

`IndivisibleSubdatum(R)`

The root datum consisting of all indivisible roots of the root datum R.

`Radical(R)`

The radical of the root datum R, ie, the toral subdatum whose root (resp. coroot) space consists of the vectors perpendicular to every coroot (resp. root).

Example H97E29

An adjoint or simply connect root datum is always a direct sum of irreducible subdata. In these cases we take $S = R$.

```
> R1 := RootDatum("A5");
> R2 := RootDatum("B4");
> R := DirectSum(R1, Dual(R2));
> DirectSumDecomposition(R);
{
    Root datum of type A5 ,
    Root datum of type C4
}

> R := RootDatum("BC2");
> I := IndivisibleSubdatum(R); I;
I: Root datum of type B2
> I subset R;
true [ 1, 2, 3, 5, 7, 8, 9, 11 ]

> R := StandardRootDatum("A", 3);
> Radical(R);
Toral root datum of dimension 1
```

TwistedRootDatum(R)

TwistedRootDatum(N)

Twist ANY *Default :* 1

Create a twisted root datum from the root datum R, or from the semisimple root datum with Cartan name N. The twist may be specified in any of the following ways:

- An integer, specifying the order of the twist;
- A permutation, specifying the action of the primitive roots;
- A pair $< D, i >$, where D is a set of distinguished orbits as sets of integers, and i is the order of the Dynkin diagram symmetry;
- A pair $< \Gamma, Q >$, where Γ is the acting group, and Q is a sequence containing the permutation of the primitive roots for each of the generators of Γ;
- A homomorphism from Γ to the symmetric group whose order is the number of roots of R, describing how the acting group Γ acts on the roots.

Example H97E30

We construct a twisted root datum in a number of ways.

```
> S := TwistedRootDatum("D4" : Twist := 3);
> S;
S: Twisted adjoint root datum of dimension 4 of type 3D4,2

> R := RootDatum("A1A3");
> DynkinDiagram(R);

A1    1

A3    2 - 3 - 4
> S := TwistedRootDatum(R : Twist := Sym(4)!(2,4));
> S;
S: Twisted adjoint root datum of dimension 4 of type 2(A1 A3)4,3

> S := TwistedRootDatum("A4" : Twist := <{{1,4},{2,3}}, 2>);
> S;
S: Twisted adjoint root datum of dimension 4 of type 2A4,2

> R := RootDatum("E6" : Isogeny := "SC");
> DynkinDiagram(R);

E6    1 - 3 - 4 - 5 - 6
              |
              2
> S := TwistedRootDatum(R : Twist := <Sym(2) ,[ Sym(6)!(1,6)(3,5) ]>);
> S;
```

```
S: Twisted simply connected root datum of dimension 6 of type 2E6,4

> R := RootDatum("D4");
> DynkinDiagram(R);

D4    3
      /
1 - 2
      \
       4
> Gamma := Sym(3);
> Gamma.1, Gamma.2;
(1, 2, 3)
(1, 2)
> S := TwistedRootDatum(R : Twist := <Gamma, [ Sym(4) | (1,3,4), (1,4) ]>);
> S;
S: Twisted adjoint root datum of dimension 4 of type 6D4,2

> R := RootDatum("A2");
> DynkinDiagram(R);

A2    1 - 2
> Roots(R);
{@
    (1 0),
    (0 1),
    (1 1),
    (-1  0),
    ( 0 -1),
    (-1 -1)
@}
> S6 := Sym(#Roots(R));
> phi := hom<Sym(2) -> S6 | S6!(1,2)(4,5)>;
> S := TwistedRootDatum(R : Twist := phi);
```

`UntwistedRootDatum(R)`

`SplitRootDatum(R)`

The split version of the (twisted) root datum R.

97.7 Morphisms of Root Data

Morphisms are currently only defined for split root data. Let $R_i = (X_i, \Phi_i, Y_i, \Phi_i^\star)$ be a root datum for $i = 1, 2$. A *morphism* of root data $\phi : R_1 \to R_2$ consists of a pair of $\mathbf{Z}$-linear maps $\phi_X : X_1 \to X_2$ and $\Phi_Y : Y_1 \to Y_2$ satisfying

1. $\phi_X(\Phi_1) \subseteq \Phi_2 \cup \{0\}$; and
2. $\phi_Y(\alpha^\star) = \phi_X(\alpha)^\star$ (with the convention that $0^\star = 0$).

A *fractional morphism* is similar, except that it consists of $\mathbf{Q}$-linear maps on the (co)root spaces $X_1 \otimes \mathbf{Q} \to X_2 \otimes \mathbf{Q}$ and $Y_1 \otimes \mathbf{Q} \to Y_2 \otimes \mathbf{Q}$. The main examples of fractional morphisms are isogeny maps (Section 97.1.6). A *dual morphism* is similar, except that the maps are $X_1 \to Y_2$ and $Y_1 \to X_2$. This is clearly equivalent to a morphism from R_1 to the dual of R_2. Finally we define a *dual fractional morphism* in the obvious way.

A (fractional) morphism $\phi : R_1 \to R_2$ also stores a sign corresponding to each simple root of R_1. This has no effect on the action of ϕ on roots or coroots, but does effect the definition of the corresponding homomorphisms of Lie algebras and groups of Lie type.

```
hom< R -> S | phiX, phiY >
```

```
hom< R -> S | phiX, phiY >
```

Construct a (fractional) morphism of root data $R \to S$ with the given linear maps or matrices of linear maps.

```
hom< R -> S | Q >
```

Construct a (fractional) morphism of root data $R \to S$ with the given sequence of root images. The sequence Q must have length $2N$ and consist of elements in the range $[0, \ldots, 2M]$, where N is the number of positive roots of R and M is the number of positive roots of S. The domain R must be semisimple.

```
Morphism(R, S, phiX, phiY)
```

```
Morphism(R, S, phiX, phiY)
```

`SimpleSigns`	.	*Default :* 1
`Check`	BoolElt	*Default :* `true`

Construct a (fractional) morphism of root data $R \to S$ with the given sequence of root images. The sequence Q must have length $2N$ and consist of elements in the range $[0, \ldots, 2M]$, where N is the number of positive roots of R and M is the number of positive roots of S. The domain R must be semisimple.

`SimpleSigns` is a sequence of signs corresponding to the simple roots, or ± 1 to indicate a constant sequence. If `Check` is set to `false`, the function does not check that the maps send (co)roots to (co)roots. This function is the same as the constructor `hom`, except for these optional parameters.

`Morphism(R, S, Q)`

`SimpleSigns` . *Default :* 1

`Check` BoolElt *Default :* `true`

Construct a (fractional) morphism of root data $R \to S$ with the given sequence of root images. The sequence Q must have length $2N$ and consist of elements in the range $[0, \ldots, 2M]$, where N is the number of positive roots of R and M is the number of positive roots of S. The domain R must be semisimple.

`SimpleSigns` is a sequence of signs corresponding to the simple roots, or ± 1 to indicate a constant sequence. If `Check` is set to `false`, the function does not check that the maps send (co)roots to (co)roots. This function is the same as the constructor `hom`, except for these optional parameters.

`DualMorphism(R, S, phiX, phiY)`

`DualMorphism(R, S, phiX, phiY)`

`Check` BoolElt *Default :* `true`

Construct a (fractional) dual morphism of root data $R \to S$ with the given linear maps or matrices of linear maps. If `Check` is set to `false`, the function does not check that the maps send (co)roots to (co)roots.

`DualMorphism(R, S, Q)`

`Check` BoolElt *Default :* `true`

Construct a (fractional) dual morphism of root data $R \to S$ with the given sequence of root images. The sequence Q must have length $2N$ and consist of elements in the range $[0, \ldots, 2M]$, where N is the number of positive roots of R and M is the number of positive roots of S. The domain R must be semisimple. If `Check` is set to `false`, the function does not check that the maps send (co)roots to (co)roots.

`RootImages(phi)`

The indices of the root images of the (dual) (fractional) morphism ϕ.

`RootPermutation(phi)`

The indices of the root images of the automorphism ϕ.

`IsIsogeny(phi)`

Returns `true` if the morphism ϕ is an isogeny, ie, ϕ_Y is onto with finite kernel.

`IdentityMap(R)`

`IdentityAutomorphism(R)`

The identity morphism $R \to R$.

Example H97E31

We construct the fractional morphism from the standard root datum of type A_3 onto the adjoint root datum of type A_3. This will allow us to construct the algebraic projection $GL_4 \to PGL_4$ in Section 103.11.

```
> RGL := StandardRootDatum( "A", 3 );
> RPGL := RootDatum( "A3" );
> A := VerticalJoin( SimpleRoots(RGL), Vector([Rationals()|1,1,1,1]) )^-1 *
>   VerticalJoin( SimpleRoots(RPGL), Vector([Rationals()|0,0,0]) );
> B := VerticalJoin( SimpleCoroots(RGL), Vector([Rationals()|1,1,1,1]) )^-1 *
>   VerticalJoin( SimpleCoroots(RPGL), Vector([Rationals()|0,0,0]) );
> phi := hom< RGL -> RPGL | A, B >;
> v := Coroot(RGL,1);
> v; phi(v);
( 1 -1  0  0)
( 2 -1  0 )
```

97.8 Constants Associated with Root Data

In this section functions for a number of constants associated with root data will be described. These constants are needed to define Lie algebras and groups of Lie type. The notation of [Car72] will be used, except that the constants are defined for right actions rather than left actions [CMT04].

`ExtraspecialPairs(R)`

The sequence of extraspecial pairs of the root datum R (see [Car72, page 58]). That is the sequence $[(r_i, s_i)]_{i=1}^{N-n}$ where r_i is minimal such that $\alpha_{r_i} + \alpha_{s_i} = \alpha_{i+n}$ (n is the rank of R and N is the number of positive roots).

`NumExtraspecialPairs(R)`

The number of extraspecial pairs of the root datum R. This function doesn't actually compute the extraspecial pairs, thus is much more efficient than calling `#ExtraspecialPairs(R)` in case extraspecial pairs are not yet computed.

`ExtraspecialPair(R,r)`

The extraspecial pair of the rth root in the root datum R. That is the pair (s, t) where s is minimal such that $\alpha_s + \alpha_t = \alpha_r$.

`ExtraspecialSigns(R)`

Return the sequence of extraspecial signs of the root datum R.

`LieConstant_p(R, r, s)`

The constant p_{rs} for the root datum R, i.e. the largest p such that $\alpha_s - p\alpha_r$ is a root. This is the same as `LeftStringLength`. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`LieConstant_q(R, r, s)`

The constant q_{rs} for the root datum R, i.e. the largest q such that $\alpha_s + q\alpha_r$ is a root. This is the same as `RightStringLength`. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`CartanInteger(R, r, s)`

The Cartan integer $\langle \alpha_r, \alpha_s^\star \rangle$ for the root datum R.

`LieConstant_N(R, r, s)`

The Lie algebra structure constant N_{rs} for the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`LieConstant_epsilon(R, r, s)`

The constant $\epsilon_{rs} = \mathrm{Sign}(N_{rs})$ for the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`LieConstant_M(R, r, s, i)`

The constant $M_{rsi} = \frac{1}{i!} N_{s_0 r} \cdots N_{s_{i-1} r}$ where $\alpha_{s_i} = i\alpha_r + \alpha_s$ for the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`LieConstant_C(R, i, j, r, s)`

The Lie group structure constant C_{ijrs} for the root datum R. The conditions $\alpha_s \neq \pm\alpha_r$ and $\alpha_r + \alpha_s \in \Phi$ must be satisfied.

`LieConstant_eta(R, r, s)`

The constant

$$\eta_{rs} = (-1)^{p_{rs}} \frac{\epsilon_{r,s-pr} \cdots \epsilon_{r,s-r}}{\epsilon_{r,s-pr} \cdots \epsilon_{r,s+(q-p-1)r}}$$

for the root datum R. The condition $\alpha_s \neq \pm\alpha_r$ must be satisfied.

`StructureConstants(R)`

The Lie algebra structure constants for the reductive Lie algebra with root datum R in the sparse format described in Section 100.2.

Example H97E32

The code below verifies some standard formulas in the root datum of type F_4:

```
> R := RootDatum("F4");
> N := NumPosRoots(R);
> r := Random([1..N]);
> s := Random([1..r-1] cat [r+1..r+N-1] cat [r+N+1..2*N]);
```

1. Agreement of the Cartan matrix with the Cartan integers.

```
> C := CartanMatrix(R);
> C[2,3] eq CartanInteger(R,2,3);
true
```

2. p_{rs} is the length of the left string through α_s in the direction of α_r.

```
> LieConstant_p(R,r,s) eq #LeftString(R,r,s);
true
```

3. q_{rs} is the length of the right string through α_s in the direction of α_r.

```
> LieConstant_q(R,r,s) eq #RightString(R,r,s);
true
```

4. $\langle \alpha_s, \alpha_r^\star \rangle = p_{rs} - q_{rs}$.

```
> CartanInteger(R,s,r) eq
> LieConstant_p(R,r,s) - LieConstant_q(R,r,s);
true
```

5. $N_{rs} = \epsilon_{rs}(p_{rs} + 1)$.

```
> LieConstant_N(R,r,s) eq
> LieConstant_epsilon(R,r,s) * (LieConstant_p(R,r,s) + 1);
true
```

97.9 Related Structures

In this section functions for creating other structures from a root datum are briefly listed. See the appropriate chapters of the Handbook for more details.

`RootSystem(R)`

The root system corresponding to the root datum R. See Chapter 96.

`CoxeterGroup(GrpFPCox, R)`

The (split) Coxeter group with root datum R. See Chapter 98. The braid group and pure braid group can be computed from the Coxeter group using the commands described in Section 98.12.

`CoxeterGroup(R)`

`CoxeterGroup(GrpPermCox, R)`

The permutation Coxeter group with root datum R. See Chapter 98.

`ReflectionGroup(R)`

`CoxeterGroup(GrpMat, R)`

The reflection group of the root datum R. See Chapter 99.

`LieAlgebraHomorphism(phi,k)`

The homomorphism of reductive Lie algebras over the ring k corresponding to the root datum morphism ϕ. See Chapter 100.

`LieAlgebra(R, k)`

The reductive Lie algebra over the ring k with root datum R. See Chapter 100.

`GroupOfLieType(R, k)`

The group of Lie type over the ring k with root datum R. See Chapter 103.

`GroupOfLieTypeHomomorphism(phi, k)`

The algebraic homomorphism of groups of Lie type over the ring k corresponding to the root datum morphism ϕ. See Chapter 103.

Example H97E33

```
> R := RootDatum("b3");
> SemisimpleType(LieAlgebra(R, Rationals()));
B3
> #CoxeterGroup(R);
48
> GroupOfLieType(R, Rationals());
$: Group of Lie type B3 over Rational Field
```

98 COXETER GROUPS

Chapter 98
COXETER GROUPS

98.1 Introduction

This chapter describes Magma functions for computing with Coxeter groups. A *Coxeter system* is a group G with finite generating set $S = \{s_1, \ldots, s_n\}$, defined by relations $s_i^2 = 1$ for $i = 1, \ldots, n$ and

$$s_i s_j s_i \cdots = s_j s_i s_j \cdots$$

for $i, j = 1, \ldots, n$ with $i < j$, where each side of this relation has length $m_{ij} \geq 2$. Traditionally, $m_{ij} = \infty$ signifies that the corresponding relation is omitted but, for technical reasons, $m_{ij} = 0$ is used in MAGMA instead. The group G is called a *Coxeter group* and S is called the set of *Coxeter generators*. Since every group in MAGMA has a preferred generating set, no distinction is made between a Coxeter system and its Coxeter group. See [Bou68] for more details on the theory of Coxeter groups.

The *rank* of the Coxeter system is $n = |S|$. A Coxeter system is said to be *reducible* if there is a proper subset I of $\{1, \ldots, n\}$ such that $m_{ij} = 2$ or $m_{ji} = 2$ whenever $i \in I$ and $j \notin I$. In this case, G is an (internal) direct product of the Coxeter subgroups $W_I = \langle s_i \mid i \in I \rangle$ and $W_{I^c} = \langle s_i \mid i \notin I \rangle$. Note that an *irreducible* Coxeter group may still be a nontrivial direct product of abstract subgroups (for example, $W(G_2) \cong S_2 \times S_3$). Two Coxeter groups are *Coxeter isomorphic* if there is a group isomorphism between them which takes Coxeter generators to Coxeter generators. In other words, the two groups are the same modulo renumbering of the generators.

MAGMA provides three methods for working with Coxeter groups:

1. As a finitely presented group with the standard presentation given above. These groups have type `GrpFPCox`. See Chapter 70 for general functions for finitely presented groups.
2. As a permutation group acting on the roots of the root system. Clearly the group must be finite. These groups have type `GrpPermCox`. See Chapter 58 for general functions for permutation groups.
3. As a reflection group, i.e. a matrix group generated by reflections. These groups have the same type as general matrix groups (`GrpMat`). They can be distinguished with the `IsReflectionGroup` function.

The first two methods are described in this chapter. The third is described in Chapter 99.

A permutation Coxeter group always has an underlying root system or root datum, and so many commands involving roots also work for these groups. A finitely presented Coxeter group does not have such an underlying structure.

The code for Coxeter groups as permutation groups was originally modelled on the corresponding part of the Chevie package of GAP [GHL+96] by Meinholf Geck, Frank Lübeck, Jean Michel and Götz Pfeiffer.

98.1.1 The Normal Form for Words

Every element w of a Coxeter group W can be written as a word

$$w = r_1 r_2 \cdots r_l$$

with each r_i in S. A *reduced expression* for w is such a word with l minimal; in this case, l is defined to be the *length* of w.

An ordering on words in S is obtained by taking the *lexicographic (alphabetic) order* induced by the existing ordering on S. The *normal form* for w in W is the smallest reduced expression for w with respect to this ordering. Algorithms for efficiently computing this normal form have been developed and implemented by R. B. Howlett. These algorithms are based on the concept of a minimal root [Bri98, BH93].

The main difference of the category of Coxeter groups (GrpFPCox) from the category of finitely presented groups (GrpFP) is that that all words are automatically put into this normal form. In particular, this means that two words are equal if, and only if, they are equal as group elements. Coxeter groups can also be constructed in the category GrpFP if the user wishes to avoid automatic normalisation of elements (see Section 98.3).

98.2 Constructing Coxeter Groups

It is possible to specify the category GrpFPCox or GrpPermCox when constructing a Coxeter group. If the category is not specified, then a GrpPermCox is returned for finite groups and a GrpFPCox is returned for infinite groups. If the category GrpPermCox is specified for an infinite group, an error is signalled.

```
CoxeterGroup(GrpFPCox, N)
```

```
CoxeterGroup(GrpPermCox, N)
```

```
CoxeterGroup(N)
```

The finite or affine Coxeter group with Cartan name given by the string N (see Section 95.6).

```
IrreducibleCoxeterGroup(GrpFPCox, X, n)
```

The finite or affine irreducible Coxeter group with Cartan name X_n, or $I_2(n)$ if $X =$"I" (see Section 95.6).

Example H98E1

```
> CoxeterGroup(GrpFPCox, "B3");
Coxeter group: Finitely presented group on 3 generators
Relations
    $.1 * $.2 * $.1 = $.2 * $.1 * $.2
    $.1 * $.3 = $.3 * $.1
    ($.2 * $.3)^2 = ($.3 * $.2)^2
```

```
    $.1^2 = Id($)
    $.2^2 = Id($)
    $.3^2 = Id($)
> CoxeterGroup("A2B2");
Coxeter group: Permutation group acting on a set of cardinality 14
Order = 48 = 2^4 * 3
    (1, 8)(2, 5)(9, 12)
    (1, 5)(2, 9)(8, 12)
    (3, 10)(4, 6)(11, 13)
    (3, 7)(4, 11)(10, 14)
```

CoxeterGroup(GrpFPCox, M)
CoxeterGroup(GrpPermCox, M)
CoxeterGroup(M)

The Coxeter group with Coxeter matrix M (see Chapter 95).

CoxeterGroup(GrpFPCox, G)
CoxeterGroup(GrpPermCox, G)
CoxeterGroup(G)

The Coxeter group with Coxeter graph G (see Chapter 95).

CoxeterGroup(GrpFPCox, C)
CoxeterGroup(GrpPermCox, C)
CoxeterGroup(C)

The Coxeter group with Cartan matrix C (see Chapter 95).

CoxeterGroup(GrpFPCox, D)
CoxeterGroup(GrpPermCox, D)
CoxeterGroup(D)

The Coxeter group with Dynkin digraph D (see Chapter 95).

Example H98E2

```
> M := SymmetricMatrix([ 1, 4,1, 3,4,1 ]);
> G<a,b,c> := CoxeterGroup(M);
> G;
Coxeter group: Finitely presented group on 3 generators
Relations
    (a * b)^2 = (b * a)^2
    a * c * a = c * a * c
    (b * c)^2 = (c * b)^2
    a^2 = Id($)
    b^2 = Id($)
    c^2 = Id($)
> M := SymmetricMatrix([ 1, 3,1, 2,3,1 ]);
> G<a,b,c> := CoxeterGroup(M);
> G;
Coxeter group: Permutation group G acting on a set of cardinality 12
Order = 24 = 2^3 * 3
    (1, 7)(2, 4)(5, 6)(8, 10)(11, 12)
    (1, 4)(2, 8)(3, 5)(7, 10)(9, 11)
    (2, 5)(3, 9)(4, 6)(8, 11)(10, 12)
> G<a,b,c> := CoxeterGroup(GrpFPCox, M);
> G;
Coxeter group: Finitely presented group on 3 generators
Relations
    a * b * a = b * a * b
    a * c = c * a
    b * c * b = c * b * c
    a^2 = Id($)
    b^2 = Id($)
    c^2 = Id($)
```

Note that a Coxeter group does not have a unique Cartan matrix.

```
> C := CartanMatrix("G2");
> W := CoxeterGroup(GrpFPCox, C);
>  CartanMatrix(W);
>> CartanMatrix(W);
               ^
Runtime error in 'CartanMatrix': Bad argument types
Argument types given: GrpFPCox
```

`CoxeterGroup(GrpFPCox, R)`

`CoxeterGroup(GrpPermCox, R)`

`CoxeterGroup(R)`

The finite Coxeter group with root system or root datum R (see Chapters 96 and 97).

`CoxeterGroup(A, B)`

The permutation Coxeter group with roots given by the rows of the matrix A and coroots given by the rows of the matrix B. The matrices A and B must have the following properties:

1. A and B must have same number of rows and the same number of columns; they must be defined over the same field, which must be the rational field, a number field, or a cyclotomic field; the entries must be real;
2. the number of columns must be at least the number of rows; and
3. AB^t must be the Cartan matrix of a finite Coxeter group.

Example H98E3

```
> R := RootDatum("A3" : Isogeny := 2);
> CoxeterGroup(R);
Coxeter group: Permutation group acting on a set of cardinality 12
Order = 24 = 2^3 * 3
    (1, 7)(2, 4)(5, 6)(8, 10)(11, 12)
    (1, 4)(2, 8)(3, 5)(7, 10)(9, 11)
    (2, 5)(3, 9)(4, 6)(8, 11)(10, 12)
```

98.3 Converting Between Types of Coxeter Group

In this section, we describe functions for converting between the various descriptions of Coxeter groups available in MAGMA.

Since a finitely presented Coxeter group W does not come with an in-built reflection representation, the optional parameters A, B, and C can be used to specify the representation. They are respectively the matrix whose rows are the simple roots, the matrix whose rows are the simple coroots, and the Cartan matrix. These must have the following properties:

1. A and B must have same number of rows and the same number of columns; they must be defined over the same field, which must be the rational field, a number field, or a cyclotomic field; the entries must be real;
2. the number of columns must be at least the number of rows; and
3. $C = AB^t$ must be a Cartan matrix for W.

It is not necessary to specify all three matrices, since any two of them will determine the third. If these matrices are not given, the default is to take A to be the identity and to take C to be the standard Cartan matrix described in Section 95.4.

`CoxeterGroup(GrpFPCox, W)`

The finitely presented Coxeter group W' isomorphic to the permutation Coxeter group W, together with the isomorphism $W \to W'$.

`CoxeterGroup(GrpFPCox, W)`

The finitely presented Coxeter group W' isomorphic to the real reflection group W (see Chapter 99).

`CoxeterGroup(GrpPermCox, W)`

A	MTRX	*Default :*
B	MTRX	*Default :*
C	MTRX	*Default :*

The permutation Coxeter group W' isomorphic to the finitely presented Coxeter group W, together with the isomorphism $W \to W'$. If W is infinite, an error is flagged.

`CoxeterGroup(GrpPermCox, W)`

The permutation Coxeter group W' isomorphic to the real reflection group W, together with the isomorphism $W \to W'$ (see Chapter 99). If W is infinite, an error is flagged.

Example H98E4

```
> W<a,b> := CoxeterGroup(GrpFPCox, "G2");
> Wp, h := CoxeterGroup(GrpPermCox, W);
> a*b;
a * b
> h(a*b);
(1, 11, 12, 7, 5, 6)(2, 4, 3, 8, 10, 9)
```

`ReflectionGroup(W)`
`CoxeterGroup(GrpMat, W)`

A	MTRX	*Default :*
B	MTRX	*Default :*
C	MTRX	*Default :*

A reflection group W' of the Coxeter group W, together with the isomorphism $W \to W'$.

`ReflectionGroup(W)`
`CoxeterGroup(GrpMat, W)`

The reflection group W' isomorphic to the permutation Coxeter group W, together with the isomorphism $W \to W'$. There are no optional parameters A, B, and C in this case because every permutation Coxeter group has a root system, and this determines the reflection representation.

Example H98E5

```
> W<a,b,c> := CoxeterGroup(GrpFPCox, "B3");
> G, h := CoxeterGroup(GrpMat, W);
> a*b; h(a*b);
a * b
[-1 -1  0]
[ 1  0  0]
[ 0  1  1]
```

`CoxeterGroup(GrpFP, W)`

The finitely presented group W' isomorphic to the finitely presented Coxeter group W, together with the isomorphism $W \to W'$.

`CoxeterGroup(GrpFP, W)`

The finitely presented group W' isomorphic to the permutation Coxeter group W, together with the isomorphism $W \to W'$.

`CoxeterGroup(GrpFP, W)`

The finitely presented group W' isomorphic to the real reflection group W, together with the isomorphism $W \to W'$ (see Chapter 99).

`CoxeterGroup(GrpPerm, W)`

The permutation group W' isomorphic to the finitely presented Coxeter group W, together with the isomorphism $W \to W'$. If W is infinite, an error is flagged.

`CoxeterGroup(GrpPerm, W)`

The permutation group W' isomorphic to the permutation Coxeter group W, together with the isomorphism $W \to W'$.

`CoxeterGroup(GrpPerm, W)`

The permutation group W' isomorphic to the real reflection group W, together with the isomorphism $W \to W'$ (see Chapter 99). If W is infinite, an error is flagged.

98.4 Operations on Coxeter Groups

See Chapter 70 for general functions for finitely presented groups, or Chapter 58 for general functions for permutation groups.

`IsIsomorphic(W1, W2)`

Returns `true` if, and only if, W_1 and W_2 are isomorphic as abstract groups. This is only implemented for permutation Coxeter groups.

`IsCoxeterIsomorphic(W1, W2)`

Returns `true` if, and only if, W_1 and W_2 are isomorphic as Coxeter groups. If `true`, a sequence giving the permutation of the generators which takes W_1 to W_2 is also returned.

`IsCartanEquivalent(W1, W2)`

Returns `true` if, and only if, the crystallographic Coxeter groups W_1 and W_2 have Cartan equivalent Cartan matrices. This only makes sense for permutation Coxeter groups.

Example H98E6

```
> W1 := CoxeterGroup(GrpFPCox, "B4");
> W2 := CoxeterGroup(GrpFPCox, "C4");
> IsCoxeterIsomorphic(W1, W2);
true [ 1, 2, 3, 4 ]
```

An example of abstractly isomorphic Coxeter groups which are not Coxeter isomorphic:

```
> W1 := CoxeterGroup("G2");
> W2 := CoxeterGroup("A1A2");
> IsIsomorphic(W1, W2);
true
> IsCoxeterIsomorphic(W1, W2);
false
```

An example of Coxeter isomorphic groups which are not Cartan equivalent:

```
> W1 := CoxeterGroup("B3");
> W2 := CoxeterGroup("C3");
> IsIsomorphic(W1, W2);
true
> IsCoxeterIsomorphic(W1, W2);
true [ 1, 2, 3 ]
> IsCartanEquivalent(W1, W2);
false
```

`RootSystem(W)`

The underlying root system of the permutation Coxeter group W.

`RootDatum(W)`

The root datum of the permutation Coxeter group W. If W does not have a root datum, an error is flagged.

Example H98E7

```
> W := CoxeterGroup("C5");
> RootSystem(W);
Root system of type C5
> RootDatum(W);
Root datum of type C5
>
> W := CoxeterGroup("H4");
> RootSystem(W);
Root system of type H4
>  RootDatum(W);
Error: This group does not have a root datum
```

`CartanName(W)`

The Cartan name of the finite or affine Coxeter group W (Section 95.6).

`CoxeterDiagram(W)`

Print the Coxeter diagram of the finite or affine Coxeter group W (Section 95.6).

`DynkinDiagram(W)`

Print the Dynkin diagram of the permutation Coxeter group W. If W is not crystallographic, an error is flagged.

Example H98E8

```
> W := CoxeterGroup("F4");
> CartanName(W);
F4
> DynkinDiagram(W);
F4    1 - 2 =>= 3 - 4
> CoxeterDiagram(W);
F4    1 - 2 === 3 - 4
```

`CoxeterMatrix(W)`

The Coxeter matrix of the Coxeter group W.

`CoxeterGraph(W)`

The Coxeter graph of the Coxeter group W.

`CartanMatrix(W)`

The Cartan matrix of the permutation Coxeter group W.

`DynkinDigraph(W)`

The Dynkin digraph of the permutation Coxeter group W.

`Rank(W)`
`NumberOfGenerators(W)`

The rank of the Coxeter group W.

`NumberOfPositiveRoots(W)`
`NumPosRoots(W)`

The number of positive roots of the Coxeter group W.

`Dimension(W)`

The dimension of the permutation Coxeter group W, ie. the dimension of the root space.

Example H98E9

```
> R := StandardRootSystem("A", 4);
> W := CoxeterGroup(R);
> Rank(W);
4
> Dimension(W);
5
```

`ConjugacyClasses(W)`

The conjugacy classes of the finite Coxeter group W. This uses the algorithm of [GP00].

`FundamentalGroup(W)`

The fundamental group of the permutation Coxeter group W. The roots and coroots of W must have integral components.

`IsogenyGroup(W)`

The isogeny group of the permutation Coxeter group W. The roots and coroots of W must have integral components.

`CoisogenyGroup(W)`

The coisogeny group of the permutation Coxeter group W. The roots and coroots of W must have integral components.

`BasicDegrees(W)`

The degrees of the basic invariant polynomials of the Coxeter group W. These are computed using the table in [Car72, page 155].

`BasicCodegrees(W)`

The basic codegrees of the Coxeter group W. These are computed using the algorithm in [LT09].

Example H98E10

The product of the basic degrees is the order of the Coxeter group; the sum of the basic degrees is the sum of the rank and the number of positive roots.

```
> W := CoxeterGroup("E6");
> degs := BasicDegrees(W);
> degs;
[ 2, 5, 6, 8, 9, 12 ]
> &*degs eq #W;
true
> &+degs eq NumPosRoots(W) + Rank(W);
true
```

`BruhatLessOrEqual(x, y)`

If Coxeter group element x is less than or equal to y in the Bruhat order [Deo77]. Suppose x is an element of the Coxeter group W. The Bruhat order is the partial order generated by the relations: $x \leq xw$ if $l(x) < l(xw)$, and $xw \leq x$ if $l(xw) < l(x)$, for $x \in W$ and w a reflection. If $l(xw) = l(x)+1$, then x is called a *Bruhat descendant* of xw. The algorithm used is a straightforward recursive procedure.

`BruhatDescendants(x)`

z GrpPermElt *Default :*

Let x be an element of the Coxeter group W, then the returned set S contains the Bruhat descendants of x. If $l(yw) = l(y) + 1$, then y is called a *Bruhat descendant* of yw. If the optional parameter z is set, only those descendants y with $z \leq y$ are returned. Algorithm: For each fundamental reflection in x it is tested whether leaving it out decreases the length of x by exactly 1. If so, it is included in the result. In particular, this algorithm does not use `BruhatLessOrEqual`.

`BruhatDescendants(X)`

z GrpPermElt *Default :*

Let X consist of elements of the Coxeter group W, then the returned set S contains the Bruhat descendants of every element of X.

If the optional parameter z is set, only those w are returned for which $z \leq w$ in the Bruhat ordering.

Example H98E11

Bruhat descendants:

```
> R := RootDatum("D4" : Isogeny := "SC");
> W := CoxeterGroup(GrpPermCox, R);
> Wfp,phi := CoxeterGroup(GrpFPCox, W);
> x := W.1*W.3*W.2*W.4*W.2*W.2*W.2*W.1;
> Eltseq(phi(x));
[ 1, 3, 2, 4, 2, 1 ]
> S := BruhatDescendants(x);
> { Eltseq(phi(w)) : w in S };
{
     [ 1, 3, 2, 4, 2 ],
     [ 3, 2, 4, 2, 1 ],
     [ 1, 2, 4, 2, 1 ],
     [ 1, 3, 2, 1, 4 ],
     [ 1, 3, 4, 2, 1 ]
}
```

98.5 Properties of Coxeter Groups

`IsFinite(W)`

Returns `true` if, and only if, the Coxeter group W is finite.

`IsAffine(W)`

Returns `true` if, and only if, the Coxeter group W is affine (Section 95.6).

`IsHyperbolic(W)`

Returns `true` if, and only if, the Coxeter group W is hyperbolic (Section 95.7).

`IsCompactHyperbolic(W)`

Returns `true` if, and only if, the Coxeter group W is compact hyperbolic (Section 95.7).

`IsIrreducible(W)`

Returns `true` if, and only if, the Coxeter group W is irreducible.

`IsSemisimple(W)`

Returns `true` if, and only if, the permutation Coxeter group W is semisimple, i.e. its rank is equal to its dimension.

`IsCrystallographic(W)`

Returns `true` if, and only if, the permutation Coxeter group W is crystallographic, i.e. if the corresponding reflection representation is defined over the integers.

`IsSimplyLaced(W)`

Returns `true` if, and only if, the Coxeter group W is simply laced, i.e. its Coxeter graph has no labels.

Example H98E12

```
> W := CoxeterGroup(GrpFPCox, HyperbolicCoxeterMatrix(22));
> IsFinite(W);
false
> IsAffine(W);
false
> IsHyperbolic(W);
true
> IsCompactHyperbolic(W);
true
> IsIrreducible(W);
true
> IsSimplyLaced(W);
true
```

```
> W := CoxeterGroup("A2 D4");
> IsIrreducible(W);
false
> IsSemisimple(W);
true
> IsCrystallographic(W);
true
> IsSimplyLaced(W);
true
```

98.6 Operations on Elements

See Chapter 70 for general functions for finitely presented groups or Chapter 58 for general functions for permutation groups.

Unlike groups of type GrpFP, elements of a group of type GrpFPCox are always converted into the normal form of Section 98.1.1.

Example H98E13

Arithmetic with words.

```
> W<[s]> := CoxeterGroup(GrpFPCox, "G2");
> w1 := W![2,1,2,1,2] ;
> w1;
s[2] * s[1] * s[2] * s[1] * s[2]
> w2 := W![1,2,2,1,2,1];
> w2;
s[2] * s[1]
> w1 * w2;
s[1] * s[2] * s[1]
> W![1,2,1,2,1,2] eq W![2,1,2,1,2,1];
true
```

`#w`

`Length(w)`

`CoxeterLength(W, w)`

The length of w as an element of the Coxeter group W, ie. the number of positive roots of W which become negative under the action of w. The # operator does not work for permutation Coxeter group elements.

`LongestElement(W)`

The unique longest element of the Coxeter group W.

`CoxeterElement(W)`

The Coxeter element of the Coxeter group W, ie. the product of the generators of W.

`CoxeterNumber(W)`

The Coxeter number of the irreducible Coxeter group W (see [Car93, page 20]).

Example H98E14

```
> W<[s]> := CoxeterGroup(GrpFPCox, "F4");
> LongestElement(W);
s[1] * s[2] * s[1] * s[3] * s[2] * s[1] * s[3] * s[2] * s[3] * s[4] * s[3] *
s[2] * s[1] * s[3] * s[2] * s[3] * s[4] * s[3] * s[2] * s[1] * s[3] * s[2] *
s[3] * s[4]
> CoxeterElement(W);
s[1] * s[2] * s[3] * s[4]
> W := CoxeterGroup("E8");
> Length(W, LongestElement(W));
120
> Length(W, CoxeterElement(W));
8
```

The Coxeter number can be described in a variety of ways.

```
> W := CoxeterGroup("D5");
> CoxeterNumber(W) eq Order(CoxeterElement(W));
true
> CoxeterNumber(W) eq #Roots(W) / Rank(W);
true
> R := RootDatum(W);
> CoxeterNumber(W) eq &+Eltseq(HighestRoot(R)) + 1;
true
```

`LeftDescentSet(W, w)`

The set of indices r of simple roots of the Coxeter group W such that the length of the product $s_r w$ is less than that of the element w.

`RightDescentSet(W, w)`

The set of indices r of simple roots of the Coxeter group W such that the length of the product $w s_r$ is less than that of the element w.

Example H98E15

```
> W := CoxeterGroup("A5");
> x := W.1*W.2*W.4*W.5;
> LeftDescentSet(W, x);
{ 1, 4 }
> RightDescentSet(W, x);
{ 2, 5 }
```

98.7 Roots, Coroots and Reflections

The functions in this section give access to the underlying root system (or datum) of a permutation Coxeter group. These functions do not apply to finitely presented Coxeter groups

Roots are stored as an indexed set

$$\{@ \alpha_1, \ldots, \alpha_N, \alpha_{N+1}, \ldots, \alpha_{2N} @\},$$

where $\alpha_1, \ldots, \alpha_N$ are the positive roots in an order compatible with height; and $\alpha_{N+1}, \ldots, \alpha_{2N}$ are the corresponding negative roots (i.e. $\alpha_{i+N} = -\alpha_i$). The simple roots are $\alpha_1, \ldots, \alpha_n$ where n is the rank.

Many of these functions have an optional argument `Basis` which may take one of the following values

1. `"Standard"`: the standard basis for the (co)root space. This is the default.
2. `"Root"`: the basis of simple (co)roots.
3. `"Weight"`: the basis of fundamental (co)weights (see Subsection 99.8.3 below).

98.7.1 Accessing Roots and Coroots

`RootSpace(W)`

`CorootSpace(W)`

The (co)root space of the Coxeter group W. This can be a vector space over a field of characteristic zero (Chapter 28), or an integer lattice in the crystallographic case (Chapter 30). The (co)reflection group of W acts on the (co)root space.

`SimpleRoots(W)`

`SimpleCoroots(W)`

The simple (co)roots of the Coxeter group W as the rows of a matrix.

Example H98E16

```
> W := CoxeterGroup("G2");
> RootSpace(W);
Full Vector space of degree 2 over Rational Field
> CorootSpace(W);
Full Vector space of degree 2 over Rational Field
> SimpleRoots(W);
[1 0]
[0 1]
> SimpleCoroots(W);
[ 2 -3]
[-1  2]
> CartanMatrix(W);
[ 2 -1]
[-3  2]
```

`NumberOfPositiveRoots(W)`

`NumPosRoots(W)`

The number of positive roots of the Coxeter group W.

`Roots(W)`

`Coroots(W)`

`Basis` MonStgElt *Default :* "*Standard*"

An indexed set containing the (co)roots of the Coxeter group W.

`PositiveRoots(W)`

`PositiveCoroots(W)`

`Basis` MonStgElt *Default :* "*Standard*"

An indexed set containing the positive (co)roots of the Coxeter group W.

`Root(W, r)`

`Coroot(W, r)`

`Basis` MonStgElt *Default :* "*Standard*"

The rth (co)root of the Coxeter group W.

`RootPosition(W, v)`

`CorootPosition(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

If v is a (co)root of the Coxeter group W, this returns its position; otherwise it returns 0. These functions will try to coerce v, which can be a vector or a sequence representing a vector, into the appropriate vector space; v should be written with respect to the basis specified by the parameter `Basis`.

Example H98E17

```
> A := Matrix(2,3, [1,-1,0, -1,1,-1]);
> B := Matrix(2,3, [1,-1,1, 0,1,-1]);
> W := CoxeterGroup(A, B);
> Roots(W);
{@
    (1 -1  0),
    (-1  1 -1),
    (0  0 -1),
    (1 -1 -1),
    (2 -2 -1),
    (1 -1 -2),
    (-1  1  0),
    (1 -1  1),
    (0 0 1),
    (-1  1  1),
    (-2  2  1),
    (-1  1  2)
@}
> PositiveCoroots(W);
{@
    (1 -1  1),
    (0  1 -1),
    (1  2 -2),
    (2  1 -1),
    (1 0 0),
    (1  1 -1)
@}
> #Roots(W) eq 2*NumPosRoots(W);
true
> Root(W, 4);
(1 -1 -1)
> Root(W, 4 : Basis := "Root");
(2 1)
> RootPosition(W, [1,-1,-1]);
4
> RootPosition(W, [2,1] : Basis := "Root");
4
```

`HighestRoot(W)`

`HighestLongRoot(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique (long) root of greatest height of the irreducible Coxeter group W.

`HighestShortRoot(W)`

`Basis` MonStgElt *Default : "Standard"*

The unique short root of greatest height of the irreducible Coxeter group W.

Example H98E18

```
> W := RootDatum("G2");
> HighestRoot(W);
(3 2)
> HighestLongRoot(W);
(3 2)
> HighestShortRoot(W);
(2 1)
```

`CoxeterForm(W)`

`DualCoxeterForm(W)`

`Basis` MonStgElt *Default : "Standard"*

The matrix of an inner product on the (co)root space of the finite Coxeter group W which is invariant under the action of W. This inner product is uniquely determined up to a constant on each irreducible component of W. The inner product is normalised so that the short roots in each crystallographic component have length one.

`AdditiveOrder(W)`

An additive order on the positive roots of the finite Coxeter group W, i.e. a sequence containing the numbers $1, \ldots, N$ in some order such that $\alpha_r + \alpha_s = \alpha_t$ implies t is between r and s. This is computed using the techniques of [Pap94].

98.7.2 Operations and Properties for Root and Coroot Indices

`Sum(W, r, s)`

The index of the sum of the rth and sth roots in the Coxeter group W, or 0 if the sum is not a root. In other words, if $t =$ `Sum(W,`r`,`s`)` $\neq 0$ then $\alpha_t = \alpha_r + \alpha_s$. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied. If W is noncrystallographic, an error is flagged.

`IsPositive(W, r)`

Returns `true` if, and only if, the rth (co)root of the Coxeter group W is a positive root.

`IsNegative(W, r)`

Returns `true` if, and only if, the rth (co)root of the Coxeter group W is a negative root.

`Negative(W, r)`

The index of the negative of the rth (co)root of the Coxeter group W. In other words, if $s =$ `Negative(W,`r`)` then $\alpha_s = -\alpha_r$.

`LeftString(W, r, s)`

Root indices in the Coxeter group W of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s - \alpha_r, \alpha_s - 2\alpha_r, \ldots, \alpha_s - p\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_p]$ where $\alpha_{r_i} = \alpha_s - i\alpha_r$ and $\alpha_s - (p+1)\alpha_r$ is not a root. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied. If W is noncrystallographic, an error is flagged.

`RightString(W, r, s)`

Root indices of the Coxeter group W of the left string through α_s in the direction of α_r, i.e. the indices of $\alpha_s + \alpha_r, \alpha_s + 2\alpha_r, \ldots, \alpha_s + q\alpha_r$. In other words, this returns the sequence $[r_1, \ldots, r_q]$ where $\alpha_{r_i} = \alpha_s + i\alpha_r$ and $\alpha_s + (q+1)\alpha_r$ is not a root. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied. If W is noncrystallographic, an error is flagged.

`LeftStringLength(W, r, s)`

The largest p such that $\alpha_s - p\alpha_r$ is a root of the Coxeter group W. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied. If W is noncrystallographic, an error is flagged.

`RightStringLength(W, r, s)`

The largest q such that $\alpha_s + q\alpha_r$ is a root of the Coxeter group W. The condition $\alpha_r \neq \pm\alpha_s$ must be satisfied. If W is noncrystallographic, an error is flagged.

Example H98E19

```
> W := RootDatum("G2");
> Sum(W, 1, Negative(W,5));
10
> IsPositive(W, 10);
false
> Negative(W, 10);
4
> P := PositiveRoots(W);
> P[1] - P[5] eq -P[4];
true
```

`RootHeight(W, r)`

`CorootHeight(W, r)`

The height of the rth (co)root of the Coxeter group W, i.e. the sum of the coefficients of α_r (respectively, $\alpha_r^\star$) with respect to the simple (co)roots.

`RootNorms(W)`

`CorootNorms(W)`

The sequence of squares of the lengths of the (co)roots of the Coxeter group W.

`RootNorm(W, r)`

`CorootNorm(W, r)`

The square of the length of the rth (co)root of the Coxeter group W.

`IsLongRoot(W, r)`

Returns `true` if, and only if, the rth root of the Coxeter group W is long, i.e. the rth coroot is short. An error is flagged unless W is irreducible and crystallographic.

`IsShortRoot(W, r)`

Returns `true` if, and only if, the rth root of the Coxeter group W is short, i.e. the rth coroot is long. An error is flagged unless W is irreducible and crystallographic.

Example H98E20

```
> W := RootDatum("G2");
> RootHeight(W, 5);
4
> F := CoxeterForm(W);
> v := VectorSpace(Rationals(),2) ! Root(W, 5);
> (v*F, v) eq RootNorm(W, 5);
true
> IsLongRoot(W, 5);
true
> LeftString(W, 1, 5);
[ 4, 3, 2 ]
> roots := Roots(W);
> for i in [1..3] do
>   RootPosition(W, roots[5]-i*roots[1]);
> end for;
4
3
2
```

98.7.3 Weights

`WeightLattice(W)`

`CoweightLattice(W)`

The (co)weight lattice of the Coxeter group W. The roots and coroots of W must have integral components.

`FundamentalWeights(W)`

`FundamentalCoweights(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The fundamental (co)weights of the Coxeter group W. The roots and coroots of W must have integral components.

`IsDominant(R, v)`

`Basis` MonStgElt *Default :* "*Standard*"

Returns `true` if, and only if, v is a dominant weight for the root datum R, ie, a nonnegative integral linear combination of the fundamental weights.

`DominantWeight(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique element in the W-orbit of the weight v which lies in the fundamental Weyl chamber, and the word in the generators which sends v to this element. The Coxeter group W must have a root datum. The weight v can be given either as a vector or as a sequence representing the vector and is coerced into the weight lattice first.

`WeightOrbit(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

The orbit of the weight v under the action of W. The Coxeter group W must have a root datum. The weight v can be given either as a vector or as a sequence representing the vector and is coerced into the weight lattice first.

Example H98E21

```
> W := CoxeterGroup("B3");
> DominantWeight(W, [1,-1,0] : Basis:="Weight");
(1 0 0)
[ 2, 3, 2, 1 ]
> #WeightOrbit(W, [1,-1,0] : Basis:="Weight");
6
```

98.8 Reflections

An element of a Coxeter group is called a *reflection* if it is conjugate to one of the Coxeter generators.

In a permutation Coxeter group, the root α acts on the root space via the reflection s_α; the coroot $\alpha^\star$ acts on the coroot space via the coreflection $s_\alpha^\star$.

`IsReflection(w)`

Returns `true` if, and only if, w is a reflection, i.e. w is conjugate to a Coxeter generator. If w is in a permutation Coxeter group, the root, coroot and root index are also returned.

`Reflections(W)`

The sequence of reflections in the finite Coxeter group W. If W is a permutation Coxeter group, the rth reflection in the sequence corresponds to the rth (co)root.

Example H98E22

```
> W<a,b> := CoxeterGroup(GrpFPCox, "A2");
> Reflections(W);
[ a, b, a * b * a, a, b, a * b * a ]
> IsReflection(a*b);
false
```

`SimpleReflections(W)`

The sequence of simple reflections in the Coxeter group W, ie, the generators of W.

`SimpleReflectionPermutations(W)`

The sequence of simple reflections in the permutation Coxeter group W, ie, the generators of W.

`Reflection(W, r)`

`ReflectionPermutation(W, r)`

The reflection in permutation Coxeter group W corresponding to the rth (co)root. If $r = 1, \ldots, n$, this is a generator of W.

`SimpleReflectionMatrices(W)`

`SimpleCoreflectionMatrices(W)`

`Basis` MonStgElt *Default : "Standard"*

The matrices giving the action of the simple (co)roots on the (co)root space of the permutation Coxeter group W.

`ReflectionMatrices(W)`

`CoreflectionMatrices(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The matrices giving the action of the (co)roots on the (co)root space of the permutation Coxeter group W.

`ReflectionMatrix(W, r)`

`CoreflectionMatrix(W, r)`

`Basis` MonStgElt *Default :* "*Standard*"

The matrix giving the action of the rth (co)root on the (co)root space of the permutation Coxeter group W.

`ReflectionWords(W)`

The sequence of words in the simple reflections for all the reflections of the Coxeter group W. These words are given as sequences of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWords(W)[r]`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

`ReflectionWord(W, r)`

The word in the simple reflections for the rth reflection of the Coxeter group W. The word is given as a sequence of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWord(W,r)`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

Example H98E23

```
> W := CoxeterGroup("B3");
> IsReflection(W.1*W.2);
false
> mx := ReflectionMatrix(W, 4);
> perm := Reflection(W, 4);
> wd := ReflectionWord(W, 4);
> rt := VectorSpace(Rationals(), 3) ! Root(W,2);
> RootPosition(W, rt * mx) eq 2^perm;
true
> perm eq &*[ Reflection(W, r) : r in wd ];
true
>
> mx := CoreflectionMatrix(W, 4);
> CorootPosition(W, Coroot(W,2) * mx) eq 2^perm;
true
```

98.9 Reflection Subgroups

A *reflection subgroup* of a Coxeter group is a subgroup which is generated by a set of reflections. Note that reflection subgroups are also Coxeter groups. The most important class of reflection subgroups are the *standard parabolic subgroups*, which are generated by a subset of the simple roots. Given a set of indices $J \subseteq \{1, \ldots, \texttt{Rank(W)}\}$, the corresponding standard parabolic is denoted W_J. A *parabolic subgroup* is a subgroup which is conjugate to a standard parabolic subgroup. Note that in a reflection subgroup, the elements are given as permutations of the roots of the *larger* group.

Most of the functions in this section are currently only implemented for permutation Coxeter groups with a root *datum* (rather than a root system).

`ReflectionSubgroup(W, a)`

The reflection subgroup of the permutation Coxeter group W generated by the roots $\alpha_{a_1}, \ldots, \alpha_{a_k}$ where $a = \{a_1, \ldots, a_k\}$ is a set of integers. This only works if W has an underlying root datum.

`ReflectionSubgroup(W, s)`

The reflection subgroup of the permutation Coxeter group W generated by simple roots $\alpha_{s_1}, \ldots, \alpha_{s_k}$ where $s = [s_1, \ldots, s_k]$ is a *sequence* of integers. In this version the roots must be simple in the root subdatum (ie. none of them may be a summand of another) otherwise an error is signalled. The simple roots will appear in the reflection subgroup in the given order. This only works if W has an underlying root datum.

`StandardParabolicSubgroup(W, J)`

The standard parabolic subgroup of the Coxeter group W generated by the simple roots $\alpha_{j_1}, \ldots, \alpha_{j_k}$ where $J = \{j_1, \ldots, j_k\} \subseteq \{1, \ldots, \texttt{Rank(W)}\}$. This function works for both finitely presented and permutation Coxeter groups.

`IsReflectionSubgroup(W, H)`

Returns `true` if, and only if, H is a reflection subgroup of the permutation Coxeter group W.

`IsParabolicSubgroup(W, H)`

Returns `true` if, and only if, H is a parabolic subgroup of the permutation Coxeter group W.

`IsStandardParabolicSubgroup(W, H)`

Returns `true` if, and only if, H is a standard parabolic subgroup of the permutation Coxeter group W.

`Overgroup(H)`

The overgroup of H, ie. the Coxeter group whose roots are permuted by the elements of the permutation Coxeter subgroup H.

`Overdatum(H)`

The root datum whose roots are permuted by the elements of the permutation Coxeter subgroup H.

`LocalCoxeterGroup(H)`

Given a Coxeter subgroup H this returns the Coxeter group L isomorphic to H but acting on the roots of H itself rather than the roots of its overgroup, together with the isomorphism $L \to H$.

Example H98E24

```
> W := CoxeterGroup("A4");
> P := StandardParabolicSubgroup(W, {1,2});
> Overgroup(P) eq W;
true
> L, h := LocalCoxeterGroup(P);
> hinv := Inverse(h);
> L.1;
(1, 4)(2, 3)(5, 6)
> h(L.1);
(1, 11)(2, 5)(6, 8)(9, 10)(12, 15)(16, 18)(19, 20)
> hinv(h(L.1));
(1, 4)(2, 3)(5, 6)
```

`Transversal(W, H)`

The indexed set of (right) coset representatives of the reflection subgroup H of the Coxeter group W. This contains the unique element of shortest length in each coset. The algorithm is due to Don Taylor (personal communication).

`TransversalWords(W, H)`

The indexed set of words of (right) coset representatives of the reflection subgroup H of the Coxeter group W. The algorithm is due to Don Taylor (personal communication).

`TransversalElt(W, H, x)`

The representative of the coset Hx in the Coxeter group W. This is the unique element of Hx of shortest length in W and also the unique element of Hx which sends every positive root of H to another positive root. The algorithm is due to Don Taylor (personal communication).

Example H98E25

```
> W := CoxeterGroup("A4");
> P := StandardParabolicSubgroup(W, {1,2});
> x := W.1 * W.2 * W.3;
> x := TransversalElt(W, P, x);
> x eq W.3;
true
> x in Transversal(W, P);
true
```

`TransversalElt(W, x, H)`

The representative of the coset xH in the Coxeter group W. This is the unique element of xH of shortest length in W and also the unique element of xH which sends every positive root of H to another positive root.

`TransversalElt(W, H, x, J)`

The representative of the coset HxJ in the Coxeter group W. This is the unique element of HxJ of shortest length in W and also the unique element of HxJ which sends every positive root of HJ to another positive root.

`Transversal(W, J)`

`Transversal(W, J, L)`

The set of right coset representatives of minimal length for the standard parabolic subgroup $W_J \leq W$. In the first form W must be finite and the result is a full transversal. In the second form W may be infinite, but the transversal produced is limited to words of length at most L.

`Transversal(W, J, K)`

The sequence of W_J, W_K-double cosets representatives of minimal length in W. Restricted to W finite. The second return value gives the generators of the standard parabolic subgroup $W_J \cap W_K^d$ for each double coset representative d.

`DirectProduct(W1, W2)`

The direct product of the Coxeter groups W_1 and W_2.

`Dual(W)`

The dual of the Coxeter group W, obtained by swapping the roots and coroots.

Example H98E26

```
> W1 := CoxeterGroup("G2");
> W2 := CoxeterGroup("C3");
> DirectProduct(W1, Dual(W2));
Coxeter group: Permutation group acting on a set of cardinality 30
Order = 576 = 2^6 * 3^2
    (1, 7)(2, 5)(3, 4)(8, 11)(9, 10)
    (1, 3)(2, 8)(5, 6)(7, 9)(11, 12)
    (13, 22)(14, 16)(17, 20)(19, 21)(23, 25)(26, 29)(28, 30)
    (13, 16)(14, 23)(15, 17)(18, 21)(22, 25)(24, 26)(27, 30)
    (14, 19)(15, 24)(16, 21)(23, 28)(25, 30)
> W1 := CoxeterGroup(GrpFPCox, "G2");
> W2 := CoxeterGroup(GrpFPCox, "A2");
> DirectProduct(W1, W2);
Coxeter group: Finitely presented group on 4 generators
Relations

    $.1 * $.3 = $.3 * $.1
    $.1 * $.4 = $.4 * $.1
    $.2 * $.3 = $.3 * $.2
    $.2 * $.4 = $.4 * $.2
    $.3 * $.4 * $.3 = $.4 * $.3 * $.4
    $.1^2 = Id($)
    $.2^2 = Id($)
    $.3^2 = Id($)
    $.4^2 = Id($)
```

98.10 Root Actions

The functions in this section give access to the action on the underlying root system (or datum) of a permutation Coxeter group. These functions do not apply to finitely presented Coxeter groups

In the following functions, the optional parameter `Basis` determines which basis the roots are given with respect to: `"Standard"` for the standard basis of the root space; `"Root"` for the basis of simple (co)roots; `"Weight"` for the basis of simple (co)weights.

`RootGSet(W)`

`CorootGSet(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The G-set of the Coxeter group W acting on the (co)roots.

Example H98E27

```
> W := CoxeterGroup("B3");
> X := RootGSet(W);
> r := Root(W, 5);
> r;
(0 1 1)
> Image(W.1, X, r);
(1 1 1)
```

`RootAction(W)`

`CorootAction(W)`

Basis MonStgElt *Default :* "*Standard*"

The map $X \times W \to X$ giving the action of the Coxeter group W on the (co)root space X.

Example H98E28

```
> W := CoxeterGroup("B3");
> act := CorootAction(W);
> act([1,-2,1], W.1);
(-1 -1  1)
```

`ReflectionGroup(W)`

`CoreflectionGroup(W)`

Basis MonStgElt *Default :* "*Standard*"

The Coxeter group W as a real reflection group (ie. as a matrix group over some subfield of $\mathbf{R}$) acting on the (co)root space, and the isomorphism from W to the (co)reflection group.

Example H98E29

```
> W := CoxeterGroup("B3");
> _, h := ReflectionGroup(W);
> W.1*W.3;
(1, 10)(2, 8)(3, 12)(4, 7)(5, 6)(11, 17)(13, 16)(14, 15)
> h(W.1*W.3);
[-1  0  0]
[ 1  1  2]
[ 0  0 -1]
```

98.11 Standard Action

Every finite Coxeter group W has a standard action. For example, the standard action group of a Coxeter group of type A_n is the symmetric group of degree $n+1$ acting on $\{1, \ldots, n\}$.

`StandardAction(W)`

The standard action of the finite Coxeter group W.

`StandardActionGroup(W)`

The group G of the standard action of the finite Coxeter group W, together with an isomorphism $W \to G$.

Example H98E30

```
> W := CoxeterGroup("A3");
> G, h := StandardActionGroup(W);
> IsSymmetric(G);
true
> h(W.1); h(W.2); h(W.3);
(1, 2)
(2, 3)
(3, 4)
```

98.12 Braid Groups

`BraidGroup(W)`

The braid group B of the Coxeter group W as an finitely presented group, together with the natural map $W \to B$. Words in the braid group are not automatically normalised. However, the braid group of type A_n with normalisation can be constructed with the command `BraidGroup(n+1)` (see Chapter 73).

`PureBraidGroup(W)`

Returns the pure braid group of the Coxeter group W, ie. the kernel of the epimorphism from the braid group of W to W. Words in the pure braid group are not automatically normalised.

Example H98E31

```
> W<a,b,c> := CoxeterGroup(GrpFPCox, "B3");
> W;
Coxeter group: Finitely presented group on 3 generators
Relations
    a * b * a = b * a * b
    a * c = c * a
    (b * c)^2 = (c * b)^2
    a^2 = Id($)
    b^2 = Id($)
    c^2 = Id($)
> B<x,y,z> := BraidGroup(W);
> B;
Finitely presented group B on 3 generators
Relations
    x * y * x = y * x * y
    x * z = z * x
    (y * z)^2 = (z * y)^2
> P := PureBraidGroup(W);
> P;
Finitely presented group P on 3 generators
Generators as words in group B
    P.1 = x^2
    P.2 = y^2
    P.3 = z^2
```

98.13 W-graphs

Given a Coxeter system (W, S), a W-graph is a (directed or undirected) graph with vertex labels and edge weights. The label attached to a vertex v is a subset of S (called the *descent set* of v) and the edge weights are scalars (usually integers).

A W-graph must determine a representation of the Hecke algebra $H = H\langle q\rangle$ of the associated Coxeter system. The vertices of the W-graph can be identified with basis elements of the representation space, and by the conventions adopted here the action of the generator T_s of H associated with an element $s \in S$ on a basis element v is given by

$$v * T_s = \begin{cases} (-q^{-1}) * v & \text{if } s \text{ is in the descent set of } v, \\ q * v + \sum'(m * u) & \text{if } s \text{ is not in the descent set of } v, \end{cases}$$

where $\sum'$ indicates the sum over all edges with terminal vertex equal to v for which s is in the descent set of the initial vertex u, and m is the weight of the edge.

For the Coxeter group calculations involved in these functions we need to know how the generators $s \in S$ act on the set of elementary roots (see [Bri98]).

MAGMA has a function `ReflectionTable` that provides the necessary information. Specifically, let W be a finitely presented Coxeter group with N elementary roots (numbered from 1 to N) and r simple reflections (numbered 1 to r). If we define

```
eltroots:=ReflectionTable(W);
```

then for $i \in \{1, \ldots, r\}$ and $j \in \{1, \ldots, N\}$, `eltroots[i,j] = k` if the i-th simple reflection takes the j-th elementary root to the k-th elementary root, or to a non-elementary root if $k = 0$, or to a negative root if $k < 0$. (This last alternative occurs if and only if $j = i$ and $k = -i$.) Knowing the table `eltroots` makes it quick and easy to do symbolic computation with elements of W, represented as sequences of integers in $\{1, \ldots, r\}$ (corresponding to words in S).

`SetVerbose("WGraph", v)`

Set the verbose printing to level v for all W-graph related functions. A level of 2 means that informative messages and progress information will be printed durng a computation.

Sometimes it is convenient to use 'mij-sequences' to specify Coxeter groups. The mij-sequence consists of the on or below diagonal entries in the Coxeter matrix. Thus if `seq` is the mij-sequence and M the Coxeter matrix then

```
M := SymmetricMatrix(seq);
```

and

```
seq := &cat[[M[i,j] :  j in [1..i]] :  i in [1..Rank(W)]];
```

`Mij2EltRootTable(seq)`

Return the elementary root action table for the Coxeter group defined by the given mij-sequence.

`Name2Mij(name)`

The mij-sequence of the Coxeter groups of type name.

Example H98E32

```
> e6:=[1,3,1,2,3,1,2,3,2,1,2,2,2,3,1,2,2,3,2,2,1];
> E6 := CoxeterGroup(GrpFPCox, SymmetricMatrix(e6) );
> ReflectionTable(E6) eq Mij2EltRootTable(e6);
true
```

The functions defined in this section are mainly concerned with W-graph posets. The motivating example for this concept is the set of all standard tableaux corresponding to a given partition, the partial order being dominance. By definition, if P is a W-graph poset then P must be in one-to-one correspondence with a basis for an H-module V (where H is the Hecke algebra associated with the given Coxeter system). In the standard tableaux example, this module is the Specht module; hence in the general case we refer to the

module V as GSM(P) (for generalized Specht module). For each $v \in P$ the set S must be the disjoint union of two sets $A(v)$ and $D(v)$, the ascents and descents of v. There must be a function $(s, v) \mapsto sv$ from $S \times P$ to P such that the action of H on GSM(P) satisfies the following rules (for all $s \in S$ and $v \in P$):

$$v * T_s = \begin{cases} sv & \text{if } sv > v, \\ sv + (q - q^{-1}) * v & \text{if } sv < v, \\ -q^{-1} * v & \text{if } sv = v \text{ and } s \in D(v), \\ q * v + q * \langle \text{earlier} \rangle & \text{if } sv = v \text{ and } s \in A(v), \end{cases}$$

where $\langle$earlier$\rangle$ denotes a linear combination of $\{u \in P \mid u < v\}$ with coefficients that are polynomials in q. For each $s \in A(v)$ either $sv = v$ or $sv > v$, and for each $s \in D(v)$ either $sv < v$ or $sv = v$. This (admittedly strange) definition is motivated by the fact that Specht modules satisfy it. If v is a standard tableau corresponding to a partition of n then a number i in $\{1, \ldots, n-1\}$ is an ascent of v if $i+1$ is in a later column of t than i, and is a descent of v if $i+1$ is in a lower row of t than i. The fact that Specht modules satisfy the formulas above is proved in the literature (e.g. Mathas' book), except that in the "weak ascent" case ($sv = v$ and $s \in A(v)$) it is not proved that the polynomial coefficients of $\{u \in P \mid u < v\}$ are all divisible by q. The fact that they are is a theorem of V. M. Nguyen (PhD thesis, University of Sydney, 2010). It turns out that there is an algorithm by which a W-graph may be constructed from a W-graph poset, the W-graph being uniquely determined by the function $(s, v) \mapsto sv$ from $S \times P \to P$ and the descent/ascent sets. The polynomial coefficients in the weak ascent case are not required. Of course the H-module determined by the resulting W-graph is isomorphic to GSM(P).

`Partition2WGtable(pi)`

Returns the W-graph table and the Weyl group for the partition `pi`, where `pi` is a nonincreasing sequence $[a_1, a_2, \ldots, a_k]$ of positive integers. It returns the table corresponding to the W-graph poset of standard tableaux of the given shape and the finitely presented Coxeter group of type A_n, where $n + 1 = \sum a_i$.

`WGtable2WG(table)`

Convert a W-graph table to a W-graph.

`TestWG(W,wg)`

This procedure can be used to test whether a presumed undirected or directed W-graph is indeed a W-graph. Two input values are required: the Coxeter group W and the W-graph. When applied to the W-graph produced by the `WGtable2WG` function, this tests whether the input table did genuinely correspond to a W-graph poset.

For example,

Example H98E33

```
> wtable, W :=Partition2WGtable([4,4,3,1]);
> wg := WGtable2WG(wtable);
> TestWG(W,wg);
```

which should cause the word `true` to be printed 66 times (as the defining relations of the Hecke algebra are checked).

Given a Coxeter system (W, S) and an element $w \in W$, let P be the set $\{x \in W \mid \text{length}(wx^{-1}) = \text{length}(w) - \text{length}(x)\}$, considered as a poset under the Bruhat order on W. Given also a subset J of $\{t \in S \mid \text{length}(wt) > \text{length}(w)\}$, for each $x \in P$ we define $D(x)$ to be union of $\{s \in S \mid \text{length}(sx) < \text{length}(x)\}$ and $\{s \in S \mid sx = xt \text{ for some } t \in J\}$. If P is now a W-graph poset with the sets $D(x)$ as the descent sets then we say that w is a W-graph determining element relative to J.

For example, suppose that (W, S) is of type A_n, and given a partition of $n+1$ let t be the (unique) standard tableau whose column group is generated by a subset of S. Let w be the maximal length element such that the tableau wt is standard. Then w is a W-graph determining element with respect to the set J consisting of those $s \in S$ that are in the column stabilizer of t.

Other examples (for any Coxeter system with finite W) are provided by the distinguished left coset representatives of maximal length for standard parabolic subgroups W_K (where the set J may be taken to be either K or the empty set).

`WGelement2WGtable(g,K)`

Returns the W-graph table and W-graph ideal of a W-graph determining element g, subset K.

Example H98E34

```
> b5 := [1,4,1,2,3,1,2,2,3,1,2,2,2,3,1];
> b5mat := SymmetricMatrix(b5);
> W := CoxeterGroup(GrpFPCox, b5mat );
> table, _ := WGelement2WGtable(W![5,4,3,2,1,2,3,4,5],{});
> wg := WGtable2WG(table);
> TestWG(W,wg);
true <1, 2> 4
true <2, 3> 3
true <3, 4> 3
true <4, 5> 3
```

`GetCells(wg)`

Return the cells of the W-graph.

`InduceWG(W,wg,seq)`

Induce a W-graph from a standard parabolic subgroup.

`InduceWGtable(J, table, W)`

Returns the table of the W-graph induced from the table of a parabolic subgroup defined by J.

`IsWGsymmetric(dwg)`

Test a W-graph for symmetry. If the graph is symmetric the second return value is the undirected version of the W-graph.

`MakeDirected(uwg)`

Convert an undirected W-graph to a directed W-graph.

`TestHeckeRep(W,r)`

Tests whether the matrices in r satisfy the defining relations of the Hecke algebra of the Coxeter group W.

`WG2GroupRep(wg)`

The matrix representation of a W-graph.

`WG2HeckeRep(W,wg)`

Returns a sequence of sparse matrices that satisfy the defining relations of the Hecke algebra.

`WGidealgens2WGtable(dgens,K)`

Returns the W-graph table and W-graph ideal of a W-graph determining generators dgens and subset K.

Example H98E35

In type E_6 we start with a rank 3 standard parabolic subgroup. The set of minimal coset representatives is a (single-generator) W-graph ideal, corresponding to the representation induced from the trivial representation of the parabolic. We compute the W-graph and find the cells. The bottom cell is necessarily an ideal in the weak order. It turns out that 3 elements are required to generate it; we can use them to test the function `WGidealgens2WGtable`.

```
> mij:=[1,3,1,2,3,1,2,3,2,1,2,2,2,3,1,2,2,3,2,2,1];
> E6 := CoxeterGroup(GrpFPCox, SymmetricMatrix(mij) );
> J := {1,3,5};
> drs := Transversal(E6,J);
> ttt := WGidealgens2WGtable([drs[1398],drs[156],drs[99]],J);
> nwg := WGtable2WG(ttt);
> TestWG(E6,nwg);
true <1, 2> 3
true <2, 3> 3
```

```
true <2, 4> 3
true <4, 5> 3
true <3, 6> 3
```

`WriteWG(file,uwg)`

`WriteWG(file,dwg)`

Writes the W-graph to a file.

98.14 Related Structures

In this section functions for creating other structures from a permutation Coxeter group are briefly listed. See the appropriate chapters of the Handbook for more details.

`CoxeterGroup(GrpFP, W)`

`Presentation(W)`

The finitely presented group isomorphic to the permutation Coxeter group W. See Chapter 70.

`ReflectionGroup(W)`

`CoxeterGroup(GrpMat, W)`

The reflection group isomorphic to the Coxeter group W. See Chapter 99.

`LieAlgebra(W, R)`

The reductive Lie algebra over the ring R with Weyl group W. If W is noncrystallographic, an error is flagged. See Section 100.5.1.

`GroupOfLieType(W, R)`

The group of Lie type over the ring R with Weyl group W. The roots and coroots of W must have integral components. See Chapter 103.

99 REFLECTION GROUPS

Chapter 99
REFLECTION GROUPS

99.1 Introduction

A reflection is a diagonalisable linear transformation of finite order whose space of fixed points is a hyperplane. A reflection group is a finite dimensional linear group over a field F, which is generated by a finite number of reflections.

There are no restrictions on the field F and there is no requirement for a reflection to be a transformation of order two. However, if F is a real field, every reflection does have order two and there is a much richer theory. In particular, every Coxeter group is a real reflection group (see Chapter 98).

The books [LT09], [Bro10] or [Kan01] are useful references for complex reflection groups. Standard references for the theory of real reflection groups include [Bou68, Chapters 4, 5, 6] and [Hum90].

99.2 Construction of Pseudo-reflections

Let V be a vector space of dimension n over a field F. As defined in Bourbaki [Bou68], a *pseudo-reflection* in MAGMA is a linear transformation of V whose space of fixed points is a subspace of dimension $n-1$, namely a hyperplane. (Some authors require a pseudo-reflection to be invertible and diagonalisable.)

A reflection, as defined above, is a pseudo-reflection and so too is a transvection. The MAGMA package described in this chapter includes code for the construction of transvections but the emphasis is on groups generated by reflections.

If r is a pseudo-reflection, then $\dim(\mathrm{im}(1-r)) = 1$ and a basis element of $\mathrm{im}(1-r)$ is called a *root* of r.

Let a be a root of the pseudo-reflection r and let $H = \ker(1-r)$ be the hyperplane of fixed points of r. For all $v \in V$ there exists $\phi(v) \in F$ such that $v - vr = \phi(v)a$. Then $\phi \in V^*$ and $\ker\phi = H$. This means that every pseudo-reflection has the form

$$vr = v - \phi(v)a$$

and its determinant is $1 - \phi(a)$. The linear functional ϕ is a *coroot* of r.

- If $\phi(a) = 1$, then r is not invertible; it is the *projection* of V onto H along a.
- If $\phi(a) = 0$ (equivalently, $a \in H$), then r is by definition a *transvection*.
- If $\phi(a) \neq 0, 1$, then r is called a *reflection*. For the most part we consider only reflections of finite order, but not necessarily of order two.

In MAGMA both V and its dual space V^* are identified with the space F^n of row vectors of length n and the standard bilinear pairing between V and V^* is $(a, b) \mapsto ab^{\mathrm{tr}}$, where b^{tr} denotes the column vector which is the *transpose* of b.

The row vector b which represents the coroot ϕ is also called a *coroot* of the pseudo-reflection; it is uniquely determined by r and a. The matrix of r is

$$I - b^{\mathrm{tr}}a$$

and, in particular, $ar = (1 - ab^{\mathrm{tr}})a$. Thus r is a reflection of finite order d if and only if $ab^{\mathrm{tr}} \neq 0, 1$ and $1 - ab^{\mathrm{tr}}$ is a d-th root of unity.

`PseudoReflection(a, b)`

The matrix of the pseudo-reflection with root a and coroot b.

`Transvection(a, b)`

The matrix of the transvection with root a and coroot b. The input is checked to ensure that the root and coroot define a transvection.

`Reflection(a, b)`

The matrix of the reflection with root a and coroot b. The input is checked to ensure that the root and coroot define a reflection.

`IsPseudoReflection(r)`

Returns `true` if r is the matrix of a pseudo-reflection, in which case a root and a coroot are returned as well.

`IsTransvection(r)`

Returns `true` if r is the matrix of a transvection, in which case a root and a coroot are returned as well.

`IsReflection(r)`

Returns `true` if r is the matrix of a reflection, in which case a root and a coroot are returned as well.

`IsReflectionGroup(G)`

Returns `true` if G is a group generated by reflections.

Example H99E1

Create a pseudo-reflection directly and then check that it is a transvection.

```
> V := VectorSpace(GF(5), 3);
> t := PseudoReflection(V![1,0,0],V![0,1,0]);
> t;
[1 0 0]
[4 1 0]
[0 0 1]
> IsTransvection(t);
true (1 0 0)
(0 1 0)
> IsReflection(t);
false
```

Example H99E2

An example of a group which can be generated by reflections even though not every given generator is a reflection.

```
> F<omega> := CyclotomicField(3);
> r := Matrix(F,2,2,[1,omega^2,0,omega]);
> IsReflection(r);
true (         0 -omega + 1)
(1/3*(2*omega + 1)                  1)
> s := Matrix(F,2,2,[0,-1,1,0]);
> IsReflection(s);
false
> G := MatrixGroup<2,F | r,s >;
> IsReflectionGroup(G);
true
> #G;
24
```

To find reflection generators for this group we look for a reflection which, together with the reflection r, generates G. (This is a rather special example; not every finite reflection group of rank two can be generated by two reflections.)

```
> exists(t){ t : t in G | IsReflection(t) and G eq sub<G|r,t> };
true
> t;
[        0 omega + 1]
[        1    -omega]
>
```

Example H99E3

The groups $\mathrm{SL}(n, q)$ are generated by transvections. To illustrate this we find representatives for the conjugacy classes of $\mathrm{GL}(3, 25)$ which are transvections and then check that the normal closure is $\mathrm{SL}(3, 25)$.

```
> G := GL(3,25);
> ccl := Classes(G);
> T := [ c : c in ccl | IsTransvection(c[3]) ];
> #T;
1
> t := T[1][3]; t;
[     1      0      0]
[     0      1      1]
[     0      0      1]
> S := ncl< G | t >;
> S eq SL(3,25);
true
```

99.2.1 Pseudo-reflections Preserving Reflexive Forms

Let J be the matrix of a non-degenerate reflexive bilinear or sesquilinear form β on the vector space V over a field F. Then β is either a symmetric, alternating or hermitian form.

We may assume that F is equipped with an automorphism σ such that $\sigma^2 = 1$. If β is a symmetric or alternating form, σ is the identity; if β is hermitian, the order of $\sigma : \alpha \mapsto \bar{\alpha}$ is two and $J = \bar{J}^{\mathrm{tr}}$. If a is the row vector $(\alpha_1, \alpha_2, \ldots, \alpha_n)$, define $\sigma(a) = (\sigma(\alpha_1), \sigma(\alpha_2), \ldots, \sigma(\alpha_n))$.

If a is a root of a pseudo-reflection r and if r preserves β, then the coroot of r is $\alpha\sigma(a)J^{\mathrm{tr}}$ for some $\alpha \in F$. Thus the matrix of r is $I - \alpha J^{\mathrm{tr}}\sigma(a)^{\mathrm{tr}}a$.

`SymplecticTransvection(a, alpha)`

The symplectic transvection with root a and multiplier α with respect to the form attached to the parent of a. If the form is not alternating a runtime error is generated.

If β is a non-degenerate alternating form preserved by a pseudo-reflection r, then the dimension of V is even and r must be a transvection. If a is a root of r, the coroot is $\alpha a J^{\mathrm{tr}}$ and the matrix of r is $I - \alpha J a^{\mathrm{tr}}a$, for some $\alpha \neq 0$ in F.

`UnitaryTransvection(a, alpha)`

The unitary transvection with root a and multiplier α with respect to the hermitian form attached to the parent of a.

The matrix of the unitary transvection is $I - \alpha J\bar{a}^{\mathrm{tr}}a$, where a is isotropic and the trace of α is 0; that is, $aJ\bar{a}^{\mathrm{tr}} = 0$ and $\alpha + \bar{\alpha} = 0$.

A runtime error is generated if the form is not hermitian, if a is not isotropic, or if the trace of α is not 0.

`UnitaryReflection(a, zeta)`

The unitary reflection with root a and determinant ζ, where ζ is a root of unity. The reflection preserves the hermitian form attached to the ambient space of a and sends a to ζa.

In the case of a unitary reflection r with matrix $I - \alpha J^{\mathrm{tr}}\sigma(a)^{\mathrm{tr}}a$, the root a must be non-isotropic and $ar = \zeta a$, where ζ is a root of unity. Therefore, $\alpha = (1-\zeta)/aJ\bar{a}^{\mathrm{tr}}$.

The vector $a^\vee = \bar{\alpha}a$ is the *coroot* of a and the definition of r becomes

$$vr = v - \beta(v, a^\vee)a.$$

`OrthogonalReflection(a)`

The reflection determined by a non-singular vector a of a quadratic space.

A *quadratic space* is a vector space V equipped with a quadratic form Q (see Chapter 88 for more details). The *polar form* of Q is the symmetric bilinear form $\beta(u, v) = Q(u+v) - Q(u) - Q(v)$. Thus $\beta(v, v) = 2Q(v)$ and therefore, if the characteristic of F is not two, Q is uniqely determined by β.

If a is non-singular (that is, $Q(a) \neq 0$), the formula

$$vr = v - Q(a)^{-1}\beta(v, a)a$$

defines a pseudo-reflection. If the characteristic of F is 2, this is a transvection; in all other cases it is a reflection. However, in characteristic 2 there is a certain ambivalence in the literature and the pseudo-reflections just defined are often called reflections.

The *coroot* of a is $a^\vee = Q(a)^{-1}a$. If the characteristic of F is not two, then $a^\vee = 2a/\beta(a, a)$ and this coincides with the usual notion of coroot, as found in [Hum90], for example. In particular, if $\beta(u, v)$ is the standard inner product $(u, v) = uv^{\mathrm{tr}}$, then the inner product and the pairing between V and its dual are essentially the same and the concepts of coroot and coroot coincide.

Example H99E4

We create an hermitian space by attaching an hermitian form J to a vector space V over a field with complex conjugation. The vector $a = (1, 0, 0, 0)$ is isotropic with respect to this form and therefore we can use it to create a unitary transvection.

```
> K<i> := CyclotomicField( 4 );
> sigma := hom< K -> K | x :-> ComplexConjugate(x) >;
> J := Matrix(4,4,[K|0,0,0,1, 0,0,1,0, 0,1,0,0, 1,0,0,0]);
> V := UnitarySpace(J,sigma);
> a := V![1,0,0,0];
> t := UnitaryTransvection(a,i);
> t;
[ 1  0  0  0]
[ 0  1  0  0]
[ 0  0  1  0]
[-i  0  0  1]
```

Continuing the previous example we note that $b = (1, 1, 1, 1)$ is non-isotropic and we create a unitary reflection of order 4 with b as root.

```
> b := V![1,1,1,1];
> InnerProduct(b,b);
4
> r := UnitaryReflection(b,i);
> r, Eigenvalues(r);
[1/4*(i + 3) 1/4*(i - 1) 1/4*(i - 1) 1/4*(i - 1)]
[1/4*(i - 1) 1/4*(i + 3) 1/4*(i - 1) 1/4*(i - 1)]
[1/4*(i - 1) 1/4*(i - 1) 1/4*(i + 3) 1/4*(i - 1)]
[1/4*(i - 1) 1/4*(i - 1) 1/4*(i - 1) 1/4*(i + 3)]
{
    <i, 1>,
    <1, 3>
}
```

99.3 Construction of Reflection Groups

In MAGMA a *pseudo-reflection group* is a group generated by a finite set of invertible pseudo-reflections. A convenient way to provide the generators for a pseudo-reflection group W is via a finite collection of roots and coroots. In this context the roots and coroots of the generators are called the *basic roots* and *basic coroots* of W.

In the most general case, even when the pseudo-reflection group W is generated by reflections, there are no known distinguished generating reflections whose roots have properties analogous to simple roots in Weyl groups or Coxeter groups. Therefore, one should be careful to distinguish between the basic roots as defined here and the simple (or fundamental) roots of real reflection groups

See Section 99.4 for the construction of real reflection groups and Section 99.5 for the construction of finite complex reflection groups.

`PseudoReflectionGroup(A, B)`

The pseudo-reflection group with the basic roots and corresponding coroots given by the rows of the matrices A and B.

Example H99E5

A direct construction of the Shephard and Todd group $G(14, 1, 2)$ with user supplied roots and coroots.

```
> F<z> := CyclotomicField(7);
> A := Matrix(F,2,3,[[z,0,1],[0,1,0]]);
> B := Matrix(F,2,3,[[1,1,1],[1,2,1]]);
> G<x,y> := PseudoReflectionGroup(A,B);
> IsReflectionGroup(G);
true
> Order(x),Order(y),Order(x*y);
14 2 28
> #G;
392
```

99.4 Construction of Real Reflection Groups

The only root of unity in the real field is -1, hence every pseudoreflection over the real field is a reflection. We call a reflection group *real* if it is defined over the reals and its simple roots and simple coroots are linearly independent. We allow real reflection groups to be defined as matrix groups over the integer ring (Chapter 18), the rational field (Chapter 20), number fields (Chapter 34), and cyclotomic fields (Chapter 36); the real field (Chapter 25) is *not* allowed since it is not infinite precision.

The real reflection groups are just the reflection representations of the Coxeter groups (Chapter 98). This allows us to compute many more properties for these groups than for general reflection groups. Note that the classification of finite real reflection groups is given in Section 95.6.

`ReflectionGroup(M)`

`ReflectionGroup(G)`

`ReflectionGroup(C)`

`ReflectionGroup(D)`

The reflection group with Coxeter matrix M, Coxeter graph G, Cartan matrix C, or Dynkin digraph D (see Chapter 95).

`ReflectionGroup(N)`

The finite or affine reflection group with Cartan name given by the string N (see Section 95.6).

`IrreducibleReflectionGroup(X, n)`

The finite or affine irreducible reflection group with Cartan name X_n (see Section 95.6).

Example H99E6

```
> C := CartanMatrix("B3" : Symmetric);
> G := ReflectionGroup(C);
> G;
MatrixGroup(3, Number Field with defining polynomial x^2 - 2 over the Rational
Field) of order 48 = 2^4 * 3
Generators:
    [-1  0  0]
    [ 1  1  0]
    [ 0  0  1]

    [  1   1   0]
    [  0  -1   0]
    [  0 $.1   1]

    [  1   0   0]
    [  0   1 $.1]
    [  0   0  -1]
```

`ReflectionGroup(R)`

The finite reflection group with root system or root datum R (see Chapters 96 and 97).

Example H99E7

```
> R := RootDatum("B3");
> ReflectionGroup(R);
MatrixGroup(3, Integer Ring) of order 48 = 2^4 * 3
Generators:
    [-1  0  0]
    [ 1  1  0]
    [ 0  0  1]

    [ 1  1  0]
    [ 0 -1  0]
    [ 0  1  1]

    [ 1  0  0]
    [ 0  1  2]
    [ 0  0 -1]
```

`ReflectionGroup(W)`

A	Mtrx	*Default :*
B	Mtrx	*Default :*
C	Mtrx	*Default :*

A reflection group W' of the Coxeter group W, together with the isomorphism $W \to W'$ (see Chapter 98). Since a Coxeter group W does not come with an in-built reflection representation, the optional parameters A, B, and C can be used to specify the representation. They are respectively the matrix whose rows are the simple roots, the matrix whose rows are the simple coroots, and the Cartan matrix. These must have the following properties:

1. A and B must have same number of rows and the same number of columns; they must be defined over the same field, which must be the rational field, a number field, or a cyclotomic field; the entries must be real;
2. the number of columns must be at least the number of rows; and
3. $C = AB^{\mathrm{tr}}$ must be a Cartan matrix for W.

It is not necessary to specify all three matrices: any two of them will determine the third. If C is not determined, it is taken to be the standard matrix described in Section 95.4.

`ReflectionGroup(W)`

The reflection group W' isomorphic to the permutation Coxeter group W, together with the isomorphism $W \to W'$ (see Chapter 98). There are no optional parameters A, B, and C in this case because every permutation Coxeter group has a root system, and this determines the reflection representation.

Example H99E8

```
> W<a,b,c> := CoxeterGroup(GrpFPCox, "B3");
> G, h := CoxeterGroup(GrpMat, W);
> a*b; h(a*b);
a * b
[-1 -1  0]
[ 1  0  0]
[ 0  1  1]
```

99.5 Construction of Finite Complex Reflection Groups

In this section, we describe the classification and construction of finite complex reflection groups.

A finite complex reflection group has a finite root system but there is no known analogue of a set of simple roots as in the theory of finite Coxeter groups. To illustrate the difficulty, one of the examples in this section constructs a complex reflection group of rank 4 which cannot be generated by fewer than 5 generators.

Nevertheless, it is possible to generalise the concept of *root datum* to the complex case and construct all complex reflection groups via their root data.

Let D be the ring of integers of a number field F which admits a well-defined operation of complex conjugation (which in the case of a real number field will be the identity automorphism). Let $\mu(D)$ be the group of roots of unity in D and let $V = F \times_D L$.

A *complex root datum* is a 4-tuple (L, L^*, Φ, ρ), where

- L and L^* are free D-modules of rank n which are in duality via a pairing $L \times L^* \to D : (a, \phi) \mapsto \langle\, a, \phi \,\rangle$;
- Φ is a finite subset of L and $\rho : \Phi \to L^*$.

For all $a \in \Phi$ we have:

1. for all $\lambda \in F$, we have $\lambda a \in \Phi$ if and only if $\lambda \in \mu(D)$;
2. for all $\lambda \in D$, we have $\rho(\lambda a) = \overline{\lambda}\rho(a)$;
3. $f(a) = 1 - \langle\, a, \rho(a) \,\rangle \in \mu(D) \setminus \{1\}$;
4. the reflection r_a of V defined by $vr_a = v - \langle\, v, \rho(a) \,\rangle a$ and the reflection r_a^* of V^* defined by $\phi r_a^* = \phi - \langle\, a, \phi \,\rangle \rho(a)$ satisfy:
   - $\Phi r_a \subseteq \Phi$ and $\Phi^* r_a^* \subseteq \Phi^*$, where $\Phi^* = \rho(\Phi)$.
   - $f(ar_b) = f(a)$ for all $a, b \in \Phi$.

Put $a^* = \rho(a)$ and $V^* = F \otimes_D L^*$. Then $\rho : \Phi \to \Phi^*$ is a bijection and the map

$$p := V \to V^* : v \mapsto \sum_{a \in \Phi} \overline{\langle\, v, a^* \,\rangle} a^*$$

is semilinear. Furthermore, $\beta(u, v) = \langle\, u, p(v) \,\rangle$ defines a non-degenerate hermitian form on the span of Φ.

The group W generated by the reflections $\{r_a \mid a \in \Phi\}$ is the *Weyl group* of the root datum. For any set $\{r_1, r_2, \ldots, r_k\}$ of reflections that generate W, every reflection in W is conjugate to a power of some r_i. The set Φ is a *root system* for W and Φ^* is the set of *coroots*.

If a_1, a_2, ..., $a_k \in \Phi$ are roots of the reflections r_1, r_2, ..., r_n which generate W, then $C = (\langle a_i, a_j^* \rangle)$ is a *complex Cartan matrix* and the a_i and a_j^* are *basic* roots and coroots of W.

Even though there is no satisfactory notion of 'simple roots', a complex reflection group can nevertheless be described by means of a complex Cartan matrix. In MAGMA if the roots are the rows of a matrix A and if the coroots are the rows of a matrix B, then $C = AB^{\mathrm{tr}}$. The matrices A and B are called *basic* root and coroot matrices.

The complex Cartan matrix can be described by a diagram similar to the Dynkin diagram of a Coxeter group. This notation was suggested by Coxeter and used by Cohen in [Coh76]. (There is a different type of diagram used by Broué, Malle and others.)

Cohen's naming scheme for the diagrams extends the standard notation A_n, B_n, ..., H_3, H_4 used for Coxeter groups. MAGMA uses a slight variation of Cohen's scheme; that is, in MAGMA, Cohen's group EN_4 is referred to as O_4.

The original numbering system for the primitive complex reflection groups is due to Shephard and Todd [ST54].

`ShephardTodd(n)`

`NumFld` BOOLELT *Default :* `false`

This function returns the primitive reflection group G_n using the Shephard and Todd numbering.

By default the matrices are written over the ring of integers of the smallest cyclotomic field which contains the character values of the reflections. If the parameter `NumFld` is set to `true`, the number field generated by the character values of the reflections is used.

The groups available via this function include all finite primitive complex reflection groups other than the symmetric groups $\mathrm{Sym}(n)$ for $n \geq 5$. The groups are listed below.

Nineteen 2-dimensional primitive complex reflection groups:

Tetrahedral family: G_4, ..., G_7
Octahedral family: G_8, ..., G_{15}
Icosahedral family: G_{16}, ..., G_{22}

Five 3-dimensional complex reflection groups:

G_{23}: $W(H_3) = \mathbf{Z}_2 \times PSL(2,5)$, order 120.
G_{24}: $W(J_3(4)) = \mathbf{Z}_2 \times PSL(2,7)$, order 336.
G_{25}: $W(L_3) = 3^{1+2} \cdot SL(2,3)$, order 648; Hessian group.
G_{26}: $W(M_3) = \mathbf{Z}_2 \times 3^{1+2} \cdot SL(2,3)$, order 1296; Hessian group.
G_{27}: $W(J_3(5)) = \mathbf{Z}_2 \times (\mathbf{Z}_3 \cdot \mathrm{Alt}(6))$, order 2160, where $\mathbf{Z}_3 \cdot \mathrm{Alt}(6)$ denotes the non-split extension of $\mathbf{Z}_3$ by $\mathrm{Alt}(6)$.

Five 4-dimensional complex reflection groups in addition to Sym(5):

G_{28}: $W(F_4) = (SL(2,3) \circ SL(2,3)) \cdot (\mathbf{Z}_2 \times \mathbf{Z}_2)$, order 1152.
G_{29}: $W(N_4) = (\mathbf{Z}_4 \circ 2^{1+4}) \cdot \mathrm{Sym}(5)$, order 7680 (splits).
G_{30}: $W(H_4) = (SL(2,5) \circ SL(2,5)) \cdot \mathbf{Z}_2$, order 14 400.
G_{31}: $W(O_4) = (\mathbf{Z}_4 \circ 2^{1+4}) \cdot Sp(4,2)$, order 46 080 (non-split) 5 generators.
G_{32}: $W(L_4) = \mathbf{Z}_3 \times Sp(4,3)$, order $155\,520 = 2^7 \times 3^5 \times 5$.

One 5-dimensional complex reflection group in addition to Sym(6):

G_{33}: $W(K_5) = \mathbf{Z}_2 \times \Omega(5,3) = \mathbf{Z}_2 \times PSp(4,3) = \mathbf{Z}_2 \times PSU(4,2)$, order $51\,840 = 2^7 \times 3^4 \times 5$.

Two 6-dimensional complex reflection groups in addition to Sym(7):

G_{34}: $W(K_6) = \mathbf{Z}_3 \cdot \widehat{\Omega}^-(6,3)$, order $39\,191\,040 = 2^9 \times 3^7 \times 5 \times 7$ (non-split), where $\widehat{\Omega}^-(6,3)$ is a semidirect product of $\Omega^-(6,3)$ by $\mathbf{Z}_2$.

G_{35}: $W(E_6) = SO(5,3) = O^-(6,2) = PSp(4,3) \cdot \mathbf{Z}_2 = PSU(4,2) \cdot \mathbf{Z}_2$, order $51\,840 = 2^7 \times 3^4 \times 5$.

One 7-dimensional complex reflection group in addition to Sym(8):

G_{36}: $W(E_7) = \mathbf{Z}_2 \times Sp(6,2)$, order $2\,903\,040 = 2^{10} \times 3^4 \times 5 \times 7$.

One 8-dimensional complex reflection group in addition to Sym(9):

G_{37}: $W(E_8) = \mathbf{Z}_2 \cdot O^+(8,2)$, order $696\,729\,600 = 2^{14} \times 3^5 \times 5^2 \times 7$ (non-split).

Example H99E9

We verify that the complex reflection group G_{24} is isomorphic to $\mathbf{Z}_2 \times \Omega(3,7)$.

```
> W := ShephardTodd(24);
> G := sub<GL(3,7) | Omega(3,7), -GL(3,7)!1>;
> IsIsomorphic(W,G):Minimal;
true Homomorphism of MatrixGroup(3, Cyclotomic Field of order 7 and degree 6)
of order 2^4 * 3 * 7 into MatrixGroup(3, GF(7)) of order 2^4 * 3 * 7
```

`ComplexReflectionGroup(C)`

`Reduced` BoolElt *Default :* `true`

This function returns the complex reflection group defined by the (complex) Cartan matrix C. When the optional parameter `Reduced` is `true` (the default), the roots and coroots are computed modulo the null space of C.

`ComplexReflectionGroup(X, n)`

`NumFld` BoolElt *Default :* `false`

This function returns the primitive reflection group of type X and rank n, using the Cohen/Coxeter naming scheme.

By default the matrices are written over the ring of integers of the smallest cyclotomic field which contains the character values of the reflections. If the parameter `NumFld` is set to `true`, the number field generated by the character values of the reflections is used.

Example H99E10

In this example we find (up to conjugacy) all subgroups of $G = W(O_4) = G_{31}$ that are generated by reflections. This shows that G cannot be generated by fewer than 5 reflections.
We begin by checking that G has only one class of reflections.

```
> G := ComplexReflectionGroup("O",4);
> print #[c[3] : c in Classes(G) | IsReflection(c[3])];
1
> R := Class(G,G.1); #R;
60
> #G;
46080
```

We proceed by building the list of reflection subgroups in 'layers', where the n-th layer consists of representatives of the subgroups generated by n reflections.

```
> L := [sub<G|G.1>];
> layers := [L];
> n := 0;
> while true do
>   n +:= 1;
>   nextlayer := [];
```

We extend each group in layer n by adjoining one additional reflection. The resulting subgroup will be generated by n or $n+1$ reflections. If we haven't seen it before we add it to the list.

```
>   for H in layers[n] do
>     for A in {sub<G|H,s> : s in R | s notin H} do
>       if forall{B : B in L | not IsConjugate(G,A,B)} then
>         Append(~nextlayer,A);
>         Append(~L,A);
>       end if;
>     end for;
>   end for;
>   if IsEmpty(nextlayer) then break; end if;
>   Append(~layers,nextlayer);
```

After the construction of each layer we print the orders of the subgroups.

```
>   print n+1,"generators";
```

```
>   print [#A : A in nextlayer];
> end while;
2 generators
[ 4, 4, 8, 6 ]
3 generators
[ 8, 8, 16, 24, 12, 16, 24, 48, 16, 96 ]
4 generators
[ 192, 16, 32, 96, 16, 192, 32, 48, 1536, 384, 64, 64, 32,
 7680, 1152, 36, 384, 120, 120, 192, 192 ]
5 generators
[ 64, 384, 3072, 128, 46080 ]
6 generators
[ 256 ]
```

Looking at the orders we see that the first time the group G_{31} appears is in layer 5. That is, it cannot be generated by 4 or fewer reflections. It is interesting to note that there is one subgroup which requires 6 generators; namely the imprimitive group $G(4,2,2) \times G(4,2,2)$.

`ShephardTodd(m, p, n)`

`ImprimitiveReflectionGroup(m, p, n)`

`NumFld` BoolElt *Default :* `false`

Let B be the direct product of n copies of the cyclic group C_m of order m and represent the elements of B by diagonal matrices $\mathrm{diag}(\theta_1, \theta_2, \ldots, \theta_n)$. The elements of the symmetric group $\mathrm{Sym}(n)$ can be represented by $n \times n$ permutation matrices and in this guise it acts on the group B; the resulting semidirect product is also known as the *wreath product* $C_m \wr \mathrm{Sym}(n)$.

For each divisor p of m define

$$A(m,p,n) := \{\, \mathrm{diag}(\theta_1, \theta_2, \ldots, \theta_n) \in B \mid (\theta_1\theta_2 \cdots \theta_n)^{m/p} = 1 \,\}.$$

It is immediately clear that $A(m,p,n)$ is a subgroup of index p in B that is invariant under the action of $\mathrm{Sym}(n)$. The semidirect product of $A(m,p,n)$ by the symmetric group $\mathrm{Sym}(n)$ is the group $G(m,p,n)$. These groups are imprimitive when $m \geq 2$. The group $G(1,1,n)$ is the symmetric group $\mathrm{Sym}(n)$ acting as permutation matrices.

Shephard and Todd proved that every irreducible imprimitive complex reflection subgroup of $GL(n, \mathbf{C})$ is conjugate to $G(m,p,n)$ for some m and p.

This function returns the Shephard and Todd group $G(m,p,n) \subset \mathrm{GL}(n,F)$, where p divides m. In general, $G(m,p,n)$ is irreducible but if $m = p = 1$, the function returns $\mathrm{Sym}(n)$ in its natural permutation representation, which is not irreducible.

By default the matrices are written over the ring of integers of the smallest cyclotomic field which contains the character values of the reflections. If the parameter `NumFld` is set to `true`, the number field generated by the character values of the reflections is used.

Example H99E11

```
> ShephardTodd(6, 3, 3);
MatrixGroup(3, Cyclotomic Field of order 6 and degree 2)
Generators:
     [0 1 0]
     [1 0 0]
     [0 0 1]

     [1 0 0]
     [0 0 1]
     [0 1 0]

     [1      0      0]
     [0      0      z]
     [0 -z + 1      0]

     [1  0   0]
     [0  1   0]
     [0  0  -1]
Mapping from: MatrixGroup(3, Cyclotomic Field of order 6 and degree 2) to GL(3,
CyclotomicField(6))
```

`ComplexRootMatrices(k)`

`ComplexRootMatrices(m, p, n)`

`NumFld` BoolElt *Default :* `false`

Given an integer n ($4 \leq n \leq 37$) the first form of the function returns basic root and coroot matrices for the primitive Shephard-Todd group G_n.

Given three positive integers m, p and n such that p divides m, the second version returns basic root and coroot matrices for the imprimitive complex reflection group $G(m, p, n)$. In both cases the functions return an invariant hermitian form, a generator for the group of roots of unity of the ring of definition, and the order of the generator.

By default the matrices are written over the ring of integers of the smallest cyclotomic field which contains the character values of the reflections. If the parameter `NumFld` is set to `true`, the number field generated by the character values of the reflections is used.

Example H99E12

```
> A,B,J,gen,ordgen := ComplexRootMatrices(13);
> A,B;
[            1               0]
[ -z^2 - z - 1               1]
[z^2 + 2*z + 1    -z^2 - z - 1]

[             2     -z^3 + z + 2]
[           z^2    z^3 + z^2 + 1]
[-z^3 + z^2 - 1          z^2 - 1]
> gen,ordgen;
-z^3
8
> G := PseudoReflectionGroup(A,B);
> #G;
96
```

`ComplexCartanMatrix(k)`

`ComplexCartanMatrix(m, p, n)`

`NumFld` BoolElt *Default :* `false`

If A and B are the basic root and coroot matrices returned by `ComplexRootMatrices` above, then this function returns AB^{tr}, where B^{tr} is the transpose of B. The meaning of the optional parameter `NumFld` has been described above.

`BasicRootMatrices(C)`

`Reduced` BoolElt *Default :* `true`

This function returns a matrix A of roots and a matrix B of coroots such that $C = AB^{\mathrm{tr}}$. The default, when the optional parameter `Reduced` is `true`, is to compute the roots and coroots modulo the null space of C.

`CohenCoxeterName(k)`

Cohen's string name and rank of the Shephard and Todd group G_k. This is an extension of the naming scheme for Coxeter groups. For example, the Shephard and Todd group G_{37} is the Coxeter group of type E_8 whereas the Shephard and Todd group G_{32} has Cohen name L_4.

`ShephardToddNumber(X, n)`

Given a string X and an integer n, this function returns the Shephard and Todd number of the complex reflection group $W(X_n)$ of type X and rank n. The rank is the dimension of the space on which the group acts; it is not always the number of generators.

The Shepard and Todd numbers range from 1 to 37. All symmetric groups (type A) have Shephard and Todd number 1, all imprimitive groups $G(m, p, n)$ have Shephard and Todd number 2, and all cyclic groups have Shephard and Todd number 3. The primitive complex reflection groups of rank 2 have Shepard and Todd numbers in the range 4 to 22. Except for the group G_4 which has type L_2, the rank 2 groups do not have Cohen–Coxeter names.

The Shephard and Todd numbers in the range 23 to 37 refer to the Cohen–Coxeter groups $W(E_6)$, $W(E_7)$, $W(E_8)$, $W(F_4)$, $W(H_3)$, $W(H_4)$, $W(J_3(4))$, $W(J_3(5))$, $W(K_5)$, $W(K_6)$, $W(L_3)$, $W(L_4)$, $W(M_3)$, $W(N_4)$, and $EW(N_4)$. Note that in MAGMA the types of the rank 3 groups $W(J_3(4))$ and $W(J_3(5))$ are $J4$ and $J5$; and the type of the rank 4 group $EW(N_4)$ is O.

As a matrix group the Coxeter group of type A is returned by the function `CoxeterGroup(GrpMat,"A",n)`, where n is the rank. The groups of types B, C and D are Coxeter groups and imprimitive complex reflection groups. Thus, as matrix groups, they can be obtained via the function `ShephardTodd(2,p,n)`, where $p = 1$ for type B or C and $p = 2$ for type D.

Example H99E13

The type of the group G_{31} is O and its rank is 4. This is the notation used in [LT09].

```
> ShephardToddNumber("J5",3);
27
> CohenCoxeterName(31);
O 4
```

Example H99E14

To construct a complex reflection group with a given name, first convert the name to its Shephard and Todd number.

```
> G := ShephardTodd(ShephardToddNumber("L",4));
> G;
MatrixGroup(4, Cyclotomic Field of order 3 and degree 2)
Generators:
    [     omega           0           0           0]
    [-omega - 1           1           0           0]
    [         0           0           1           0]
    [         0           0           0           1]

    [         1 omega + 1           0           0]
    [         0     omega           0           0]
```

```
[        0 omega + 1          1          0]
[        0          0          0          1]

[         1          0          0          0]
[         0          1 -omega - 1          0]
[         0          0      omega          0]
[         0          0 -omega - 1          1]

[        1          0          0          0]
[        0          1          0          0]
[        0          0          1 omega + 1]
[        0          0          0      omega]
```

`ComplexRootDatum(k)`

`ComplexRootDatum(m, p, n)`

`NumFld` BoolElt *Default :* `false`

A root datum for the Shephard and Todd group G_k or, in the second form of the function, the imprimitive group $G(m, p, n)$. This is returned as a 5-tuple Φ, Φ^*, ρ, W, J, where Φ is the sequence of roots, Φ^* the sequence of coroots, $\rho : A \to B$ is a bijective map, W is the complex reflection group of the root datum, and J is an hermitian form preserved by W.

99.6 Operations on Reflection Groups

See Chapter 59 for general functions for matrix groups. Note that most of the functions in this section only work for real reflection groups.

`IsCoxeterIsomorphic(W1, W2)`

Returns `true` if, and only if, the real reflection groups W_1 and W_2 are isomorphic as Coxeter groups.

`IsCartanEquivalent(W1, W2)`

Returns `true` if, and only if, the crystallographic real reflection groups W_1 and W_2 have Cartan equivalent Cartan matrices.

Example H99E15

```
> W1 := ReflectionGroup("B3");
> W2 := ReflectionGroup("C3");
> IsCoxeterIsomorphic(W1, W2);
true [ 1, 2, 3 ]
> IsCartanEquivalent(W1, W2);
false
```

`CartanName(W)`

The Cartan name of the finite or affine real reflection group W (Section 95.6).

`CoxeterDiagram(W)`

A display of the Coxeter diagram of the real reflection group W (Section 95.6). If W is not affine or finite, an error is flagged.

`DynkinDiagram(W)`

A display of the Coxeter diagram of the real reflection group W (Section 95.6). If W is not affine or finite, or if W is not crystallographic, an error is flagged.

Example H99E16

```
> G := CompleteGraph(3);
> W := ReflectionGroup(G);
> CartanName(W);
A~2
> CoxeterDiagram(W);
A~2    1 - 2
       |   |
       - 3 -
```

`RootSystem(W)`

The root system of the finite real reflection group W (Chapter 96). If W is infinite, an error is flagged.

`RootDatum(W)`

The root datum of the finite real reflection group W (Chapter 97). The roots and coroots of W must have integral components, and W must be finite.

`CoxeterMatrix(W)`

The Coxeter matrix of the real reflection group W (Section 95.2).

`CoxeterGraph(W)`

The Coxeter graph of the real reflection group W (Section 95.3).

`CartanMatrix(W)`

The Cartan matrix of the real reflection group W (Section 95.4).

`DynkinDigraph(W)`

The Dynkin digraph of the real reflection group W (Section 95.5).

`Rank(W)`

`NumberOfGenerators(W)`

The rank of the reflection group W.

Example H99E17

```
> R := StandardRootSystem("A", 4);
> W := ReflectionGroup(R);
> Rank(W);
4
> Dimension(W);
5
```

`FundamentalGroup(W)`

The fundamental group of the real reflection group W (Subsection 97.1.6). The roots and coroots of W must have integral components.

`IsogenyGroup(W)`

The isogeny group of the real reflection group W, together with the injection into the fundamental group (Subsection 97.1.6). The roots and coroots of W must have integral components.

`CoisogenyGroup(W)`

The fundamental group of the real reflection group W together with the projection onto the fundamental group (Subsection 97.1.6). The roots and coroots of W must have integral components.

`BasicDegrees(W)`

The degrees of the basic invariant polynomials of the reflection group W. These are computed using the table in [Car72, page 155] if the group is real, and using the algorithm of [LT09] in other cases. If W is infinite, an error is flagged.

`BasicCodegrees(W)`

The basic codegrees of the reflection group W. These are computed using the algorithm of [LT09]. If W is infinite, an error is flagged.

Example H99E18

The product of the basic degrees is the order of the Coxeter group; the sum of the basic degrees is the sum of the rank and the number of positive roots.

```
> W := ReflectionGroup("E6");
> degs := BasicDegrees(W);
> degs;
[ 2, 5, 6, 8, 9, 12 ]
> &*degs eq #W;
true
> &+degs eq NumPosRoots(W) + Rank(W);
true
```

`LongestElement(W)`

The unique longest element in the finite real reflection group W.

`CoxeterElement(W)`

The Coxeter element in the reflection group W, ie. the product of the generators.

`CoxeterNumber(W)`

The order of the Coxeter element in the real reflection group W.

Example H99E19

Operations on groups.

```
> W := ReflectionGroup("A4");
> LongestElement(W);
[ 0  0  0 -1]
[ 0  0 -1  0]
[ 0 -1  0  0]
[-1  0  0  0]
> CoxeterElement(W);
[-1 -1 -1 -1]
[ 1  0  0  0]
[ 0  1  0  0]
[ 0  0  1  0]
```

`LeftDescentSet(W, w)`

The set of indices r of simple roots of the finite real reflection group W such that the length of the product $s_r w$ is less than that of the element w.

`RightDescentSet(W, w)`

The set of indices r of simple roots of the finite real reflection group W such that the length of the product ws_r is less than that of the element w.

Example H99E20

```
> W := ReflectionGroup("A5");
> x := W.1*W.2*W.4*W.5;
> LeftDescentSet(W, x);
{ 1, 4 }
> RightDescentSet(W, x);
{ 2, 5 }
```

99.7 Properties of Reflection Groups

See Chapter 59 for general functions for matrix groups.

`IsReflectionGroup(G)`

Returns `true` if G is a group generated by reflections. It need not be the case that all the group elements returned by `Generators(G)` are reflections.

`RootsAndCoroots(G)`

Returns the orders of the reflections, the roots and the coroots of the reflection group G.

`IsRealReflectionGroup(G)`

Returns `true` if, and only if, the matrix group G is a real reflection group. If `true`, the simple orders, roots, and coroots are also returned.

Example H99E21

```
> W := ComplexReflectionGroup("A", 4);
> IsReflectionGroup(W);
true
> IsRealReflectionGroup(W);
true

[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]

[ 2 -1  0  0]
[-1  2 -1  0]
[ 0 -1  2 -1]
[ 0  0 -1  2]
> W := ComplexReflectionGroup("M", 3);
> IsReflectionGroup(W);
true
>  IsRealReflectionGroup(W);
                          ^
Runtime error in 'IsRealReflectionGroup': The group must be defined over the
reals
```

`IsCrystallographic(W)`

Returns `true` if, and only if, the real reflection group W is crystallographic, i.e. its Cartan matrix has integral entries.

`IsSimplyLaced(W)`

Returns `true` if, and only if, the real reflection group W is simply laced, i.e. its Coxeter graph has no labels.

Example H99E22

```
> W := ReflectionGroup("A~2 D4");
> IsFinite(W);
false
> IsCrystallographic(W);
true
> IsSimplyLaced(W);
true
```

`Dual(G)`

The dual of the reflection group G, ie, the reflection group gotten by swapping roots with coroots.

`Overgroup(H)`

The overgroup of H, ie. the reflection group whose roots are permuted by the elements of the reflection subgroup H.

`Overdatum(H)`

The root datum whose roots are permuted by the elements of the reflection subgroup H.

Every Coxeter group W has a standard action. For example, the standard action group of a Coxeter group of type A_n is the symmetric group of degree $n+1$ acting on $\{1, \ldots, n\}$.

`StandardAction(W)`

The standard action of the reflection group W.

`StandardActionGroup(W)`

The group G of the standard action of the reflection group W, together with an isomorphism $W \to G$.

99.8 Roots, Coroots and Reflections

Many of these functions have an optional argument `Basis` which may take one of the following values

1. `"Standard"`: the standard basis for the (co)root space. This is the default.
2. `"Root"`: the basis of simple (co)roots.
3. `"Weight"`: the basis of fundamental (co)weights (see Subsection 99.8.3 below).

99.8.1 Accessing Roots and Coroots

`RootSpace(W)`

`CorootSpace(W)`

The base space of the reflection group W. If W is not a reflection group, an error occurs.

Example H99E23

```
> W := ComplexReflectionGroup("M", 3);
> RootSpace(W);
Full Vector space of degree 3 over Cyclotomic Field of order 24 and degree 8
```

`SimpleOrders(W)`

The sequence of simple orders of the reflection group W. If W is not a reflection group, an error is flagged.

`SimpleRoots(W)`

`SimpleCoroots(W)`

The simple (co)roots of the reflection group W as the rows of a matrix, i.e. A (resp. B).

`NumberOfPositiveRoots(W)`

`NumPosRoots(W)`

The number of positive roots of the real reflection group W. This is also the number of positive coroots. The total number of (co)roots is twice the number of positive (co)roots. This number is finite if, and only if, W is finite.

`Roots(W)`

`Coroots(W)`

`Basis` MonStgElt *Default : "Standard"*

The indexed set of (co)roots of the real reflection group W, i.e. $\{@\,\alpha_1, \ldots \alpha_{2N}\,@\}$ (resp. $\{@\,\alpha_1^\star, \ldots \alpha_{2N}^\star\,@\}$). If W is infinite, an error is flagged.

`PositiveRoots(W)`

`PositiveCoroots(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The indexed set of positive (co)roots of the real reflection group W, that is, $\{@ \alpha_1, \ldots \alpha_N @\}$ (resp. $\{@ \alpha_1^\star, \ldots \alpha_N^\star @\}$). If W is infinite, an error is flagged.

`Root(W, r)`

`Coroot(W, r)`

`Basis` MonStgElt *Default :* "*Standard*"

The rth (co)root α_r (resp. $\alpha_r^\star$) of the real reflection group W. If W is infinite, an error is flagged.

`RootPosition(W, v)`

`CorootPosition(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

If v is a (co)root in the finite real reflection group W, return its index; otherwise return 0. These functions will try to coerce v into the appropriate lattice; v should be written with respect to the basis specified by the parameter `Basis`. If W is infinite, an error is flagged.

Example H99E24

```
> W := ReflectionGroup("A3");
> Roots(W);
{@
    (1 0 0),
    (0 1 0),
    (0 0 1),
    (1 1 0),
    (0 1 1),
    (1 1 1),
    (-1  0  0),
    (0 -1  0),
    (0  0 -1),
    (-1 -1  0),
    (0 -1 -1),
    (-1 -1 -1)
@}
> PositiveCoroots(W);
{@
    (2 -1  0),
    (-1  2 -1),
    (0 -1  2),
    (1  1 -1),
```

```
    (-1  1  1),
    (1 0 1)
@}
> #Roots(W) eq 2*NumPosRoots(W);
true
> Root(W, 4);
(1 1 0)
> Root(W, 4 : Basis := "Root");
(1 1 0)
> RootPosition(W, [1,1,0]);
4
> W := ReflectionGroup("A3");
> Roots(W);
{@
    (1 0 0),
    (-1 -1 -3),
    (1 2 4),
    (0 -1 -3),
    (0 1 1),
    (1 1 1),
    (-1  0  0),
    (1 1 3),
    (-1 -2 -4),
    (0 1 3),
    (0 -1 -1),
    (-1 -1 -1)
@}
> PositiveCoroots(W);
{@
    (2 -1  0),
    (-1  2 -1),
    (0 1 0),
    (1  1 -1),
    (-1  3 -1),
    (1  2 -1)
@}
> #Roots(W) eq 2*NumPosRoots(W);
true
> Root(W, 4);
(0 -1 -3)
> Root(W, 4 : Basis := "Root");
(1 1 0)
> RootPosition(W, [0,-1,-3]);
4
```

99.8.2 Reflections

The root α acts on the root space via the reflection s_α; the coroot $\alpha^\star$ acts on the coroot space via the coreflection $s_\alpha^\star$.

`ReflectionMatrices(W)`

`CoreflectionMatrices(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The sequence of reflections in the finite real reflection group W. The rth reflection in the sequence corresponds to the rth (co)root.

`SimpleReflectionMatrices(W)`

`SimpleCoreflectionMatrices(W)`

`Basis` MonStgElt *Default :* "*Standard*"

The matrices giving the action of the simple (co)roots on the (co)root space of the finite real reflection group W.

`ReflectionMatrix(W, r)`

`CoreflectionMatrix(W, r)`

`Basis` MonStgElt *Default :* "*Standard*"

The reflection in finite real reflection group W corresponding to the rth (co)root. If $r = 1, \ldots, n$, this is a generator of W.

`SimpleReflectionPermutations(W)`

The sequence of permutations giving the action of the simple (co)roots of the finite reflection group W on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutations(W)`

The sequence of permutations giving the action of the (co)roots of the finite reflection group W on the (co)roots. This action is the same for roots and coroots.

`ReflectionPermutation(W, r)`

The permutation giving the action of the rth (co)root of the finite reflection group W on the (co)roots. This action is the same for roots and coroots.

`ReflectionWords(W)`

The sequence of words in the simple reflections for all the reflections of the real reflection group W. These words are given as sequences of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWords(W)[r]`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

`ReflectionWord(W, r)`

The word in the simple reflections for the rth reflection of the real reflection group W. The word is given as a sequence of integers. In other words, if $a = [a_1, \ldots, a_l] =$ `ReflectionWord(W,r)`, then $s_{\alpha_r} = s_{\alpha_{a_1}} \cdots s_{\alpha_{a_l}}$.

Example H99E25

```
> Q := RationalField();
> W := ReflectionGroup("A3");
> mx := ReflectionMatrix(W, 4);
> perm := ReflectionPermutation(W, 4);
> RootPosition(W, Vector(Q, Eltseq(Root(W,2))) * mx) eq 2^perm;
true
> mx := CoreflectionMatrix(W, 4);
> CorootPosition(W, Coroot(W,2) * mx) eq 2^perm;
true
```

Length(w)

CoxeterLength(w)

The length of w as an element of the Coxeter group W, ie. the number of positive roots of W which become negative under the action of w.

99.8.3 Weights

WeightLattice(W)

CoweightLattice(W)

The (co)weight lattice of the real reflection group W. The roots and coroots of W must have integral components.

FundamentalWeights(W)

FundamentalCoweights(W)

Basis MonStgElt *Default : "Standard"*

The fundamental weights of the real reflection group W given as the rows of a matrix. The roots and coroots of W must have integral components.

Example H99E26

```
> W := ReflectionGroup("E6");
> WeightLattice(W);
Lattice of rank 6 and degree 6
Basis:
(4  3  5  6  4  2)
(3  6  6  9  6  3)
(5  6 10 12  8  4)
(6  9 12 18 12  6)
(4  6  8 12 10  5)
(2  3  4  6  5  4)
Basis Denominator: 3
```

```
> FundamentalWeights(W);
[ 4/3    1  5/3    2  4/3  2/3]
[   1    2    2    3    2    1]
[ 5/3    2 10/3    4  8/3  4/3]
[   2    3    4    6    4    2]
[ 4/3    2  8/3    4 10/3  5/3]
[ 2/3    1  4/3    2  5/3  4/3]
```

`IsDominant(R, v)`

`Basis` MonStgElt *Default :* "*Standard*"

Returns `true` if, and only if, v is a dominant weight for the root datum R, ie, a nonnegative integral linear combination of the fundamental weights.

`DominantWeight(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique dominant weight in the same W-orbit as v, where W is a real reflection group and v is a weight given as a vector or a sequence representing a vector. The second value returned is a Coxeter group element taking v to the dominant weight.

`WeightOrbit(W, v)`

`Basis` MonStgElt *Default :* "*Standard*"

The W-orbit of v as an indexed set, where W is a real reflection group and v is a weight given as a vector or a sequence representing a vector. The first element in the orbit is always dominant. The second value returned is a sequence of Coxeter group elements taking the dominant weight to the corresponding element of the orbit.

Example H99E27

```
> W := CoxeterGroup("B3");
> DominantWeight(W, [1,-1,0] : Basis:="Weight");
(1 0 0)
$.2 * $.3 * $.2 * $.1
> #WeightOrbit(W, [1,-1,0] : Basis:="Weight");
6
```

99.9 Related Structures

In this section we briefly list functions for creating other structures from a reflection group. See the appropriate chapters of the Handbook for more details.

`CoxeterGroup(GrpFPCox, W)`

The Coxeter group isomorphic to the real reflection group W. See Chapter 98.

`CoxeterGroup(GrpPermCox, W)`

The permutation Coxeter group isomorphic to the finite real reflection group W. See Chapter 98.

`LieAlgebra(W, R)`

The reductive Lie algebra over the ring R with Weyl group W. Unless W is finite, real, and crystallographic, an error is flagged. See Section 100.5.1.

`GroupOfLieType(W, k)`

The group of Lie type over the field k with Weyl group W. Unless W is finite, real, and crystallographic, an error is flagged. The roots and coroots of W must also have integral components. See Chapter 103.

100 LIE ALGEBRAS

Chapter 100
LIE ALGEBRAS

100.1 Introduction

This chapter is concerned with finite dimensional Lie algebras. A large number of specialised functions are provided for these algebras. We refer to [dG00] for a general introduction to the theory of Lie algebras and their algorithms. For some of the functions described here that rely on a non-trivial algorithm we will indicate a precise reference.

Lie algebras are viewed as free modules over a base ring R with a multiplication satisfying the usual Lie axioms. Some functions require additional conditions on the base ring; for example, many functions require that the base ring be a field.

The main computational machinery in MAGMA for Lie algebras assumes that they are given either as structure constant algebras or as matrix algebras. Functions are provided which, given a finitely presented finite dimensional Lie algebra, will attempt to construct an isomorphic structure constant Lie algebra. As a structure constant algebra, the Lie algebra L of dimension n over a ring R is defined in MAGMA by giving the n^3 *structure constants* $a_{ij}^k \in R (1 \leq i, j, k \leq n)$ such that, if $\{e_1, e_2, \ldots, e_n\}$ is the basis of L, $e_i * e_j = \sum_{k=1}^{n} a_{ij}^k * e_k$.

In MAGMA V2.19 there is more functionality for Lie algebras defined by structure constants than for matrix Lie algebras. Throughout this chapter the algebra representation appropriate for a given intrinsic will be noted. For information on matrix algebras considered as associative algebras see Chapter 83.

In addition, some functions are provided for finitely presented Lie algebras and Lie algebras generated by extremal elements, and databases of solvable Lie algebras, nilpotent Lie algebras, and nilpotent orbits in simple Lie algebras are available.

100.1.1 Guide for the Reader

As mentioned above, the most extensively supported Lie algebras in MAGMA are structure constant Lie algebras and matrix Lie algebras. The methods for constructing these (by explicitly specifying structure constants or matrices) are described in Sections 100.2.

Well known simple finite Lie algebras can be more easily constructed by specifying the type. The classical, reductive, Lie algebras (A_n, B_n, C_n, D_n, E_6, E_7, E_8, F_4, G_2) and their twisted variants are described in Section 100.5.1, the Witt Lie algebras and its derivatives (of *Cartan-Type*) in Section 100.5.2, and the Melikian Lie algebras in Section 100.5.3. Those interested primarily in classical Lie algebras may want to skip to Section 100.5.1, which includes a number of examples to get started.

Elementary properties of these Lie algebras (bases, types, Weyl group, etc.) are described in Section 100.8. This section also contains information about isomorphism testing. Other properties (nilpotency, simplicity) are discussed in Section 100.10. Some further operations that only apply to matrix Lie algebras may be found in Section 100.13.

Constructors such as direct sums, subalgebras, centralisers, Cartan subalgebras, derived series, etc. are treated in Sections 100.7 and 100.9; construction of homomorphisms can be found in Section 100.14. The construction of elements of Lie algebras is described in Section 100.6, and operations on them in Section 100.11.

In addition to these Lie algebras MAGMA supports two other types of Lie algebras. Firstly finitely presented Lie algebras, as free Lie algebras modulo a set of relations, described in Section 100.3. Secondly Lie algebras generated by extremal elements, described in Section 100.4.

More specialistic functions for structure constant Lie algebras are described in Sections 100.12 (the natural module), 100.15 (automorphisms of classical-type Lie algebras), 100.16 (restrictable Lie algebras), and 100.17 (universal enveloping algebras).

MAGMA also provides databases and recognition procedures for small-dimensional solvable and nilpotent Lie algebras (described in Section 100.18), a database of semisimple subalgebras of simple Lie algebras (described in Section 100.19), and a database of nilpotent orbits in simple Lie algebras (described in Section 100.20).

Other chapters that may be of interest are Chapter 101 on Kac-Moody Lie algebras and Chapter 102 on Quantum Groups. Furthermore, Chapter 104 deals with representations of Lie algebras and groups of Lie type. Of particular importance is Section 104.3.1, dealing with the construction of representations of Lie algebras.

100.2 Constructors for Lie Algebras

The construction of a Lie algebra defined by structure constants is identical to that of a general structure constant algebra. Most constructors take two optional parameters: `Check` and `Rep`.

By default, the conditions for the algebra to be a Lie algebra are checked. If the user decides to omit this check, by setting the parameter `Check` to `false`, and the algebra is not actually Lie then functions in this section will fail or give incorrect answers.

The optional parameter `Rep` can be used to select the internal representation of the structure constants. The possible values for `Rep` are "`Dense`", "`Sparse`" and "`Partial`", with the default being "`Dense`". In the dense format, the n^3 structure constants are stored as n^2 vectors of length n. This is the best representation if most of the structure constants are non-zero. The sparse format, intended for use when most structure constants are zero, stores the positions and values of the non-zero structure constants. The partial format stores the vectors, but records for efficiency the positions of the non-zero structure constants.

`LieAlgebra< R, n | Q : parameters >`

`LieAlgebra< M | Q : parameters >`

`Check`	BOOLELT	*Default :* `true`
`Rep`	MONSTGELT	*Default :* "*Dense*"

This function creates the Lie structure constant algebra L over the free module $M = R^n$, with standard basis $\{e_1, e_2, \ldots, e_n\}$, and structure constants a_{ij}^k being given by the sequence Q. The sequence Q can be of any of the following three forms. Note that in all cases the actual ordering of the structure constants is the same: the only difference is that their partitioning into blocks varies.

(i) A sequence of n sequences of n sequences of length n. The j-th element of the i-th sequence is the sequence $[a_{ij}^1, \ldots, a_{ij}^n]$, or the element $(a_{ij}^1, \ldots, a_{ij}^n)$ of M, giving the coefficients of the product $e_i * e_j$.

(ii) A sequence of n^2 sequences of length n, or n^2 elements of M. Here the coefficients of $e_i * e_j$ are given by position $(i-1)n + j$ of Q.

(iii) A sequence of n^3 elements of the ring R. The sequence elements are the structure constants themselves, in the order $a_{11}^1, a_{11}^2, \ldots, a_{11}^n, a_{12}^1, a_{12}^2, \ldots, a_{nn}^n$. So a_{ij}^k lies in position $(i-1)n^2 + (j-1)n + k$ of Q.

`LieAlgebra< R, n | T :` *parameters* `>`

`Check`	BoolElt	*Default :* `true`
`Rep`	MonStgElt	*Default :* "*Dense*"

This function creates the Lie structure constant algebra L with standard basis $\{e_1, e_2, \ldots, e_n\}$ over the ring R. The sequence T contains quadruples $< i, j, k, a_{ij}^k >$ giving the non-zero structure constants. All other structure constants are defined to be 0.

`LieAlgebra< t | T :` *parameters* `>`

`Check`	BoolElt	*Default :* `true`
`Rep`	MonStgElt	*Default :* "*Dense*"

This function creates the Lie structure constant algebra L over the integers, with standard basis $\{e_1, e_2, \ldots, e_n\}$. The sequence T contains quadruples $< i, j, k, a_{ij}^k >$ (where the a_{ij}^k are integers) giving the non-zero structure constants. All other structure constants are defined to be 0. The argument t is a sequence of length n consisting of nonnegative integers giving the moduli of the basis elements. Thus let t_i denote the i-th element of t; then $t_i e_i = 0$. So if $t_i = 0$, then $ke_i \neq 0$ for all integers k.

`LieAlgebra(A)`

Given an associative structure-constant algebra A, create the Lie algebra L consisting of the elements in A with the induced Lie product $(x, y) \to x * y - y * x$. As a second value the map identifying the elements of L and A is returned.

`LieAlgebra(A)`

Given an associative matrix algebra A, create a structure-constant Lie algebra L isomorphic to A with the induced Lie product $(x, y) \to x * y - y * x$.

`AbelianLieAlgebra(R, n)`

`Rep` MonStgElt *Default : "Sparse"*

Create the abelian Lie algebra of dimension n over the ring R.

Example H100E1

We construct the Heisenberg Lie algebra, then a Lie algebra from an associative algebra, and finally a Lie algebra over the integers (also called a Lie ring).

```
> T:= [ <1,2,3,1>, <2,1,3,-1> ];
> LieAlgebra< Rationals(), 3 | T >;
Lie Algebra of dimension 3 with base ring Rational Field
> A:= Algebra( GF(27), GF(3) );
> LieAlgebra(A);
Lie Algebra of dimension 3 with base ring GF(3)
> T:= [ <1,2,2,2>, <2,1,2,2> ];
> t:= [0,4];
> K:= LieAlgebra< t | T : Rep:= "Dense" >; K;
Lie Algebra of dimension 2 with base ring Integer Ring
Column moduli: [0, 4]
> LowerCentralSeries( K );
[
    Lie Algebra of dimension 2 with base ring Integer Ring
    Column moduli: [0, 4],
    Lie Algebra of dimension 1 with base ring Integer Ring
    Column moduli: [2],
    Lie Algebra of dimension 0 with base ring Integer Ring
]
```

`ChangeBasis(L, B)`

`Rep` MonStgElt *Default : "Dense"*

Create a new Lie structure constant algebra L', isomorphic to L, by recomputing the structure constants with respect to the basis B. The basis B can be specified as a set or sequence of elements of L, a set or sequence of vectors, or a matrix. The second returned value is the isomorphism from L to L'.

As above, the optional parameter `Rep` can be used to select the internal representation of the structure constants. Note that the default is dense representation, regardless of the representation used by L.

`MatrixLieAlgebra(R, n)`

Given a ring R and an integer n, create the full Lie algebra of matrices of degree d over R.

`MatrixLieAlgebra(A)`

Given an associative matrix algebra A, create the matrix Lie algebra L consisting of the elements in A with the induced Lie product $(x, y) \to x * y - y * x$.

`Algebra(M)`

`LieAlgebra(M)`

Return a structure-constant Lie algebra isomorphic to the matrix Lie algebra M.

Example H100E2

We construct the subalgebra of the matrix Lie algebra of 2×2 matrices, consisting of upper triangular matrices.

```
> L:= MatrixLieAlgebra( Rationals(), 2 );
> a:= L!Matrix( [[1,0],[0,0]] );
> b:= L!Matrix( [[0,0],[1,0]] );
> c:= L!Matrix( [[0,0],[0,1]] );
> K:= sub< L | [ a, b, c ] >;
> Dimension(K);
3
> IsSolvable(K);
true
> IsNilpotent(K);
false
```

100.3 Finitely Presented Lie Algebras

A finitely presented Lie algebra is constructed as the quotient of a free Lie algebra on a finite number of generators. Denote the set of generators by $X = \{x_1, \ldots, x_n\}$. Let F denote the base ring. Then the free Lie algebra generated by the x_i over the ring F is denoted by $L_F(X)$. The free magma on X is the set of the x_i together with all bracketed expressions in the x_i, e.g., $((x_1, x_2), ((x_1, x_3), x_2)))$. The free Lie algebra $L_F(X)$ is spanned by $M(X)$. However, the elements of this set are not linearly independent. It is a nontrivial problem to describe a basis of the free Lie algebra. One of several possibilities is the well-known *Hall basis*. Currently MAGMA does not support calculations involving bases of the free Lie algebra, as they are of little use for our main problem: the construction of a basis and multiplication table for a finitely-presented Lie algebra.

It is convenient to define an ordering on the elements of $M(X)$. First of all, each generator is assigned a degree. Usually, the degree of all x_i is taken to be one, but it is also possible to assign different degrees. The degree of a bracket (a, b) is defined to be the sum of the degrees of a and b. Let m, m' be two elements of $M(X)$. Then define $m < m'$ if the degree of m is less than the degree of m'. If their degrees are equal, then define $m < m'$ if $m = x_i$ and $m' = (a', b')$, for some a', b' in $M(X)$. If both m and m' are generators of the same degree, so that $m = x_i$, $m' = x_j$, then define $m < m'$ if $i < j$. Finally, if both m and

m' are bracketed expressions, that is, $m = (a, b)$ and $m' = (a', b')$, then define $m < m'$ if $a < a'$ or $a = a'$ and $b < b'$.

In the free Lie algebra, the relations $(a, b) = -(b, a)$, and $(a, a) = 0$ hold. In MAGMA this is used to rewrite an arbitrary element as a linear combination of elements of the form (a, b) with $a < b$. If instead we were to work relative to a basis for $L_F(X)$, then the use of the Jacobi identity when rewriting elements can lead to rather large expressions. Thus, mathematically speaking, in MAGMA rather than work in the free Lie algebra, we actually work in the free nonassociative anticommutative algebra. However, as our main interest lies in finitely-presented Lie algebras, this is usually not a problem.

100.3.1 Construction of the Free Lie Algebra

`FreeLieAlgebra(F, n)`

Given a ring F and a positive integer n, this function creates the free n-generator Lie algebra over the ring F. The generators are ordered, with the first generator being the biggest in the ordering, and the last generator the smallest. The angle bracket notation can be used to assign names to the generators.

Example H100E3

The following statement creates the MAGMA object corresponding to the free Lie algebra on three generators over the field $\mathbf{F}_2$.

```
> L<a,b,c>:= FreeLieAlgebra(GF(2), 3);
```

100.3.2 Properties of the Free Lie Algebra

`Rank(L)`

The number of generators of the free Lie algebra L.

`CoefficientRing(L)`

`BaseRing(L)`

The coefficient ring of L.

100.3.3 Operations on Elements of the Free Lie Algebra

Once a free Lie algebra has been created the user can construct a bracketed expression (a, b), either by simply typing it literally as `(a,b)`, or by using the multiplication operator as in `a*b`. Recall that MAGMA rewrites elements so they are in the form (a, b) with $a < b$. On some occasions this can lead to the introduction of a minus sign. Also, if an element contains a subexpression of the form (a, a), it will be rewritten to 0.

We can multiply and add elements, and multiply them by scalars.

```
x + y
```

```
x - y
```

```
x * y
```

```
L ! 0
```

```
Zero(L)
```

The zero element of the free Lie algebra L.

Example H100E4

```
> L<z,y,x> := FreeLieAlgebra(Rationals(), 3);
> x*y;
(x, y)
> (x, y);
(x, y)
> ((x*y)*z);
-(z, (x, y))
> ((x, y), z);
-(z, (x, y))
> ((x, y),(y, x));
0
> 2*((x, y), z) - ((x, z), (y, z)) + 1/2*(x, (x, (y, z)));
-((x, z), (y, z)) + 1/2*(x, (x, (y, z))) - 2*(z, (x, y))
```

```
IsLeaf(m)
```

Given a monomial element m of the free Lie algebra L, return `true` if m is a generator and `false` otherwise. If the result is `true` then the second return value is an integer i such that m is `L.i`. If the result is `false` then $a, b \in L$ are also returned such that m is a multiple of (a, b).

Note that in the latter case m is not equal to (a, b), but merely equal to a scalar multiple of (a, b). See the example for a possible method of retrieving the appropriate scalar.

Example H100E5

```
> L<z,y,x>:= FreeLieAlgebra(Rationals(), 3);
> IsLeaf(x);
true 3
> m := 2*((x, y), z);
> m;
-2*(z, (x, y))
> il, a, b := IsLeaf(m);
> il, a, b;
false z
(x, y)
> m eq (a, b);
false
> m eq LeadingCoefficient(m)*(a,b);
true
```

100.3.4 Construction of a Finitely-Presented Lie Algebra

`LieAlgebra(R)`

Given a set or sequence R of elements of a free Lie algebra L, let I be the ideal of L generated by the elements of R. It is assumed that the quotient algebra $Q = L/I$ is finite dimensional. This function returns the structure constant Lie algebra K isomorphic to the quotient Q. If the quotient Q is infinite dimensional then the program will not terminate. (The question of determining whether the quotient is finite dimensional is known to be undecidable.) The function can be interrupted by pressing `Ctrl-C`. The elements of R are referred to as *relations*.

This function works if the base ring is either a field or equal to the ring of integers. In these two cases slightly different objects are returned.

If the base ring is a field then four values are returned:

(a) A structure constant algebra K isomorphic to the quotient Q;

(b) A sequence G comprising sequences of integers;

(c) A sequence B of elements of the free Lie algebra L;

(d) A map $f : B \times B \to L$.

The sequence B maps to a basis of the quotient algebra, so it is a basis of a complement of the ideal I in the free Lie algebra L. The elements of B are in one-to-one correspondence with the basis elements of K.

If all the relations of R are homogeneous (i.e., if they are linear combinations of elements of the same degree), then Q is graded. The sequence G contains information about the grading. It consists of sequences of length two. The first element of each subsequence is the degree of a homogeneous subspace H, while the second element is the dimension of H. The basis elements of K are ordered with respect to increasing

degree. So from G it is straightforward to read off the degree of each basis element. If the relations are not homogeneous then the sequence G is empty. Finally, f is a map that takes two elements from B as arguments, and returns their product (in L) modulo the ideal I. The algorithm used is described in [dG00], §7.4.

Secondly, in the case in which the base ring is the ring of integers, four values are returned:

(a) A structure constant algebra K isomorphic to the quotient Q;

(b) A sequence G comprising sequences of integers;

(c) A sequence B that is always empty;

(d) A map $f : K \to L$.

Here the structure constant algebra is defined over the ring of integers, so it may have torsion. The sequence G is nonempty only if the input relations are homogeneous in which case it contains the dimensions of the homogeneous components. The function f is a map that takes an element u of K and returns an element of the free algebra L that maps to u under the projection map (from the free algebra to the quotient).

Example H100E6

In this example we compute the subalgebra K of E_7 spanned by the positive root spaces.

```
> L<x7,x6,x5,x4,x3,x2,x1>:= FreeLieAlgebra(RationalField(), 7);
> pp:= { [1,3], [3,4], [2,4], [4,5], [5,6], [6,7] };
> R:= [ ];
> g:= [ L.i : i in [1..7] ];
> for i in [1..7] do
>     for j in [i+1..7] do
>         if [i,j] in pp then
>            a:= (g[i],(g[i],g[j]));
>            Append( ~R, a );
>            Append( ~R, (g[j],(g[j],g[i])) );
>         else
>            Append( ~R, (g[i],g[j]) );
>         end if;
>     end for;
> end for;
> R;
[
    -(x6, x7), -(x7, (x5, x7)), (x5, (x5, x7)), -(x4, x7),
    -(x3, x7), -(x2, x7), -(x1, x7), -(x5, x6), -(x6, (x4, x6)),
    (x4, (x4, x6)), -(x3, x6), -(x2, x6), -(x1, x6), -(x5, (x4, x5)),
    (x4, (x4, x5)), -(x3, x5), -(x2, x5), -(x1, x5), -(x4, (x3, x4)),
    (x3, (x3, x4)), -(x2, x4), -(x1, x4), -(x3, (x2, x3)), (x2, (x2, x3)),
    -(x1, x3), -(x2, (x1, x2)), (x1, (x1, x2))
]
> time K, G, B, f := LieAlgebra(R);
```

```
Time: 0.280
> K;
Lie Algebra of dimension 63 with base ring Rational Field
> #B;
63
> B[63];
(x7, (x5, (x4, (x3, (x2, (x1, (x6, (x4, (x3, (x2, (x5, (x4,
    (x3, (x6, (x4, (x5, x7))))))))))))))))
```

Example H100E7

In this example we construct a finitely presented Lie ring (i.e., Lie algebra over the integers).

```
> L<y,x>:= FreeLieAlgebra( Integers(), 2 );
> R:= [ x*(x*(x*y))-2*x*y, 2*y*(x*(x*y)), 3*y*(y*(x*y))-x*(x*y),
>  x*(y*(x*(y*(x*y)))) ];
> K,g,b,f:= LieAlgebra( R );
> K;
Lie Algebra of dimension 8 with base ring Integer Ring
Column moduli: [2, 2, 2, 8, 8, 8, 0, 0]
> f(K.4);
(y, (x, y))
> LowerCentralSeries( K );
[
    Lie Algebra of dimension 8 with base ring Integer Ring
    Column moduli: [2, 2, 2, 8, 8, 8, 0, 0],
    Lie Algebra of dimension 6 with base ring Integer Ring
    Column moduli: [2, 2, 2, 8, 8, 8],
    Lie Algebra of dimension 6 with base ring Integer Ring
    Column moduli: [2, 2, 2, 4, 8, 8],
    Lie Algebra of dimension 6 with base ring Integer Ring
    Column moduli: [2, 2, 2, 4, 4, 8],
    Lie Algebra of dimension 6 with base ring Integer Ring
    Column moduli: [2, 2, 2, 4, 4, 4],
    Lie Algebra of dimension 5 with base ring Integer Ring
    Column moduli: [2, 2, 2, 4, 4],
    Lie Algebra of dimension 4 with base ring Integer Ring
    Column moduli: [2, 2, 2, 4],
    Lie Algebra of dimension 3 with base ring Integer Ring
    Column moduli: [2, 2, 2],
    Lie Algebra of dimension 2 with base ring Integer Ring
    Column moduli: [2, 2],
    Lie Algebra of dimension 1 with base ring Integer Ring
    Column moduli: [2],
    Lie Algebra of dimension 0 with base ring Integer Ring
]
```

`quo< L | R >`

This function is similar to the function LieAlgebra in that it constructs a structure constant Lie algebra K isomorphic to the quotient L/I, where I is the ideal of L generated by the elements (relations) of the sequence R. In addition to K, an invertible map from L to K is returned.

Example H100E8

In this example we demonstrate the use of the quotient constructor for finitely presented Lie algebras.

```
> L<x,y> := FreeLieAlgebra(Rationals(), 2);
> R := [ x*(x*y)-2*x, y*(y*x)-2*y ];
> K, phi := quo<L | R>;
> K;
Lie Algebra of dimension 3 with base ring Rational Field
> SemisimpleType(K);
A1
> [ b @@ phi : b in Basis(K) ];
[
   y,
   x,
   (y, x)
]
> phi(x*y);
( 0  0 -1)
```

`NilpotentQuotient(R, d)`

Given a set or sequence R of elements of a free Lie algebra L, let I be the ideal of L generated by the elements of R. Let d be a positive integer or `Infinity()`. This function constructs the class d nilpotent quotient of the Lie algebra L/I, a finite dimensional algebra. The function returns the same values as LieAlgebra.

This function is similar to the function LieAlgebra except that the quotient is constructed in the free nilpotent Lie algebra of class d. All elements of degree strictly larger than `d` will be added to the ideal, so the quotient will be finite-dimensional and nilpotent of class at most `d`.

Example H100E9

In this example, we compute a nilpotent quotient.

```
> L<y,x> := FreeLieAlgebra(Rationals(), 2);
> R := [(x, (x, (x, y))) - (y, (y, (x, y)))];
> time K, G, B, f := NilpotentQuotient(R, 10);
Time: 0.040
> K;
```

```
Lie Algebra of dimension 109 with base ring Rational Field
> #B;
109
> B[100];
(y, (x, (x, (y, (x, (y, (x, (x, (x, y)))))))))
> G;
[
    [ 1, 2 ],
    [ 2, 1 ],
    [ 3, 2 ],
    [ 4, 2 ],
    [ 5, 4 ],
    [ 6, 5 ],
    [ 7, 10 ],
    [ 8, 15 ],
    [ 9, 26 ],
    [ 10, 42 ]
]
> f(B[3], B[13]);
-(y, (x, (x, (x, (x, (y, (x, y)))))))) + (x, (y, (x, (x, (x, (y, (x, y)))))))
```

100.3.5 Homomorphisms of the Free Lie Algebra

`hom< L -> M | Q >`

Given a free Lie algebra L of dimension n over R and either a Lie algebra M over R or a module M over R, construct the homomorphism from L to M specified by Q. The sequence Q must have length `Rank(L)` and be of the form $[m_1, \ldots, m_n]$ ($m_i \in M$) indicating that the i-th generator of L maps to m_i.

Note that this is in general only a module homomorphism, and it is not checked whether it is an algebra homomorphism.

Example H100E10

We construct the Lie algebra of type A_1 as quotient of a free Lie algebra, using homomorphisms between a free Lie algebra and a structure constant Lie algebra. First, we construct the free Lie algebra and a structure constant Lie algebra of type A_1. The elements of a Chevalley basis are obtained by a call to `ChevalleyBasis`.

```
> L<e,f> := FreeLieAlgebra(Rationals(), 2);
> M := LieAlgebra("A1", Rationals() : Isogeny := "SC");
> pos, neg, cart := ChevalleyBasis(M);
> pos, neg, cart;
[ (0 0 1) ]
[ (1 0 0) ]
```

```
[ (0 1 0) ]
```

Next, we construct a homomorphism from L to M that sends e to the positive root element, and f to the negative root element. We construct a map from M to L that sends the positive root to e, the negative root to f, and the Cartan element to $-(e, f)$.

```
> phi := hom<L -> M | [ pos[1], neg[1] ]>;
> phi(e), phi(f), phi(e*f);
(0 0 1) (1 0 0) ( 0 -1  0)
> imgs := [ L | f, (f,e), e];
> psi := map<M -> L | x :-> &+[ x[i]*imgs[i] : i in [1..3] ]>;
> psi(cart[1]);
-(f, e)
> psi(phi((e,(e,f))));
-2*e
> assert forall{b : b in Basis(M) | phi(psi(b)) eq b };
```

Finally, we create a sequence of relations showing that the maps `phi` and `psi` are each others inverses for a small set of elements of L. We then compute the quotient of the free Lie algebra with respect to these relations.

```
> R := { x - psi(phi(x)) : x in {e, f, (e,f), (e,(e,f)), (f,(f,e))} };
> L2 := quo<L | R>;
> L2;
Lie Algebra of dimension 3 with base ring Rational Field
> SemisimpleType(L2);
A1
```

100.4 Lie Algebras Generated by Extremal Elements

A non-zero element x of a Lie algebra L over the field K is extremal if $[x, [x, y]] \in Kx$ for all $y \in L$. If x is extremal, the existence of a linear map $f_x : L \to K$ such that $[x, [x, y]] = f_x(y)x$ for all $y \in L$ immediately follows from linearity of $[\cdot, \cdot]$.

In this section we describe functions for computing with Lie algebras generated by such extremal elements. For a simple connected undirected finite graph Γ we consider an algebraic variety X over K whose K-points parametrize Lie algebras generated by extremal elements. Here the generators of the Lie algebras correspond to the vertices of the graph, and we prescribe commutation relations corresponding to the nonedges of Γ.

Details of the setup may be found in [Roo11]; we describe the essential ingredients here.

Assume that Γ is a connected undirected finite graph with n vertices, without loops or multiple bonds, and that K is a field of characteristic distinct from 2. We let Π be the vertex set of Γ and denote adjacency of two vertices $x, y \in \Pi$ by $i \sim j$.

We denote by $F(K, \Gamma)$ the quotient of the free Lie algebra over K generated by Π modulo the relations $[x, y] = 0$ for all $x, y \in \Pi$ with $x \not\sim y$. We write F^* for the space of all K-linear functions on F. For every $f \in (F^*)^\Pi$ we denote by $L(K, \Gamma, f)$ (often abbreviated to

$L(f)$) the quotient of $F(K,\Gamma)$ by the ideal $I(f)$ generated by the infinitely many elements $[x,[x,y]] - f_x(y)x$ for $x \in \Pi$, $y \in F$.

By construction $L(f)$ is a Lie algebra generated by $|\Pi| = n$ extremal elements, the extremal generators corresponding to the vertices of Γ and commuting whenever they are not adjacent. The element $f_x \in F^*$ is a parameter expressing the extremality of $x \in \Pi$.

In the Lie algebra $L(0)$ the elements of Π map to sandwich elements. This algebra is finite-dimensional, by [ZK90] this Lie algebra is finite-dimensional; for general $f \in (F^*)^\Pi$ we have $\dim(L(f)) \leq \dim(L(0))$ by [CSUW01, Lemma 4.3]. It is therefore natural to focus on the Lie algebras $L(f)$ of maximal possible dimension, i.e., those of dimension $\dim(L(0))$. We define the set $X := \{f \in (F^*)^\Pi \mid \dim(L(f)) = \dim(L(0))\}$, the parameter space for all maximal-dimensional Lie algebras of the form $L(f)$.

The functions currently implemented in MAGMA allow computation of X and $L(f)$, for any f, for the cases where X is an affine space (which is unproven, but true in all currently known cases).

Lie algebras generated by extremal elements are of type `AlgLieExtr`. The verbose flag `"AlgLieExtr"` may be set between 1 and 5 to show details and progress of the various computations.

100.4.1 Constructing Lie Algebras Generated by Extremal Elements

`ExtremalLieAlgebra(K, n)`

`CommGens`	SEQENUM	*Default :* []
`HeisenbergPairs`	SEQENUM	*Default :* []

Construct the Lie algebra over the field K generated by n extremal elements. The characteristic of K must be distinct from 2.

The optional argument `CommGens` contains pairs of integers (i,j), with $1 \leq i,j \leq n$, describing that generators x_i and x_j commute, i.e., $[x_i,x_j] = 0$.

The optional argument `HeisenbergPairs` contains pairs of integers (i,j), with $1 \leq i \leq n$ and $1 \leq j \leq \dim(L(0))$, describing that $f_{x_i}(b_j)$ should be taken equal to 0. (Note that if it is required to have $j > n$ it would be necessary to have prior knowledge about the basis of $L(0)$).

`ExtremalLieAlgebra(K, G)`

`HeisenbergPairs`	SEQENUM	*Default :* []

Construct the Lie algebra over the field K whose extremal generators are described by the graph G, i.e., with $|V(G)|$ generators, and x_i and x_j commute whenever vertices x_i and x_j of G are not adjacent.

See `ExtremalLieAlgebra` above for a description of the optional argument `HeisenbergPairs`.

100.4.2 Properties of Lie Algebras Generated by Extremal Elements

`NumberOfGenerators(L)`

The number of generators of L.

`CoefficientRing(L)`

`BaseRing(L)`

The coefficient ring of L. Immediately after construction, this is equal to the field K provided as argument to `ExtremalLieAlgebra`. However, after the multiplication table has been computed (see below), the coefficient ring would in general be a multivariate polynomial ring over K describing the parameter space.

`CommutatorGraph(L)`

The graph describing the extremal generators of L and their commutator relations.

Example H100E11

We construct a Lie algebra generated by 4 extremal elements in two different manners.

```
> QQ := Rationals();
> L := ExtremalLieAlgebra(QQ, BipartiteGraph(2,2));
> Ngens(L), CoefficientRing(L);
4 Rational Field
> G := CommutatorGraph(L); G;
Graph
Vertex  Neighbours
1       3 4 ;
2       3 4 ;
3       1 2 ;
4       1 2 ;
> L := ExtremalLieAlgebra(QQ, 4 : CommGens := [<1,2>,<3,4>]);
> Ngens(L), CoefficientRing(L);
4 Rational Field
> G := CommutatorGraph(L); G;
Graph
Vertex  Neighbours
1       3 4 ;
2       3 4 ;
3       1 2 ;
4       1 2 ;
```

`Basis(L)`

Compute a monomial basis for $L(0)$ (this is also a monomial basis for $L(f)$ for any $f \in X$; see the introduction of Section 100.4).

The first return value is a sequence consisting of monomials of the free Lie algebra over K with n generators, where K is the coefficient ring of L and n is the number of generators. The second return value is a sequence consisting of functions c. Each of these functions may be applied to a sequence of generators and a composition function. These may be used to construct the basis elements in other environments.

The algorithm used in this function is due to W. de Graaf.

`ZBasis(L)`

For L a Lie algebra generated by extremal elements over the field of rational numbers, compute a basis of the corresponding Lie ring over the integers.

This function returns three sequences B, T, C, respectively, describing bases for $L(0)$ over **any** field K. B is a not necessarily monomial basis, with torsion described by T. It is such that if $T[i]$ is nonzero, m say, then $B[i]$ is zero unless the characteristic of K divides m.

The third sequence, C, is a sequence of monomials that linearly span $L(0)$ over any field K. Note, however, that if T contains nonzero elements, then C would in general contain superfluous elements and therefore not be a basis.

The algorithm used in this function is due to W. de Graaf. The only currently known case with nontrivial torsion is for $\Gamma(L) = K_5$.

`Dimension(L)`

The dimension of $L(0)$. This value is computed via a basis computation, so potentially quite time-consuming.

Example H100E12

We continue the previous example H100E11 and demonstrate the computation of a basis of $L(0)$.

```
> B, C := Basis(L);
> B;
[
    $.1,
    $.2,
    $.3,
    $.4,
    ($.4, $.2),
    ($.4, $.1),
    ($.3, $.2),
    ($.3, $.1),
    ($.4, ($.3, $.2)),
    ($.4, ($.3, $.1)),
    ($.2, ($.4, $.1)),
    ($.2, ($.3, $.1)),
```

```
    ($.4, ($.2, ($.3, $.1))),
    ($.3, ($.2, ($.4, $.1))),
    ($.2, ($.4, ($.3, $.1)))
]
> [ c(["x","y","z","u"], func<i,j|i cat j>) : c in C ];
[ x, y, z, u, uy, ux, zy, zx, uzy, uzx, yux, yzx, uyzx, zyux, yuzx ]
> A := FreeAlgebra(Rationals(), 4);
> [ c([A.1,A.2,A.3,A.4], func<x,y|x*y>) : c in C ];
[
    $.1,
    $.2,
    $.3,
    $.4,
    $.4*$.2,
    $.4*$.1,
    $.3*$.2,
    $.3*$.1,
    $.4*$.3*$.2,
    $.4*$.3*$.1,
    $.2*$.4*$.1,
    $.2*$.3*$.1,
    $.4*$.2*$.3*$.1,
    $.3*$.2*$.4*$.1,
    $.2*$.4*$.3*$.1
]
> #B, #C, Dimension(L);
15 15 15
```

`MultiplicationTable(~L)`

`HowMuch`	MonStgElt	*Default :* "*Auto*"
`MemLimit`	RngIntElt	*Default :* ∞
`FullJacobi`	BoolElt	*Default :* `false`

Force computation of a general multiplication table for L, i.e., one that may be used for constructing $L(f)$ for any $f \in X$ (see the introduction to this section 100.4). This computation is necessary for constructing instances as described in Section 100.4.3, but it will be done automatically if needed. Data about the variety X is computed concurrently and stored internally; see Section 100.4.4 for the relevant functions in accessing that information.

The optional parameters may be used to influence the computation, although the defaults should generally work well. `HowMuch` may be set to "Auto" (the default), "Top" or "Full" and prescribes whether only the first `Ngens(L)` rows of the multiplication table are computed ("Top"), or all entries ("Full"). If set to "Auto" some fraction of the multiplication table is computed depending on the dimension of L and the other parameters.

`MemLimit` may be set to a positive integer m, and if given MAGMA will attempt to limit its memory usage to m MB, by limiting the portion of the multiplication table that is being computed.

`FullJacobi` may be set to `true` in order to force checking the Jacobi identity for all basis elements, thus providing more certainty with regards to the information about the parameter space X. Note that even if this parameter is set to `true` a heuristic (Monte-Carlo) method is used, as considering all $\dim(L(0))^3$ triples quickly becomes infeasible as the dimension grows.

The verbose flag `"AlgLieExtr"` may be set to 3 or more to obtain some information about the default choices MAGMA makes with regards to these parameters.

`MultiplicationTable(L)`

`Rep`	MONSTGELT	*Default :* "*Auto*"
`Check`	BOOLELT	*Default :* `true`

A general multiplication table for L.

If `Rep` is set to "Dense" it will be returned as a sequence of sequences of vectors over `CoefficientRing(L)`. If `Rep` is set to "Sparse" it will be returned as a sequence of 4-tuples. If `Rep` is set to "Auto" a choice between these representations is made depending on $\dim(L)$. Both these representations may be used on the right hand side of the `LieAlgebra` constructor.

The optional parameter `Check` controls whether the Jacobi identity is verified for all triples (if `true` it will actually be checked for all $\dim(L(0))^3$ triples, as opposed to the behaviour of the procedural version, `MultiplicationTable(~L)`, described above).

Note that this function is impractical in terms of CPU time and memory usage once $\dim(L)$ exceeds approximately 50. In such cases, the Lie algebra is more easily studied using the functions described in Section 100.4.3.

Example H100E13

We construct the generic Lie algebra generated by 3 extremal elements and construct a structure constant Lie algebra using the multiplication table.

```
> L := ExtremalLieAlgebra(Rationals(), 3);
> L:Maximal;
Lie algebra generated by 3 extremal elements, defined over Rational
Field
> MultiplicationTable(~L);
> L:Maximal;
Lie algebra generated by 3 extremal elements, originally defined over
Rational Field
  Now living over Polynomial ring of rank 4 over Rational Field
  Dimension: 8
  Picked 4 f-values:
    f(2, [1]) = f21
    f(3, [1]) = f31
```

```
    f(3, [2]) = f32
    f(1, [32]) = f132
> Dimension(L);
8
> MT := MultiplicationTable(L);
> MT[4][8];
(0   -1/2*f31*f32   0   -1/2*f132   0   0   0   1/2*f32)
> M := LieAlgebra<CoefficientRing(L), 8 | MT>;
> M;
Lie Algebra of dimension 8 with base ring Polynomial ring of rank 4
over Rational Field
> M.4*M.8;
(0   -1/2*f31*f32   0   -1/2*f132   0   0   0   1/2*f32)
> M.1*(M.1*M.2);
(f21   0   0   0   0   0   0   0)
```

100.4.3 Instances of Lie Algebras Generated by Extremal Elements

`Instance(L)`

`Rep`	MonStgElt	*Default :* "*Auto*"
`Check`	BoolElt	*Default :* `true`

The Lie algebra $L(f)$ for general f. The Lie algebra returned will in general be defined over a multivariate polynomial ring.

This function is identical to `MultiplicationTable`, except that it returns a Lie algebra rather than a multiplication table. Please refer to that function for information on the optional arguments `Rep` and `Check`. Note that this function also is impractical in terms of CPU time and memory usage once $\dim(L)$ exceeds approximately 50. In such cases, the Lie algebra is more easily studied by constructing particular instances of $L(f)$ individually, as described below.

`Instance(L, Q)`

`Rep`	MonStgElt	*Default :* "*Auto*"
`Check`	BoolElt	*Default :* `true`

Construct $L(f)$ where the i-th free parameter of X is set to Q[i]. Consult `L:Maximal` or `FreefValues` to obtain information about the free parameters. The coefficient ring of the Lie algebra M returned will be equal to `Universe(Q)`. As a second return value, an invertible map from M to the free Lie algebra of rank `Ngens(L)` is returned.

The optional argument `Rep` may be "Auto", "Dense" or "Sparse" (refer to the documentation at `MultiplicationTable` for more information). `Check` may be set to `true` or `false` and determines whether the Jacobi identity is checked on the Lie algebra returned.

Example H100E14

We construct the generic Lie algebra generated by 3 extremal elements and study one of its instances.

```
> L := ExtremalLieAlgebra(Rationals(), 3);
> MultiplicationTable(~L);
> L:Maximal;
Lie algebra generated by 3 extremal elements, originally defined over
Rational Field
  Now living over Polynomial ring of rank 4 over Rational Field
  Dimension: 8
  Picked 4 f-values:
    f(2, [1]) = f21
    f(3, [1]) = f31
    f(3, [2]) = f32
    f(1, [32]) = f132
 > M := Instance(L); M;
Lie Algebra of dimension 8 with base ring Polynomial ring of rank 4
over Rational Field
> M.1*(M.1*M.2);
(f21   0   0   0   0   0   0   0)
```

So in the most general case, $[x_1, [x_1, x_2]] = f_{x_2}(x_1)x_1$. Next, we consider an instance where we set $f_{x_2}(x_1) = 1/7$, $f_{x_3}(x_1) = 1/5$, $f_{x_3}(x_2) = 1/3$ and $f_{x_1}([x_3, x_2]) = 1$.

```
> N, phi := Instance(L, [Rationals()|1/7,1/5,1/3,1]);
> N;
Lie Algebra of dimension 8 with base ring Rational Field
> SemisimpleType(N);
A2
> N.1*(N.1*N.2);
(1/7   0   0   0   0   0   0   0)
> y := phi(N.2); z := phi(N.3);
> Parent(y):Minimal;
Free Lie algebra of rank 3 over Rational Field
> (y,(y,z));
-($.2, ($.3, $.2))
> (y,(y,z)) @@ phi;
(  0 1/3   0   0   0   0   0   0)
> (y,(y,z)) @@ phi @ phi;
1/3*$.2
```

100.4.4 Studying the Parameter Space

`FreefValues(L)`

The values $f_x(b)$ generating the parameter space X (see the introduction to this section 100.4 for details). This function returns two sequences: the first of the $f_x(b)$ as elements of `CoefficientRing(L)` and the second of the pairs (x, b) as two-tuples of integers.

`fValue(L, x, b)`

The value $f_x(b)$ as an element of `CoefficientRing(L)`.

`fValueProof(L, x, b)`

Print a proof of correctness for the value $f_x(b)$.

Example H100E15

We consider the generic Lie algebra generated by 4 extremal elements.

```
> L := ExtremalLieAlgebra(Rationals(), 4);
> vals, pairs := FreefValues(L);
> vals;
[
    f21,
    f31,
    f41,
    f32,
    f42,
    f43,
    f143,
    f243,
    f142,
    f132,
    f1432,
    f2431
]
> #vals;
12
> pairs;
[ <2, 1>, <3, 1>, <4, 1>, <3, 2>, <4, 2>, <4, 3>, <1, 5>, <2, 5>, <1,
6>, <1, 8>, <1, 11>, <2, 12> ]
```

This shows that $\dim(X) = 12$. We compute some values $f_x(b)$.

```
> fValue(L, 1, 5);
f143
> fValue(L, 4, 17);
-f41*f42
> fValueProof(L, 4, 17);
f(4, [241]) -> -f(4,[2])*f(4,[1]) {f(x,[y,[x,N]]) = -f(x,y)f(x,N) by
```

```
  assoc. of f and anti-comm. of L}
    f(4, [2]) = f42 {Free}
    f(4, [1]) = f41 {Free}
= -f41*f42
```

`DimensionsEstimate(L, g)`

`NumSamples`	RngIntElt	*Default :* ∞
`Check`	BoolElt	*Default :* `true`
`Rep`	MonStgElt	*Default :* "*Auto*"
Verbose	`AlgLieExtr`	*Maximum :* 10

Estimate the dimensions of the subvarieties of the parameter space X of L giving rise to irreducible Lie algebra modules of different dimensions.

This procedure repeatedly (exactly `NumSamples` times) invokes `Instance(L, g())` to produce a Lie algebra M. The composition series of M are computed, and the dimension e of its simple factor is stored. Then, for each of these e encountered, the dimension of the subvariety (inside the algebraic variety X) that contains Lie algebras whose top factor has dimension e is estimated using the dimension d of the full f-variety. (Here d is taken to be the number of free f-values computed; see `FreefValues`).

If the verbose flag `"AlgLieExtr"` is set 3 or more, then after each step the estimate is printed as a sequence of triples (e, n, s): n is the number of times dimension e was encountered, and s the estimate for the dimension of the subvariety.

Upon finishing (which will only happen if `NumSamples` is set to some finite number) that sequence of triples is returned. The second return value is a multiset containing the dimensions encountered in the search.

Note that this procedure assumes that X itself is an affine variety (which has been proved if `CommutatorGraph(L)` is a connected simply laced Dynkin diagram of finite or affine type) and that `g` produces uniformly random elements of X. If either of these two is not the case, the estimates produced are likely wrong. Moreover, `g` must produce sequences of elements of a finite field.

The optional argument `Rep` may be "Auto", "Dense" or "Sparse" (refer to the documentation at `MultiplicationTable` for more information). `Check` may be set to `true` or `false` and determines whether the Jacobi identity is checked on the Lie algebras constructed.

`InstancesForDimensions(L, g, D)`

`Check` BoolElt *Default :* `true`

For each $d \in D$ attempt to find an instance of L whose simple factor has dimension d, by repeatedly invoking `Instance(L, g())`. The result is returned in the form of an associative array A such that, for all $d \in D$, $A[d]$ is a triple (v, M, ϕ) where v is such that `Instance(L, v)` is M, and ϕ is an invertible map from M to the free Lie algebra.

See DimensionsEstimate for the required properties of `g`. The optional parameter `Check` may be set to `true` or `false` and determines whether the Jacobi identity is checked on the Lie algebras constructed.

Example H100E16

We consider the generic Lie algebra generated by 3 extremal elements.

```
> L := ExtremalLieAlgebra(Rationals(), 3);
> FreefValues(L);
[
    f21,
    f31,
    f32,
    f132
]
[ <2, 1>, <3, 1>, <3, 2>, <1, 4> ]
```

So $\dim(X) = 4$. We create a function `g` used to construct random instances of L over GF(5).

```
> g := func< | [ Random(GF(5)) : i in [1..4] ]>;
> M := Instance(L, g()); M;
Lie Algebra of dimension 8 with base ring GF(5)
> SemisimpleType(M);
A2
```

So in this case `g()` yielded a Lie algebra of type A_2. We use `g` to obtain information about X, using 500 random instances.

```
> DimensionsEstimate(L, g : NumSamples := 500);
[ <3, 121, "3.12">, <8, 379, "3.83"> ]
{* 3^^121, 8^^379 *}
```

This shows that 379 instances were found where M was simple of dimension 8, and 121 cases where M had a simple factor of dimension 3. Using this result one might conjecture that there is a codimension 1 subspace of X with Lie algebras whose simple factor has dimension 3.

```
> A := InstancesForDimensions(L, g, {3,8} : Check := false);
> A[3];
<[ 2, 1, 4, 4 ], Lie Algebra of dimension 8 with base ring GF(5),
Mapping from: Lie Algebra of dimension 8 with base ring GF(5) to Free
Lie algebra of rank 3 over GF(5) given by a rule>
> M := A[3][2]; MM := M/SolvableRadical(M); MM;
```

```
Lie Algebra of dimension 3 with base ring GF(5)
> SemisimpleType(MM);
A1
> M := A[8][2]; IsSimple(M);
true
> SemisimpleType(M);
A2
```

100.5 Families of Lie Algebras

The radical of a Lie algebra is the maximal soluble ideal. A Lie algebra is called *reductive* if its radical is equal to its centre, and *semisimple* if its radical is trivial. A Lie algebra is *almost reductive (resp. simple, semisimple)* if the corresponding group of Lie type is reductive (resp. simple, semisimple). Note that these concepts are equivalent if the field has characteristic zero.

The commands in this section construct almost reductive Lie algebras over an arbitrary field. Such Lie algebras have a corresponding root datum. The matrix versions of these commands give the standard matrix representation, which is the smallest degree representation (with a few exceptions for small characteristic fields).

100.5.1 Almost Reductive Lie Algebras

The intrinsics `LieAlgebra` and `MatrixLieAlgebra` described below take as first argument an object which describes the type of the reductive Lie algebra to be constructed. Specifically, it may be one of the five following types:

(a) A string describing the Cartan type;

(b) A root datum (see Chapter 97);

(c) A crystallographic root system (see Chapter 96);

(d) A Dynkin diagraph (see Section 95.5);

(e) A crystallographic Cartan matrix C (see Section 95.4).

In the cases (a), (d), and (e) these intrinsics take an optional argument `Isogeny`. See Section 103.2 for the possible values of this flag.

`LieAlgebra(T, k)`

`Isogeny` . *Default :* "*Ad*"

Construct the reductive Lie algebra of type T over the ring k.

`MatrixLieAlgebra(T, k)`

`Isogeny` . *Default :* "*Ad*"

Construct the reductive matrix Lie algebra of type T over the ring k.

Example H100E17

We construct some (semi)simple Lie algebras.

```
> LieAlgebra("D7", RationalField());
Lie Algebra of dimension 91 with base ring Rational Field
> LieAlgebra("G2", GF(5));
Lie Algebra of dimension 14 with base ring GF(5)
> L := LieAlgebra( "G2 B3", Rationals() );
> L;
Lie Algebra of dimension 35 with base ring Rational Field
> DirectSumDecomposition(L);
[
    Lie Algebra of dimension 14 with base ring Rational Field,
    Lie Algebra of dimension 21 with base ring Rational Field
]
> LieAlgebra( "E8", GF(2) );
Lie Algebra of dimension 248 with base ring GF(2)
```

Example H100E18

This example demonstrates the use of the `Isogeny` option. Over a field of characteristic zero, this option only effects the basis used. In characteristic p, it sometimes effects the isomorphism type of the algebra. For type A_n with $p|(n+1)$, the default Isogeny is "Ad" (adjoint), which gives an algebra with nontrivial derived subalgebra but no centre:

```
> L := LieAlgebra("A4", GF(5));
> Dimension(L);
24
> Dimension(L*L);
23
> Dimension(Centre(L));
0
```

If you take Isogeny to be "SC" (simply connected), you get a perfect algebra with a nontrivial centre.

```
> L := LieAlgebra("A4", GF(5) : Isogeny:="SC");
> Dimension(L);
24
> Dimension(L*L);
24
> Dimension(Centre(L));
1
```

If $p^2|(n+1)$ there is an intermediate isogeny type which has both a centre and a nontrivial derived algebra:

```
> L := LieAlgebra("A24", GF(5) : Isogeny:=5);
> Dimension(L);
624
```

```
> Dimension(L*L);
623
> Dimension(Centre(L));
1
```

Similar results can be obtained by constructing the Lie algebra from a root datum. This kind of phenomenon happens whenever the characteristic divides the order of the fundamental group of your root datum. See [Hog82] for more details.

```
> R := RootDatum("E6");
> #FundamentalGroup(R);
3
> L := LieAlgebra(R,GF(3));
> L;
Lie Algebra of dimension 78 with base ring GF(3)
> L*L;
Lie Algebra of dimension 77 with base ring GF(3)
```

`LieAlgebra(N, k, p)`

`LieAlgebra(R, k, p)`

The twisted (almost) semisimple Lie algebra over the finite field k with Cartan type N given as a string or root datum R, with twist given by the permutation p. The twist should either be a permutation of the indices of the simple roots, or of the indices of all roots.

`TwistedLieAlgebra(R, k)`

Given a twisted root datum R and a finite field k, construct the twisted Lie algebra $L = R(k)$.

This variant has 5 return values. First, the twisted Lie algebra L. Second, a homomorphism ϕ from L into the split Lie algebra L' (over a suitable field extension of k); Third, L'; Fourth, a split toral subalgebra H of L, and, fifth, a split toral subalgebra H' of L', such that $\phi(H) \subseteq H'$.

See also TwistedBasis.

Example H100E19

We construct two twisted Lie algebras.

```
> DynkinDiagram("E6");
E6    1 - 3 - 4 - 5 - 6
              |
              2
> LieAlgebra( "E6", GF(5), Sym(6)!(1,6)(3,5) );
Lie Algebra of dimension 78 with base ring GF(5)
> Rt := TwistedRootDatum(RootDatum("D4") : Twist := 3);
> k := GF(7);
```

```
> L, phi, Lp, H, Hp := TwistedLieAlgebra(Rt, k);
> L;
Lie Algebra of dimension 28 with base ring GF(7)
> Lp;
Lie Algebra of dimension 28 with base ring GF(7^3)
> phi(L.3);
(0 0 ksi^49 ksi^7 ksi 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> IsSplitToralSubalgebra(L, H);
true
> IsSplitToralSubalgebra(Lp, Hp);
true
> forall{b : b in Basis(H) | phi(b) in Hp};
true
```

100.5.2 Cartan-Type Lie Algebras

Simple Lie algebras over fields of characteristic 0 have been classified and are precisely the twisted forms of Lie algebras of types $A_l, B_l, C_l, D_l, E_6, E_7, E_8, F_4$ and G_2 (see previous Subsection). Over fields of finite characteristic p, the analogues of these algebras are called *classical-type* (including the exceptional algebras). Over such fields there are other simple Lie algebras, the first of them found by Witt sometimes before 1937. For $p \geq 7$, the only non-classical simple Lie algebras are the Lie algebras of *Cartan-type*, which we discuss in this section. For $p = 5$, one further class of simple Lie algebras occurs: *Melikian* algebras, which are discussed in the next section. In characteristic 2 and 3, the classification of simple Lie algebras is not yet complete.

Cartan-type Lie algebras are non-classical Lie algebras which arise from infinite dimensional algebras of differential operators over $\mathbf{C}$:

- (generalised) Witt algebras,
- special and conformal special Lie algebras,
- Hamiltonian and conformal Hamiltonian Lie algebras,
- and contact Lie algebras.

The notation and the description of these Lie algebras closely follow Strade and Farnsteiner [Str04] and [SF88]. Where the notation of the two books differs, we follow [Str04].

Let F be a finite field of characteristic $p > 0$ and m a positive integer. We refer for the definition of $O(m)$ and $x^{(a)}$ to [Str04, 2.1]. The basis of $O(m)$ is $\{x^{(a)} | 0 \leq a, a \in \mathrm{N}^m\}$.

Let n be a sequence of positive integers of length m and set $N := \sum_{i=1}^{m} n_i$. Define

$$O(m, n) := \langle x^{(a)} | 0 \leq a_i < p^{n_i} \rangle$$

For $i = 1, \ldots, m$ denote by ∂_i the derivation of $O(m)$ defined by

$$\partial_i(x_j^{(r)}) = \delta_{i,j} x_j^{(r-1)}.$$

Now define

$$W(m,n) := \sum_{i=1}^{m} O(m)\partial_i.$$

The algebra $W(m,n)$ is the *Witt* algebra and has dimension mp^N over F. In particular, $W(1,[1])$ is the standard p-dimensional Witt algebra.

The Witt algebra $W(m,n)$ is simple unless $p=2$ and $m=1$ ([SF88, 4.2.4(1)]) and is restrictable if and only if $n=[1,\ldots,1]$ ([SF88, 4.2.4(2)]).

Further define

$$\Omega^0(m,n) := O(m,n),$$

$$\Omega^1(m,n) := \mathrm{Hom}_{O(m,n)}(W(m,n), O(m,n)),$$

$$\Omega^r(m,n) := \bigwedge^r \Omega^1(m,n),$$

$$\Omega(m,n) := \bigoplus \Omega^r(m,n).$$

Let $m \geq 2$ and $\omega_S = dx_1 \wedge \ldots \wedge dx_m$. Define the following subalgebras of $W(m,n)$:

$$S(m,n) := \{D \in W(m,n) | D(\omega_S) = 0\},$$

$$CS(m,n) := \{D \in W(m,n) | D(\omega_S) \in F\omega_S\}.$$

The algebra $S(m,n)$ is the *special* and $CS(m,n)$ is the *conformal special* Lie algebra. The dimension of $S(m,n)$ over F is $(m-1)p^N + 1$ and the dimension of $CS(m,n)$ is $\dim S(m,n) + 1$.

Suppose $m \geq 3$. Then the algebra $S(m,n)^{(1)}$ is simple ([SF88, 4.3.5(1)]) and is restrictable if and only if $n=[1,\ldots,1]$ ([SF88, 4.3.5(2)]).

Let $p>2$, $m=2r\geq 2$ and let $\omega_H = \sum_{i=1}^{r} dx_i \wedge dx_{i+r}$. Define the following subalgebras of $W(m,n)$:

$$H(m,n) := \{D \in W(m,n) | D(\omega_H) = 0\},$$

$$CH(m,n) := \{D \in W(m,n) | D(\omega_H) \in F\omega_H\}.$$

The algebra $H(m,n)$ is the *Hamiltonian* and $CH(m,n)$ is the *conformal Hamiltonian* Lie algebra. The dimension of $H(m,n)$ over F is $p^N - 1$ and the dimension of $CH(m,n)$ is $\dim H(m,n) + 1$.

The algebra $H(m,n)^{(2)}$ is simple ([SF88, 4.4.5(1)]) and is restrictable if and only if $n=[1,\ldots,1]$ ([SF88, 4.4.5(2)]). And, if $m>2$, then $H(m,n)^{(2)} = H(m,n)^{(1)}$.

Let $p>2$, $m=2r+1\geq 3$ and let $\omega_K = dx_m + \sum_{i=1}^{r}(x_i dx_{i+r} - x_{i+r}dx_i)$. Define the following subalgebra of $W(m,n)$:

$$K(m,n) := \{D \in W(m,n) | D(\omega_K) \in O(m,n)\omega_K\},$$

The algebra $K(m,n)$ is the *contact* Lie algebra. The dimension of $K(m,n)$ over F is p^N.

The algebra $K(m,n)^{(1)}$ is simple ([SF88, 4.5.5(1)]) and is restrictable if and only if $n=[1,\ldots,1]$ ([SF88, 4.5.6]). If $m+3 \not\equiv 0 \bmod p$, then $K(m,n)^{(1)} = K(m,n)$.

```
WittLieAlgebra(F, m, n)
```

Check BoolElt *Default :* false

The Witt algebra $W(m, n)$ is constructed over the finite field F, where m must be a positive integer and n a sequence of positive integers of length m. If the optional argument Check is true, the algebra is checked to be Lie upon construction.

An invertible map from the polynomial ring P over F of degree $2m$ to $W(m, n)$ is returned as second value, to assist in identifying the elements of $W(m, n)$. For $1 \leq i \leq m$ the i-th generator of P maps to x_i in $W(m, n)$, and for $m + 1 \leq i \leq 2m$ the i-th generator of P maps to δ_{i-m} in $W(m, n)$.

Example H100E20

We compute the Witt algebra $W(2, [2, 1])$ over $GF(9)$ and verify the multiplication of $x_1^{(1)}\delta_1$ and $x_1^{(2)}x_2^{(1)}\delta_2$.

```
> W, phi := WittLieAlgebra(GF(9), 2, [2,1]);
> W;
Lie Algebra of dimension 54 with base ring GF(3^2)
> IsSimple(W);
true
> P<x1, x2, d1, d2> := Domain(phi);
> phi(x1*d1);
(0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> (phi(x1*d1)*phi(x1^2*x2*d2)) @@ phi;
2*x1^2*x2*d2
```

and the standard Witt algebra $W(1, [1])$ over $GF(2)$:

```
> W := WittLieAlgebra(GF(2), 1, [1]);
> W;
Lie Algebra of dimension 2 with base ring GF(2)
> IsSimple(W);
false
> IsRestrictedLieAlgebra(W);
true [ (0 0), (0 1) ]
```

```
SpecialLieAlgebra(F, m, n)
ConformalSpecialLieAlgebra(F, m, n)
```

Check BoolElt *Default :* false

The (conformal) special Lie algebra $(C)S(m, n)$ is constructed over the finite field F, where $m \geq 2$ must be an integer and n a sequence of positive integers of length m. If the optional argument Check is true, Magma checks that the algebra constructed is a Lie algebra.

The intrinsic `SpecialLieAlgebra` returns the Witt algebra $W(m, n)$ in which it is embedded as the second return value. In addition, similarly to `WittLieAlgebra`, a map from the polynomial ring P of degree $2m$ over F to $S(m, n)$ is returned as the third return value, and a map from P to $W(m, n)$ as the fourth return value.

Similarly, `ConformalSpecialLieAlgebra` returns the special Lie algebra $S(m, n)$ which it contains and the Witt Lie algebra $W(m, n)$ in which it is embedded in as second and third return values. Maps from P to $CS(m, n)$, $S(m, n)$, and $W(m, n)$ are returned as fourth, fifth, and sixth return values, respectively.

Example H100E21

We compute both $S(3, [1, 2, 1])$ and $CS(3, [1, 2, 1])$ over $GF(9)$:

```
> CS,S,W := ConformalSpecialLieAlgebra( GF(9), 3, [1,2,1] );
> CS;S;W;
Lie Algebra of dimension 164 with base ring GF(3^2)
Lie Algebra of dimension 163 with base ring GF(3^2)
Lie Algebra of dimension 243 with base ring GF(3^2)
> IsSimple(S);
false
> IsSimple(S*S);
true
> IsRestrictedLieAlgebra(S*S);
false []
```

`HamiltonianLieAlgebra(F, m, n)`

`ConformalHamiltonianLieAlgebra(F, m, n)`

`Check` BoolElt *Default :* `false`

The (conformal) Hamiltonian Lie algebra $(C)H(m, n)$ is constructed over the finite field F of characteristic at least 3, where $m \geq 2$ must be even and n a sequence of positive integers of length m. If the optional argument `Check` is `true`, the algebra is checked to be Lie upon construction.

The intrinsic `HamiltonianlLieAlgebra` returns the Witt Lie algebra $W(m, n)$ in which it is embedded as the second return value. Additionally, similarly to `WittLieAlgebra`, a map from the polynomial ring P of degree $2m$ over F to $H(m, n)$ is returned as the third return value, and a map from P to $W(m, n)$ as the fourth return value.

Similarly, `ConformalHamiltonianLieAlgebra` returns the Hamiltonian Lie algebra $H(m, n)$ it contains and the Witt Lie algebra $W(m, n)$ in which it is embedded as the second and third return values. Maps from P to $CH(m, n)$, $H(m, n)$, and $W(m, n)$ are returned as the fourth, fifth, and sixth return values, respectively.

Example H100E22

We compute both $H(2,[2,2])$ and $CH(2,[2,2])$ over $GF(9)$:

```
> CH,H,W := ConformalHamiltonianLieAlgebra( GF(9), 2, [2,2] );
> CH;H;W;
Lie Algebra of dimension 81 with base ring GF(3^2)
Lie Algebra of dimension 80 with base ring GF(3^2)
Lie Algebra of dimension 162 with base ring GF(3^2)
> IsSimple(H);
false
> IsSimple(H*H);
true
> IsSimple(H*H*H);
true
> IsRestrictedLieAlgebra(H*H*H);
false []
```

`ContactLieAlgebra(F, m, n)`

`Check` BoolElt *Default :* `false`

The contact Lie algebra $K(m,n)$ is constructed over the finite field F of characteristic at least 3, where $m \geq 3$ must be odd and n a sequence of positive integers of length m. If the optional argument `Check` is `true`, the algebra is checked to be Lie upon construction.

The intrinsic `ContactLieAlgebra` returns the Witt Lie algebra $W(m,n)$ in which it is embedded as the second return value. Additionally, similarly to `WittLieAlgebra`, a map from the polynomial ring P of degree $2m$ over F to $K(m,n)$ is returned as the third return value, and a map from P to $W(m,n)$ as the fourth return value.

Example H100E23

We compute the contact Lie algebra $K(3,[1,1,1])$ over $GF(5)$:

```
> K,W := ContactLieAlgebra( GF(5), 3, [1,1,1] );
> K;W;
Lie Algebra of dimension 125 with base ring GF(5)
Lie Algebra of dimension 375 with base ring GF(5)
> K*K eq K;
true
> IsSimple(K);
true
```

100.5.3 Melikian Lie Algebras

The Melikian Lie Algebras are a class of simple Lie algebras over finite fields of characteristic 5, parameterized by two positive integers n_1, n_2. We follow the explicit construction by Strade [Str04, Section 4.3].

Let F be a field of characteristic $p = 5$ and recall the definition of $O(m, n)$ and $W(m, n)$ from Section 100.5.2. Define $W = W(2, [n_1, n_2])$, $O = O(2, [n_1, n_2])$, and take W' to be a copy of W. We equip the vector space $W \oplus O \oplus W'$ with a bilinear product $[\cdot, \cdot]$ that is defined by the following equations, where $D, E \in W$ and $f, f_1, f_2, g, g_1, g_2 \in O$.

- On $W \times W$, the usual multiplication in W.
- On $W \times O$: $[D, f] = D(f) - 2\mathrm{div}(D)f$.
- On $W \times W'$: $[D, E'] = ([D, E])' + 2\mathrm{div}(D)E'$.
- On $O \times O$: $[f, g] = 2(g\delta_2(f) - f\delta_2(g))\delta_1' + 2(f\delta_1(g) - g\delta_1(f))\delta_2'$.
- On $O \times W'$: $[f, E'] = fE$.
- On $W' \times W'$: $[f_1\delta_1' + f_2\delta_2', g_1\delta_1' + g_2\delta_2'] = f_1g_2 - f_2g_1$.

Here div is the linear map defined by $\mathrm{div}(f\delta_i) = \delta_i f$. It follows that $M(n_1, n_2)$, of dimension $5^{n_1+n_2+1}$, is a simple Lie algebra [Str04, Lemma 4.3.1, Theorem 4.3.3].

`MelikianLieAlgebra(F, n1, n2)`

`Check` BoolElt *Default :* `false`

The Melikian Lie algebra $M = M(n_1, n_2)$ over F. An invertible map from the polynomial ring P of degree 6 over F to M is returned as second value, to assist in identifying the elements of M. Here the six generators of P represent x_1, x_2, δ_1, δ_2, δ_1', δ_2', respectively.

Example H100E24

We construct $M(2, 1)$ over $\mathbf{F}_5$ and inspect some of its properties.

```
> M, phi := MelikianLieAlgebra(GF(5), 2, 1);
> M;
Lie Algebra of dimension 625 with base ring GF(5)
> IsSimple(M);
true
```

Next, we construct subspaces (not subalgebras) W, O, W' of M.

```
> P<x1, x2, d1, d2, dp1, dp2> := Domain(phi);
> V := VectorSpace(GF(5), Dimension(M));
> W := sub<V | [ V | phi(x1^i*x2^j*d) : i in [0..24], j in [0..4],
>                                                    d in [d1,d2] ]>;
> O := sub<V | [ V | phi(x1^i*x2^j) : i in [0..24], j in [0..4] ]>;
> Wp := sub<V | [ V | phi(x1^i*x2^j*d) : i in [0..24], j in [0..4],
>                                                     d in [dp1,dp2] ]>;
> Dimension(W), Dimension(O), Dimension(Wp);
```

```
250 125 250
> Dimension(W meet O), Dimension(W meet Wp), Dimension(O meet Wp);
0 0 0
```

Finally, we verify that these subspaces multiply as required by the definition.

```
> m := func< A, B | sub<V | [ V | M!a*M!b : a in Basis(A), b in Basis(B) ]> >;
> WxWp := m(W, Wp); [ WxWp subset VV : VV in [W, O, Wp] ];
[ false, false, true ]
```

So indeed $[W, W'] \subseteq W'$.

```
> VV := [W, O, Wp]; VVnm := ["W", "O", "W'" ];
> mm := function(A, B)
>   AB := m(A, B);
>   for i in [1..#VV] do
>     if AB eq VV[i] then return VVnm[i]; end if;
>   end for;
>   return "??";
> end function;
> mm(W, Wp);
W'
> for i,j in [1..#VV] do
>   printf "[ %2o, %2o ] = %2o%o", VVnm[i], VVnm[j], mm(VV[i], VV[j]),
>     (j eq 3) select "\n" else ", ";
> end for;
[  W,  W ] =  W, [  W,  O ] =  O, [  W, W' ] = W'
[  O,  W ] =  O, [  O,  O ] = W', [  O, W' ] =  W
[ W',  W ] = W', [ W',  O ] =  W, [ W', W' ] =  O
```

100.6 Construction of Elements

`Zero(L)`

`L ! 0`

The zero element of the Lie algebra L.

`Random(L)`

Given a Lie algebra L defined over a finite ring, a random element is returned.

100.6.1 Construction of Elements of Structure Constant Algebras

`elt< L | r1,r2,...,rn >`

Given a Lie algebra L of dimension n over a ring R, and ring elements $r_1, r_2, \ldots, r_n \in R$ construct the element $r_1 * e_1 + r_2 * e_2 + \ldots + r_n * e_n$ of L.

`L ! Q`

Given a Lie algebra L of dimension n and a sequence $Q = [r_1, r_2, \ldots, r_n]$ of elements of the base ring R of L, the element $r_1 * e_1 + r_2 * e_2 + \ldots + r_n * e_n$ of L is constructed.

`BasisProduct(L, i, j)`

Returns the product of the i-th and j-th basis element of the Lie algebra L.

`BasisProducts(L)`

`Rep` MonStgElt *Default : "Dense"*

Returns the products of all basis elements of the Lie algebra L.

The optional parameter `Rep` may be used to specify the format of the result. If `Rep` is set to "Dense", the products are returned as a sequence Q of n sequences of n elements of L, where n is the dimension of L. The element $Q[i][j]$ is the product of the i-th and j-th basis elements.

If `Rep` is set to "Sparse", the products are returned as a sequence Q containing quadruples (i, j, k, a_{ijk}) signifying that the product of the i-th and j-th basis elements is $\sum_{k=1}^{n} a_{ijk} b_k$, where b_k is the k-th basis element and $n = \dim(L)$.

100.6.2 Construction of Matrix Elements

Matrix Lie elements can be constructed using the functions below. For more information on constructing matrices see Section 83.2.2.

`elt< R | L >`
`R ! L`

Create the element of the matrix Lie algebra R of degree n whose entries are the n^2 elements of the sequence L.

`DiagonalMatrix(L, Q)`

Diagonal matrix in the matrix Lie algebra L, given by the sequence Q of ring elements.

`ScalarMatrix(L, r)`

Scalar matrix in the matrix Lie algebra L, defined by the ring element r.

100.7 Construction of Subalgebras, Ideals and Quotients

If the coefficient ring R of a Lie algebra L is a Euclidean domain, then submodules and ideals can be constructed in MAGMA; if R is a field then quotients can be constructed in MAGMA. Note that left, right, and two-sided ideals are identical in a Lie algebra.

`sub< L | A >`

Creates the subalgebra S of the Lie algebra L that is generated by the elements defined by A, where A is a list of one or more items of the following types:

(a) An element of L;

(b) A set or sequence of elements of L;

(c) A subalgebra or ideal of L;

(d) A set or sequence of subalgebras or ideals of L.

As well as the subalgebra S itself, the constructor returns the inclusion homomorphism $f : S \to L$.

`ideal< L | A >`

Creates the ideal I of the Lie algebra L generated by the elements defined by A, where A is a list of one or more items of the following types:

(a) An element of L;

(b) A set or sequence of elements of L;

(c) A subalgebra or ideal of L;

(d) A set or sequence of subalgebras or ideals of L.

As well as the ideal I itself, the constructor returns the inclusion homomorphism $f : I \to L$.

`quo< L | A >`

Forms the quotient algebra L/I, where I is the two-sided ideal of L generated by the elements defined by A, where A is a list of one or more items of the following types:

(a) An element of L;

(b) A set or sequence of elements of L;

(c) A subalgebra or ideal of L;

(d) A set or sequence of subalgebras or ideals of L.

As well as the quotient L/I itself, the constructor returns the natural homomorphism $f : L \to L/I$.

`L / S`

The quotient of the Lie algebra L by the ideal closure of the subalgebra S.

Example H100E25

We construct the quotient of the matrix Lie algebra of 2×2 matrices, by the ideal spanned by the identity matrix.

```
> L := MatrixLieAlgebra( Rationals(), 2 );
> Dimension(L);
4
> I := ideal< L | L!Matrix([[1,0],[0,1]]) >;
> Dimension(I);
1
> K := L/I;
> Dimension(K);
3
> SemisimpleType( K );
A1
```

`QuotientWithPullback(L, I)`

Given a Lie algebra L and an ideal I of L, the quotient L/I is constructed. As second return value, the natural homomorphism $f : L \to L/I$ is returned.

As third return value, a function g is returned. This g takes an element $y \in I$ and returns an $x \in L$ and a vector space V such that $f(x + v) = y$ for all $v \in V$. As fourth return value, a function h is returned. This h takes an element $y \in I$ and returns the subalgebra of L generated by x and V, with x and V as above.

Example H100E26

We consider an ideal of the Lie algebra of type G_2 over the field with 3 elements.

```
> R := RootDatum("G2");
> L := LieAlgebra(R, GF(3));
> pos,neg,cart := StandardBasis(L);
> shrt := [ i : i in [1..NumPosRoots(R)] | IsShortRoot(R, i) ];
> shrt;
[ 1, 3, 4 ]
> I := ideal<L | pos[shrt]>;
> _, str1 := ReductiveType(I); str1;
The 7-dim simple constituent of a Lie algebra of type A2
```

So apparently I is isomorphic to the 7-dimensional simple constituent of a Lie algebra of type A_2. We will now use `QuotientWithPullback` to construct L/I.

```
> LI, proj, pb, pbsub := QuotientWithPullback(L, I);
> _, str2 := ReductiveType(LI); str2;
The 7-dim simple constituent of a Lie algebra of type A2
```

So apparently $I \simeq L/I$! Finally, we will demonstrate the use of the additional return values. First, we verify that an element of I maps to 0 in L/I:

```
> proj(pos[1]);
```

```
(0 0 0 0 0 0 0)
```

And then we consider the preimage in L of a randomly chosen element of L/I.

```
> y := LI![0,1,1,1,1,0,1];
> y;
(0 1 1 1 1 0 1)
> x, V := pb(y);
> x;
(0 1 0 0 1 0 0 1 0 1 0 0 0 1)
> #V;
2187
> assert #V eq #I;
> {* proj(x + v) eq y : v in V *};
{* true^^2187 *}
```

So indeed $x + v$ is a preimage of y for all $v \in V$.

```
> M := pbsub(y);
> M, M meet I;
Lie Algebra of dimension 8 with base ring GF(3)
Lie Algebra of dimension 7 with base ring GF(3)
> _,str3 := ReductiveType(M);
> str3;
Twisted Lie algebra of type 2A2 [Ad]
```

100.8 Operations on Lie Algebras

`L eq K`

Returns `true` if, and only if, the Lie algebras L and K are equal.

`L ne K`

Returns `true` if, and only if, the Lie algebras L and K are not equal.

`L subset K`

Returns `true` if, and only if, the Lie algebra L is contained in the Lie algebra K.

`L notsubset K`

Returns `true` if, and only if, the Lie algebra L is not contained in the Lie algebra K.

`L meet M`

The intersection of the Lie algebras L and M is returned. Note that L and M have a common superalgebra.

`L * M`

The Lie algebra product $[L, M]$ of the algebras L and M is returned. Note that L and M must have a common superalgebra.

`L ^ n`

The (left-normed) n-th power of the (structure constant) Lie algebra L, i.e., $((\ldots(L*L)*\ldots)*L)$ is constructed.

`Morphism(L, M)`

The map giving the morphism from the (structure constant) Lie algebra L to M is constructed. Either L is a subalgebra of M, in which case the embedding of L into M is returned, or M is a quotient algebra of L, in which case the natural epimorphism from L onto M is returned.

`IsIsomorphic(L, M)`

`HL`	AlgLie	*Default :* `false`
`HM`	AlgLie	*Default :* `false`

Returns `true` if the Lie algebras L and M are isomorphic. It is currently implemented for trivial cases (such as when the dimensions differ), reductive Lie algebras, solvable Lie algebras up to dimension 4, nilpotent Lie algebras up to dimension 6 (some special cases excluded). The solvable and nilpotent cases are handled using the databases for such algebras described in Section 100.18).

In the case of reductive Lie algebras, split maximal toral subalgebras for L and M may be provided in the optional arguments HL and HM, respectively. If these are not provided an attempt is made to compute them, a process which may fail, particularly in characteristic 0.

This intrinsic has two return values: the first a boolean describing whether L and M are isomorphic. If so, the second is an isomorphism from L to M, otherwise the second is a string describing the reason for non-isomorphism.

An error is thrown if isomorphism cannot be determined.

`IsKnownIsomorphic(L, M)`

`HL`	AlgLie	*Default :* `false`
`HM`	AlgLie	*Default :* `false`

Returns `true` if Magma can determine isomorphism between Lie algebras L and M. If so, the second return value is whether L and M are isomorphic, and the third is an isomorphism or a string (describing the reason for non-isomorphism). Refer to IsIsomorphic for more details on applicability and the meanings of the return values.

`IsIsomorphism(m)`

Returns true if the mapping m between two Lie algebras is an isomorphism of Lie algebras.

Example H100E27

We demonstrate that B_2 and C_2 are isomorphic over $\mathbf{Q}$.

```
> k := Rationals();
> L := LieAlgebra("B2", k); M := LieAlgebra("C2", k);
> b, c := IsIsomorphic(L, M);
> b;
true
> IsIsomorphism(c);
true
> c(L.1);
(0 0 1 0 0 0 0 0 0 0)
```

We demonstrate that B_3 and C_3 are non-isomorphic over $\mathbf{Q}$.

```
> L := LieAlgebra("B3", k); M := LieAlgebra("C3", k);
> b, c := IsIsomorphic(L, M);
> b;
false
> c;
21-dim component of L1 of type R1: Adjoint root datum of dimension 3 of type B3
didn't match R2:
Adjoint root datum of dimension 3 of type C3
```

We demonstrate that two distinct isogenies of B_2 are isomorphic over $\mathbf{Q}$.

```
> L := LieAlgebra("B2", k : Isogeny := "Ad");
> M := LieAlgebra("B2", k : Isogeny := "SC");
> b, c := IsIsomorphic(L, M);
> b;
true
```

For larger nilpotent algebras MAGMA cannot decide on the isomorphism question.

```
> L := LieAlgebra("B4", k);
> pL, _, _ := StandardBasis(L);
> subL := sub<L | pL>;
> subL;
Lie Algebra of dimension 16 with base ring Rational Field
> M := LieAlgebra("C4", k);
> pM, _, _ := StandardBasis(M);
> subM := sub<M | pM>;
> subL;
Lie Algebra of dimension 16 with base ring Rational Field
> IsNilpotent(subL), IsNilpotent(subM);
true true
> a,b,c := IsKnownIsomorphic(subL, subM);
> a;
false
```

Example H100E28

We demonstrate that in characteristic 3 the Lie algebras of type G_2 and A_2 have isomorphic nontrivial ideals.

```
> k := GF(3);
> CSL := CompositionSeries(LieAlgebra("G2", k));
> CSL;
[
    Lie Algebra of dimension 7 with base ring GF(3),
    Lie Algebra of dimension 14 with base ring GF(3)
]
> L := CSL[1];
> CSM := CompositionSeries(LieAlgebra("A2", k));
> CSM;
[
    Lie Algebra of dimension 7 with base ring GF(3),
    Lie Algebra of dimension 8 with base ring GF(3)
]
> M := CSM[1];
> a,b,c := IsKnownIsomorphic(L, M);
> a;
true
> b, c;
true Mapping from: AlgLie: L to AlgLie: M given by a rule
> IsIsomorphism(c);
true
```

100.8.1 Basic Invariants

`CoefficientRing(L)`

`BaseRing(L)`

The coefficient ring (or base ring) over which the Lie algebra L is defined.

`Dimension(L)`

The dimension of the Lie algebra L.

`#L`

The cardinality of the Lie algebra L, if the coefficient ring is finite.

`Moduli(L)`

This returns a sequence of integers, of length equal to the dimension of L. If the i-th element of this sequence is a_i then a_i is the minimal non-negative integer such that $a_i e_i = 0$. So if L is defined over a field, then the sequence consists of zeros.

Example H100E29

```
> T:= [ <1,2,2,2>, <2,1,2,2> ];
> t:= [0,4];
> L:= LieAlgebra< t | T : Rep:= "Dense" >;
> Moduli(L);
[ 0, 4 ]
```

100.8.2 Changing Base Rings

`ChangeRing(L, S)`

Given a Lie algebra L with base ring R, together with a ring S, this function constructs the Lie algebra M with base ring S obtained by coercing the coefficients of elements of L into S. The homomorphism from L to M is produced as second return value.

`ChangeRing(L, S, f)`

Given a Lie algebra L with base ring R, together with a ring S and a map $f : R \to S$, this function constructs the Lie algebra M with base ring S obtained by mapping the coefficients of elements of L into S via f. The homomorphism from L to M is produced as the second return value.

100.8.3 Bases

`BasisElement(A, i)`

`A . i`

The i-th basis element of the algebra L.

`Basis(A)`

The basis of the algebra L, as a sequence of elements of L.

`IsIndependent(Q)`

Given a set or sequence Q of elements of the R-algebra L, this functions returns `true` if these elements are linearly independent over R; otherwise `false`.

`ExtendBasis(S, L)`

`ExtendBasis(Q, L)`

Given an algebra L and either a subalgebra S of dimension m of L or a sequence Q of m linearly independent elements of L, this function returns a sequence containing a basis of L such that the first m elements are the basis of S resp. the elements in Q.

100.8.4 Operations for Semisimple and Reductive Lie Algebras

`SemisimpleType(L)`

`CartanName(L)`

Let L be a Lie algebra. If L has a nondegenerate Killing form, then (over some algebraic extension of the ground field) L is the direct sum of absolutely simple Lie algebras. These Lie algebras have been classified and the classes are named A_n, B_n, C_n, D_n, E_6, E_7, E_8, F_4 and G_2. This function returns a single string containing the types of the direct summands of L.

For a description of the algorithm used in the general case we refer to [dG00], §5.17.1. For Lie algebras over fields of characteristic 2 and 3 the algorithm used is described in [Roo10], Chapter 5.

Example H100E30

We compute the semisimple type of the Levi subalgebra of a subalgebra of the simple Lie algebra of type D_7.

```
> L := LieAlgebra("D7", RationalField());
> L;
Lie Algebra of dimension 91 with base ring Rational Field
> K := Centralizer(L, sub<L | [L.1,L.2,L.3,L.4]>);
> K;
Lie Algebra of dimension 41 with base ring Rational Field
> _,S := HasLeviSubalgebra(K);
> S;
Lie Algebra of dimension 6 with base ring Rational Field
> SemisimpleType(S);
A1 A1
```

`ReductiveType(L)`

`ReductiveType(L, H)`

`AssumeAlmostSimple` BoolElt *Default :* `false`

Let L be a Lie algebra of a reductive algebraic group, and H a split maximal toral subalgebra of L. This function identifies the isomorphism type of L.

This function has four return values. The first is the appropriate root datum and the second return value a textual description of L. The third return value is a sequence Q, containing a decomposition of L into direct summands. Finally, the fourth return value is a sequence P of records, such that $P[i]$ contains additional information (often a proof of correctness) of the identification of $Q[i]$.

If a split maximal toral subalgebra H is not given, an attempt is made to compute one by calling `SplitMaximalToralSubalgebra` if the characteristic of the base field k is at least 5, or `SplitToralSubalgebra` if $\mathrm{char}(k)$ is 2 or 3. Note that, if k is

infinite, such a subalgebra cannot in general be computed so the second parameter H must be supplied for this function to work.

If the optional parameter `AssumeAlmostSimple` is set to true, the (possibly time consuming) step of computing a direct sum decomposition of L is skipped.

Moreover, note that if L is the Lie algebra of a simple algebraic group but itself non-simple (such as for example A_n of intermediate type in characteristic $n+1$), the third return value Q may not be the direct sum decomposition of L but simply $[L]$.

Example H100E31

We consider a particular Lie algebra of type A_3 over $k = \mathrm{GF}(2)$.

```
> RA3 := RootDatum("A3" : Isogeny := 2);
> L := LieAlgebra(RA3, GF(2));
> D := DirectSumDecomposition(L);
> D;
[
    Lie Algebra of dimension 14 with base ring GF(2),
    Lie Algebra of dimension 1 with base ring GF(2)
]
> R, str, Q, _ := ReductiveType(L);
> R;
RA3: Root datum of dimension 3 of type A3
> str;
Lie algebra of type A3[ 2]
> Q;
[
    Lie Algebra of dimension 15 with base ring GF(2)
]
```

Note that this is an example where Q is not the direct sum decomposition of L. Instead, L in its whole is recognised as the Lie algebra of a simple algebraic group. In the remainder of the example, we investigate the 14-dimensional ideal of L.

```
> M := D[1]; M;
Lie Algebra of dimension 14 with base ring GF(2)
> R, _, _, P := ReductiveType(M);
> R;
R: Adjoint root datum of dimension 2 of type G2
```

So this computation claims that $L \simeq M \oplus k$, where M is of type G_2. Let us use the additional return values to verify that fact.

```
> pos  := P[1]‘ChevBasData‘BasisPos;
> neg  := P[1]‘ChevBasData‘BasisNeg;
> cart := P[1]‘ChevBasData‘BasisCart;
> IsChevalleyBasis(M, RootDatum("G2"), pos, neg, cart);
```

```
true [ <1, 2, 0>, <1, 3, 0>, <1, 4, 0>, <2, 5, 0> ]
```

This demonstrates the fact that the Lie algebra of type G_2 is a constituent of the Lie algebra of type A_3 over fields of characteristic 2.

`RootSystem(L)`

Given a semisimple Lie algebra L with a split Cartan subalgebra, this function computes the root system of L. This function returns four values:

(a) The roots of L with respect to the Cartan subalgebra which is output by `CartanSubalgebra(L)`. This is a sequence of vectors where the positive roots come first, followed by the negative roots.

(b) A sequence of elements of L which are the root vectors corresponding to the roots of L (so the first element corresponds to the first root and so on).

(c) A sequence of simple roots.

(d) The Cartan matrix of the root system with respect to the sequence of simple roots.

Example H100E32

We compute the root system of the simple Lie algebra of type G_2 over the rational field.

```
> L := LieAlgebra("G2", RationalField());
> R, Rv, fund, C:=RootSystem(L);
> R;
[
    (1 0),
    (0 1),
    (1 1),
    (2 1),
    (3 1),
    (3 2),
    (-1  0),
    ( 0 -1),
    (-1 -1),
    (-2 -1),
    (-3 -1),
    (-3 -2)
]
> Rv;
[ (0 0 0 0 0 0 0 0 1 0 0 0 0 0), (0 0 0 0 0 0 0 0 0 1 0 0 0 0),
(0 0 0 0 0 0 0 0 0 0 1 0 0 0), (0 0 0 0 0 0 0 0 0 0 0 1 0 0),
(0 0 0 0 0 0 0 0 0 0 0 0 1 0), (0 0 0 0 0 0 0 0 0 0 0 0 0 1),
(0 0 0 0 0 1 0 0 0 0 0 0 0 0), (0 0 0 0 1 0 0 0 0 0 0 0 0 0),
(0 0 0 1 0 0 0 0 0 0 0 0 0 0), (0 0 1 0 0 0 0 0 0 0 0 0 0 0),
(0 1 0 0 0 0 0 0 0 0 0 0 0 0), (1 0 0 0 0 0 0 0 0 0 0 0 0 0) ]
```

`RootDatum(L)`

Here L is a semisimple Lie algebra. This function returns the root datum D of L with respect to the Cartan subalgebra which is output by `CartanSubalgebra(L)`. We note that the order of the positive roots in D is not necessarily the same as the order in which they appear in the root system of L.

Example H100E33

We set up the root datum of a Lie algebra, and extract the Cartan matrix.

```
> L:= LieAlgebra("F4", Rationals());
> rd := RootDatum(L);
> rd;
Root datum of type F4
> CartanMatrix(rd);
[ 2  0 -1  0]
[ 0  2  0 -1]
[-1  0  2 -1]
[ 0 -1 -2  2]
```

`ChevalleyBasis(L)`

`ChevalleyBasis(L, H)`

`AssumeAlmostSimple` BoolElt *Default :* `false`

Given a semisimple Lie algebra L with a split maximal toral subalgebra H, this function returns three sequences, x, y and h of elements of L. They form a Chevalley basis of L. The first sequence gives basis elements corresponding to positive roots, the second to the negative roots and the third to basis elements in a Cartan subalgebra. If a split maximal toral subalgebra H is not given, an attempt is made to compute one.

For Lie algebras over fields of characteristic 2 and 3 the algorithm used is described in [CR09]. In particular, this involves computing a direct sum decomposition of L, which can be quite time consuming. If there is reason to believe that L is (almost) simple, the optional parameter `AssumeAlmostSimple` should be set to `true`.

Example H100E34

We construct a Chevalley basis for two Lie algebras.

```
> L := LieAlgebra("A2", RationalField());
> x, y, h:= ChevalleyBasis(L);
> x; y; h;
[ (0 0 0 0 0 1 0 0), (0 0 0 0 0 0 1 0), (0 0 0 0 0 0 0 1) ]
[ (0 0 1 0 0 0 0 0), (0 1 0 0 0 0 0 0), (1 0 0 0 0 0 0 0) ]
[ (0 0 0 1 0 0 0 0), (0 0 0 0 1 0 0 0) ]
> L := LieAlgebra("A3", Rationals());
```

```
> print RootDatum(L) : Maximal;
Root datum of type A3 with simple roots
[ 1  0  1]
[ 1 -2  1]
[ 0  1 -2]
and simple coroots
[ 1  1  1]
[ 0 -1  0]
[ 0  0 -1]
```

`ChevalleyBasis(L, H, R)`

Given a semisimple Lie algebra L with a split maximal toral subalgebra H, and an irreducible root datum R, this function computes a Chevalley basis of L with respect to H and R. This basis is returned in the form of three sequences, x, y and h of elements of L, where the first sequence gives basis elements corresponding to positive roots, the second to the negative roots and the third to basis elements in the toral subalgebra H.

`IsChevalleyBasis(L, R, x, y, h)`

Returns `true` if x, y and h form a Chevalley basis of the Lie algebra L with respect to the root datum R. If so, return a sequence describing the extraspecial signs as second return value.

Example H100E35

We compute a Chevalley basis for a Lie algebra of type E_6 inside one of type E_7.

```
> R := RootDatum("E7");
> L1 := LieAlgebra(R, GF(2));
> p1,n1,c1 := StandardBasis(L1);
> L1;
Lie Algebra of dimension 133 with base ring GF(2)
> DynkinDiagram(R);
E7    1 - 3 - 4 - 5 - 6 - 7
              |
              2
> S, proj := sub<R | [1..6]>;
> S;
S: Root datum of dimension 7 of type E6
> #proj;
72
> projpos := [i : i in proj | i le NumPosRoots(R)];
> #projpos;
36
> L2 := sub<L1 | p1[projpos], n1[projpos]>;
> L2;
```

```
Lie Algebra of dimension 78 with base ring GF(2)
> H2 := L2 meet SplitMaximalToralSubalgebra(L1);
> H2;
Lie Algebra of dimension 6 with base ring GF(2)
> p2,n2,c2 := ChevalleyBasis(L2, H2, RootDatum("E6"));
> ok := IsChevalleyBasis(L2, RootDatum("E6"), p2, n2, c2);
> ok;
true
```

`TwistedBasis(L, H, R)`

For a Lie algebra L, a split toral subalgebra H of L, and a twisted root datum R, the function constructs a "twisted basis" of L.

Let k be the coefficient ring of L and K an extension field of k of degree equal to the twisting degree of R. This function has 4 return values. First, $L' = L \otimes K$; second, a homomorphism ϕ from L to L', third, a record containing a Chevalley basis of L' with respect to the untwisted root datum of R; fourth, a matrix describing the action of the Frobenius automorphism of K on the positive roots of the Chevalley basis of L'.

Such a basis constitutes a proof that L' is of type R. Consult [Roo10], Chapter 5.3, for more details on such twisted bases.

Example H100E36

We investigate a twisted basis of the Lie algebra of type ${}^2\mathrm{A}_2$ over the field with 5 elements. Let δ be the automorphism of the root system of type A_2, let k =GF(5), and let K =GF(5^2).

```
> R := TwistedRootDatum(RootDatum("A2") : Twist := 2);
> L := TwistedLieAlgebra(R, GF(5));
> H := SplitToralSubalgebra(L);
> LK, phi, ChevBas, m := TwistedBasis(L, H, R);
> m;
[     0      1]
[     1      0]
```

This matrix `m` shows that δ acts as expected on the Chevalley basis elements of `LK` $= L \otimes K$. We verify the correctness of `m`.

```
> K := CoefficientRing(LK);
> simp := ChevBas`BasisPos[[1..Rank(R)]];
> simp;
[ (     0      0      0      0      0      1  ksi^8      0),
  (     0      0      0      0      0      1 ksi^16      0) ]
> fr := FrobeniusMap(K);
> frv := func<x | Vector([ fr(i) : i in Eltseq(x)])>;
> [ Position(simp, frv(x)) : x in simp ];
```

```
[ 2, 1 ]
```

So indeed the Frobenius map (acting on the coordinates of LK) acts as δ. This is equivalent [Roo10, Lemma 5.3] to the basis elements of L being stable under the composition of the Frobenius map (this time acting on the Chevalley basis of $L \otimes K$) and the root system automorphism δ. We verify this assertion explicitly for this example.

```
> p := ChevBas‘BasisPos;
> n := ChevBas‘BasisNeg;
> c := ChevBas‘BasisCart;
> pi := Sym(6)!(1, 2)(4, 5);
> ChevBasLK := VectorSpaceWithBasis([ Vector(x) : x in p cat n cat c]);
> piL := DiagramAutomorphism(LK, pi);
```

Now δ acts on $L \otimes K$ as `T`, and `fr` is still the Frobenius automorphism of the field K. The images of the basis elements of L under `delta` composed with `fr` are as follows:

```
> for i in [1..Dimension(L)] do
>    b := phi(L.i);
>    printf "i = %o, b =    %o\n", i, Coordinates(ChevBasLK, Vector(b));
>    printf "   pi(b)^fr = %o\n", [ fr(i) : i in
>                              Coordinates(ChevBasLK, Vector(piL(b))) ];
> end for;
i = 1, b =    [ 0, 0, 0, 0, 0, ksi^9, 0, 0 ]
   (b*T)^fr = [ 0, 0, 0, 0, 0, ksi^9, 0, 0 ]
i = 2, b =    [ 0, 0, 0, ksi^5, ksi, 0, 0, 0 ]
   (b*T)^fr = [ 0, 0, 0, ksi^5, ksi, 0, 0, 0 ]
i = 3, b =    [ 0, 0, 0, ksi^9, ksi^21, 0, 0, 0 ]
   (b*T)^fr = [ 0, 0, 0, ksi^9, ksi^21, 0, 0, 0 ]
i = 4, b =    [ 0, 0, 0, 0, 0, 0, ksi^5, ksi ]
   (b*T)^fr = [ 0, 0, 0, 0, 0, 0, ksi^5, ksi ]
i = 5, b =    [ 0, 0, 0, 0, 0, 0, ksi, ksi^5 ]
   (b*T)^fr = [ 0, 0, 0, 0, 0, 0, ksi, ksi^5 ]
i = 6, b =    [ ksi, ksi^5, 0, 0, 0, 0, 0, 0 ]
   (b*T)^fr = [ ksi, ksi^5, 0, 0, 0, 0, 0, 0 ]
i = 7, b =    [ ksi^21, ksi^9, 0, 0, 0, 0, 0, 0 ]
   (b*T)^fr = [ ksi^21, ksi^9, 0, 0, 0, 0, 0, 0 ]
i = 8, b =    [ 0, 0, ksi^9, 0, 0, 0, 0, 0 ]
   (b*T)^fr = [ 0, 0, ksi^9, 0, 0, 0, 0, 0 ]
```

Thus, all the basis elements of L are stable under the composition of the diagram automorphism δ and the Frobenius automorphism.

The `WeylGroup` functions are only available for structure constant Lie algebras.

`WeylGroup(L)`

`WeylGroup(GrpPermCox, L)`

The Weyl group of the reductive Lie algebra L, as a permutation Coxeter group (see Chapter 98).

`WeylGroup(GrpFPCox, L)`

The Weyl group of the reductive Lie algebra L, as a Coxeter group (see Chapter 98).

`WeylGroup(GrpMat, L)`

The Weyl group of the reductive Lie algebra L, as a reflection group (see Chapter 98).

100.9 Operations on Subalgebras and Ideals

`DirectSum(L, M)`

Given Lie algebras L and M, this intrinsic constructs a Lie algebra of dimension $n + m$, where n and m are the dimensions of L and M, respectively. The basis of the new algebra is the concatenation of the bases of L and M and the products $a * b$ where $a \in L$ and $b \in M$ are defined to be zero.

`IndecomposableSummands(L)`

`DirectSumDecomposition(L)`

Given a Lie algebra L, the function returns the direct sum decomposition of L as a sequence of ideals of L whose sum is L and each of which cannot be further decomposed into a direct sum of ideals.

The algorithms used for this function are described in [dG00], §4.12 (semisimple case), §1.15 (general case).

Example H100E37

We compute the direct sum decomposition of the simple Lie algebra of type D_2 over the rational field.

```
> L := LieAlgebra("D2", RationalField());
> L;
Lie Algebra of dimension 6 with base ring Rational Field
> D := DirectSumDecomposition(L);
> D;
[
    Lie Algebra of dimension 3 with base ring Rational Field,
    Lie Algebra of dimension 3 with base ring Rational Field
]
> Morphism(D[1], L);
[ 0  1  0  0  0  0]
[ 0  0  1 -1  0  0]
[ 0  0  0  0  1  0]
> Morphism(D[2], L);
[1 0 0 0 0 0]
[0 0 1 1 0 0]
[0 0 0 0 0 1]
```

100.9.1 Standard Ideals and Subalgebras

`Centre(L)`
`Center(L)`

Given a Lie algebra L, returns the centre of L.

`Centraliser(L, K)`
`Centralizer(L, K)`

Given a Lie algebra L and a subalgebra K of L, returns the centraliser of K in L, and its injection into L.

`Centraliser(L, x)`
`Centralizer(L, x)`

Given a Lie algebra L and an element x of L, returns the centraliser of x in L, and its injection into L.

`Normaliser(L, K)`
`Normalizer(L, K)`

Given a Lie algebra L and a subalgebra K of L, returns the normaliser of K in L, and its injection into L.

`SolubleRadical(L)`
`SolvableRadical(L)`

Given a Lie algebra L, returns the soluble radical of L.

We refer to [dG00], §2.6 for the algorithm used to implement this function.

`Nilradical(L)`

Given a Lie algebra L, returns the nilradical of L.

The algorithm makes use of Cartan subalgebras. We refer to [dG00], pp. 84, 85 for its description.

Example H100E38

We demonstrate the functions for performing basic operations with Lie algebras such as centre, normalizer etc.

```
> L := LieAlgebra("D4", RationalField());
> L;
Lie Algebra of dimension 28 with base ring Rational Field
> Centre(L);
Lie Algebra of dimension 0 with base ring Rational Field
> K := sub< L | [L.1, L.2, L.3] >;
> Centralizer(L, K);
Lie Algebra of dimension 10 with base ring Rational Field
> Normalizer(L, K);
```

```
Lie Algebra of dimension 19 with base ring Rational Field
> M := Centralizer(L, K);
> S := SolvableRadical(M);
> S;
Lie Algebra of dimension 10 with base ring Rational Field
> Morphism(S, L);
[1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0 0 -1 0 0 0 -1 0 0 -1 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0]
> Nilradical(M);
Lie Algebra of dimension 9 with base ring Rational Field
```

100.9.2 Cartan and Toral Subalgebras

`CartanSubalgebra(L)`

Given a Lie algebra L, this function returns a Cartan subalgebra of L. The algorithm works for Lie algebras L defined over a field F such that $|F| > \dim L$ and for restricted Lie algebras of characteristic p. If the Lie algebra does not fit into one of these classes then the correctness of the output is not guaranteed.

The algorithm used is described in [dG00], §3.2.

`IsCartanSubalgebra(L, H)`

The intrinsic returns `true` if H is a Cartan subalgebra of L, i.e., whether H is nilpotent and $N_L(H) = 0$.

Example H100E39

We compute a Cartan subalgebra of the simple Lie algebra of type A_4 over the rational field.

```
> L := LieAlgebra("F4", RationalField());
> L;
Lie Algebra of dimension 52 with base ring Rational Field
> H := CartanSubalgebra(L);
Lie Algebra of dimension 4 with base ring Rational Field
> H*H;
Lie Algebra of dimension 0 with base ring Rational Field
> Normalizer(L, H);
Lie Algebra of dimension 4 with base ring Rational Field
```

`SplittingCartanSubalgebra(L)`

`SplitMaximalToralSubalgebra(L)`

Given a Lie algebra L over a field k of characteristic at least 5, a split Cartan subalgebra (equivalently, a split maximal toral subalgebra) is computed for L.

The algorithm used is discussed in [CM09], Sections 5 and 6. This algorithm is proved to work ([CM09, Theorem 6.7]) if L is the Lie algebra of a k-split connected reductive group. In other cases, should the algorithm terminate, the output is guaranteed to be correct.

`IsSplittingCartanSubalgebra(L, H)`

Determine whether H is a splitting Cartan subalgebra of L, i.e., whether H is a Cartan subalgebra and the adjoint action of H on L splits completely over the coefficient ring of L.

`SplitToralSubalgebra(L)`

`TryMaximal` . *Default :* `true`

The intrinsic attempts to compute a split toral subalgebra of a Lie algebra L defined over a finite field k. This procedure uses a heuristic algorithm, described in [Roo10, Chapter 3], that works in many cases even if the characteristic of k is small. Moreover, it attempts to compute a split toral subalgebra of maximal size.

If the function returns without error, the resulting subalgebra H is a split toral subalgebra that does not lie inside a split toral subalgebra H' of larger dimension. It is, however, not guaranteed that H is of maximal dimension among all split toral subalgebras.

The optional parameter `TryMaximal` may be used as follows. If set to `true` (the default) the reductive rank r of L is computed first, and the algorithm attempts to compute a split toral subalgebra of dimension r. If set to `false`, the first split toral subalgebra found is returned. Finally, if `TryMaximal` is set to an integer $n \geq 1$, the algorithm attempts to find a split toral subalgebra of dimension n. In the latter case, if no split toral subalgebra of dimension n can be found, the biggest that has been found is returned; if on the other hand a split toral subalgebra of dimension *larger* than n is encountered, that is returned.

`IsSplitToralSubalgebra(L, H)`

Given a restrictable Lie algebra L over a finite field, the function returns `true` is H is a split toral subalgebra of L, i.e., whether $[H, H] = 0$, all elements of H are semisimple, and the basis elements are invariant under the q-map associated to L.

Example H100E40

We construct a twisted Lie algebra L of type ${}^3\mathrm{D}_4$ over the field $k = \mathrm{GF}(3^3)$ and verify that the subalgebra H returned by `SplitToralSubalgebra` is indeed a split toral subalgebra. Then, we test whether $C = C_L(H)$ is a (split) toral subalgebra of L.

```
> k := GF(3, 3);
```

```
> L, phi := TwistedLieAlgebra(TwistedRootDatum("D4" : Twist := 3), k);
> H := SplitToralSubalgebra(L);
> H;
Lie Algebra of dimension 2 with base ring GF(3^3)
> IsSplitToralSubalgebra(L, H);
true
> C := Centraliser(L,H); C;
Lie Algebra of dimension 4 with base ring GF(3^3)
> IsToralSubalgebra(L,C), IsSplitToralSubalgebra(L, C);
true false
```

Now we let K be the big field, $\mathrm{GF}(3^9)$, and test if $C \otimes K$ is a split toral subalgebra of $L \otimes K$.

```
> LK := Codomain(phi);
> LK;
Lie Algebra of dimension 28 with base ring GF(3^9)
> CK := sub<LK | [ phi(b) : b in Basis(C) ]>;
> IsSplitToralSubalgebra(LK, CK);
true
```

100.9.3 Standard Series

`CompositionSeries(L)`

A composition series is computed for the (structure constant) Lie algebra L. The function returns three values:

(a) a sequence containing the composition series as an ascending chain of subalgebras such that the successive quotients are irreducible L-modules;

(b) a sequence containing the composition factors as structure constant algebras;

(c) a transformation matrix to a basis compatible with the composition series, that is, the first basis elements form a basis of the first term of the composition series, the next extend these to a basis for the second term etc.

`CompositionFactors(L)`

Compute the composition factors of a composition series for the Lie algebra L. This function returns the same as the second return value of `CompositionSeries` above, but will often be very much quicker.

`MinimalIdeals(L : parameters)`

`Limit` RngIntElt *Default :* ∞

Returns the minimal left/right/two-sided ideals of the (structure constant) Lie algebra L (in non-decreasing size). If `Limit` is set to n, at most n ideals are calculated and the second return value indicates whether all of the ideals were computed.

`MaximalIdeals(L : parameters)`

`Limit` RngIntElt *Default :* ∞

Returns the maximal left/right/two-sided ideals of the (structure constant) Lie algebra L (in non-decreasing size). If `Limit` is set to n, at most n ideals are calculated and the second return value indicates whether all of the ideals were computed.

`DerivedSeries(L)`

Given a Lie algebra L, this function returns a sequence of ideals of L that form its derived series.

`LowerCentralSeries(L)`

Given a Lie algebra L, this function returns a sequence of ideals of L that form its lower central series.

`UpperCentralSeries(L)`

Given a Lie algebra L, this function returns a sequence of ideals of L that form the upper central series of L. The function repeatedly uses the algorithm for computing centres while keeping track of the pre-images of the ideals factored out.

Example H100E41

We compute each of the type of series of a particular subalgebra of the simple Lie algebra of type F_4 over the rational field.

```
> L:=LieAlgebra("F4", RationalField());
> L;
Lie Algebra of dimension 52 with base ring Rational Field
> K:=sub< L | [L.1, L.12, L.23, L.34, L.45] >;
> DerivedSeries(K);
[
    Lie Algebra of dimension 20 with base ring Rational Field,
    Lie Algebra of dimension 16 with base ring Rational Field,
    Lie Algebra of dimension 7 with base ring Rational Field,
    Lie Algebra of dimension 0 with base ring Rational Field
]
> LowerCentralSeries(K);
[
    Lie Algebra of dimension 20 with base ring Rational Field,
    Lie Algebra of dimension 16 with base ring Rational Field,
    Lie Algebra of dimension 12 with base ring Rational Field,
    Lie Algebra of dimension 8 with base ring Rational Field,
    Lie Algebra of dimension 5 with base ring Rational Field,
    Lie Algebra of dimension 2 with base ring Rational Field,
    Lie Algebra of dimension 1 with base ring Rational Field,
    Lie Algebra of dimension 0 with base ring Rational Field
]
> UpperCentralSeries(K);
```

```
[
    Lie Algebra of dimension 2 with base ring Rational Field,
    Lie Algebra of dimension 3 with base ring Rational Field,
    Lie Algebra of dimension 5 with base ring Rational Field,
    Lie Algebra of dimension 8 with base ring Rational Field,
    Lie Algebra of dimension 12 with base ring Rational Field,
    Lie Algebra of dimension 16 with base ring Rational Field,
    Lie Algebra of dimension 20 with base ring Rational Field
]
```

100.9.4 The Lie Algebra of Derivations

`LieAlgebraOfDerivations(L)`

Given a Lie algebra L, this function constructs its Lie algebra of derivations $\mathrm{Der}(L)$. As second return value, a record containing maps from L to $\mathrm{Der}(L)$ and vice versa, and from $\mathrm{Der}(L)$ to the matrix Lie algebra acting on L is returned.

Example H100E42

We consider the Lie algebra of derivations of D_4 in characteristic 2 or, more precisely, the 26-dimensional simple constituent L that exists in all varieties of D_4 in characteristic 2.

```
> SetSeed(1);
> R := RootDatum("D4");
> D4 := LieAlgebra(R, GF(2));
> pos,neg,cart := StandardBasis(D4);
> L := D4*D4; L;
Lie Algebra of dimension 26 with base ring GF(2)
> IsSimple(L);
true
> DerL, maps := LieAlgebraOfDerivations(L);
> DerL;
Lie Algebra of dimension 52 with base ring GF(2)
> SemisimpleType(DerL);
F4
```

So the Lie algebra of derivations is of type F_4. Let us consider one of the maps that was returned as second value.

```
> maps;
rec<recformat<mp_DerL_to_L: Map, mp_L_to_DerL: Map, mp_DerL_to_mats:
Map, mp_mats_to_DerL: Map> |
    mp_DerL_to_L := Mapping from: AlgLie: DerL to AlgLie: L given by a
        rule [no inverse],
    mp_L_to_DerL := Mapping from: AlgLie: L to AlgLie: DerL given by a
        rule [no inverse],
    mp_DerL_to_mats := Mapping from: AlgLie: DerL to Matrix Lie
```

```
        Algebra given by a rule [no inverse],
    mp_mats_to_DerL := Mapping from: Matrix Lie Algebra to AlgLie:
        DerL given by a rule [no inverse]>
> adL := AdjointRepresentation(L);
> f := maps‘mp_DerL_to_mats;
> [ f(b) in Image(adL) : b in Basis(DerL) ];
[ false, true, true, true, true, true, true, true, false, false, true,
false, true, false, false, false, true, false, true, true, true,
false, false, false, true, true, false, false, false, true, true,
false, false, false, true, true, false, false, true, false, true,
false, true, false, false, false, true, false, true, false, false,
false ]
```

So, unsurprisingly, some of the basis elements of $\mathrm{Der}(L)$ are actually elements from L, but others are not. We consider one more of these maps and investigate how L lies in $\mathrm{Der}(L)$.

```
> g := maps‘mp_L_to_DerL;
> I := ideal<DerL | [ g(b) : b in Basis(L) ]>; I;
Lie Algebra of dimension 26 with base ring GF(2)
> pos2, neg2, cart2 := ChevalleyBasis(DerL, SplitToralSubalgebra(DerL));
> [i : i in [1..#pos2] | pos2[i] in I ];
[ 3, 4, 6, 7, 8, 10, 12, 13, 15, 17, 19, 21 ]
> RF4 := RootDatum("F4");
> [ i : i in [1..NumPosRoots(RF4)] | IsShortRoot(RF4, i) ];
[ 3, 4, 6, 7, 8, 10, 12, 13, 15, 17, 19, 21 ]
```

So we conclude that the original Lie algebra L of type D_4 exists as the short roots of the Lie algebra of derivations $\mathrm{Der}(L)$ of type F_4.

100.10 Properties of Lie Algebras and Ideals

`KillingMatrix(L)`

Given a Lie algebra L such that $\{x_1, \ldots, x_n\}$ is a basis of L, return the Killing matrix of L, which is defined to be the matrix $(\mathrm{Tr}(\mathrm{ad}x_i \cdot \mathrm{ad}x_j))$.

Example H100E43

```
> L:=LieAlgebra("B2",RationalField());
> KillingMatrix(L);
[ 0  0  0 -6  0  0  0  0  0  0]
[ 0  0 -6  0  0  0  0  0  0  0]
[ 0 -6  0  0  0  0  0  0  0  0]
[-6  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  6]
[ 0  0  0  0  0  0  0  0  6  0]
[ 0  0  0  0  0  0  6  0  0  0]
```

```
[ 0  0  0  0  0  0  0  6  0  0]
[ 0  0  0  0  0  6  0  0  0  0]
[ 0  0  0  0  6  0  0  0  0  0]
```

`IsAbelian(L)`

Given a Lie algebra L, return `true` if L is abelian.

`IsSoluble(L)`
`IsSolvable(L)`

Given a Lie algebra L, return `true` if L is soluble.

`IsNilpotent(L)`

Given a Lie algebra L, return `true` if L is nilpotent.

`IsCentral(L, M)`

Given a subalgebra M of the Lie algebra L, return `true` if M is central in L.

`IsSimple(L)`

Given a Lie algebra L, return `true` if L is simple.

`IsSemisimple(L)`

Given a Lie algebra L, return `true` if L is semisimple.

`IsReductive(L)`

Given a Lie algebra L, return `true` if L is reductive.

`HasLeviSubalgebra(L)`

Given a Lie algebra L, this function determines whether L has a Levi subalgebra. If the result is `true`, then the function also returns a semisimple subalgebra (complement to the solvable radical) of L. If L is defined over a field of characteristic 0, then it always has a Levi subalgebra. However, if L is a Lie algebra of characteristic $p > 0$ then L need not have a Levi subalgebra but the function will always find one if it exists.

A description of the algorithm used is contained in [dG00], §4.13.

`IsClassicalType(L)`

Determines if the reductive Lie algebra L is of classical-type. Note that all reductive Lie algebras over fields of characteristic 0 are considered to be classical-type.

Example H100E44

We test various predicates in the context of the simple Lie algebra of type D_3 over the rational field.

```
> L:=LieAlgebra("D3",RationalField());
> L;
Lie Algebra of dimension 15 with base ring Rational Field
> K:=sub< L | [L.1,L.2,L.3] >;
> M:=Centralizer(L, K);
> M;
Lie Algebra of dimension 4 with base ring Rational Field
> R:=SolvableRadical(M);
> R;
Lie Algebra of dimension 4 with base ring Rational Field
> HasLeviSubalgebra(M);
true Lie Algebra of dimension 0 with base ring Rational Field
> K:=Centralizer(L, sub< L | [L.1,L.2,L.3] >);
> K;
Lie Algebra of dimension 4 with base ring Rational Field
> IsSolvable(K);
true
> IsNilpotent(K);
false
> R:= SolvableRadical(K);
> IsSolvable(R);
true
> IsNilpotent(R);
true
> N:= Nilradical(K);
> IsNilpotent(N);
true
```

100.11 Operations on Elements

`x + y` `x - y` `x * y`

`IsCentral(L, M)`

Given an element x of the Lie algebra L, return `true` if x is central in L.

`NonNilpotentElement(L)`

Given a (structure constant) Lie algebra L, this function returns an element of L that is *not* nilpotent, or the zero element of L if no such element exists.

The algorithm follows [dG00], §2.7.

Example H100E45

We construct a non-nilpotent element of a Lie algebra.

```
> L:=LieAlgebra("G2",RationalField());
> NonNilpotentElement(L);
(0 0 0 0 0 1 0 0 0 0 0 0 0 0)
```

`AdjointMatrix(L, x)`

`RightAdjointMatrix(L, x)`

Given a (structure constant) Lie algebra L and an element x of a subalgebra or ideal of L, return the matrix of $\mathrm{ad}x$ as an element of a matrix Lie algebra.

Example H100E46

```
> L:=LieAlgebra("B2",RationalField());
> AdjointMatrix(L, L.1);
[ 0  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 1  0  0  0  0  0  0  0  0  0]
[ 2  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 0 -1  0  0  0  0  0  0  0  0]
[ 0  0  1  0  0  0  0  0  0  0]
[ 0  0  0  0  0 -1  0  0  0  0]
```

100.11.1 Indexing

`a[i]`

If a is an element of a structure constant Lie algebra L of dimension n and $1 \leq i \leq n$ is a positive integer, then the i-th component of the element a is returned (as an element of the base ring R of L).

If a is an element of a matrix Lie algebra L of degree n and $1 \leq i \leq n$ then the ith row of the matrix a is returned.

`a[i] := r`

Given an element a belonging to a structure constant Lie algebra of dimension n over R, a positive integer $1 \leq i \leq n$ and an element $r \in R$, the i-th component of the element a is redefined to be r.

If a is an element of a matrix Lie algebra L of degree n over R and $1 \leq i \leq n$, the ith row of the matrix a is redefined to be the vector r over R.

`a[i, j]`

`a[i, j] := r`

For an element a of a matrix Lie algebra L of degree n and integers $1 \leq i, j \leq n$ return the element in the ith row and jth column of a or set this element to be r where r is an element of the coefficient ring of L.

100.12 The Natural Module

`Module(L)`

The module R^n underlying the Lie algebra L.

`RModule(L)`

The module R^n acted on by the matrix Lie algebra L.

`BaseModule(L)`

The space R^n acted on by the matrix Lie algebra L.

`Degree(L)`

The degree of the Lie algebra L. If L is a structure constant algebra, this is just the dimension of L. If L is a matrix Lie algebra, this is the degree of the matrices in L.

`Degree(a)`

Given an element a belonging to the Lie algebra L, the dimension of L is returned.

`ElementToSequence(a)`

`Eltseq(a)`

The sequence of coefficients of the Lie element a.

`Coordinates(M, a)`

Let a be an element of a Lie algebra L and let M be a subalgebra of L containing a. This function returns the coefficients of a with respect to the basis of L.

`InnerProduct(a, b)`

The (Euclidean) inner product of the coefficient vectors of a and b, where a and b are elements of some Lie algebra.

`Support(a)`

The support of the Lie algebra element a; i.e. the set of indices of the non-zero components of a.

100.13 Operations for Matrix Lie Algebras

This section describes the functionality provided for matrix Lie algebras which is additional to that provided for structure constant Lie algebras. For further information see Chapter 83.

`BaseModule(M)`

The natural module on which the matrix Lie algebra M acts.

`Generic(M)`

The full matrix algebra in which the matrix Lie algebra M is naturally embedded.

`Kernel(X)`
`Nullspace(X)`

The kernel of the homomorphism represented by the Lie matrix algebra element X.

`NullspaceOfTranspose(X)`
`RowNullSpace(X)`

The row nullspace of the homomorphism represented by the Lie matrix algebra element X.

100.14 Homomorphisms

`hom< L -> M | Q >`

Given a (structure constant) Lie algebra L of dimension n over R and either a Lie algebra M over R or a module M over R, the homomorphism from L to M specified by Q is constructed. The sequence Q may be of the form $[b_1, \ldots, b_n]$, $b_i \in B$, indicating that the i-th basis element of L is mapped to b_1 or of the form $[< a_1, b_1 >, \ldots, < a_n, b_n >]$ indicating that a_i maps to b_i, where the $a_i (1 \leq i \leq n)$ must form a basis of L.

Note that this is in general only a module homomorphism, and no check is made for it being an algebra homomorphism.

100.15 Automorphisms of Classical-type Reductive Algebras

`IdentityAutomorphism(L)`

The trivial automorphism of the Lie algebra L.

`InnerAutomorphism(L, x)`

The inner automorphism of the Lie algebra L induced by x, where x is an element of the corresponding group of Lie type.

`InnerAutomorphismGroup(L)`

The group of Lie type G corresponding to the Lie algebra L. The map $G \to \mathrm{Aut}(L)$ is returned as second value.

`DiagonalAutomorphism(L, v)`

The diagonal automorphism of the Lie algebra L induced by the vector v.

`GraphAutomorphism(L, p)`

`DiagramAutomorphism(L, p)`

`SimpleSigns` ANY *Default :* 1

The graph automorphism of the Lie algebra L induced by the permutation p. This must be either a permutation of the indices of the simple roots, or a permutation of the indices of all roots.

The optional parameter `SimpleSigns` can be used to specify the signs corresponding to each simple root. This should either be a sequence of integers ± 1, or a single integer ± 1.

Example H100E47

We construct an automorphism of order three for the simple Lie algebra of type D_4.

```
> DynkinDiagram( "D4" );
D4    3
     /
1 - 2
     \
      4
> p:= Sym(4)!(1,3,4);
> L:= LieAlgebra( "D4", Rationals() );
> f:= GraphAutomorphism( L, p );
> f(L.3);
(0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> f(L.4);
(0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> f(L.5);
(0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
```

100.16 Restrictable Lie Algebras

A restricted Lie algebra is a Lie algebra over a field of characteristic $p > 0$, equipped with a restriction map $x \to x^p$, satisfying the axioms given in [Jac62]. A restrictable Lie algebra is a Lie algebra which can be equipped with a restriction map. A Lie algebra is restrictable if and only if ad$L$ is closed under the pth power map. Hence restrictable Lie algebras have a standard restriction map induced by the adjoint representation. For many purposes, it suffices to know that a Lie algebra is restrictable, without needing to know a restriction.

By convention, a Lie algebra over a field of characteristic zero is always considered restrictable, and the restriction map is the identity map.

In MAGMA, we do not make a distinction between the concepts of restricted and restrictable. Note however that a Lie algebra can have a nonstandard restriction map.

`IsRestrictable(L)`
`IsRestricted(L)`
`IspLieAlgebra(L)`

Returns `true` if, and only if, the Lie algebra L is restrictable. If L is restrictable, the restriction map is returned as a second value.

`RestrictionMap(L)`
`pMap(L)`

The restriction map of the Lie algebra L. If L is not restrictable, an error is signalled.

Example H100E48

```
> L:= LieAlgebra( "A2", GF(5) );
> IsRestrictable( L );
true Mapping from: AlgLie: L to AlgLie: L given by a rule [no inverse]
> pmap:= pMap( L );
> pmap( 2*L.3 + L.4);
(0 0 0 1 0 0 0 0)
```

`RestrictedSubalgebra(Q)`
`pSubalgebra(Q)`

Given a sequence Q of elements from the Lie algebra L, the function returns the restricted subalgebra generated by the elements of Q, i.e., the smallest subalgebra containing Q which is also closed under the restriction map. If the parent of Q is not restrictable, an error is signalled.

`pClosure(L, M)`

Given Lie algebras L and M such that $L \leq M$, this function returns the closure of L under the restriction map of M. If L is not a subalgebra of M or M is not restrictable, an error is signalled.

`IsRestrictedSubalgebra(L, M)`

`IspSubalgebra(L, M)`

Return `true` if and only if the Lie algebra L is a restricted Lie subalgebra of M with the same restriction map. Note that if L is constructed using the `pClosure` intrinsic, this will always be true. However if L is constructed as a subalgebra, this may be false even if L is restrictable, since the restriction map of L will be the standard map rather than the restriction map of M.

`pQuotient(L, M)`

Given Lie algebras L and M such that $L \leq M$, this function returns the quotient of L by the p-closure of the Lie algebra M, with respect to the inherited restriction map.

`JenningsLieAlgebra(G)`

Let G be a p-group. Then the quotients of the successive terms of the Jennings series of G can be viewed as vector spaces over the field of p elements. The direct sum of these vector spaces carries the structure of a Lie algebra (coming from the commutator of G). This function returns two values. Firstly, the Lie algebra constructed from G by this process. This Lie algebra is graded. The second returned value is a sequence of sequences of two elements. The first element is the degree of a homogeneous component while the second element is its dimension. The basis elements of the Lie algebra are ordered according to increasing degree. This means that from the dimensions of the homogeneous components it is possible to derive the degree of each basis element.

Lie algebras constructed in this way are naturally restricted. Moreover, if x is a homogeneous element of degree d, then the p-th power image of x is homogeneous of degree pd.

Example H100E49

```
> G:= SmallGroup( 3^6, 196 );
> L, gr:= JenningsLieAlgebra( G );
> L;
Lie Algebra of dimension 6 with base ring GF(3)
> gr;
[
    [ 1, 3 ],
    [ 2, 1 ],
    [ 3, 2 ]
```

```
]
// So the first three basis elements are of degree 1,
// the fourth basis element is of degree 2, and so on.
> pmap:= pMap( L );
> pmap( L.1 );
(0 0 0 0 1 1)
```

100.17 Universal Enveloping Algebras

This section describes the functionality for universal enveloping algebras of Lie algebras. If a Lie algebra is semisimple and defined over a field of characteristic 0, then it is possible to write down an integral basis of the universal enveloping algebra that has nice properties. To accommodate this possibility, two constructions of a universal enveloping algebra are provided: a general construction, and one in which this integral basis is used. First we briefly describe the theoretical background behind universal enveloping algebras.

In MAGMA, universal enveloping algebras have type `AlgUE` and their elements have type `AlgUEElt`. Integral universal enveloping algebras have type `AlgIUE` and their elements have type `AlgIUEElt`. General algebras having a PBW basis (see below) have type `AlgPBW` (elements type `AlgPBWElt`) which inherit from types `Alg` and `Rng`. Consequently, the type `AlgIUE` inherits from `AlgPBW`.

100.17.1 Background

100.17.1.1 Universal Enveloping Algebras

Let L be a Lie algebra over the field F having basis $x_1, \ldots, x_n$. The universal enveloping algebra $U(L)$ of L is the associative algebra with identity, generated by n symbols which are also denoted by $x_1, \ldots, x_n$. These generators satisfy the relations

$$x_j x_i - x_i x_j = [x_j, x_i], 1 \leq i, j \leq n > .$$

Here $[x_j, x_i]$ is the product in the Lie algebra L, so it is a certain linear combination of the x_k.

The theorem of Poincaré-Birkhoff-Witt states that a basis of $U(L)$ is formed by the set of all elements

$$x_1^{k_1} \cdots x_n^{k_n},$$

where the k_i are non-negative integers. Furthermore, the product of two such basis elements may be rewritten as a linear combination of basis elements using the defining relations $x_j x_i - x_i x_j = [x_j, x_i]$ for $j > i$.

100.17.1.2 The Integral Form of a Universal Enveloping Algebra

If the Lie algebra L happens to be (split) semisimple and of characteristic 0, then the universal enveloping algebra has a nice basis described by [Kos66]. The first step in constructing this basis involves taking a Chevalley basis of L, consisting of the elements $y_1, \ldots, y_s$, $h_1, \ldots, h_r$ and $x_1, \ldots, x_s$. Here the y_i and x_i are root vectors belonging to negative roots and positive roots, respectively. The h_i are basis elements of a Cartan subalgebra. In the universal enveloping algebra we use the divided powers

$$y_i^{(n)} = \frac{y_i^n}{n!}, \quad x_i^{(n)} = \frac{x_i^n}{n!},$$

and the binomials

$$\binom{h_i}{k} = \frac{h_i(h_i-1)\cdots(h_i-k+1)}{k!}.$$

A basis of $U(L)$ is formed by the elements

$$y_1^{(m_1)} \cdots y_s^{(m_s)} \binom{h_1}{k_1} \cdots \binom{h_r}{k_r} x_1^{(n_1)} \cdots x_s^{(n_s)}.$$

This basis has the useful property that if we multiply two basis elements, the structure constants will be integers (usually of quite moderate size). So this is a basis of an integral form of the universal enveloping algebra.

100.17.2 Construction of Universal Enveloping Algebras

`UniversalEnvelopingAlgebra(L)`

This creates the universal enveloping algebra U of the Lie algebra L. Here the i-th basis element of L (i.e., `L.i`) corresponds to the i-th generator of U (i.e., `U.i`). Every product of generators is rewritten as a linear combination of Poincaré-Birkhoff-Witt monomials (cf. Section 100.17.1.1).

`IntegralUEA(L)`

`IntegralUEAlgebra(L)`

`IntegralUniversalEnvelopingAlgebra(L)`

Given a semisimple Lie algebra L of characteristic 0, create the integral universal enveloping algebra U of L. The basis described in Section 100.17.1.2 is used.

Let x, y and h denote the output of `ChevalleyBasis(L)`. Let s be the length of x, and r the length of h. Then every generator of U corresponds to an element of x, y or h. If $1 \leq i \leq s$ then the i-th generator of U (i.e., `U.i`) corresponds to the i-th element of y. It is printed as `y_i`. If $s+1 \leq i \leq s+r$, then the i-th generator of U corresponds to the k-th element of h, where $k = i - s$. It is printed as `[ h_k ; 1 ]` (i.e., `h_k` choose 1). Finally, if $s+r+1 \leq i \leq 2s+r$, then the i-th generator corresponds to the k-th element of x, where $k = i - s - r$. It is printed as `x_k`.

Using this form of the universal enveloping algebra has two advantages. Firstly, the structure constants are integers which usually remain relatively small. Secondly, multiplication of elements is, in general, much faster than is the case with universal enveloping algebras that employ PBW bases.

Example H100E50

```
> T:= [ <4,1,1,1>, <1,4,1,-1>, <4,1,3,1>, <1,4,3,-1>, <4,2,2,1>, <2,4,2,-1>,
> <4,3,1,1>, <3,4,1,-1>, <3,1,2,1>, <1,3,2,-1> ];
> L:= LieAlgebra< Rationals(), 4 | T >;
> U:= UniversalEnvelopingAlgebra(L);
> U.4*U.1;
x_1*x_4 + x_1 + x_3
> L:= LieAlgebra("F4", Rationals());
> U:= IntegralUEA(L);
> U.29*U.1;
y_1*x_1 + [ h_1 ; 1 ]
> (1/4)*U.29^2*U.1^2;
y_1^(2)*x_1^(2) + y_1*[ h_1 ; 1 ]*x_1 - 2*y_1*x_1 + [ h_1 ; 2 ]
```

In the last example we divided by 4 because `U.29^2 = 2 U.29^(2)`, and likewise for `U.1^2`.

`AssignNames(~U, Q)`

Assign the names in the sequence Q to the generators of the algebra U.

`ChangeRing(U, S)`

Given a universal enveloping algebra U with base ring R, together with a ring S, construct the algebra U' with base ring S obtained by coercing the coefficients of elements of U into S.

100.17.3 Related Structures

`CoefficientRing(U)`

`BaseRing(U)`

The ring of coefficients of the universal enveloping algebra U.

`Algebra(U)`

The Lie algebra corresponding to the universal enveloping algebra U.

100.17.4 Elements of Universal Enveloping Algebras

Most functions in this section are applicable both to universal enveloping algebras and to integral universal enveloping algebras. Therefore, they are only documented once. An exception is the function `HBinomial`, which is only applicable to integral universal enveloping algebras.

100.17.4.1 Creation of Elements

`U ! 0`

`Zero(U)`

The zero element of the universal enveloping algebra U.

`U ! 1`

`One(U)`

The identity element of the universal enveloping algebra U.

`U . i`

The i-th generator of the universal enveloping algebra U.

`U ! r`

Returns r as an element of the enveloping algebra U where r may be anything coercible into the coefficient ring of U or an element of another enveloping algebra of the same type as U whose coefficients can be coerced into the coefficient ring of U.

`HBinomial(U, i, n)`

`HBinomial(h, n)`

This function is applicable only in the case of integral universal enveloping algebras. It is used for constructing the "binomial" elements h_i choose n. In the first form U is an integral universal enveloping algebra, and i is an index between 1 and the rank of the root datum. In the second form, the element h is simply `U.(s+i)`, where s is the number of positive roots.

Example H100E51

```
> L:= LieAlgebra("E6",Rationals());
> U:= IntegralUEA(L);
> HBinomial(U, 4, 10);
[ h_4 ; 10 ]
```

100.17.4.2 Operations on Elements

`x + y` `x - y` `x * y` `c * x` `x * c` `x ^ n`

`Monomials(u)`

The sequence of the monomials that occur in the element u of a universal enveloping algebra.

`Coefficients(u)`

The sequence of coefficients of the monomials in the element u of a universal enveloping algebra. The k-th element of this sequence corresponds exactly to the k-th monomial in the sequence returned by `Monomials(u)`.

`Degree(u, i)`

Given an element u of a universal enveloping algebra U and an integer i, this function returns the degree of u in the i-th generator of U.

Example H100E52

```
> L:= LieAlgebra("G2",Rationals());
> U:= IntegralUEA(L);
> c:= U.7*U.2;c;
y_2*[ h_1 ; 1 ] + 3*y_2
> Monomials(c);
[
    y_2*[ h_1 ; 1 ],
    y_2
]
> Coefficients(c);
[ 1, 3 ]
> c:= U.10*U.7*U.2; c;
y_2*[ h_1 ; 1 ]*x_2 + 6*y_2*x_2 + [ h_1 ; 1 ]*[ h_2 ; 1 ] + 3*[ h_2 ; 1 ]
> Degree(c, 2);
1
> Degree(c, 7);
1
> Degree(c, 8);
1
```

100.18 Solvable and Nilpotent Lie Algebras Classification

This section describes functions for working with the classification of solvable Lie algebras of dimension 2, 3, and 4, and the classification of nilpotent Lie algebras having dimensions 3,4,5, and 6. The classification of solvable Lie algebras is taken from [dG05], and applies to algebras over any base field. The classification of nilpotent Lie algebras is taken from [dG07]. It lists the nilpotent Lie algebras over any base field, with the exception of fields of characteristic 2, when the dimension is 6.

The functions described here fall into two categories: functions for creating the Lie algebras of the classification, and a function for identifying a given solvable Lie algebra of dimension 2,3,4 or a given nilpotent Lie algebra of dimension 3,4,5,6 as a member of the list.

First we describe the classifications, in order to define names for the Lie algebras that occur. We then describe the functions for working with them in MAGMA.

100.18.1 The List of Solvable Lie Algebras

We denote a solvable Lie algebra of dimension n by L_n^k, where k ranges between 1 and the number of classes of solvable Lie algebras of dimension n. If the class depends on a parameter, say a, then we denote the Lie algebra by $L_n^k(a)$. In such cases we also state conditions under which $L_n^k(a)$ is isomorphic to $L_n^k(b)$ (if there are any). We list the nonzero commutators only. The field over which the Lie algebra is defined is denoted by F. Here is the list of classes of solvable Lie algebras having dimension not greater than 4:

L_2^1 Abelian.

L_2^2 $[x_2, x_1] = x_1$.

L_3^1 Abelian.

L_3^2 $[x_3, x_1] = x_1$, $[x_3, x_2] = x_2$.

$L_3^3(a)$ $[x_3, x_1] = x_2$, $[x_3, x_2] = ax_1 + x_2$.

$L_3^4(a)$ $[x_3, x_1] = x_2$, $[x_3, x_2] = ax_1$. Condition of isomorphism: $L_3^4(a) \cong L_3^4(b)$ if and only if there is an $\alpha \in F^*$ with $a = \alpha^2 b$.

L_4^1 Abelian.

L_4^2 $[x_4, x_1] = x_1$, $[x_4, x_2] = x_2$, $[x_4, x_3] = x_3$.

$L_4^3(a)$ $[x_4, x_1] = x_1$, $[x_4, x_2] = x_3$, $[x_4, x_3] = -ax_2 + (a+1)x_3$.

L_4^4 $[x_4, x_2] = x_3$, $[x_4, x_3] = x_3$.

L_4^5 $[x_4, x_2] = x_3$.

$L_4^6(a, b)$ $[x_4, x_1] = x_2$, $[x_4, x_2] = x_3$, $[x_4, x_3] = ax_1 + bx_2 + x_3$.

$L_4^7(a, b)$ $[x_4, x_1] = x_2$, $[x_4, x_2] = x_3$, $[x_4, x_3] = ax_1 + bx_2$. Isomorphism condition: $L_4^7(a, b) \cong L_4^7(c, d)$ if and only if there is an $\alpha \in F^*$ with $a = \alpha^3 c$ and $b = \alpha^2 d$.

L_4^8 $[x_1, x_2] = x_2$, $[x_3, x_4] = x_4$.

$L_4^9(a)$ $[x_4, x_1] = x_1 + ax_2$, $[x_4, x_2] = x_1$, $[x_3, x_1] = x_1$, $[x_3, x_2] = x_2$. Condition on the parameter a: $T^2 - T - a$ has no roots in F. Isomorphism condition: $L_4^9(a) \cong L_4^9(b)$ if and only if the characteristic of F is not 2 and there is an $\alpha \in F^*$ with $a + \frac{1}{4} = \alpha^2(b + \frac{1}{4})$, or the characteristic of F is 2 and $X^2 + X + a + b$ has roots in F.

$L_4^{10}(a)$ $[x_4, x_1] = x_2$, $[x_4, x_2] = ax_1$, $[x_3, x_1] = x_1$, $[x_3, x_2] = x_2$. Condition on F: the characteristic of F is 2. Condition on the parameter a: $a \notin F^2$. Isomorphism condition: $L_4^{10}(a) \cong L_4^{10}(b)$ if and only if $Y^2 + X^2 b + a$ has a solution $(X, Y) \in F \times F$ with $X \neq 0$.

$L_4^{11}(a, b)$ $[x_4, x_1] = x_1$, $[x_4, x_2] = bx_2$, $[x_4, x_3] = (1 + b)x_3$, $[x_3, x_1] = x_2$, $[x_3, x_2] = ax_1$. Condition on F: the characteristic of F is 2. Condition on the parameters a, b: $a \neq 0$, $b \neq 1$. Isomorphism condition: $L_4^{11}(a, b) \cong L_4^{11}(c, d)$ if and only if $\frac{a}{c}$ and $(\delta^2 + (b + 1)\delta + b)/c$ are squares in F, where $\delta = (b + 1)/(d + 1)$.

L_4^{12} $[x_4, x_1] = x_1$, $[x_4, x_2] = 2x_2$, $[x_4, x_3] = x_3$, $[x_3, x_1] = x_2$.

$L_4^{13}(a)$ $[x_4, x_1] = x_1 + ax_3$, $[x_4, x_2] = x_2$, $[x_4, x_3] = x_1$, $[x_3, x_1] = x_2$.

$L_4^{14}(a)$ $[x_4, x_1] = ax_3$, $[x_4, x_3] = x_1$, $[x_3, x_1] = x_2$. Condition on parameter a: $a \neq 0$. Isomorphism condition: $L_4^{14}(a) \cong L_4^{14}(b)$ if and only if there is an $\alpha \in F^*$ with $a = \alpha^2 b$.

100.18.2 Comments on the Classification over Finite Fields

Over general fields the lists are not "precise" in the sense that some classes that depend up on a parameter have an associated isomorphism condition, but not a precise parametrization of the Lie algebras in that class. However, for algebras over finite fields we are able to give a precise list, by restricting the parameter values in some cases. In this section we describe how this is done. Here F will be a finite field of size q with primitive root γ.

* If the characteristic of F is 2, then there are two algebras of type $L_3^4(a)$, namely $L_3^4(0)$ and $L_3^4(1)$. If the characteristic is not 2, then there are three algebras of this type, $L_3^4(0)$, $L_3^4(1)$, $L_3^4(\gamma)$.

* The class $L_4^7(a, b)$ splits into three classes: $L_4^7(a, a)$ $(a \in F)$, $L_4^7(a, 0)$ $(a \neq 0)$, $L_4^7(0, b)$ $(b \neq 0)$. Among the algebras of the first class there are no isomorphisms. However, for the other two classes we have the following:-

(i) $L_4^7(a, 0) \cong L_4^7(b, 0)$ if and only if there is an $\alpha \in F^*$ such that $a = \alpha^3 b$. If $q \equiv 1 \bmod 3$, then exactly a third of the elements of F^* are cubes, namely the γ^i with i divisible by 3. So in this case we get three algebras, $L_4^7(1, 0)$, $L_4^7(\gamma, 0)$, $L_4^7(\gamma^2, 0)$. If $q \not\equiv 1 \bmod 3$ then $F^3 = F$, and hence there is only one algebra, namely $L_4^7(1, 0)$.

(ii) $L_4^7(0, a) \cong L_4^7(0, b)$ if and only if there is an $\alpha \in F^*$ such that $a = \alpha^2 b$. So if q is even then we get one algebra, $L_4^7(0, 1)$. If q is odd we get two algebras, $L_4^7(0, 1)$, $L_4^7(0, \gamma)$.

* In [dG05] it is shown that there is only one Lie algebra in the class $L_4^9(a)$. We let e be the smallest positive integer such that $T^2 - T - \gamma^e$ has no roots in F. Then we take the Lie algebra $L_4^9(\gamma^e)$ as representative of the class.
* Over a finite field of characteristic 2 there are no Lie algebras of type $L_4^{10}(a)$, as $F^2 = F$ in that case.
* There is only one Lie algebra of type $L_4^{11}(a, b)$ over a field of characteristic 2, namely $L_4^{11}(1, 0)$.
* If q is even then there is only one algebra of type $L_4^{14}(a)$, namely $L_4^{14}(1)$. If q is odd, then there are two algebras, $L_4^{14}(1)$ and $L_4^{14}(\gamma)$.

100.18.3 The List of Nilpotent Lie Algebras

We denote a nilpotent Lie algebra of dimension r by N_r^k, where k ranges between 1 and the number of classes of nilpotent Lie algebras of dimension r. If the class depends on a parameter, say a, then we denote the Lie algebra by $N_r^k(a)$. The complete list of isomorphism classes of nilpotent Lie algebras having dimensions 3, 4, 5 and 6, *where in dimension 6 we exclude base fields of characteristic 2* are as follows:

N_3^1 Abelian.
N_3^2 $[x_1, x_2] = x_3$.
N_4^1 Abelian.
N_4^2 $[x_1, x_2] = x_3$.
N_4^3 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$.
N_5^1 Abelian.
N_5^2 $[x_1, x_2] = x_3$.
N_5^3 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$.
N_5^4 $[x_1, x_2] = x_5$, $[x_3, x_4] = x_5$.
N_5^5 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_5$, $[x_2, x_4] = x_5$.
N_5^6 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_2, x_3] = x_5$.
N_5^7 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$.
N_5^8 $[x_1, x_2] = x_4$, $[x_1, x_3] = x_5$.
N_5^9 $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_2, x_3] = x_5$.

There are nine 6-dimensional nilpotent Lie algebras denoted N_6^k for $k = 1, \ldots, 9$ which are the direct sum of N_5^k and a 1-dimensional abelian ideal. Consequently, we get the following Lie algebras:-

N_6^{10} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_6$, $[x_4, x_5] = x_6$.
N_6^{11} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_6$, $[x_2, x_3] = x_6$, $[x_2, x_5] = x_6$.
N_6^{12} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_6$, $[x_2, x_5] = x_6$.
N_6^{13} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_5$, $[x_2, x_4] = x_5$, $[x_1, x_5] = x_6$, $[x_3, x_4] = x_6$.

N_6^{14} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_2, x_3] = x_5$, $[x_2, x_5] = x_6$, $[x_3, x_4] = -x_6$.
N_6^{15} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_2, x_3] = x_5$, $[x_1, x_5] = x_6$, $[x_2, x_4] = x_6$.
N_6^{16} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_2, x_5] = x_6$, $[x_3, x_4] = -x_6$.
N_6^{17} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_1, x_5] = x_6$, $[x_2, x_3] = x_6$.
N_6^{18} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_1, x_4] = x_5$, $[x_1, x_5] = x_6$.
$N_6^{19}(a)$ $[x_1, x_2] = x_4$, $[x_1, x_3] = x_5$, $[x_2, x_4] = x_6$, $[x_3, x_5] = ax_6$.
N_6^{20} $[x_1, x_2] = x_4$, $[x_1, x_3] = x_5$, $[x_1, x_5] = x_6$, $[x_2, x_4] = x_6$.
$N_6^{21}(a)$ $[x_1, x_2] = x_3$, $[x_1, x_3] = x_4$, $[x_2, x_3] = x_5$, $[x_1, x_4] = x_6$, $[x_2, x_5] = ax_6$.
$N_6^{22}(a)$ $[x_1, x_2] = x_5$, $[x_1, x_3] = x_6$, $[x_2, x_4] = ax_6$, $[x_3, x_4] = x_5$.
N_6^{23} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_5$, $[x_1, x_4] = x_6$, $[x_2, x_4] = x_5$.
$N_6^{24}(a)$ $[x_1, x_2] = x_3$, $[x_1, x_3] = x_5$, $[x_1, x_4] = ax_6$, $[x_2, x_3] = x_6$,$[x_2, x_4] = x_5$.
N_6^{25} $[x_1, x_2] = x_3$, $[x_1, x_3] = x_5$, $[x_1, x_4] = x_6$.
N_6^{26} $[x_1, x_2] = x_4$, $[x_1, x_3] = x_5$, $[x_2, x_3] = x_6$.

Note that for all classes that depend on a parameter a, the Lie algebra with parameter a is isomorphic to the Lie algebra (from the same class) with parameter b if and only if there is an $\alpha \in F^*$ with $a = \alpha^2 b$.

100.18.4 Intrinsics for Working with the Classifications

`SolvableLieAlgebra( F, n, k :` *parameters*`)`

This function returns the solvable Lie algebra L_n^k over the field F. The multiplication table is exactly the same as that given in the classification of solvable algebras above, where the basis element x_i corresponds to the i-th basis element of the Lie algebra returned.

`pars` SeqEnum *Default :* []

If the Lie algebra L_n^k depends on one or more parameters, then the parameter `pars` specifies the parameter values corresponding to the Lie algebra which is required.

Example H100E53

```
> F<a>:= RationalFunctionField( Rationals() );
> K:= SolvableLieAlgebra( F, 3, 3 : pars:= [a] );
> K.3*K.1;
(0 1 0)
> K.3*K.2;
(a 1 0)
```

`NilpotentLieAlgebra( F, r, k : parameters)`

This function returns the nilpotent Lie algebra N_r^k over the field F. The multiplication table is exactly the same as that given in the classification of nilpotent algebras above, where the basis element x_i corresponds to the i-th basis element of the Lie algebra returned.

`pars` SeqEnum *Default :* []

If the Lie algebra N_r^k depends upon one or more parameters, then the parameter `pars` specifies the parameter values corresponding to the Lie algebra which is required.

Example H100E54

```
> F<a>:= RationalFunctionField( Rationals() );
> K:= NilpotentLieAlgebra( F, 6, 19 : pars:= [a^3] );
> K.3*K.5;
(  0   0   0   0   0 a^3)
```

`AllSolvableLieAlgebras(F, d)`

Given a finite field F and d an integer equal to 2, 3 or 4, this function returns a sequence containing all solvable Lie algebras of dimension d over the field F.

`AllNilpotentLieAlgebras(F, d)`

Given a finite field F and d an integer equal to 3, 4, 5 or 6, this function returns a sequence containing all nilpotent Lie algebras of dimension d over the field F. If the dimension is 6 then the characteristic of F may not be 2.

`IdDataSLAC(L)`

Given a solvable Lie algebra L of dimension 2, 3, or 4, this function returns data that identifies L with the isomorphic algebra in the classification of solvable Lie algebras. (SLAC stands for Solvable Lie Algebras Classification.) Three objects are returned: a string, a sequence and a map.

The string gives the name of the Lie algebra as it occurs in the classification, with information about the field and the parameters.

The sequence contains the parameters of the Lie algebra in the classification to which L is isomorphic.

The map is an isomorphism from L to the corresponding Lie algebra contained in the classification.

`IdDataNLAC(L)`

Given a nilpotent Lie algebra L of dimension 3, 4, 5 or 6 this function returns data that identifies L with the isomorphic algebra in the classification of nilpotent Lie algebras. (NLAC stands for Nilpotent Lie Algebras Classification.) Three objects are returned: a string giving the name of the algebra N in the classification, a sequence giving the parameters for N, and the isomorphism mapping L to N.

`MatrixOfIsomorphism(f)`

Given an isomorphism f as returned by either `IdDataSLAC` or `IdDataNLAC`, this function returns the matrix of that isomorphism. The row convention is used, i.e., the i-th row contains the coordinates of the image of the i-th basis element of the domain of f.

Example H100E55

We define a solvable Lie algebra of dimension 4 that depends on a parameter a. We identify this Lie algebra as a member of the classification.

```
> F<a>:= RationalFunctionField( Rationals() );
> T:= [ <1,2,2,1>, <1,2,3,a>, <1,4,4,a>, <2,1,2,-1>, <2,1,3,-a>, <4,1,4,-a> ];
> L:= LieAlgebra< F, 4 | T >;
> s,p,f:= IdDataSLAC( L );
> s;
L4_6( Univariate rational function field over Rational Field
Variables: a, 0, -a/(a^2 + 2*a + 1) )
> p;
[
    0,
    -a/(a^2 + 2*a + 1)
]
> MatrixOfIsomorphism( f );
[0   (-a - 1)/(a - 1)   (-a - 1)/(a - 1)   (a^2 + 2*a + 1)/(a^2 - a)]
[0   -1/(a - 1)   -a/(a - 1)   (a + 1)/(a - 1)]
[0   -1/(a^2 - 1)   -a/(a^2 - 1)   a/(a - 1)]
[1/(a + 1)   0   0   0]
```

So generically, the Lie algebra is isomorphic to $L_4^6(0, -a/(a^2+2a+1))$. We see that the parameters are not defined if $a = -1$. Furthermore, the isomorphism is not defined if $a = \pm 1$, or $a = 0$. We investigate those cases.

```
> a:= 1;
> T:= [ <1,2,2,1>, <1,2,3,a>, <1,4,4,a>, <2,1,2,-1>, <2,1,3,-a>, <4,1,4,-a> ];
> L:= LieAlgebra< Rationals(), 4 | T >;
> s,p,f:= IdDataSLAC( L );
> s;
L4_3( Rational Field, 0 )
> MatrixOfIsomorphism( f );
[ 0  1  1  0]
```

```
[ 0  0 -1  1]
[ 0  0  0  1]
[ 1  0  0  0]
> a:= -1;
> T:= [ <1,2,2,1>, <1,2,3,a>, <1,4,4,a>, <2,1,2,-1>, <2,1,3,-a>, <4,1,4,-a> ];
> L:= LieAlgebra< Rationals(), 4 | T >;
> s,p,f:= IdDataSLAC( L );
> s;
L4_7( Rational Field, 0, 1 )
> MatrixOfIsomorphism( f );
[   0  1/2  1/2  1/2]
[   0  1/2 -1/2 -1/2]
[   0  1/2 -1/2  1/2]
[   1    0    0    0]
> a:= 0;
> T:= [ <1,2,2,1>, <1,2,3,a>, <1,4,4,a>, <2,1,2,-1>, <2,1,3,-a>, <4,1,4,-a> ];
> L:= LieAlgebra< Rationals(), 4 | T >;
> s,p,f:= IdDataSLAC( L );
> s;
L4_4( Rational Field )
> MatrixOfIsomorphism( f );
[ 0  0  1  0]
[ 0  1  0 -1]
[ 0  1  0  0]
[ 1  0  0  0]
```

We see that for $a = 1$ the Lie algebra is isomorphic to $L_4^3(0)$, and the isomorphism is defined over any field. If $a = -1$, then the Lie algebra is isomorphic to $L_4^7(0, 1)$. However, the isomorphism is not defined if the characteristic of the field is 2. But then we are back in the case $a = 1$. Finally, for $a = 0$ the Lie algebra is isomorphic to L_4^4.

Example H100E56

The positive part of the simple Lie algebra of type G_2 is a nilpotent Lie algebra of dimension six. We identify it in the classification of nilpotent algebras, both in characteristic 0, and in characteristic 3.

```
> L:= LieAlgebra( "G2", Rationals() );
> x,y,h:= ChevalleyBasis( L );
> x;
[ (0 0 0 0 0 0 0 0 1 0 0 0 0 0), (0 0 0 0 0 0 0 0 0 0 1 0 0 0 0), (0 0 0
0 0 0 0 0 0 0 1 0 0 0), (0 0 0 0 0 0 0 0 0 0 0 1 0 0), (0 0 0 0 0 0 0
0 0 0 0 0 1 0), (0 0 0 0 0 0 0 0 0 0 0 0 0 0 1) ]
```

So we see that the positive part is spanned by basis vectors `L.i` with i=9, 10, 11, 12, 13 and 14. So

```
> K:= sub< L | [ L.i : i in [9,10,11,12,13,14] ] >;
> name,pp,f:= IdDataNLAC( K );
> name;
```

```
N6_16( Rational Field )
> MatrixOfIsomorphism( f );
[  1   0   0   0   0   0]
[  0   1   0   0   0   0]
[  0   0   1   0   0   0]
[  0   0   0 1/2   0   0]
[  0   0   0   0 1/6   0]
[  0   0   0   0   0 1/6]
> L:= LieAlgebra( "G2", GF(3) );
> K:= sub< L | [ L.i : i in [9,10,11,12,13,14] ] >;
> name,pp,f:= IdDataNLAC( K );
> name;
N6_19( Finite field of size 3, 0 )
```

We see that in characteristic 3 L is isomorphic to a Lie algebra from a different class.

100.19 Semisimple Subalgebras of Simple Lie Algebras

Here we describe the functions for working with the classification of the semisimple subalgebras of the simple Lie algebras. These subalgebras have been classified for the simple Lie algebras over the complex numbers, of ranks up to 8. They have been classified up to linear equivalence. Two subalgebras K_1, K_2 of a Lie algebra L are linearly equivalent if for every representation of L the induced representations of K_1, K_2 are equivalent. The basic function for dealing with them returns a directed graph, describing the inclusions among the subalgebras, and having the subalgebras as labels of the vertices. (We refer to [dG11] for the background details of this classification.)

`SubalgebrasInclusionGraph( t )`

Here t has to be a simple type of rank not exceeding 8. This function returns a directed graph G. The vertices of this graph are numbered from 1 to the number of semisimple subalgebras. Furthermore, the last vertex is numbered 0. A vertex has a label that is the semisimple subalgebra corresponding to it. The label of the last vertex (numbered 0), has the Lie algebra L of type t as its label. All other semisimple Lie algebras are subalgebras of this one.

The Lie algebra L (and its subalgebras) is defined over the rational numbers, or over a cyclotomic field. It is sometimes necessary to take an extension, because for some types not all subalgebras are defined over the rationals.

Moreover, in G there is an edge from the vertex with label K_1 to the vertex with label K_2 if and only if K_1 has a subalgebra that is linearly equivalent (as subalgebra of L) to K_2. We remark that it does not mean that K_2 is a subalgebra of K_1 (rather that it is linearly equivalent to a subalgebra of K_1).

Example H100E57

We consider the subalgebras of the Lie algebra of type C_3. We compute the types of its maximal subalgebras.

```
> G:= SubalgebrasInclusionGraph( "C3" );
> G;
Digraph
Vertex  Neighbours
1       ;
2       ;
3       ;
4       ;
5       ;
6       ;
7       ;
8       2 4 ;
9       5 10 ;
10      1 2 ;
11      1 2 3 ;
12      1 5 6 ;
13      3 4 6 ;
14      10 11 ;
15      9 12 14 ;
0       7 8 13 15 ;
> v:= Vertices(G);
> Label( v[10] );
Lie Algebra of dimension 6 with base ring Rational Field
> SemisimpleType( Label( v[7] ) );
A1
> SemisimpleType( Label( v[8] ) );
A2
> SemisimpleType( Label( v[13] ) );
A1 A1
> SemisimpleType( Label( v[15] ) );
A1 C2
```

`RestrictionMatrix( G, k )`

Here G is a subalgebras inclusion graph of the simple Lie algebra L, as output by the previous function, and k is a nonzero integer, corresponding to a vertex. This function returns the restriction matrix corresponding to L and the Lie algebra that is the label of the k-th vertex of G. This restriction matrix maps weights in a representation of L to weights of the subalgebra, and can be used to decompose a representation of L, as a representation of the subalgebra.

Example H100E58

We decompose the adjoint representation of the Lie algebra of type D_4, when viewed as a representation of its subalgebra of type G_2.

```
> G:= SubalgebrasInclusionGraph( "D4" );
> v:= Vertices(G);
> tt:= [ SemisimpleType( Label(a) ) : a in v ];
> Index( tt, "G2" );
17
> M:= RestrictionMatrix( G, 17 );
> R:= RootDatum( "D4" : Isogeny:= "SC" );
> S:= RootDatum( "G2" : Isogeny:= "SC" );
> D:= AdjointRepresentationDecomposition(R);
> E:= Branch( S, D, M );
> WeightsAndMultiplicities(E);
[
    (0 1),
    (1 0)
]
[ 1, 2 ]
```

100.20 Nilpotent Orbits in Simple Lie Algebras

Take a simple Lie algebra over the complex numbers, and consider the connected component of its automorphism group that contains the identity. This group acts on the Lie algebra, and there is interest in understanding the nature of its orbits. The nilpotent orbits for simple Lie algebras have been classified. We refer to the book by Collingwood and McGovern [CM93] for the details of this classification.

The main technical tools used for the classification are the weighted Dynkin diagram and the sl_2-triple. The weighted Dynkin diagram is the Dynkin diagram of the root system of the Lie algebra, with labels that can be 0, 1, 2. A nilpotent orbit is uniquely determined by its weighted Dynkin diagram. By the Jacobson-Morozov theorem a nilpotent element of a semisimple Lie algebra can be embedded (as nilpositive element) in an sl_2-triple. Now two nilpotent elements are conjugate (under the group) if and only if the corresponding sl_2-triples are conjugate. This yields a bijection between nilpotent orbits and conjugacy classes of simple subalgebras isomorphic to sl_2.

This section describes functions for working with the classification of nilpotent orbits in simple Lie algebras. One of the main invariants of a nilpotent orbit is its weighted Dynkin diagram. We represent such a diagram by a sequence of its labels; they are mapped to the nodes of the Dynkin diagram in the order determined by the Cartan matrix of the root datum. Also, an sl_2-triple is represented by a sequence $[f, h, e]$ of three elements of a Lie algebra; these satisfy the commutation relations $[h, e] = 2e$, $[h, f] = -2f$, $[e, f] = h$.

Throughout this section we consider orbits that are not the zero orbit.

`IsGenuineWeightedDynkinDiagram( L, wd )`

Given a simple Lie algebra L, and a sequence wd consisting of integers that are 0, 1, or 2, this function returns `true` if wd corresponds to a nilpotent orbit (in other words, if it is the weighted Dynkin diagram of a nilpotent orbit). If wd does corresponds to a nilpotent orbit, an sl_2-triple in L, such that the third element lies in the nilpotent orbit corresponding to the weighted Dynkin diagram is returned. If wd does not correspond to a nilpotent orbit. the second return value is a sequence consisting of three zeros of L.

Example H100E59

We can use this function to find the classification of the nilpotent orbits of a given Lie algebra. First we construct all possible weighted Dynkin diagrams, and then we remove those that do not correspond to an orbit.

```
> L:= LieAlgebra( RootDatum("D4"), Rationals() );
> [ w : i,j,k,l in [0,1,2] | IsGenuineWeightedDynkinDiagram(L, w)
>     where w := [i,j,k,l] ];
[
    [ 0, 0, 0, 2 ],
    [ 0, 0, 2, 0 ],
    [ 0, 1, 0, 0 ],
    [ 0, 2, 0, 0 ],
    [ 0, 2, 0, 2 ],
    [ 0, 2, 2, 0 ],
    [ 1, 0, 1, 1 ],
    [ 2, 0, 0, 0 ],
    [ 2, 0, 2, 2 ],
    [ 2, 2, 0, 0 ],
    [ 2, 2, 2, 2 ]
]
```

`NilpotentOrbit( L, wd )`

This returns the nilpotent orbit in the simple Lie algebra L with weighted Dynkin diagram given by the sequence wd. It is *not* checked whether the weighted Dynkin diagram really corresponds to a nilpotent orbit.

`NilpotentOrbit( L, e )`

This returns the nilpotent orbit in the simple Lie algebra L having representative e. Here e has to be a nilpotent element of the Lie algebra. This condition is not checked by the function.

Example H100E60

```
> L:= LieAlgebra( RootDatum("A2"), Rationals() );
> NilpotentOrbit( L, [2,2] );
Nilpotent orbit in Lie algebra of type A2
> NilpotentOrbit( L, L.1 );
Nilpotent orbit in Lie algebra of type A2
```

`NilpotentOrbits( L )`

Given a simple Lie algebra L, this function returns the sequence of all nilpotent orbits in the simple Lie algebra L.

Example H100E61

We compute the nilpotent orbits of the Lie algebra of type D_4, and observe that they are the same as those found in Example H100E59.

```
> L:= LieAlgebra( RootDatum("D4"), Rationals() );
> o:= NilpotentOrbits(L);
> [ WeightedDynkinDiagram(orb) : orb in o ];
[
    [ 2, 2, 2, 2 ],
    [ 2, 0, 2, 2 ],
    [ 2, 2, 0, 0 ],
    [ 0, 2, 0, 2 ],
    [ 0, 2, 2, 0 ],
    [ 0, 2, 0, 0 ],
    [ 1, 0, 1, 1 ],
    [ 2, 0, 0, 0 ],
    [ 0, 0, 0, 2 ],
    [ 0, 0, 2, 0 ],
    [ 0, 1, 0, 0 ]
]
```

`Partition( o )`

Here o is a nilpotent orbit in a simple Lie algebra of classical type (i.e., of type A_n, B_n, C_n or D_n). The nilpotent orbits for the Lie algebras of these types have been classified in terms of partitions. This function returns the partition corresponding to the orbit.

Example H100E62

```
> L:= LieAlgebra( RootDatum("D4"), Rationals() );
> orbs:= NilpotentOrbits( L );
> Partition( orbs[5] );
[ 4, 4 ]
> Partition( orbs[6] );
[ 3, 3, 1, 1 ]
```

`SL2Triple( o )`

Given a nilpotent orbit o in a simple Lie algebra L, this function returns an sl_2-triple, $[f, h, e]$ of elements of L, such that e lies in the nilpotent orbit.

`SL2Triple( L, e )`

Given a semisimple Lie algebra L of characteristic 0, and a nilpotent element e of L, this function returns an sl_2-triple $[f, h, e]$ of elements of L. It may also work for other Lie algebras, and in other characteristics, but this is not guaranteed.

`Representative( o )`

Given a nilpotent orbit o for a simple Lie algebra L, this function returns an $e \in L$ lying in the orbit.

`WeightedDynkinDiagram( o )`

Given a nilpotent orbit o for a simple Lie algebra L, this function returns its weighted Dynkin diagram.

Example H100E63

We take some nilpotent element in the Lie algebra of type E_8 and we find the weighted Dynkin diagram of the orbit it lies in.

```
> L:= LieAlgebra( RootDatum("E8"), Rationals() );
> x,_,_:= ChevalleyBasis(L);
> orb:= NilpotentOrbit( L, x[1]+x[10]-x[30]+3*x[50]-2*x[100] );
> WeightedDynkinDiagram( orb );
[ 1, 0, 0, 0, 0, 0, 0, 1 ]
```

101 KAC-MOODY LIE ALGEBRAS

Chapter 101
KAC-MOODY LIE ALGEBRAS

101.1 Introduction

Lie algebras of finite dimension are well understood, and numerous procedures for performing calculations with them are described in Chapter 100. An important class of infinite dimensional Lie algebras is that of *Kac-Moody* Lie algebras. The principal text on this subject is a book by Kac [Kac90]. Let us briefly introduce these Lie algebras.

A *generalized Cartan matrix* is an integral matrix $A = (a_{ij})_{i,j=1}^{n}$ such that $a_{ii} = 2$, $a_{ij} < 0$ for $i \neq j$, and $a_{ij} = 0$ implies $a_{ji} = 0$. (Note that in particular, a Cartan matrix in the usual sense is a generalized Cartan matrix.)

To a generalized Cartan matrix we associate a Kac-Moody Lie algebra $\mathfrak{g}(A)$. This Lie algebra is generated by $3n$ elements e_i, f_i, h_i $(i = 1, \ldots, n)$ satisfying the following defining relations:

$$[h_i, h_j] = 0, [e_i, f_i] = h_i, [e_i, f_j] = 0 \text{ if } i \neq j,$$

$$[h_i, e_j] = a_{ij} e_j, [h_i, f_j] = -a_{ij} f_j,$$

$$(\mathrm{ad} e_i)^{1-a_{ij}} e_j = 0, (\mathrm{ad} f_i)^{1-a_{ij}} f_j = 0 \text{ if } i \neq j.$$

The class of Kac-Moody Lie algebras breaks up into three subclasses:

(a) There is a vector θ of positive integers such $A\theta$ is a positive vector. In this case the Lie algebra $\mathfrak{g}(A)$ is finite-dimensional and reductive.

(b) There is a vector δ of positive integers such that $A\delta = 0$. In this case $\mathfrak{g}(A)$ is infinite-dimensional, but is of polynomial growth. These Lie algebras are called *affine Lie algebras*.

(c) There is a vector α of positive integers such that $A\alpha$ is negative. In this case $\mathfrak{g}(A)$ is infinite-dimensional and of exponential growth.

The procedures for finite-dimensional Lie algebras are described in Chapter 100. The affine Lie algebras are described in Section 101.3. The Kac-Moody Lie algebras of type (c) are not yet available.

101.2 Generalized Cartan Matrices

`IsGeneralizedCartanMatrix(C)`

Whether the square matrix C is a generalized Cartan matrix.

`KacMoodyClass(C)`

The class of the indecomposable generalized Cartan matrix C. The first return value is a string, "a", "b" or "c", corresponding to the three cases described in the introduction 101.1. The second is a positive integral column vector v such that Cv is positive, 0 or negative, respectively (so this return value corresponds to the vectors θ, δ and α in the introduction).

`KacMoodyClasses(C)`

The class of the possibly decomposable generalized Cartan matrix C. Three sequences are returned: the first is a sequence of strings "a", "b" or "c", describing the class of each component; the second is a positive integral vector v such that Cv is positive, 0 or negative, respectively (see `KacMoodyClass`).

The third sequence Q contains integral sequences Q_i such that the i-th component is formed by taking the rows and columns with index j, for $j \in Q_i$.

Example H101E1

First, we consider an indecomposable Cartan matrix.

```
> C := Matrix(Integers(), 3, 3, [2,-1,0, -5,2,-1, 0,-1,2]);
> s, v := KacMoodyClass(C);
> s;
c
> v;
[2]
[5]
[1]
> C*v;
[-1]
[-1]
[-3]
```

As a second example, we consider a decomposable Cartan matrix.

```
> C := CartanMatrix("B2 A~3");
> S, V, Q := KacMoodyClasses(C);
> S;
[ a, b ]
> Q;
[
    [ 1, 2 ],
    [ 3, 4, 5, 6 ]
]
```

```
> C1 := Submatrix(C, Q[1], Q[1]);
> KacMoodyClass(C1);
a
> C2 := Submatrix(C, Q[2], Q[2]);
> KacMoodyClass(C2);
b
```

101.3 Affine Kac-Moody Lie Algebras

For affine Lie algebras there exists a well-known explicit construction of these in terms of an underlying finite-dimensional Lie algebra and a central extension (see [Kac90, Chapters 7,8]). We briefly reiterate the construction here. Suppose A is an affine Cartan matrix, so that $\mathfrak{g}(A)$ is an affine Lie algebra; then A is of affine Cartan type $\tilde{\mathrm{X}}_n$ for X=A,B,C,D,E,F, or G, and some n. If we let $\mathfrak{g}_0$ be the finite variant (i.e., a Lie algebra of Cartan type X_n) then

$$\mathfrak{g}(A) \cong \mathfrak{g}_0 \otimes \mathbf{C}[t, t^{-1}] \oplus \mathbf{C}c \oplus \mathbf{C}d$$

for some formal basis elements c and d, where $\mathbf{C}[t, t^{-1}]$ is the ring of Laurent polynomials over $\mathbf{C}$. In MAGMA we represent affine Lie algebras and their elements using the form on the right hand side.

Multiplication is given by

$$[t^k \otimes x \oplus \lambda c \oplus \mu d, t^{k_1} \otimes y \oplus \lambda_1 c \oplus \mu_1 d] =$$

$$(t^{k+k_1} \otimes [x, y] + \mu k_1 t^{k_1} \otimes y - \mu_1 k t^k \otimes x) \oplus k\delta_{k,-k_1}(x|y)c,$$

where $(x|y)$ denotes a fixed non-degenerate invariant symmetric bilinear $\mathbf{C}$-valued form on $\mathfrak{g}_0$.

If we fix E_i, F_i to be canonical generators of g_0, then the canonical generators of $\mathfrak{g}(A)$, as described in the introduction (101.1) are given by $e_0 = t \otimes E_0$, $f_0 = t^{-1} \otimes F_0$, and $e_i = 1 \otimes E_i$, $f_i = 1 \otimes F_i$, for $i = 1, \ldots, l$, where l is the rank of the Cartan matrix.

Affine Lie algebras and their elements are of type `AlgKac` and `AlgKacElt` respectively.

101.3.1 Constructing Affine Kac-Moody Lie Algebras

`AffineLieAlgebra(N, F)`

Construct the affine Kac-Moody Lie algebra of type N over the field F. N should be a string describing an affine Cartan type (e.g. `A~3`). See Section 95.6 for more information on the conventions, syntax, and functions for creating and working with affine Cartan matrices.

`AffineLieAlgebra(C, F)`

Construct the affine Kac-Moody Lie algebra with affine Cartan matrix C over the field F.

Example H101E2

We demonstrate the construction functions.

```
> L := AffineLieAlgebra("G~2", Rationals());
> L;
Affine Kac-Moody Lie algebra over Rational Field
> C := Matrix(Integers(),3,3,[2,-1,-1,-1,2,-1,-1,-1,2]);
> CartanName(C);
A~2
> L := AffineLieAlgebra(C, Rationals());
> L;
Affine Kac-Moody Lie algebra over Rational Field
```

101.3.2 Properties of Affine Kac-Moody Lie Algebras

`CartanMatrix(L)`

The Cartan matrix of L.

`CartanName(L)`

The Cartan type of L.

`Dimension(L)`

Infinity.

`CoefficientRing(L)`

The coefficient ring of L.

`FiniteLieAlgebra(L)`

The Lie algebra $\mathfrak{g}_0$ underlying L (see the Introduction, Section 101.1).

`LaurentSeriesRing(L)`

The Laurent series ring $\mathbf{C}[t, t^{-1}]$ underlying L (see the Introduction, Section 101.1).

`StandardGenerators(L)`

The standard generators of L. These are returned as three sequences, the first containing the e_i, the second containing the f_i, and the last containing the h_i. Note that the root usually labeled "0" occurs as the last element of each of these sequences.

Example H101E3

We demonstrate some properties of affine Lie algebras.

```
> L := AffineLieAlgebra("A~2", Rationals());
> L;
Affine Kac-Moody Lie algebra over Rational Field
> Lf := FiniteLieAlgebra(L);
> Lf;
Lie Algebra of dimension 8 with base ring Rational Field
> SemisimpleType(Lf);
A2
> e,f,h := StandardGenerators(L);
> e;
[ (0 0 0 0 0 1 0 0), (0 0 0 0 0 0 1 0), (t)*(1 0 0 0 0 0 0 0) ]
> F<e1,e2,e0,f1,f2,f0> := FreeLieAlgebra(Rationals(), 6);
> phi := hom<F -> L | e cat f>;
> phi(e1);
(0 0 0 0 0 1 0 0)
> phi(e1*e0) eq phi(e1)*phi(e0);
true
```

101.3.3 Constructing Elements of Affine Kac-Moody Lie Algebras

`L . i`

The i-th basis element of the finite dimensional Lie algebra underlying L, as an element of L.

`HasAttribute(L, "c")`

`HasAttribute(L, "d")`

Return `true` and the basis element c or d of L, according to the second argument of `HasAttribute`.

`elt< L | <[<`p_1, y_1`>, ...], `λ, μ`> >`

For a 3-tuple t such that t_1 is a sequence of elements of $\mathbf{C}[t, t^{-1}] \times \mathfrak{g}_0$, and t_2 and t_3 are elements of the coefficient ring of L, construct

$$\sum_{(p,y)\in t_1} p \otimes y \oplus t_2 c \oplus t_3 d \in L.$$

See EltTup below for the converse function.

101.3.4 Properties of Elements of Affine Kac-Moody Lie Algebras

`EltTup(x)`

The element x of the affine Lie algebra L as a three-tuple t such that

$$x = \sum_{(p,y)\in t_1} p \otimes y \oplus t_2 c \oplus t_3 d.$$

The first entry, t_1, is a sequence of pairs $(p, y) \in \mathbf{C}[t, t^{-1}] \times \mathfrak{g}_0$, t_2 is the coefficient of c and t_3 is the coefficient of d.

`IsZero(x)`

Whether x is zero.

`x eq y`

Whether x and y are equal.

`x + y`
`x - y`
`x * y`

Respectively the sum, difference, and multiplication of x and y.

`-x`

The negation of x.

Example H101E4

We perform various computations with elements of an affine Lie algebra.

```
> L<t> := AffineLieAlgebra("B~3", Rationals());
> Lf := FiniteLieAlgebra(L);
> e,f,h := StandardGenerators(L);
> E,F,H := StandardBasis(Lf);
> e[1] eq L!E[1];
true
> x := e[4];
> x;
(t)*(1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> EltTup(x);
<[
    <t, (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)>
], 0, 0>
> elt<L | EltTup(x) > eq x;
true
> y := elt<L | <[<t^2-t^-2, F[1]>,<-2,Lf.3>], -1/3, 1> >;
> y;
```

```
(-2)*(0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0) + (-t^-2 + t^2)*(0 0
0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0) -1/3*c + d
> z := t^3*L.2 - 1/5*h[1] + 1/7*L‘c-L‘d;
> z;
(t^3)*(0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0) + (2/5)*(0 0 0 0 0 0
0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0) (-1/5)*(0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0
0 0 0 0 0) + 1/7*c -1*d
> x*(y*z) + y*(z*x) + z*(x*y);
0
```

102 QUANTUM GROUPS

Chapter 102
QUANTUM GROUPS

102.1 Introduction

This chapter describes the functionality for quantum groups in MAGMA. First there are a few sections that briefly describe the theoretical background behind quantum groups (or, more precisely, quantized enveloping algebras). This fixes the notation and the terminology that we use (these vary somewhat in the literature). For this we mainly follow [Jan96]. In the remainder we describe the functions that exist in MAGMA for constructing and working with quantum groups and their representations.

In MAGMA, quantized enveloping algebras have type `AlgQUE` and their elements have type `AlgQUEElt`. These types inherit from `AlgPBW` and `AlgPBWElt` respectively, which are general types for algebras with a PBW basis and their elements and inherit from `GenMPolB`, `Alg` and `Rng` and their element types.

102.2 Background

102.2.1 Gaussian Binomials

Let v be an indeterminate over $\mathbf{Q}$. For a positive integer n we set

$$[n]_v = v^{n-1} + v^{n-3} + \cdots + v^{-n+3} + v^{-n+1}.$$

We say that $[n]_v$ is the *Gaussian integer* corresponding to n. The *Gaussian factorial* $[n]_v!$ is defined by

$$[0]_v! = 1,\ [n]_v! = [n]_v[n-1]_v \cdots [1]_v \text{ for } n > 0.$$

Finally, the *Gaussian binomial* is

$$\binom{n}{k}_v = \frac{[n]!}{[k]![n-k]!}.$$

102.2.2 Quantized Enveloping Algebras

Let L be a semisimple Lie algebra with root system Φ. By $\Delta = \{\alpha_1, \ldots, \alpha_l\}$ we denote a fixed set of simple roots of Φ. Let $C = (C_{ij})$ be the Cartan matrix of Φ (with respect to Δ, i.e., $C_{ij} = \langle \alpha_i, \alpha_j^\vee \rangle$). Let $d_1, \ldots, d_l$ be the unique sequence of positive integers with greatest common divisor 1, such that $d_i C_{ji} = d_j C_{ij}$, and set $(\alpha_i, \alpha_j) = d_j C_{ij}$. (We note that this implies that (α_i, α_i) is divisible by 2.) By P we denote the weight lattice, and we extend the form $(\ ,\ )$ to P by bilinearity.

By $W(\Phi)$ we denote the Weyl group of Φ. It is generated by the simple reflections $s_i = s_{\alpha_i}$ for $1 \leq i \leq l$ (where s_α is defined by $s_\alpha(\beta) = \beta - \langle \beta, \alpha^\vee \rangle \alpha$).

We work over the field $\mathbf{Q}(q)$. For $\alpha \in \Phi$ we set

$$q_\alpha = q^{\frac{(\alpha,\alpha)}{2}},$$

and for a non-negative integer n, $[n]_\alpha = [n]_{v=q_\alpha}$; $[n]_\alpha!$ and $\binom{n}{k}_\alpha$ are defined analogously.

The quantized enveloping algebra $U_q(L)$ is the associative algebra (with one) over $\mathbf{Q}(q)$ generated by F_α, K_α, K_α^{-1}, E_α for $\alpha \in \Delta$, subject to the following relations

$$\begin{aligned} K_\alpha K_\alpha^{-1} = K_\alpha^{-1} K_\alpha = 1,\ K_\alpha K_\beta &= K_\beta K_\alpha \\ E_\beta K_\alpha &= q^{-(\alpha,\beta)} K_\alpha E_\beta \\ K_\alpha F_\beta &= q^{-(\alpha,\beta)} F_\beta K_\alpha \\ E_\alpha F_\beta &= F_\beta E_\alpha + \delta_{\alpha,\beta} \frac{K_\alpha - K_\alpha^{-1}}{q_\alpha - q_\alpha^{-1}} \end{aligned}$$

together with, for $\alpha \neq \beta \in \Delta$,

$$\sum_{k=0}^{1-\langle \beta, \alpha^\vee \rangle} (-1)^k \binom{1 - \langle \beta, \alpha^\vee \rangle}{k}_\alpha E_\alpha^{1-\langle \beta, \alpha^\vee \rangle - k} E_\beta E_\alpha^k = 0$$

$$\sum_{k=0}^{1-\langle \beta, \alpha^\vee \rangle} (-1)^k \binom{1 - \langle \beta, \alpha^\vee \rangle}{k}_\alpha F_\alpha^{1-\langle \beta, \alpha^\vee \rangle - k} F_\beta F_\alpha^k = 0.$$

The quantized enveloping algebra has an automorphism ω defined by $\omega(F_\alpha) = E_\alpha$, $\omega(E_\alpha) = F_\alpha$ and $\omega(K_\alpha) = K_\alpha^{-1}$. Also there is an anti-automorphism τ defined by $\tau(F_\alpha) = F_\alpha$, $\tau(E_\alpha) = E_\alpha$ and $\tau(K_\alpha) = K_\alpha^{-1}$. We have $\omega^2 = 1$ and $\tau^2 = 1$.

If the Dynkin diagram of Φ admits a diagram automorphism π, then π induces an automorphism of $U_q(L)$ in the obvious way (π is a permutation of the simple roots; we permute the F_α, E_α, $K_\alpha^{\pm 1}$ accordingly).

Now we view $U_q(L)$ as an algebra over $\mathbf{Q}$, and we let $\overline{\ \ } : U_q(L) \to U_q(L)$ be the automorphism defined by $\overline{F_\alpha} = F_\alpha$, $\overline{K_\alpha} = K_\alpha^{-1}$, $\overline{E_\alpha} = E_\alpha$, $\overline{q} = q^{-1}$. This map is called the *bar-automorphism.*

102.2.3 Representations of $U_q(L)$

Let $\lambda \in P$ be a dominant weight. Then there is a unique irreducible highest-weight module over $U_q(L)$ with highest weight λ. We denote it by $V(\lambda)$. It has the same character as the irreducible highest-weight module over L with highest weight λ. Furthermore, every finite-dimensional $U_q(L)$-module is a direct sum of irreducible highest-weight modules. In [Gra04] a few algorithms for constructing $V(\lambda)$ are given. In the MAGMA implementation the algorithm based on Gröbner bases is used.

It is well-known that $U_q(L)$ is a Hopf algebra. The comultiplication $\Delta : U_q(L) \to U_q(L) \otimes U_q(L)$ is defined by

$$\begin{aligned}\Delta(E_\alpha) &= E_\alpha \otimes 1 + K_\alpha \otimes E_\alpha \\ \Delta(F_\alpha) &= F_\alpha \otimes K_\alpha^{-1} + 1 \otimes F_\alpha \\ \Delta(K_\alpha) &= K_\alpha \otimes K_\alpha.\end{aligned}$$

(Note that we use the same symbol (Δ) to denote a set of simple roots of Φ; of course this does not cause confusion.) The counit $\varepsilon : U_q(L) \to \mathbf{Q}(q)$ is a homomorphism defined by $\varepsilon(E_\alpha) = \varepsilon(F_\alpha) = 0$, $\varepsilon(K_\alpha) = 1$. Finally, the antipode $S : U_q(L) \to U_q(L)$ is an anti-automorphism given by $S(E_\alpha) = -K_\alpha^{-1}E_\alpha$, $S(F_\alpha) = -F_\alpha K_\alpha$, $S(K_\alpha) = K_\alpha^{-1}$.

Using Δ we can make the tensor product $V \otimes W$ of two $U_q(L)$-modules V, W into a $U_q(L)$-module. The counit ε yields a trivial 1-dimensional $U_q(L)$-module. And with S we can define a $U_q(L)$-module structure on the dual V^* of a $U_q(L)$-module V, by $(u \cdot f)(v) = f(S(u) \cdot v)$.

The Hopf algebra structure given above is not the only one possible. For example, we can twist Δ, ε, S by an automorphism, or an anti-automorphism f. The twisted comultiplication is given by

$$\Delta^f = f \otimes f \circ \Delta \circ f^{-1},$$

the twisted antipode by

$$S^f = f \circ S \circ f^{-1},$$

if f is an automorphism, and

$$S^f = f \circ S^{-1} \circ f^{-1},$$

if f is an anti-automorphism. The twisted counit is given by $\varepsilon^f = \varepsilon \circ f^{-1}$.

102.2.4 PBW-type Bases

The first problem one has to deal with when working with $U_q(L)$ is finding a basis of it, along with an algorithm for expressing the product of two basis elements as a linear combination of basis elements. First of all we have that $U_q(L) \cong U^- \otimes U^0 \otimes U^+$ (as vector spaces), where U^- is the subalgebra generated by the F_α, U^0 is the subalgebra generated by the K_α, and U^+ is generated by the E_α. So a basis of $U_q(L)$ is formed by all elements FKE, where F, K, E run through bases of U^-, U^0, U^+ respectively.

Finding a basis of U^0 is easy: it is spanned by all $K_{\alpha_1}^{r_1} \cdots K_{\alpha_l}^{r_l}$, where $r_i \in \mathbf{Z}$. For U^- and U^+ we use the so-called *PBW-type* bases. They are defined as follows. For $\alpha, \beta \in \Delta$

we set $r_{\beta,\alpha} = -\langle \beta, \alpha^\vee \rangle$. Then for $\alpha \in \Delta$ we have the automorphism $T_\alpha : U_q(L) \to U_q(L)$ defined by

$$\begin{aligned} T_\alpha(E_\alpha) &= -F_\alpha K_\alpha \\ T_\alpha(E_\beta) &= \sum_{i=0}^{r_{\beta,\alpha}} (-1)^i q_\alpha^{-i} E_\alpha^{(r_{\beta,\alpha}-i)} E_\beta E_\alpha^{(i)}, \ (\alpha \neq \beta) \\ T_\alpha(K_\beta) &= K_\beta K_\alpha^{r_{\beta,\alpha}} \\ T_\alpha(F_\alpha) &= -K_\alpha^{-1} E_\alpha \\ T_\alpha(F_\beta) &= \sum_{i=0}^{r_{\beta,\alpha}} (-1)^i q_\alpha^{i} F_\alpha^{(i)} F_\beta F_\alpha^{(r_{\beta,\alpha}-i)}, \ (\alpha \neq \beta) \end{aligned}$$

(where $E_\alpha^{(k)} = E_\alpha^k/[k]_\alpha!$, and likewise for $F_\alpha^{(k)}$).

Let $w_0 = s_{i_1} \cdots s_{i_t}$ be a reduced expression for the longest element in the Weyl group $W(\Phi)$. For $1 \leq k \leq t$ set $F_k = T_{\alpha_{i_1}} \cdots T_{\alpha_{i_{k-1}}}(F_{\alpha_{i_k}})$, and $E_k = T_{\alpha_{i_1}} \cdots T_{\alpha_{i_{k-1}}}(E_{\alpha_{i_k}})$. Then $F_k \in U^-$, and $E_k \in U^+$. Furthermore, the elements $F_1^{m_1} \cdots F_t^{m_t}$, $E_1^{n_1} \cdots E_t^{n_t}$ (where the m_i, n_i are non-negative integers) form bases of U^- and U^+ respectively.

The elements F_α and E_α are said to have weight $-\alpha$ and α respectively, where α is a simple root. Furthermore, the weight of a product ab is the sum of the weights of a and b. Now elements of U^-, U^+ that are linear combinations of elements of the same weight are said to be homogeneous. It can be shown that the elements F_k, and E_k are homogeneous of weight $-\beta$ and β respectively, where $\beta = s_{i_1} \cdots s_{i_{k-1}}(\alpha_{i_k})$.

In the following we use the notation $F_k^{(m)} = F_k^m/[m]_{\alpha_{i_k}}!$, and $E_k^{(n)} = E_k^n/[n]_{\alpha_{i_k}}!$.

We refer to [Gra01] for an account of algorithms for expressing the product of two elements of a PBW-type basis as a linear combination of such elements. These algorithms are implemented in Magma.

102.2.5 The Z-form of $U_q(L)$

For $\alpha \in \Delta$ set

$$\binom{K_\alpha}{n} = \prod_{i=1}^{n} \frac{q_\alpha^{-i+1} K_\alpha - q_\alpha^{i-1} K_\alpha^{-1}}{q_\alpha^i - q_\alpha^{-i}}.$$

Then according to [Lus90], Theorem 6.7 the elements

$$F_1^{(k_1)} \cdots F_t^{(k_t)} K_{\alpha_1}^{\delta_1} \binom{K_{\alpha_1}}{m_1} \cdots K_{\alpha_l}^{\delta_l} \binom{K_{\alpha_l}}{m_l} E_1^{(n_1)} \cdots E_t^{(n_t)},$$

(where $k_i, m_i, n_i \geq 0$, $\delta_i = 0, 1$) form a basis of $U_q(L)$, such that the product of any two basis elements is a linear combination of basis elements with coefficients in $\mathbf{Z}[q, q^{-1}]$. The quantized enveloping algebra over $\mathbf{Z}[q, q^{-1}]$ with this basis is called the $\mathbf{Z}$-form of $U_q(L)$, and denoted by $U_{\mathbf{Z}}$. Since $U_{\mathbf{Z}}$ is defined over $\mathbf{Z}[q, q^{-1}]$ we can specialize q to any nonzero element ϵ of a field F, and obtain an algebra U_ϵ over F. In particular, if we take $\epsilon = 1$, then we obtain an algebra U_1 over $\mathbf{Q}$. Let I be the ideal of U_1 generated by $K_{\alpha_1} - 1, \ldots, K_{\alpha_l} - 1$. Then U_1/I is isomorphic to the universal enveloping algebra $U(L)$

of L. Also, the homomorphism $U_q(L) \to U(L)$ maps the basis above onto an integral basis of $U(L)$ ([Lus90]).

We call $q \in \mathbf{Q}(q)$, and $\epsilon \in F$ the quantum parameter of $U_q(L)$ and U_ϵ respectively.

102.2.6 The Canonical Basis

As in Section 102.2.4 we let U^- be the subalgebra of $U_q(L)$ generated by the F_α for $\alpha \in \Delta$. Kashiwara and Lusztig have (independently) given constructions of a basis of U^- with very nice properties, called the *canonical basis*.

Let $w_0 = s_{i_1} \cdots s_{i_t}$, and the elements F_k be as in Section 102.2.4. Then, in order to stress the dependency of the monomial

$$F_1^{(n_1)} \cdots F_t^{(n_t)}$$

on the choice of reduced expression for the longest element in $W(\Phi)$ we say that it is a w_0-monomial. The integer n_1 is called its first exponent.

Now we let $^-$ be the automorphism of U^- defined in Section 102.2.2. Elements that are invariant under $^-$ are said to be bar-invariant.

By results of Lusztig ([Lus93], Theorem 42.1.10, [Lus96], Proposition 8.2), there is a unique basis $\mathbf{B}$ of U^- with the following properties. Firstly, all elements of $\mathbf{B}$ are bar-invariant. Secondly, for any choice of reduced expression w_0 for the longest element in the Weyl group, and any element $X \in \mathbf{B}$ we have that $X = x + \sum_i \zeta_i x_i$, where x, x_i are w_0-monomials, $x \neq x_i$ for all i, and $\zeta_i \in q\mathbf{Z}[q]$. The basis $\mathbf{B}$ is called the canonical basis. If we work with a fixed reduced expression for the longest element in $W(\Phi)$, and write $X \in \mathbf{B}$ as above, then we say that x is the *principal monomial* of X.

Let $\mathcal{L}$ be the $\mathbf{Z}[q]$-lattice in U^- spanned by $\mathbf{B}$. Then $\mathcal{L}$ is also spanned by all w_0-monomials (where w_0 is a fixed reduced expression for the longest element in $W(\Phi)$).

Now let $\widetilde{w}_0$ be a second reduced expression for the longest element in $W(\Phi)$. Let x be a w_0-monomial, and let X be the element of $\mathbf{B}$ with principal monomial x. Write X as a linear combination of $\widetilde{w}_0$-monomials, and let $\widetilde{x}$ be the principal monomial of that expression. Then we write $\widetilde{x} = R_{w_0}^{\widetilde{w}_0}(x)$. Note that $x = \widetilde{x} \bmod q\mathcal{L}$.

Now let $\mathcal{B}$ be the set of all $x \bmod q\mathcal{L}$, where x runs through the set of w_0-monomials. Then $\mathcal{B}$ is a basis of the $\mathbf{Z}$-module $\mathcal{L}/q\mathcal{L}$. Moreover, $\mathcal{B}$ is independent of the choice of w_0. Let $\alpha \in \Delta$, and let $\widetilde{w}_0$ be a reduced expression for the longest element in $W(\Phi)$, starting with s_α. The Kashiwara operators $\widetilde{F}_\alpha : \mathcal{B} \to \mathcal{B}$ and $\widetilde{E}_\alpha : \mathcal{B} \to \mathcal{B} \cup \{0\}$ are defined as follows. Let $b \in \mathcal{B}$ and let x be the w_0-monomial such that $b = x \bmod q\mathcal{L}$. Set $\widetilde{x} = R_{w_0}^{\widetilde{w}_0}(x)$. Let $\widetilde{x}'$ be the $\widetilde{w}_0$-monomial constructed from $\widetilde{x}$ by increasing its first exponent by 1. Then $\widetilde{F}_\alpha(b) = R_{\widetilde{w}_0}^{w_0}(\widetilde{x}') \bmod q\mathcal{L}$. For $\widetilde{E}_\alpha$ we let $\widetilde{x}'$ be the $\widetilde{w}_0$-monomial constructed from $\widetilde{x}$ by decreasing its first exponent by 1, if this exponent is ≥ 1. Then $\widetilde{E}_\alpha(b) = R_{\widetilde{w}_0}^{w_0}(\widetilde{x}') \bmod q\mathcal{L}$. Furthermore, $\widetilde{E}_\alpha(b) = 0$ if the first exponent of $\widetilde{x}$ is 0. It can be shown that this definition does not depend on the choice of w_0, $\widetilde{w}_0$. Furthermore we have $\widetilde{F}_\alpha \widetilde{E}_\alpha(b) = b$, if $\widetilde{E}_\alpha(b) \neq 0$, and $\widetilde{E}_\alpha \widetilde{F}_\alpha(b) = b$ for all $b \in \mathcal{B}$.

Now let $V(\lambda)$ be a highest-weight module over $U_q(L)$, with highest weight λ. Let v_λ be a fixed highest weight vector. Then $\mathbf{B}_\lambda = \{X \cdot v_\lambda \mid X \in \mathbf{B}\} \setminus \{0\}$ is a basis of $V(\lambda)$,

called the *canonical basis* of $V(\lambda)$. Let $\mathcal{L}(\lambda)$ be the $\mathbf{Z}[q]$-lattice in $V(\lambda)$ spanned by $\mathbf{B}_\lambda$. We let $\mathcal{B}(\lambda)$ be the set of all $x \cdot v_\lambda \bmod q\mathcal{L}(\lambda)$, where x runs through all w_0-monomials, such that $X \cdot v_\lambda \neq 0$, where $X \in \mathbf{B}$ is the element with principal monomial x. Then the Kashiwara operators are also viewed as maps $\mathcal{B}(\lambda) \to \mathcal{B}(\lambda) \cup \{0\}$, in the following way. Let $b = x \cdot v_\lambda \bmod q\mathcal{L}(\lambda)$ be an element of $\mathcal{B}(\lambda)$, and let $b' = x \bmod q\mathcal{L}$ be the corresponding element of $\mathcal{B}$. Let y be the w_0-monomial such that $\widetilde{F}_\alpha(b') = y \bmod q\mathcal{L}$. Then $\widetilde{F}_\alpha(b) = y \cdot v_\lambda \bmod q\mathcal{L}(\lambda)$. The description of $\widetilde{E}_\alpha$ is analogous. (In [Jan96], Chapter 9 a different definition is given; however, by [Jan96], Proposition 10.9, Lemma 10.13, the two definitions agree).

The set $\mathcal{B}(\lambda)$ has $\dim V(\lambda)$ elements. We let Γ be the coloured directed graph defined as follows. The points of Γ are the elements of $\mathcal{B}(\lambda)$, and there is an arrow with colour $\alpha \in \Delta$ connecting $b, b' \in \mathcal{B}$, if $\widetilde{F}_\alpha(b) = b'$. The graph Γ is called the *crystal graph* of $V(\lambda)$.

In [Gra02] algorithms are given for computing the action of the Kashiwara operators on $\mathcal{B}$ (without computing $\mathbf{B}$ first), and for computing elements of $\mathbf{B}$.

102.2.7 The Path Model

In this section we recall some basic facts on Littelmann's path model.

From Section 102.2.2 we recall that P denotes the weight lattice. Let P_R be the vector space over R spanned by P. Let Π be the set of all piecewise linear paths $\xi : [0,1] \to P_R$, such that $\xi(0) = 0$. For $\alpha \in \Delta$ Littelmann defined *path operators* $f_\alpha, e_\alpha : \Pi \to \Pi \cup \{0\}$. Let λ be a dominant weight and let ξ_λ be the path joining λ and the origin by a straight line. Let Π_λ be the set of all nonzero $f_{\alpha_{i_1}} \cdots f_{\alpha_{i_m}}(\xi_\lambda)$ for $m \geq 0$. Then $\xi(1) \in P$ for all $\xi \in \Pi_\lambda$. Let $\mu \in P$ be a weight, and let $V(\lambda)$ be the highest-weight module over $U_q(L)$ of highest weight λ. A theorem of Littelmann states that the number of paths $\xi \in \Pi_\lambda$ such that $\xi(1) = \mu$ is equal to the dimension of the weight space of weight μ in $V(\lambda)$ ([Lit95], Theorem 9.1).

All paths appearing in Π_λ are so-called Lakshmibai–Seshadri paths (LS-paths for short). They are defined as follows. Let $\leq$ denote the Bruhat order on $W(\Phi)$. For $\mu, \nu \in W(\Phi) \cdot \lambda$ (the orbit of λ under the action of $W(\Phi)$), write $\mu \leq \nu$ if $\tau \leq \sigma$, where $\tau, \sigma \in W(\Phi)$ are the unique elements of minimal length such that $\tau(\lambda) = \mu$, $\sigma(\lambda) = \nu$. Now a rational path of shape λ is a pair $\pi = (\nu, a)$, where $\nu = (\nu_1, \ldots, \nu_s)$ is a sequence of elements of $W(\Phi) \cdot \lambda$, such that $\nu_i > \nu_{i+1}$ and $a = (a_0 = 0, a_1, \cdots, a_s = 1)$ is a sequence of rationals such that $a_i < a_{i+1}$. The path π corresponding to these sequences is given by

$$\pi(t) = \sum_{j=1}^{r-1} (a_j - a_{j-1})\nu_j + \nu_r(t - a_{r-1})$$

for $a_{r-1} \leq t \leq a_r$. Now an LS-path of shape λ is a rational path satisfying a certain integrality condition (see [Lit94], [Lit95]). We note that the path $\xi_\lambda = ((\lambda), (0,1))$ joining the origin and λ by a straight line is an LS-path of shape λ. Furthermore, all paths obtained from ξ_λ by applying the path operators are LS-paths of shape λ.

From [Lit94], [Lit95]) we transcribe the following:

(a) Let π be an LS-path. Then $f_\alpha \pi$ is an LS-path or 0; and the same holds for $e_\alpha \pi$.

(b) The action of f_α, e_α can easily be described combinatorially (see [Lit94]).

(c) The endpoint of an LS-path is an integral weight.

(d) Let $\pi = (\nu, a)$ be an LS-path. Then by $\phi(\pi)$ we denote the unique element σ of $W(\Phi)$ of shortest length such that $\sigma(\lambda) = \nu_1$.

Let λ be a dominant weight. Then we define a labeled directed graph Γ as follows. The points of Γ are the paths in Π_λ. There is an edge with label $\alpha \in \Delta$ from π_1 to π_2 if $f_\alpha \pi_1 = \pi_2$. Now by [Kas96] this graph Γ is isomorphic to the crystal graph of the highest-weight module with highest weight λ. So the path model provides an efficient way of computing the crystal graph of a highest-weight module, without constructing the module first. Also we see that $f_{\alpha_{i_1}} \cdots f_{\alpha_{i_r}} \xi_\lambda = 0$ is equivalent to $\widetilde{F}_{\alpha_{i_1}} \cdots \widetilde{F}_{\alpha_{i_r}} v_\lambda = 0$, where $v_\lambda \in V(\lambda)$ is a highest weight vector (or rather the image of it in $\mathcal{L}(\lambda)/q\mathcal{L}(\lambda)$), and the $\widetilde{F}_{\alpha_k}$ are the Kashiwara operators on $\mathcal{B}(\lambda)$ (see Section 102.2.6).

102.3 Gauss Numbers

`GaussNumber(n, v)`

Given an integer n and a ring element v, this function returns the Gauss number corresponding to n with parameter v, i.e., the element $[n]_v = v^{n-1} + v^{n-3} + \cdots + v^{-n+3} + v^{-n+1}$.

`GaussianFactorial(n, v)`

Given an integer n and a ring element v, this function returns the Gaussian factorial corresponding to n with parameter v, i.e., the element $[n]_v! = [n]_v[n-1]_v \cdots [1]_v$.

`GaussianBinomial(n, k, v)`

Given an integer n, an integer k and a ring element v, this function returns the Gaussian binomial n choose k with parameter v, i.e., the element $[n]_v!/([k]_v![n-k]_v!)$.

Example H102E1

```
> F<q>:= RationalFunctionField(Rationals());
> GaussianBinomial(5, 3, q^2);
(q^24 + q^20 + 2*q^16 + 2*q^12 + 2*q^8 + q^4 + 1)/q^12
```

102.4 Construction

`QuantizedUEA(R)`

`QuantizedUEAlgebra(R)`

`QuantizedUniversalEnvelopingAlgebra(R)`

This creates the quantized enveloping algebra U corresponding to the root datum R. The algebra U will be defined over the rational function field in one variable, q, over the rational numbers.

Let n and r respectively be the number of positive roots, and the rank of R. Then U has $2n+r$ generators, accessible as `U.1`, `U.2` and so on. The first n of these are printed as `F_1`, ... , `F_n`. They generate a PBW-type basis of the subalgebra U^- (cf. Section 102.2.4). The next r generators are printed as `K_1`, ... , `K_r`; together with their inverses they generate the algebra U^0. The final n generators are printed as `E_1`, ... , `E_n`. They generate a PBW-type basis of U^+.

In U we use a basis of the integral form of U (Section 102.2.5). This means that instead of F_k^s and E_k^s we use the divided powers $F_k^{(s)}$ and $E_k^{(s)}$. Furthermore, a general basis element of U^0 is a product of elements which are of the form $[K_i;t]$, or $K_i[K_i;t]$. Here $[K_i;t]$ represents the "binomial" K_i choose t as described in Section 102.2.5.

`w0` SeqEnum *Default :*

It is also possible to give a reduced expression for the longest element in the Weyl group, by setting the optional parameter `w0` equal to a sequence of indices lying between 1 and the rank of R. If we replace each index by the corresponding simple reflection, then a reduced expression for the longest element in the Weyl group has to be obtained. In that case the PBW-basis relative to that sequence will be created (and used in subsequent computations). If this parameter is not given, then the lexicographically smallest reduced expression will be used.

Example H102E2

We construct the quantum group corresponding to the root datum of type C_3.

```
> R:= RootDatum("C3");
> U:= QuantizedUEA(R);
> U.9; U.10; U.15;
F_9
K_1
E_3
> U.21*U.14*U.10*U.9*U.1;
1/q*F_1*F_9*K_1*E_2*E_9 - 1/q*F_1*F_9*K_1*E_6 + 1/q^3*F_1*K_1*[ K_3 ; 1 ]*E_2 -
    F_9*E_3*E_9 + F_9*E_8 - 1/q^2*[ K_3 ; 1 ]*E_3
```

Now we construct the same algebra, but use the PBW-basis relative to a different reduced expression of the longest element in the Weyl group.

```
> U:= QuantizedUEA(R : w0:= [2,3,1,2,3,1,2,3,1]);
```

```
> U.21*U.14*U.10*U.9*U.1;
q^2*F_1*F_9*K_1*E_2*E_9 + (q^2 - 1)/q^3*F_9*K_1*[ K_2 ; 1 ]*E_6*E_9 -
    1/q^2*F_9*K_1*K_2*E_6*E_9 - q^2*F_1*F_9*K_1*E_4 + q^2*F_1*K_1[ K_1 ; 1 ]*E_2 +
    q*F_3*K_1*E_2*E_9 + (-q^2 + 1)/q^3*F_9*K_1*[ K_2 ; 1 ]*E_7 +
    1/q^2*F_9*K_1*K_2*E_7 + (q^2 - 1)/q*K_1[ K_1 ; 1 ]*[ K_2 ; 1 ]*E_6
    - K_1[ K_1 ; 1 ]*K_2*E_6 - q*F_3*K_1*E_4 + q*F_1*E_2
```

`AssignNames(U, S)`

Assign the names in the sequence S to the generators of the algebra U.

`ChangeRing(U, R)`

Return the algebra identical to the algebra U but having coefficient ring R.

102.5 Related Structures

`CoefficientRing(U)`

This returns the ring of coefficients of the quantized enveloping algebra U.

`RootDatum(U)`

This returns the root datum corresponding to the quantized enveloping algebra U.

`PositiveRootsPerm(U)`

Given a quantized universal enveloping algebra U with root datum R returns a sequence consisting of the integers between 1 and the number of positive roots of R. If the k-th element of this sequence is m, then the generator F_k of U is of weight $-\beta_m$, where β_m is the m-th positive root of R (as returned by `PositiveRoots(R)`). (For the definition of weight of an element of U see Section 102.2.4.) Furthermore, the generator E_k is of weight β_m.

Example H102E3

```
> R:= RootDatum("D4");
> U:= QuantizedUEA(R);
> CoefficientRing(U);
Univariate rational function field over Rational Field
Variables: q
> RootDatum(U);
Adjoint root datum of type D4
> PositiveRootsPerm(U);
[ 1, 5, 2, 8, 6, 3, 12, 11, 9, 10, 7, 4 ]
```

So for instance this means that F_6 is of weight $-\beta_3$.

102.6 Operations on Elements

The generators of a quantized enveloping algebra U can be constructed by using the dot operator, e.g., `U.5`. More general elements can then be constructed using the operations of scalar multiplication, addition, and multiplication.

Note that for the generators denoted F_k and E_k we use divided powers instead of normal powers. This means for instance that $F_k^s = [s]!F_k^{(s)}$, i.e., exponentiation causes multiplication by a scalar factor.

`x + y` `x - y` `x * y` `c * x` `x * c` `x ^ n`

`U ! 0`
`Zero(U)`

The zero element of the quantized enveloping algebra U.

`U ! 1`
`One(U)`

The identity element of the quantized enveloping algebra U.

`U . i`

The i-th generator of the quantized enveloping algebra U. Let the root datum have s positive roots and rank r. If $1 \leq i \leq s$ then `U.i` is F_i. If $s+1 \leq i \leq s+r$, then `U.i` is K_j where $j = i - s$. If $s + r + 1 \leq i \leq 2s + r$ then `U.i` is E_j, where $j = i - s - r$.

`U ! r`

Returns r as an element of the quantized universal enveloping algebra U where r may be anything coercible into the coefficient ring of U or an element of another quantized enveloping algebra whose coefficients may be coerced into the coefficient ring of U.

`KBinomial(U, i, s)`
`KBinomial(K, s)`

Given a quantized enveloping algebra U corresponding to a root datum of rank r, an integer i between 1 and r, and a positive integer s, return the element $[K_i; s]$. This can be used to construct general elements in the subalgebra U^0 (cf. Section 102.2.4).

Or given an element $K = K_i$, i.e., equal to `U.(n+i)`, where n is the number of positive roots of the root datum, return $[K; s]$.

`Monomials(u)`

Given an element u of a quantized enveloping algebra, returns the sequence consisting of the monomials of u. This sequence corresponds exactly to the one returned by `Coefficients(u)`.

`Coefficients(u)`

Given an element u of a quantized enveloping algebra, returns the sequence consisting of the coefficients of the monomials that occur in u. This sequence corresponds exactly to the one returned by `Monomials(u)`.

`K ^ -1`

Given a generator K of a quantized enveloping algebra U of the form K_i, i.e., it is equal to `U.k`, for some $n+1 \leq k \leq n+r$ where U corresponds to a root datum of rank r with n positive roots, return the inverse of K.

`Degree(u, i)`

Given an element u of a quantized enveloping algebra U and an integer $1 \leq i \leq n$ or $n+r+1 \leq i \leq 2n+r$, where the root datum corresponding to U has n positive roots and rank r (i.e., `U.i` is equal to F_i or to E_k, where $k = i-n-r$), return the degree of u in the generator F_i if $1 \leq i \leq n$, otherwise return the degree of u in the generator E_k, where $k = i-n-r$.

`KDegree(m, i)`

Given a single monomial m in a quantized enveloping algebra and an integer $1 \leq i \leq r$, where r is the rank of the corresponding root datum return a tuple of 2 integers, where the first is 0 or 1, and the second is non-negative. Denote this tuple by $\langle d, k \rangle$. If $d = 0$ then the factor $[K_i; k]$ occurs in the monomial m. If $d = 1$, then the factor $K_i[K_i; k]$ occurs in the monomial m.

Example H102E4

```
> R:= RootDatum("G2");
> U:= QuantizedUEA(R);
> u:= U.10*U.7^3*U.1;
> m:= Monomials(u); m;
[
    F_1*K_1[ K_1 ; 2 ]*E_2,
    F_1*[ K_1 ; 1 ]*E_2,
    F_1*K_1*E_2,
    K_1[ K_1 ; 1 ]*E_3,
    E_3
]
> Coefficients(u);
[
    (q^6 - q^4 - q^2 + 1)/q^17,
    (q^2 - 1)/q^14,
    1/q^15,
    (-q^2 + 1)/q^9,
    -1/q^8
]
> Degree(m[1], 1);
```

```
1
> Degree(m[1], 9);
0
> Degree(m[1], 10);
1
> KDegree(m[1], 1);
<1, 2>
> U.7^-1;
(-q^2 + 1)/q*[ K_1 ; 1 ] + K_1
> U.7*U.7^-1;
1
```

102.7 Representations

In this section we describe some functions for working with left-modules over quantized enveloping algebras. For a general introduction into algebra modules in MAGMA we refer to Chapter 89.

`HighestWeightRepresentation(U, w)`

Given a quantized enveloping algebra U corresponding to a root datum of rank r and a sequence w of non-negative integers of length r, returns the irreducible representation of U with highest weight w. The object returned is a function which given an element of U computes its matrix.

`HighestWeightModule(U, w)`

Given a quantized enveloping algebra U corresponding to a root datum of rank r and a sequence w of non-negative integers of length r, returns the irreducible U-module with highest weight w. The object returned is a left module over U.

Example H102E5

```
> R:= RootDatum("G2");
> U:= QuantizedUEA(R);
> f:= HighestWeightRepresentation(U, [1,1]);
> f(U.6);
[ 0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0]
[ 0  1  0  0  0  0  0]
[ 0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0]
[ 0  0  0  0 -q  0  0]
[ 0  0  0  0  0  0  0]
> M:= HighestWeightModule(U, [1,0]);
> U.6^M.5;
(0  0  0  0  0 -q  0)
```

`WeightsAndVectors(V)`

For a module V over a quantized universal enveloping algebra this returns two sequences. The first sequence consists of the weights that occur in V. The second sequence is a sequence of sequences of elements of V, in bijection with the first sequence. The i-th element of the second sequence consists of a basis of the weight space of weight equal to the i-th weight of the first sequence.

`HighestWeightsAndVectors(V)`

This function is analogous to the previous one. Except in this case the first sequence consists of highest weights, i.e., those weights which occur as highest weights of an irreducible constituent of V. The second sequence consists of sequences that contain the corresponding highest weight vectors. So the submodules generated by the vectors in the second sequence form a direct sum decomposition of V.

`CanonicalBasis(V)`

Given a (left-) module V over a quantized universal enveloping algebra, returns the canonical basis of V. If V is not irreducible, then the union of the canonical bases of the irreducible components of V is returned.

Example H102E6

```
> U:= QuantizedUEA(RootDatum("B2"));
> V:= HighestWeightModule(U, [1,0]);
> C:= CanonicalBasis(V); C;
[
    V: (1 0 0 0 0),
    V: (0 1 0 0 0),
    V: (0 0 1 0 0),
    V: (0 0 0 1 0),
    V: (    0      0      0      0 -1/q^2)
]
```

We can compute the action of elements of U with respect to the canonical basis by using `ModuleWithBasis`:

```
> M:= ModuleWithBasis(C);
> ActionMatrix(M, U.1);
[0 0 0 0 0]
[1 0 0 0 0]
[0 0 0 0 0]
[0 0 0 0 0]
[0 0 0 1 0]
```

`TensorProduct(Q)`

Given a sequence Q of left-modules over a quantized universal enveloping algebra, returns the module M that is the tensor product of the elements of Q. It also returns a map from the Cartesian product of the elements of Q to M. This maps a tuple t to the element of M that is formed by tensoring the elements of t.

Example H102E7

```
> U:= QuantizedUEA(RootDatum("B2"));
> v1:= HighestWeightModule(U, [1,0]);
> V1:= HighestWeightModule(U, [1,0]);
> V2:= HighestWeightModule(U, [0,1]);
> W, f:= TensorProduct([V1,V2]);
> Dimension(W);
20
> HighestWeightsAndVectors(W);
[
    (1 1),
    (0 1)
]
[
    [
        W: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ],
    [
        W: (0   0   1   0   0   q^4   0   0   -q^7/(q^2 + 1)   0   0   0   0   0
            0   0   0   0   0   0)
    ]
]
> f(<V1.2,V2.4>);
W: (0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0)
```

So in particular we see that $V1 \otimes V2$ is the direct sum of two irreducible modules, one with highest weight $(1, 1)$, the other with highest weight $(0, 1)$. The corresponding highest-weight vectors are also given.

102.8 Hopf Algebra Structure

In this section we describe the functions for working with the Hopf algebra structure of a quantized universal enveloping algebra (cf. Section 102.2.3).

`UseTwistedHopfStructure(U, f, g)`

The Hopf algebra structure that is used by default is the one described in Section 102.2.3. As explained in that same section, it is possible to twist this by an automorphism, or an antiautomorphism.

Given a quantized universal enveloping algebra U and (anti-) automorphisms f and g of U where g is the inverse of f (this is not checked by MAGMA) set U to use the corresponding twisted Hopf algebra structure.

This command has to be given before using the Hopf algebra structure, otherwise the default structure will be used. This includes creating a tensor product.

For some (anti-) automorphisms we refer to Section 102.9.

`HasTwistedHopfStructure(U)`

This function checks whether the quantized enveloping algebra U has been set to use a twisted Hopf structure. If the first value returned by this function is `true`, then the (anti-) automorphism and its inverse are also returned.

`Counit(U)`

Returns the counit of the quantized enveloping algebra U. It is a map from U into the ground field of U.

`Antipode(U)`

Returns the antipode of the quantized enveloping algebra U. It is an antiautomorphism of U.

`Comultiplication(U, d)`

Returns the comultiplication of degree d of the quantized enveloping algebra U. This is a map from U into the d-fold tensor power of U. The comultiplication given in Section 102.2.3 is of degree 2. The comultiplications of higher degree are obtained by repeating this map. So in particular, d has to be at least 2.

An element of the d-fold tensor power of U is represented (rather primitively) by a list of d-tuples, each followed by a coefficient. The d-tuples are d-tuples of basis elements of U. The element represented by this list is the sum of the elements obtained by multiplying the i-th coefficient and the tensor product of the elements in the i-th d-tuple.

Example H102E8

```
> U:= QuantizedUEA(RootDatum("A3"));
> d:= Comultiplication(U, 2);
> d(U.1);
[*
<1, F_1>,
1,
<F_1, K_1>,
1,
<F_1, [ K_1 ; 1 ]>,
(-q^2 + 1)/q
*]
```

102.9 Automorphisms

`BarAutomorphism(U)`

For a quantized enveloping algebra U this returns the bar-automorphism of U (Section 102.2.2). The map returned by this function has its inverse stored, which can be retrieved using `Inverse`.

`AutomorphismOmega(U)`

For a quantized enveloping algebra U this returns the automorphism of U that is denoted by ω (Section 102.2.2). The map returned by this function has its inverse stored, which can be retrieved using `Inverse`.

`AntiAutomorphismTau(U)`

For a quantized enveloping algebra U this returns the anti-automorphism of U that is denoted by τ (Section 102.2.2). The map returned by this function has its inverse stored, which can be retrieved using `Inverse`.

`AutomorphismTalpha(U, k)`

Let U be a quantized enveloping algebra, and let k be an integer between 1 and the rank of the root datum. Then this function returns the automorphism T_{α_k} of U, corresponding to the k-th simple root (Section 102.2.4). The map returned by this function has its inverse stored, which can be retrieved using `Inverse`.

`DiagramAutomorphism(U, p)`

`GraphAutomorphism(U, p)`

Let U be a quantized enveloping algebra, and let p be a permutation of $\{1, \ldots, r\}$, where r is the rank of the root datum. Here p must represent a diagram automorphism of the root datum (i.e., it leaves the Dynkin diagram invariant). Then this function returns the corresponding automorphism of U (see Section 102.2.2). The map returned by this function has its inverse stored, which can be retrieved using `Inverse`.

Example H102E9

```
> R:= RootDatum("G2");
> U:= QuantizedUEA(R);
> b:= BarAutomorphism(U);
> b(U.3);
(q^10 - q^6 - q^4 + 1)/q^4*F_1^(2)*F_6 + (q^4 - 1)/q^2*F_1*F_5 + F_3
```

A known result states that $T_{\alpha_r}^{-1} = \tau \circ T_{\alpha_r} \circ \tau$. We check that for the quantum group of type C_3, and the third simple root.

```
> U:= QuantizedUEA(RootDatum("C3"));
> t:= AntiAutomorphismTau(U);
> T:= AutomorphismTalpha(U, 3);
> Ti:= Inverse(T);
> f:= t*T*t;
> &and[ Ti(U.i) eq f(U.i) : i in [1..21] ];
true
```

A diagram automorphism maps the canonical basis into itself. We check that for the set of elements of the canonical basis of the quantized enveloping algebra of type D_4 of weight $\alpha_1 + 3\alpha_2 + 2\alpha_3 + 2\alpha_4$. (Here α_i is the i-th simple root.) The chosen diagram automorphism maps this weight to $2\alpha_1 + 3\alpha_2 + \alpha_3 + 2\alpha_4$. Therefore we also compute the elements of the canonical basis of that weight.

```
> U:= QuantizedUEA(RootDatum("D4"));
> p:= SymmetricGroup(4)!(1,3,4);
> d:= DiagramAutomorphism(U, p);
> e1:= CanonicalElements(U, [1,3,2,2]);
> e2:= CanonicalElements(U, [2,3,1,2]);
> &and[ d(x) in e2 : x in e1 ];
true
```

102.10 Kashiwara Operators

`Falpha(m, i)`

Given a monomial m in U^- for some quantized enveloping algebra U, i.e., m must be a monomial in the first n generators of U, where n is the number of positive roots of the corresponding root datum, returns another monomial in the negative part of U that is obtained by applying the i-th Kashiwara operator $\tilde{F}_i$ to m (see Section 102.2.6). Here i must lie between 1 and the rank of the root datum.

`Ealpha(m, i)`

Given a monomial m in U^- for some quantized enveloping algebra U, i.e., m must be a monomial in the first n generators of U, where n is the number of positive roots of the corresponding root datum, return $\tilde{E}_i(m)$ (see Section 102.2.6) if the i-th Kashiwara operator $\tilde{E}_i$ is applicable to m. Otherwise the zero element of U is returned. Here i must lie between 1 and the rank of the root datum.

Example H102E10

```
> R:= RootDatum("F4");
> U:= QuantizedUEA(R);
> m:= U.1*U.5*U.10*U.18*U.24;
> m;
F_1*F_5*F_10*F_18*F_24
> Falpha(m, 3);
F_1*F_6*F_7*F_10*F_18*F_24
> Ealpha(m, 4);
F_1*F_4*F_5*F_7*F_9*F_18*F_24
> Ealpha(m, 2);
0
```

102.11 The Path Model

In this section we describe functions for working with Littelmann's path model (cf. Section 102.2.7). A special role is played by the zero path. The path operators cannot be applied to the zero path. However, on some occasions they do produce the zero path.

`DominantLSPath(R, hw)`

Given a root datum R and a sequence hw of non-negative integers returns the path that is the straight line from the origin to hw.

`Falpha(p, i)`

Given a (non-zero) path p and an integer i between 1 and the rank of the root datum returns the result of applying the path operator f_{α_i} to p (where α_i is the i-th simple root).

`Ealpha(p, i)`

Given a (non-zero) path p and an integer i between 1 and the rank of the root datum returns the result of applying the path operator e_{α_i} to p (where α_i is the i-th simple root).

`WeightSequence(p)`

For a path p this returns the sequence of weights that, along with the sequence of rational numbers, defines the path (cf. Section 102.2.7).

`RationalSequence(p)`

For a path p this returns the sequence of rational numbers that, along with the sequence of weights, defines the path (cf. Section 102.2.7).

`EndpointWeight(p)`

Returns the weight which is the end point of the path p.

`Shape(p)`

Returns the weight which is the shape of the path p.

`WeylWord(p)`

Returns a reduced expression for the element σ of the Weyl group, of shortest length such that $\sigma(\lambda) = \nu_1$, where λ is the shape of the path p, and ν_1 is the first weight in the sequence `WeightSequence(p)`. The reduced expression is represented as a sequence of integers between 1 and the rank of the root datum. In this sequence the index i represents the i-th simple reflection.

`IsZero(p)`

Returns `true` if the path p is the zero path, `false` otherwise.

`p1 eq p2`

Returns `true` if the paths $p1$ and $p2$ are equal, `false` otherwise.

Example H102E11

```
> R:= RootDatum("B2");
> p:= DominantLSPath(R, [ 2, 3 ]);
> p;
LS-path of shape (2 3) ending in (2 3)
> Falpha(p, 1);
LS-path of shape (2 3) ending in (0 5)
> Ealpha(Falpha(p, 1), 1);
LS-path of shape (2 3) ending in (2 3)
> p1:= Falpha(Falpha(Falpha(p, 1), 2), 1);
> p1;
LS-path of shape (2 3) ending in (-1  5)
> WeightSequence(p1);
[
    (5 -7),
    (-2  7)
]
> RationalSequence(p1);
[ 0, 1/7, 1 ]
> WeylWord(p1);
[ 2, 1 ]
```

So $s_2 s_1(2,3) = (5,-7)$.

`CrystalGraph(R, hw)`

For a root datum R and a sequence of non-negative integers hw (of length equal to the rank of the root datum), this function returns the corresponding crystal graph G, along with a sequence of paths. The graph G is a directed labelled graph. The labels on the edges are integers between 1 and the rank of the root system. If there is an edge from i to j with label s, then $f_{\alpha_s}(p_i) = p_j$, where p_i, p_j are the i-th and j-th elements of the sequence of paths returned by this function (and f_{α_s} is the root operator corresponding to the s-th simple root). In other words, the i-th path is the i-th point of the graph G.

Example H102E12

```
> R:= RootDatum("G2");
> G, pp:= CrystalGraph(R, [0,1]);
> G;
Digraph
Vertex  Neighbours
1       2 ;
2       3 ;
3       4 ;
4       5 6 ;
```

```
5       7 ;
6       8 ;
7       9 ;
8       10 ;
9       11 ;
10      11 ;
11      12 ;
12      13 ;
13      14 ;
14      ;
> e:= Edges(G);
> e[10];
[9, 11]
> Label(e[10]);
1
> Falpha(pp[9], 1) eq pp[11];
true
```

102.12 Elements of the Canonical Basis

`CanonicalElements(U, w)`

Given a quantized enveloping algebra U, corresponding to a root datum R of rank r and a sequence w of non-negative integers of length r returns the sequence consisting of the elements of the canonical basis of the negative part of U that are of weight ν, where ν denotes the linear combination of the simple roots of R defined by w (i.e., $\nu = w[1]\alpha_1 + \cdots + w[r]\alpha_r$ and $\alpha_1, \ldots, \alpha_r$ denote the simple roots of R).

Example H102E13

```
> R:= RootDatum("F4");
> U:= QuantizedUEA(R);
> c:= CanonicalElements(U, [1,2,1,1]); c;
[
    F_1*F_3^(2)*F_9*F_24,
    q*F_1*F_3^(2)*F_9*F_24 + F_1*F_3^(2)*F_23,
    q^4*F_1*F_3^(2)*F_9*F_24 + F_1*F_3*F_7*F_24,
    q^5*F_1*F_3^(2)*F_9*F_24 + q^4*F_1*F_3^(2)*F_23 + q*F_1*F_3*F_7*F_24 +
        F_1*F_3*F_21,
    q^4*F_1*F_3^(2)*F_9*F_24 + F_2*F_3*F_9*F_24,
    q^5*F_1*F_3^(2)*F_9*F_24 + q^4*F_1*F_3^(2)*F_23 + q*F_2*F_3*F_9*F_24 +
        F_2*F_3*F_23,
    (q^6 + q^2)*F_1*F_3^(2)*F_9*F_24 + q^2*F_1*F_3*F_7*F_24 +
        q^2*F_2*F_3*F_9*F_24 + F_2*F_7*F_24,
    (q^7 + q^3)*F_1*F_3^(2)*F_9*F_24 + (q^6 + q^2)*F_1*F_3^(2)*F_23 +
        q^3*F_1*F_3*F_7*F_24 + q^3*F_2*F_3*F_9*F_24 + q^2*F_1*F_3*F_21 +
```

```
        q^2*F_2*F_3*F_23 + q*F_2*F_7*F_24 + F_2*F_21,
    q^8*F_1*F_3^(2)*F_9*F_24 + q^4*F_1*F_3*F_7*F_24 + q^4*F_2*F_3*F_9*F_24 +
        q^2*F_2*F_7*F_24 + F_3*F_4*F_24,
    q^9*F_1*F_3^(2)*F_9*F_24 + q^8*F_1*F_3^(2)*F_23 + q^5*F_1*F_3*F_7*F_24 +
        q^5*F_2*F_3*F_9*F_24 + q^4*F_1*F_3*F_21 + q^4*F_2*F_3*F_23 +
        q^3*F_2*F_7*F_24 + q*F_3*F_4*F_24 + q^2*F_2*F_21 + F_3*F_18
]
> b:= BarAutomorphism(U);
> [ b(u) eq u : u in c ];
[ true, true, true, true, true, true, true, true, true, true ]
```

All elements of the canonical basis are invariant under the bar-automorphism.

Example H102E14

In the next example we show how to use the crystal graph to determine whether an element of the canonical basis acting on the highest weight vector of an irreducible module gives zero or not.

```
> U:= QuantizedUEA(RootDatum("A2"));
> G, p:= CrystalGraph(RootDatum(U), [1,1]);
> e:= Edges(G);
> for edge in e do
> print edge, Label(edge);
> end for;
[1, 2] 1
[1, 3] 2
[2, 4] 2
[3, 5] 1
[4, 6] 2
[5, 7] 1
[6, 8] 1
[7, 8] 2
```

We see that $f_{\alpha_1} f_{\alpha_2} f_{\alpha_2} f_{\alpha_1}(p_1) = p_8$ (where p_i is the i-th path in p). We apply the same sequence of Kashiwara operators to the identity element of U.

```
> Falpha(Falpha(Falpha(Falpha(One(U), 1), 2), 2), 1);
F_1*F_2*F_3
```

Now the element of the canonical basis with this principal monomial (see Section 102.2.6) acting on the highest weight vector of the irreducible module with highest weight `[1,1]` gives a non-zero result. The weight of this monomial is $2\alpha_1 + 2\alpha_2$. All other elements of the canonical basis of this weight give zero, as there is only one point of the crystal graph that gives a monomial of this weight.

```
> V:= HighestWeightModule(U, [1,1]);
> ce:= CanonicalElements(U, [2,2]);
> ce;
[
    F_1^(2)*F_3^(2),
    (q^3 + q)*F_1^(2)*F_3^(2) + F_1*F_2*F_3,
    q^4*F_1^(2)*F_3^(2) + q*F_1*F_2*F_3 + F_2^(2)
```

```
]
> v0:= V.1;
> ce[2]^v0;
V: (  0    0    0    0    0    0    0 -1/q)
> ce[1]^v0;
V: (0 0 0 0 0 0 0 0)
> ce[3]^v0;
V: (0 0 0 0 0 0 0 0)
```

102.13 Homomorphisms to the Universal Enveloping Algebra

`QUAToIntegralUEAMap(U)`

Given a quantized enveloping algebra U returns the map from U onto the integral form of the universal enveloping algebra of the corresponding Lie algebra (cf. Section 102.2.5). We refer to Section 100.17 for an account of universal enveloping algebras in MAGMA.

Example H102E15

```
> U:= QuantizedUEA(RootDatum("C3"));
> f:= QUAToIntegralUEAMap(U);
> p:= CanonicalElements(U, [1,2,1]);
> [ f(u) : u in p ];
[
    y_1*y_2^(2)*y_3,
    2*y_1*y_2^(2)*y_3 + y_1*y_2*y_5,
    y_1*y_2^(2)*y_3 + y_1*y_2*y_5 + y_1*y_7,
    y_1*y_2^(2)*y_3 + y_2*y_3*y_4 - y_2*y_6,
    2*y_1*y_2^(2)*y_3 + y_1*y_2*y_5 + y_2*y_3*y_4 - y_2*y_6 + y_4*y_5,
    2*y_1*y_2^(2)*y_3 + y_1*y_2*y_5 + 2*y_2*y_3*y_4 - y_2*y_6 + y_4*y_5,
    y_1*y_2^(2)*y_3 + y_1*y_2*y_5 + y_2*y_3*y_4 + y_1*y_7 + y_4*y_5 + y_8
]
```

So this allows one to construct elements of the canonical basis of a universal enveloping algebra (of a semisimple Lie algebra).

103 GROUPS OF LIE TYPE

Chapter 103
GROUPS OF LIE TYPE

103.1 Introduction

This chapter describes MAGMA functions for computing with groups of Lie type. These functions are based on [CMT04] for split types, and [Hal05] for twisted types.

Given an extended root datum and ring with a Γ-action, a group of Lie type can be constructed in MAGMA. Such groups include reductive Lie groups (when the ring is $\mathbf{R}$ or $\mathbf{C}$), reductive algebraic groups (when the ring is an algebraically closed field), and finite groups of Lie type (when the ring is a finite field).

103.1.1 The Steinberg Presentation

The approach to computation in split groups of Lie type described here is based on the Steinberg presentation[Ste62] Let G be a split group of Lie type with root datum R over the ring k. Suppose the roots of R are $\alpha_1, \ldots, \alpha_{2N}$ ordered as in Section 97.5 and n is the rank of R. Then G contains *root elements* $x_r(t) = x_{\alpha_r}(t)$ for t in k. If R is semisimple, the root elements generate G. In the general case, it is necessary to introduce extra torus elements. Let $Y = \mathbf{Z}^d$ be the coroot space of the root datum. The torus is taken to be the abelian group $Y \otimes k^\times$, represented as the set of vectors in k^d with each component invertible, and multiplication is performed componentwise. The Weyl group of G is just the Coxeter group of the root datum RD. Redundant generators n_r are also included, corresponding to the generators s_r of the Weyl group.

Since the generating set is parametrised by field elements it is generally not possible to define G within the category of finitely presented groups `GrpFP`, so groups of Lie type form their own category, `GrpLie`.

Note that groups of Lie type in MAGMA are designed primarily for fields whose elements are exact. While it is possible to define these groups over real and complex fields (Chapter 25), no attempt has been made to control rounding error in this case.

103.1.2 Bruhat Normalisation

The Bruhat decomposition [Car93, Chapter 2] gives us a useful normal form for elements of a split group of Lie type defined over a field k. Every $g \in G$ can be written in the form $uh\dot{w}u'$ where

1. u is a unipotent element written in the form $\prod_{r=1}^{N} x_r(t_r)$;
2. h is a torus element represented as an element of R^d with each entry invertible;
3. $\dot{w} = \dot{s}_{r_1} \cdots \dot{s}_{r_k}$ where $s_{r_1} \cdots s_{r_k}$ is a reduced word for w in the Weyl group.
4. $u' = \prod_{r \in \Phi_w^+} x_r(t'_r)$ where $\Phi_w^+ = \{r \mid \alpha_r \text{ and } \alpha_r w \text{ are positive}\}$ and the terms are in the usual order.

103.1.3 Twisted Groups of Lie type

Let G be a connected reductive linear algebraic group defined over the field k. We say that H is a *form* of G if it there is a $\bar{k}$-isomorphism between then, for $\bar{k}$ the algebraic closure of k. If some maximal torus of $G(\bar{k})$ is a k-split torus, we say that G is *split*, otherwise G is *twisted*. If some maximal torus of $G(\bar{k})$ is defined over k, we say that G is *quasisplit*. There is a unique split form of every reductive linear algebraic group.

The group $\Gamma := \mathrm{Gal}(\bar{k} : k)$ acts on G in the usual way and G is a Γ-group in the sense of the Section 68.10. The group $\mathrm{Aut}(G)$ of algebraic automorphisms of G is also a Γ-group. The twisted forms of G are in one-to-one correspondence with the 1-cocycles of Γ on $\mathrm{Aut}(G)$ and the forms are conjugate if and only if the cocycles are cohomologous. For practical purposes it is sufficient to compute the cohomology of $\Gamma = \mathrm{Gal}(K : k)$ on $\mathrm{Aut}_K(G)$ for some finite Galois extension K of k, where $\mathrm{Aut}_K(G)$ is the group of K-algebraic automorphisms of G.

The action of Γ on G induces an action on the root datum of G, and so we get an extended root datum. If G is quasisplit, then it is determined by the extended root datum and the action of Γ on K. In general, a cocycle is required to fully determine G.

103.2 Constructing Groups of Lie Type

103.2.1 Split Groups

The following optional parameters are common to most of the intrinsics described in this section:

`Normalising` BoolElt *Default :* `true`

The flag `Normalising` determines whether elements will be automatically converted to Bruhat form. This flag is automatically set to `false`if the group is defined over a nonfield.

`Isogeny` BoolElt *Default :* "*Ad*"

`Signs` Any *Default :* 1

The optional parameters `Isogeny` and `Signs` can take the values described in Section 97.2.

`Method` MonStgElt *Default :* "*Default*"

The method to be used for operations with unipotent elements. See [CHM08] for more details on the algorithms. Possible values are

- `"CollectionFromLeft"` uses collection from left.
- `"CollectionFromOutside"` uses collection from outside.
- `"Classical"` uses formulas for classical types [CHM08]. This is only available for groups defined over a sparse (classical) root datum.
- `"Collection"` will choose the best of the above methods automatically.
- `"SymbolicFromLeft"` uses Hall polynomials, which are computed using collection from left.

- `"SymbolicFromOutside"` uses Hall polynomials, which are computed using collection from outside.
- `"SymbolicClassical"` uses Hall polynomials, which are computed by formulas. This is only available for groups defined over a sparse (classical) root datum.
- `"Symbolic"` will choose the best symbolic method automatically.
- `"Default"` will choose the best of all above methods automatically.

`GroupOfLieType(N, k)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Cartan name given by the string N (see Section 95.6) over the ring k.

`GroupOfLieType(N, q)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Cartan name given by the string N (see Section 95.6) over the finite field of order q.

`GroupOfLieType(W, k)`

`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Weyl group W over the ring k. The group W must be a finite Coxeter group, given either as a permutation group or as a reflection group.

`GroupOfLieType(W, q)`

`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Weyl group W over the finite field of order q. The group W must be a finite Coxeter group, given either as a permutation group or as a reflection group.

`GroupOfLieType(R, k)`

`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with root datum R over the ring k.

`GroupOfLieType(R, q)`

`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with root datum R over the finite field of order q.

`GroupOfLieType(C, k)`

`GroupOfLieType(D, k)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Cartan matrix C or Dynkin digraph D, over the ring k.

`GroupOfLieType(C, q)`

`GroupOfLieType(D, q)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the group of Lie type with Cartan matrix C or Dynkin digraph D, over the finite field of order q.

`SimpleGroupOfLieType(X, n, k)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the simple group of Lie type with Cartan name X_n over the ring k, where the Cartan name is given by the string X and integer n (see also Section 95.6).

`SimpleGroupOfLieType(X, n, q)`

`Isogeny`	BoolElt	*Default :* "*Ad*"
`Signs`	Any	*Default :* 1
`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

Construct the simple group of Lie type with name X_n over the finite field of order q, where the Cartan name is given by the string X and integer n (see also Section 95.6).

`GroupOfLieType(L)`

The group of Lie type corresponding to the Lie algebra L. The Lie algebra must be the algebraic (i.e., it must correspond to some group), and Magma must be able to determine that it is algebraic.

`IsNormalising(G)`

Returns the value of the flag `Normalising` of the group of Lie type G.

Example H103E1

```
> G := GroupOfLieType("E8", 2);
> G;
G: Group of Lie type E8 over Finite field of size 2
```

103.2.2 Galois Cohomology

If G is a linear algebraic group defined over the field k and L is the algebraic closure of k, then the group $\Gamma := \mathrm{Gal}(L : k)$ acts on G in the usual way and G becomes a Γ-group in the sense of the Section 68.10 and $\mathrm{Aut}(G)$, the group of algebraic automorphisms of G also becomes a Γ-group.

Now the twisted forms of G are in one-to-one correspondence to the 1-cocycles of Γ on $\mathrm{Aut}(G)$ and the forms are conjugate if and only if the cocycles are cohomologous.

For practical purposes it is sufficient to compute the cohomology of $\mathrm{Gal}(K : k)$ on $\mathrm{Aut}_K(G)$ for some finite Galois field extension of k, where $\mathrm{Aut}_K(G)$ is the group of K-algebraic automorphisms of G.

These functions are based on [Hal05].

`GammaGroup(k, G)`

Returns the group of Lie type G as a Γ-group with $\Gamma = \mathrm{Gal}(K : k)$, where K is the base field of G. The field k must be a subfield of K.

`GammaGroup(k, A)`

Returns the group $A = \mathrm{Aut}_K(G)$ of automorphisms of the group of Lie type G as a Γ-group with $\Gamma = \mathrm{Gal}(K : k)$, where K is the base field of G. The field k must be a subfield of K.

`ActingGroup(G)`

`ActingGroup(A)`

Given the group of Lie type G or the group A of its automorphisms as a Γ-group, return $\Gamma = \mathrm{Gal}(K : k)$ together with the map m from the abstract Galois group Γ into the set of field automorphisms, such that $m(\gamma)$ is the actual field automorphism for every $\gamma \in \Gamma$.

`ExtendGaloisCocycle(c)`

`GBAl`	MonStgElt	*Default :* "*Walk*"
`Printeqs`	BoolElt	*Default :* `false`

The analogue to `ExtendCocycle`. Given a cocycle c in $H^1(\Gamma, A/A_0)$, where $A = \mathrm{Aut}_K(G)$ and $\Gamma = \mathrm{Gal}(K : k)$, extend the cocycle to a cocycle in $H^1(\Gamma, A)$. The optional parameter `GBAl` can be used to set the algorithm used for computing the Gröbner bases. The parameter `Printeqs` may be used to print out the polynomials whose Gröbner bases are computed. The current implementation only works for finite fields.

`GaloisCohomology(A)`

`GBAl`	MonStgElt	*Default :* "*Walk*"
`Printeqs`	BoolElt	*Default :* `false`
`Recompute`	BoolElt	*Default :* `false`

Computes the Galois cohomology $H^1(\Gamma, \mathrm{Aut}_K(G))$, where A is the automorphism group of G as a Γ-group returned by `GammaGroup` and $\Gamma = \mathrm{Gal}(K : k)$. The optional parameter `GBAl` can be used to set the algorithm used for computing the Gröbner bases. The parameter `Printeqs` may be used to print out the polynomials whose Gröbner bases are computed. And `Recompute` may be used to recompute the Galois cohomology. The current implementation only works for finite fields.

`IsInTwistedForm(x, c)`

Returns `true` if and only if the element x of a group of Lie type is contained in the twisted form of its parent defined by the cocycle c.

Example H103E2

Compute the Galois cohomology of $A_3(5^2)$:

```
> q := 5;
> k := GF(q);
> K := GF(q^2);
>
> G := GroupOfLieType( "A3", K : Isogeny:="SC" );
> A := AutomorphismGroup(G);
>
> AGRP := GammaGroup( k, A );
> Gamma,m := ActingGroup(AGRP);
> Gamma;
Symmetric group Gamma acting on a set of cardinality 2
Order = 2
    (1, 2)
> m;
Mapping from: GrpPerm: Gamma to Set of all maps from GF(5^2) to GF(5^2)
given by a rule [no inverse]
> action  := GammaAction(AGRP);
>
> time GaloisCohomology(AGRP);
[
    [
        One-Cocycle
        defined by [
        Automorphism of $: Group of Lie type A3 over Finite field of size 5^2
        given by: Mapping from: $: Group of Lie type  to $: Group of Lie type
        Composition of Mapping from: $: Group of Lie type  to $: Group of
        Lie type  given by a rule and
        Mapping from: $: Group of Lie type  to $: Group of Lie type
        given by a rule
        Decomposition:
          Mapping from: GF(5^2) to GF(5^2)
        Composition of Mapping from: GF(5^2) to GF(5^2) given by a rule and
        Mapping from: GF(5^2) to GF(5^2) given by a rule,
          Id($),
          1
        ]
    ],
    [
        One-Cocycle
        defined by [
        Automorphism of $: Group of Lie type A3 over Finite field of size 5^2
        given by: Mapping from: $: Group of Lie type  to $: Group of Lie type
        Composition of Mapping from: $: Group of Lie type  to $: Group of
        Lie type  given by a rule and
        Mapping from: $: Group of Lie type  to $: Group of Lie type
```

```
        given by a rule
        Decomposition:
          Mapping from: GF(5^2) to GF(5^2)
        Composition of Mapping from: GF(5^2) to GF(5^2) given by a rule and
        Mapping from: GF(5^2) to GF(5^2) given by a rule,
          (1, 3),
          1
        ]
    ]
]
Time: 0.470
```

Now create the trivial cocycle:

```
> TrivialOneCocycle( AGRP );
One-Cocycle
defined by [
Automorphism of $: Group of Lie type A3 over Finite field of size 5^2
given by: Mapping from: $: Group of Lie type  to $: Group of Lie type
given by a rule
Decomposition:
  Mapping from: GF(5^2) to GF(5^2) given by a rule,
  Id($),
  1
]
>
```

And now the cocycle defining the group ${}^2A_3(5)$ and check for two elements if they are contained in ${}^2A_3(5)$:

```
> c := OneCocycle( AGRP, [GraphAutomorphism(G, Sym(3)!(1,3))] );
>
> x := Random(G);
> IsInTwistedForm( x, c );
false
>
> x := elt< G | <1,y>, <3,y @ m(Gamma.1)> > where y is Random(K);
> IsInTwistedForm( x, c );
true
>
```

103.2.3 Twisted Groups

The description of the twisted groups of Lie type is based on the extended root data, as described in the Section 97.1.7. These functions are mainly based on [Hal05].

`TwistedGroupOfLieType(c)`

Given the cocycle c on the group of automorphisms of a split group of Lie type G, return the twisted form of G, defined by that cocycle.

`TwistedGroupOfLieType(R, k, K)`

`Normalising`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*Default*"

The twisted group of Lie type defined over the field k with coefficients in the field K corresponding to the twisted root datum R.

`BaseRing(G)`

`CoefficientRing(G)`

The coefficient ring of the (twisted) group of Lie type G, that is the base ring of the untwisted overgroup of G.

`DefRing(G)`

The ring over which the (twisted) group of Lie type G is defined. If G is split, this is the same as the base ring of G.

`UntwistedOvergroup(G)`

The untwisted overgroup, inside which the twisted group of Lie type G was constructed.

Example H103E3

The twisted group ${}^2A_3(5)$ as a subgroup of $A_3(5^2)$.

```
> R := RootDatum("A3" : Twist := 2);
> G := TwistedGroupOfLieType(R,5,25);
> G;
G: Twisted group of Lie type 2A3,2 over GF(5) with entries over GF(5^2)
> BaseRing(G);
Finite field of size 5^2
> DefRing(G);
Finite field of size 5
> UntwistedOvergroup(G);
Group of Lie type A3 over GF(5^2)
```

`RelativeRootElement(G,delta,t)`

The relative root element corresponding to the relative root δ of the twisted group of Lie type G and the field elements given by the sequence t. This is the element $u_\delta(t)$ in [Hal05, (4.5)].

Example H103E4

Here we create the same group as in the previous example, but using a cocycle.

```
> q := 5; k := GF(q); K := GF(q^2);
>
> G := GroupOfLieType( "A3", K );
> A := AutomorphismGroup(G);
>
> AGRP := GammaGroup( k, A );
> c := OneCocycle( AGRP, [GraphAutomorphism(G, Sym(3)!(1,3))] );
>
> T := TwistedGroupOfLieType(c);
> T eq TwistedGroupOfLieType(RootDatum("A3":Twist:=2),k,K);
true
> G eq UntwistedOvergroup(T);
true
>
> x := Random(G); x in T;
false
>

103.3 Operations on Groups of Lie Type

Many of the basic operations for Coxeter groups are shortcuts for obtaining information about the underlying root datum (Chapter 97). Such functions are listed here; see Sections 97.3, 97.4, 97.5, and 98.4 for more details and examples of their use.

`G eq H`

Returns `true` iff the groups of Lie type G and H are equal.

`G subset H`

Returns `true` iff the group of Lie type G is a subset of H.

`IsAlgebraicallyIsomorphic(G, H)`

Returns `true` if the semisimple groups G and H are isomorphic as algebraic groups (i.e. they have the same base rings and isomorphic root data). If `true`, then the second value returned is an isomorphism.

`IsIsogenous(G, H)`

Returns `true` if G and H are isogenous. The groups must be semisimple and defined over the same field. If `true`, the subsequent values returned are: the corresponding adjoint group G_{ad}, the homomorphisms $G_{ad} \to G$ and $G_{ad} \to H$, the corresponding simply connected root datum G_{sc}, and the homomorphisms $G \to G_{sc}$ and $H \to G_{sc}$.

`IsCartanEquivalent(G, H)`

Returns `true` if, and only if, the groups of Lie type G and H are Cartan equivalent, i.e. they have isomorphic Dynkin diagrams and defined over the same ring.

`BaseRing(G)`

`CoefficientRing(G)`

The base ring k of the group of Lie type G.

`BaseExtend(G, K)`

Given a group of Lie type G with base ring k and a larger ring K, return the group $G(K)$ gotten by extending the base ring and the injection $G \to G(K)$.

`ChangeRing(G, K)`

Given a group of Lie type G and a ring K, return the group with the same root datum, but defined over a different ring.

`Generators(G)`

Generators for the group of Lie type G as an abstract group. This is currently only implemented when the base ring is a finite field.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of generators for the group of Lie type G as an abstract group. This is currently only implemented when the base ring is a finite field.

`AlgebraicGenerators(G)`

A set of generators for the group of Lie type G as an algebraic group.

`NumberOfAlgebraicGenerators(G)`

`Nalggens(G)`

The number of generators for the group of Lie type G as an algebraic group.

Example H103E5

```
> k<z> := GF(4);
> G := GroupOfLieType("A2", k : Normalising:=false);
> Generators(G);
[ x1(1) , x4(1) , x1(z) , x4(z) , x2(1) , x5(1) , x2(z) , x5(z) , ( z   1) ,
(1   z)  ]
> AlgebraicGenerators(G);
[ x1(1) , x2(1) , x4(1) , x5(1) , ( z   1) , ( 1   z)  ]
```

`Order(G)`
`#G`

The order of the group of Lie type G.

`FactoredOrder(G)`

The factored order of the group of Lie type G.

`Dimension(G)`

The dimension of the group of Lie type G, considered as an algebraic variety.

Example H103E6

```
> G := GroupOfLieType("G2", 3);
> Order(G);
4245696
> FactoredOrder(G);
[ <2, 8>, <13, 1>, <3, 6>, <7, 1> ]
> G := GroupOfLieType("G2", Rationals());
> Order(G);
Infinity
> Dimension(G);
14
```

`CartanName(G)`

The Cartan name of the group of Lie type G.

`RootDatum(G)`

The root datum of the group of Lie type G.

`DynkinDiagram(G)`

Print the Dynkin diagram of the group of Lie type G.

`CoxeterDiagram(G)`

Print the Coxeter diagram of the group of Lie type G.

`CoxeterMatrix(G)`

The Coxeter matrix of the group of Lie type G.

`CoxeterGraph(G)`

The Coxeter graph of the group of Lie type G.

`CartanMatrix(G)`

The Cartan matrix of the group of Lie type G.

`DynkinDigraph(G)`

The Dynkin digraph of the group of Lie type G.

`Rank(G)`
`ReductiveRank(G)`

The reductive rank of the group of Lie type G, i.e. the dimension of the underlying root datum.

`SemisimpleRank(G)`

The semisimple rank of the group of Lie type G, i.e. the rank of the underlying root datum.

`CoxeterNumber(G)`

The Coxeter number of the group of Lie type G, i.e. the order of the Coxeter element in the Weyl group of G.

`WeylGroup(G)`
`WeylGroup(GrpPermCox, G)`

The Weyl group of the group of Lie type G as a permutation Coxeter group. This is a crystallographic Coxeter group, see Chapter 98.

`WeylGroup(GrpFPCox, G)`

The Weyl group of the group of Lie type G as a finitely presented Coxeter group. This is a crystallographic Coxeter group, see Chapter 98.

`WeylGroup(GrpMat, G)`

The Weyl group of the group of Lie type G as a reflection group. This is a crystallographic Coxeter group, see Chapter 99.

`FundamentalGroup(G)`

The fundamental group of the group of Lie type G, together with the projection of the weight lattice onto the fundamental group.

`IsogenyGroup(G)`

The isogeny group of the group of Lie type G, together with its injection into the fundamental group.

`CoisogenyGroup(G)`

The coisogeny group of the group of Lie type G, together with its projection onto the fundamental group.

103.4 Properties of Groups of Lie Type

`IsFinite(G)`

Return `true` if and only if the group of Lie type G is finite.

`IsAbelian(G)`

Returns `true` if the group of Lie type G is abelian.

`IsSimple(G)`

Returns `true` if the group of Lie type G is a simple group as an algebraic group, ie, G has no proper *connected* normal subgroups. This is true if, and only if, the underlying root datum is irreducible. Note that this does not usually mean that G is simple as an abstract group. In previous releases of Magma this function was incorrectly called `IsIrreducible`.

`IsSimplyLaced(G)`

Returns `true` if the group of Lie type G is simply laced, i.e. its Dynkin diagram contains no multiple bonds.

`IsSemisimple(G)`

Returns `true` if the group of Lie type G is semisimple.

`IsAdjoint(G)`

Returns `true` if, and only if, the group of Lie type G is adjoint (i.e. the isogeny group is trivial).

`IsWeaklyAdjoint(G)`

Returns `true` if, and only if, the group of Lie type G is weakly adjoint, i.e. its isogeny group is isomorphic to $\mathbf{Z}^n$, where n is the difference between the rank and the semisimple rank of G. Note that if G is semisimple then this function is identical to `IsAdjoint`.

`IsSimplyConnected(G)`

Returns `true` if, and only if, the group of Lie type G is simply connected (i.e. the isogeny group is equal to the fundamental group, i.e. the coisogeny group is trivial).

`IsWeaklySimplyConnected(G)`

Returns `true` if, and only if, the group of Lie type G is weakly simply connected, i.e. its coisogeny group is isomorphic to $\mathbf{Z}^n$, where n is the difference between the rank and the semisimple rank of G. Note that if G is semisimple then this function is identical to IsSimplyConnected.

`IsSplit(G)`

Returns `true` if and only if the group of Lie type G is split.

`IsTwisted(G)`

Returns `true` if and only if the group of Lie type G is twisted.

103.5 Constructing Elements

`elt< G | L >`

Given a group of Lie type G over the ring R and a list L of appropriate objects, construct an element of G. Suppose the underlying root datum has dimension d, rank n, and roots $\alpha_1, \ldots, \alpha_{2N}$. Each entry in the list can be one of the following:

1. A tuple $< r, t >$ where $r = 1, \ldots, 2N$ and $t \in R$. This corresponds to the unipotent term $x_r(t)$.
2. A sequence of tuples as in item (1).
3. A sequence $[t_1, \ldots, t_N]$ of elements of R. This corresponds to the unipotent element $x_1(t_1) \cdots x_N(t_N)$.
4. An integer $r = 1, \ldots, 2N$. This corresponds to the Weyl group representative n_r.
5. A Weyl group element w, either as a word or as a permutation. This corresponds to the Weyl group representative $\dot{w}$.
5. A vector $v \in R^d$ with each entry invertible. This corresponds to an element of the torus.
6. An element of G.

`Identity(G)`
`Id(G)`
`G ! 1`
`elt< G | >`

The identity element of the group of Lie type G.

Example H103E7

```
> G := GroupOfLieType("A5", Rationals() : Normalising := false);
> V := VectorSpace(Rationals(), 5);
> NumPosRoots(G);
15
> elt< G | <5,1/2>, 1,3,2, [1,2,3,4,5,6,7,8,9,10,11,12,13,14,15],
>          V![6,1/3,-1,3,2/3] >;
x5(1/2) n1 n3 n2 x1(1) x2(2) x3(3) x4(4) x5(5) x6(6) x7(7) x8(8) x9(9)
x10(10) x11(11) x12(12) x13(13) x14(14) x15(15) ( 6 1/3  -1   3 2/3)
```

`TorusTerm(G, r, t)`

The torus term $h_r(t) = \alpha_r^\star \otimes t$ in the group of Lie type G, where r is the index of the coroot $\alpha_r^\star$ and t an element of the base ring of G.

`CoxeterElement(G)`

The Coxeter element of the group of Lie type G, i.e. the representative of the Coxeter element in the Weyl group of G.

`Random(G)`

`Uniform` BoolElt *Default :* `true`

An element of the finite group of Lie type G chosen at random. The base ring of G must be finite. If the optional parameter `Uniform` is set to `true`, the random elements to be distributed uniformly. If the optional parameter `Uniform` is set to `false`, this function is much faster but the random elements are not distributed uniformly. Instead each double coset of the Borel subgroup occurs with equal frequency, and the elements are uniformly distributed within each double coset.

`Eltlist(g)`

The list corresponding to the element g of a group of Lie type.

`CentrePolynomials(G)`

`CenterPolynomials(G)`

A set of polynomials which are satisfied by the coordinates of a torus element h of the group of Lie type G if, and only if, h is in the centre of G.

Example H103E8

The centre of a semisimple group is finite, so the centre polynomials can be used to find all central elements.

```
> G := GroupOfLieType("B3", Rationals() : Isogeny:="SC");
> pols := CentrePolynomials(G);
> pols;
{
    -h[2] + h[3]^2,
    h[1]^2 - h[2],
    -h[1]*h[3]^2 + h[2]^2
}
> S := Scheme(AffineSpace(Rationals(), 3), Setseq(pols));
> pnts := RationalPoints(S);
> pnts;
{@ (0, 0, 0), (1, 1, -1), (1, 1, 1) @}
```

The rational points of S can be converted into elements of G, taking care to eliminate any point which has a coordinate equal to zero:

```
> V := VectorSpace(Rationals(), 3);
> [ elt< G | V!Eltseq(pnt) > : pnt in pnts | &*Eltseq(pnt) ne 0 ];
[ (1  1 -1) , 1 ]
```

103.6 Operations on Elements

103.6.1 Basic Operations

`g * h`

The product of two elements of a group of Lie type. If the Normalising flag is set for the group, then the product is normalised using the algorithms of [CMT04, CHM08]. Otherwise, the words are just concatenated.

Example H103E9

If the `Normalising` flag is set, the product is normalised, otherwise multiplication is just concatenation.

```
> G := GroupOfLieType("G2", GF(3) : Normalising:=false );
> V := VectorSpace(GF(3),2);
> g := elt< G | 1,2,1,2, V![2,2], <1,2>,<5,1> >;
> h := elt< G | <3,2>, V![1,2], 1 >;
> g*h;
n1 n2 n1 n2 (2 2) x1(2) x5(1) x3(2) (1 2) n1
> H := GroupOfLieType("G2", GF(3) : Normalising:=true  );
> g := elt< H | 1,2,1,2, V![2,2], <1,2>,<5,1> >;
> h := elt< H | <3,2>, V![1,2], 1 >;
```

```
> g*h;
x2(1) x3(1) (1 2) n1 n2 n1 n2 n1 x4(1)
```

`g ^ -1`

`Inverse(G)`

The inverse of the element g of a group of Lie type.

`g ^ n`

The nth power of the element g of a group of Lie type.

`g ^ h`

The conjugate $h^{-1}gh$, where g and h are elements of a group of Lie type.

`(g, h)`

`Commutator(g, h)`

The commutator $g^{-1}h^{-1}gh$ of g and h, where g and h are elements of a group of Lie type.

`Normalise(~g)`

`Normalize(~g)`

`Normalise(g)`

`Normalize(g)`

Normalise the element g of a group of Lie type G. The procedural form is slightly more efficient than the functional form. If the `Normalise` flag is set for G, this operation has no effect. This uses the algorithms of [CMT04, CHM08].

Example H103E10

Arithmetic in groups of Lie type.

```
> k<z> := GF(4);
> G := GroupOfLieType("C3", k);
> V := VectorSpace(k, 3);
> g := elt< G | 1,2,3, <3,z>,<4,z^2>, V![1,z^2,1] >;
> g;
n1 n2 n3 x3(z) x4(z^2) ( 1 z^2   1)
> h := elt< G | [0,1,z,1,0,z^2,1,1,z] >;
> h;
x2(1) x3(z) x4(1) x6(z^2) x7(1) x8(1) x9(z)
> g * h^-1;
x3(1) x5(z) x6(z^2) x8(1) (z^2 z^2   z) n1 n2 n3 x3(z^2) x5(z^2)
> g^3;
x3(z) x5(1) x7(z^2) x8(z^2) ( 1   1   z) n1 n2 n3 n1 n2 n3 n1 n2 n3 x1(1)
```

```
x2(z^2) x3(1) x4(z) x7(z) x9(z)
```

103.6.2 Decompositions

`Bruhat(g)`

Given an element g of a group of Lie type the Bruhat decomposition of g is returned. The function returns elements u, h, $\dot{w}$, u' with the properties described in Subsection 103.1.3 and so that $g = uh\dot{w}u'$.

Example H103E11

```
> k<z> := GF(4);
> G := GroupOfLieType("C3", k);
> V := VectorSpace(k, 3);
> g := elt< G | 1,2,3, <3,z>,<4,z^2>, V![1,z^2,1] >;
> Normalise(g);
x7(z^2) x8(z^2) (z^2 z^2   z) n1 n2 n3 x3(1) x6(z)
> u, h, w, up := Bruhat(g);
> u; h; w; up;
x7(z^2) x8(z^2)
(z^2 z^2   z)
n1 n2 n3
x3(1) x6(z)
```

`MultiplicativeJordanDecomposition(x)`

The multiplicative Jordan decomposition of the element x of the group of Lie type.

103.6.3 Conjugacy and Cohomology

`ConjugateIntoTorus(g)`

Given an semisimple element g in a finite group of Lie type, return a torus element t and conjugator x such that $t = xgx^{-1}$. The elements returned may be defined over a larger field that the input element.

`ConjugateIntoBorel(g)`

Given a semisimple element g in a finite group of Lie type, return a Borel element b and conjugator x such that $b = xgx^{-1}$. The elements returned may be defined over a larger field that the input element. Although any element of a group of Lie type can be conjugated into the Borel subgroup, this function is currently only implemented for semisimple elements.

`Lang(c, q)`

Given an element c in a finite group of Lie type and q a power of the characteristic, return a solution a of the Lang equation $c = a^- Fa$. Here F is the Frobenius automorphism gotten by q powers in the field.

103.7 Properties of Elements

`IsSemisimple(x)`

Return `true` if, and only if, the element x of the group of Lie type is semisimple.

`IsUnipotent(x)`

Return `true` if, and only if, the element x of the group of Lie type is unipotent.

`IsCentral(x)`

Return `true` if, and only if, the element x of the group of Lie type is in the centre of its parent group.

103.8 Roots, Coroots and Weights

The roots are stored as an indexed set

$$\{@ \alpha_1, \ldots, \alpha_N, \alpha_{N+1}, \ldots, \alpha_{2N} @\},$$

where $\alpha_1, \ldots, \alpha_N$ are the positive roots in an order compatible with height; and $\alpha_{N+1}, \ldots, \alpha_{2N}$ are the corresponding negative roots (i.e. $\alpha_{i+N} = -\alpha_i$). The simple roots are $\alpha_1, \ldots, \alpha_n$ where n is the rank.

Many of these functions have an optional argument `Basis` which may take one of the following values

1. `"Standard"`: the standard basis for the (co)root space. This is the default.
2. `"Root"`: the basis of simple (co)roots.
3. `"Weight"`: the basis of fundamental (co)weights (see Subsection 99.8.3 below).

103.8.1 Accessing Roots and Coroots

`RootSpace(G)`
`CorootSpace(G)`

The lattice containing the (co)roots of the group of Lie type G.

`SimpleRoots(G)`
`SimpleCoroots(G)`

The simple (co)roots of the group of Lie type G as the rows of a matrix.

`NumberOfPositiveRoots(G)`
`NumPosRoots(G)`

The number of positive roots of the group of Lie type G.

`Roots(G)`
`Coroots(G)`

`Basis` MonStgElt *Default :* "*Standard*"

An indexed set containing the (co)roots of the group of Lie type G.

`PositiveRoots(G)`
`PositiveCoroots(G)`

`Basis` MonStgElt *Default :* "*Standard*"

An indexed set containing the positive (co)roots of the group of Lie type G.

`Root(G, r)`
`Coroot(G, r)`

`Basis` MonStgElt *Default :* "*Standard*"

The rth (co)root of the group of Lie type G.

`RootPosition(G, v)`
`CorootPosition(G, v)`

`Basis` MonStgElt *Default :* "*Standard*"

If v is a (co)root of the group of Lie type G, this returns its position; otherwise it returns 0.

Example H103E12

```
> G := GroupOfLieType("A3", 25 : Isogeny := 2);
> Roots(G);
{@
    (1 0 0),
    (0 1 0),
    (1 0 2),
    (1 1 0),
    (1 1 2),
    (2 1 2),
    (-1  0  0),
    (0 -1  0),
    (-1  0 -2),
    (-1 -1  0),
    (-1 -1 -2),
    (-2 -1 -2)
@}
> PositiveCoroots(G);
{@
    (2 -1 -1),
    (-1  2  0),
    (0 -1  1),
    (1  1 -1),
    (-1  1  1),
    (1 0 0)
@}
> #Roots(G) eq 2*NumPosRoots(G);
true
> Coroot(G, 4);
(1  1 -1)
> Coroot(G, 4 : Basis := "Root");
(1 1 0)
> CorootPosition(G, [1,1,-1]);
4
> CorootPosition(G, [1,1,0] : Basis := "Root");
4
```

`HighestRoot(G)`

`HighestLongRoot(G)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique (long) root of greatest height in the root datum of the group of Lie type G.

`HighestShortRoot(G)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique short root of greatest height in the root datum of the group of Lie type G.

Example H103E13

```
> G := GroupOfLieType("G2", RealField());
> HighestRoot(G);
(3 2)
> HighestLongRoot(G);
(3 2)
> HighestShortRoot(G);
(2 1)
```

103.8.2 Reflections

The reflections in the Weyl group have representatives in the group of Lie type.

`Reflections(G)`

The sequence of representatives of reflections in the group of Lie type G.

`Reflection(G, r)`

The representative of the reflections in the rth root in the group of Lie type G.

Example H103E14

```
> G := GroupOfLieType("A2", Rationals());
> Reflections(G);
[ n1 , n2 , n1 n2 n1  ]
```

103.8.3 Operations and Properties for Root and Coroot Indices

`RootHeight(G, r)`

`CorootHeight(G, r)`

The height of the rth (co)root of the group of Lie type G, i.e. the sum of the coefficients of α_r (resp. $\alpha_r^\star$) with respect to the simple (co)roots.

`RootNorms(G)`

`CorootNorms(G)`

The sequence of squares of the lengths of the (co)roots of the group of Lie type G.

`RootNorm(G, r)`

`CorootNorm(G, r)`

The square of the length of the rth (co)root of the group of Lie type G.

`IsLongRoot(G, r)`

Returns `true` if, and only if, the rth root of the group of Lie type G is long, i.e. the rth coroot is short.

`IsShortRoot(G, r)`

Returns `true` if, and only if, the rth root of the group of Lie type G is short, i.e. the rth coroot is long.

`AdditiveOrder(G)`

An additive order on the positive roots of the group of Lie type G, i.e. a sequence containing the numbers $1, \ldots, N$ in some order so that $\alpha_r + \alpha_s = \alpha_t$ implies t is between r and s. This is computed using the techniques of [Pap94]

Example H103E15

```
> G := GroupOfLieType("A5", GF(3));
> a := AdditiveOrder(G);
> Position(a, 2);
6
> Position(a, 3);
10
```

103.8.4 Weights

`WeightLattice(G)`

`CoweightLattice(G)`

The (co)weight lattice of the group of Lie type G.

`FundamentalWeights(G)`

`FundamentalCoweights(G)`

`Basis` MonStgElt *Default :* "*Standard*"

The fundamental (co)weights of the group of Lie type G as the rows of a matrix.

`DominantWeight(G, v)`

`Basis` MonStgElt *Default :* "*Standard*"

The unique dominant weight in the same W-orbit as v, where W is the Weyl group of G and v is a weight given as a vector or a sequence representing a vector. The second value returned is a Weyl group element taking v to the dominant weight.

103.9 Building Groups of Lie Type

Currently the only subgroups of a group of Lie type that can be constructed are subsystem subgroups.

`SubsystemSubgroup(G, a)`

The subsystem subgroup of the group of Lie type G generated by the standard maximal torus and the root subgroups with roots $\alpha_{a_1}, \ldots, \alpha_{a_k}$ where $a = \{a_1, \ldots, a_k\}$ is a set of integers.

`SubsystemSubgroup(G, s)`

The subsystem subgroup of the group of Lie type G generated by the standard maximal torus and the root subgroups with roots $\alpha_{s_1}, \ldots, \alpha_{s_k}$ where $s = [s_1, \ldots, s_k]$ is a *sequence* of integers. In this version the roots must be simple in the root subdatum (i.e. none of them may be a summand of another) otherwise an error is signalled. The simple roots will appear in the subdatum in the given order.

Example H103E16

```
> G := GroupOfLieType("A4",Rationals());
> PositiveRoots(G);
{@
    (1 0 0 0),
    (0 1 0 0),
    (0 0 1 0),
    (0 0 0 1),
    (1 1 0 0),
    (0 1 1 0),
    (0 0 1 1),
    (1 1 1 0),
    (0 1 1 1),
    (1 1 1 1)
@}
> H := SubsystemSubgroup(G, [6,1,4]);
> H;
H: Group of Lie type A3 over Rational Field
> PositiveRoots(H);
{@
    (0 1 1 0),
    (1 0 0 0),
    (0 0 0 1),
    (1 1 1 0),
    (0 1 1 1),
    (1 1 1 1)
@}
> h := elt<H|<2,2>,1>;
> h;  G!h;
x2(2) n1
x1(2) ( 1 -1  1 -1) n2 n3 n2
```

`DirectProduct(G1, G2)`

The direct product of the groups G_1 and G_2. The two groups must have the same base ring.

`Dual(G)`

The dual of the group of Lie type G, obtained by swapping the roots and coroots.

`SolubleRadical(G)`

The soluble radical of the group of Lie type G.

`StandardMaximalTorus(G)`

The standard maximal torus of the group of Lie type G.

Example H103E17

```
> G1 := GroupOfLieType( "A5", GF(7) );
> G2 := GroupOfLieType( "B4", GF(7) );
> DirectProduct(G1, Dual(G2));
$: Group of Lie type A5 C4 over Finite field of size 7
>
> G := GroupOfLieType(StandardRootDatum("A",3), GF(17));
> SolubleRadical(G);
$: Torus group of Dimension 1 over Finite field of size 17
```

103.10 Automorphisms

The following functions construct the standard automorphisms of a group of Lie type, as described in [Car72] (except for the graph automorphism of G_2). In many cases, including the finite groups, every automorphism is a product of these standard automorphisms.

103.10.1 Basic Functionality

`AutomorphismGroup(G)`

Automorphism group of a group of Lie type G.

`IdentityAutomorphism(G)`

`One(A)`

`Id(A)`

The identity automorphism of the group of Lie type G.

`Mapping(a)`

The map object associated with the automorphism a.

`Automorphism(m)`

Given a map object m from G to G, which is an isomorphism, returns the associated automorphism as an automorphism of a group of Lie type.

`h * g`

The composition of the group of Lie type automorphisms h and g.

`h ^ n`

The nth power of the group of Lie type automorphism h.

`g ^ h`

The conjugate $h^{-1}gh$, where g and h are group of Lie type automorphisms g and h

`Domain(A)`
`Codomain(A)`
`Domain(h)`
`Codomain(h)`

Domain or codomain of an automorphism of a group of Lie type or of the group of automorphisms.

103.10.2 Constructing Special Automorphisms

`InnerAutomorphism(G, x)`

The inner automorphism taking $g \in G$ to g^x, where x is an element of the group of Lie type G.

`DiagonalAutomorphism(G, v)`

The diagonal automorphism of the semisimple group of Lie type G given by the vector v. Let n be the semisimple rank of G and let k be its base field. Then v must be a vector in k^n with every component nonzero. The function returns the automorphism given by the character χ defined by $\chi(\alpha_i) = v_i$, where α_i is the ith simple root. Since our groups are algebraic, a diagonal automorphism is just a special case of an inner automorphism.

`GraphAutomorphism(G, p)`
`DiagramAutomorphism(G, p)`

`SimpleSigns` ANY *Default :* 1

The graph automorphism of the group of Lie type G given by the permutation p. The permutation must act on the indices of simple roots of G or the indices of all roots of G. The graph automorphism of the group of type G_2 has not been implemented yet.

The optional parameter SimpleSigns can be used to specify the signs corresponding to each simple root. This should either be a sequence of integers ± 1, or a single integer ± 1.

`FieldAutomorphism(G, sigma)`

The field automorphism of the group of Lie type G induced by σ, an element of the automorphism group of the base field of G

`RandomAutomorphism(G)`
`Random(A)`

A random element in A, the automorphism group of the group of Lie type G.

`DualityAutomorphism(G)`

The duality automorphism of G. This is an automorphism that takes every unipotent term $x_r(t)$ to $x_s(\pm t)$, where $s =$`Negative(RootDatum(G),r))`.

`FrobeniusMap(G,q)`

The Frobenius automorphism of the finite group of Lie type G gotten by qth powers in the base field. The integer q must be a power of the characteristic of the base field of G.

103.10.3 Operations and Properties of Automorphisms

`DecomposeAutomorphism(h)`

Given a group of Lie type automorphism h, this returns a field automorphism f, a graph automorphism g and an inner automorphism i such that $h = fgi$. This only works for groups defined over finite fields. The algorithm is due to Scott Murray and Sergei Haller.

`IsAlgebraic(h)`

Returns `true` if and only if the automorphism h is algebraic.

Example H103E18

Some automorphisms of $B_2(4)$

```
> G := GroupOfLieType("B2", GF(4));
> A := AutomorphismGroup(G);
> A!1 eq IdentityAutomorphism(G);
true
> g := GraphAutomorphism(G, Sym(2)!(1,2));
> g;
Automorphism of Group of Lie type B2 over Finite field of size 2^2
given by: Mapping from: Group of Lie type  to Group of Lie type
given by a rule
Decomposition:
  Mapping from: GF(2^2) to GF(2^2) given by a rule,
  (1, 2),
  1
```

The automorphism of $B_2(4)$ whose stabiliser is ${}^2B_2(4)$ is constructed by the following code.

```
> sigma := iso< GF(4) -> GF(4) | x :-> x^2, x :-> x^2 >;
> h := FieldAutomorphism(G, sigma) * g;
> h in A;
true
> f,g,i := DecomposeAutomorphism(h);
> assert f*g*i eq h;
```

103.11 Algebraic Homomorphisms

`GroupOfLieTypeHomomorphism(phi, k)`

The algebraic homomorphism of groups of Lie type over the ring k corresponding to the root datum morphism ϕ. See Chapter 103.

Example H103E19

This example constructs the algebraic projection $GL_4(\mathbf{Q}) \to PGL_4(\mathbf{Q})$.

```
> RGL := StandardRootDatum( "A", 3 );
> RPGL := RootDatum( "A3" );
> A := VerticalJoin( SimpleRoots(RGL), Vector([Rationals()|1,1,1,1]) )^-1 *
>   VerticalJoin( SimpleRoots(RPGL), Vector([Rationals()|0,0,0]) );
> B := VerticalJoin( SimpleCoroots(RGL), Vector([Rationals()|1,1,1,1]) )^-1 *
>   VerticalJoin( SimpleCoroots(RPGL), Vector([Rationals()|0,0,0]) );
> phi := GroupOfLieTypeHomomorphism( hom< RGL -> RPGL | A, B >, Rationals() );
> GL := Domain( phi );
> phi( elt<GL|<1,2>, Vector([Rationals()| 7,1,11,1])> );
x1(2) (   7 1/11   11)
```

103.12 Twisted Tori

The functionality presented here deals with the computation of the twisted tori of a finite group of Lie type.

Note that for a given group $G(k)$, the twisted tori are returned as subgroups of the standard torus of $G(K)$ for the smallest field extension K of k, where this is possible.

For finite fields and an untwisted group of Lie type $G(k)$, a twisted torus $T_w(k)$ of $G(k)$ has the form

$$T_w(k) = \{t \in T(K) | t^{\sigma w} = t\},$$

where $T(K)$ is the standard K-split torus of $G(K)$, σ is the generator of the Galois group $\mathrm{Gal}(K : k)$ and w is an element of the Weyl group of $G(k)$.

`TwistedTorusOrder(R, w)`

Given the root datum R and a Weyl group element w, computes the orders of the cyclic components of the twisted torus $T_w(k) \subset G(R, k)$ as sequence of polynomials in q, the order of the field k.

`TwistedToriOrders(G)`

`TwistedToriOrders(R)`

Given a group of Lie type G or a root datum R, takes for every concjugacy class of the Weyl group of G a representative w, and computes `TwistedTorusOrder(R, w)`. Returns the sequence of the lists consisting of `TwistedTorusOrder(R, w)` and w for every concjugacy class.

`TwistedTorus(G, w)`

Computes the twisted torus $T_w(k)$ of the group of Lie type G for the given element w of the Weyl group of G. Returned is the list consisting of three elements, first of them being the sequence of orders of cyclic parts of the torus, the second being the sequence of generators of the respective orders and the third being w. See [Hal05] for the algorithm used.

`TwistedTori(G)`

Computes one twisted torus $T_w(k)$ of the group of Lie type G for each conjugacy class w^W of the Weyl group W of G. A sequence of them is returned. See [Hal05] for the algorithm used.

Example H103E20

We compute all twisted tori of $A_1(5)$:

```
> G := GroupOfLieType("A1", 5);
> TwistedToriOrders(G);
[ [*
    [
        q - 1
    ],
    Id($)
*], [*
    [
        q + 1
    ],
    (1, 2)
*] ]
> TwistedTori(G);
[ [*
    [ 4 ],
    [ (2)  ],
    Id($)
*], [*
    [ 6 ],
    [ ( k.1^4)  ],
    (1, 2)
*] ]
```

As we may notice, the second one is contained in the group over the quadratic field extension:

```
> Universe($1[2][2]);
$: Group of Lie type A1 over Finite field of size 5^2
```

Example H103E21

These are the orders of the decompositions of all (up to conjugacy) maximal tori of the group $G_2(q)$ as polynomials in q:

```
> R := RootDatum("G2");
> [ t[1] : t in TwistedToriOrders(R) ];
[
    [  q - 1,  q - 1  ],
    [  q + 1,  q + 1  ],
    [  q^2 - 1        ],
    [  q^2 - 1        ],
    [  q^2 + q + 1    ],
    [  q^2 - q + 1    ]
]
```

103.13 Sylow Subgroups

We present here the functionality which allows to compute the Sylow subgroups of finite groups of Lie type.

`PrintSylowSubgroupStructure(G)`

This procedure prints out a list of all primes p dividing the order of the group of Lie type G along with the "goodness" of p, the exponent of p in the factorisation of $|G|$ and a sequence of integers. The positive integers give the orders of the decomposition of a torus T_w into cyclic groups such that the Sylow subgroup is contained in $\langle T_w, C_W(w)\rangle$. The negative number indicates the p-part coming from $C_W(w)$. If more than one such torus exists, then one line is printed for each of them.

A prime is said to be "GOOD" if it is equal to the characteristic of the base field k of G, "good" if the Sylow subgroup is abelian, thus contained in a torus, and "bad" if it is not abelian and thus not contained in a torus. See [Hal05] for the algorithm used.

`SylowSubgroup(G, p)`

Compute a p-Sylow subgroup S of the group of Lie type G. Returned is a list of a two sequences. The second sequence contains generators of S. The first one is a sequence of integers giving the orders of the respective generator if the generator is a torus element and the negative of the order of $\langle g\rangle/(\langle g\rangle \cap T_w)$ in case the generator g is not a torus element. See [Hal05] for the algorithm used.

Example H103E22

Compute

```
> G := GroupOfLieType("G2", 5);
> PrintSylowSubgroupStructure(G);
G: Group of Lie type G2 over Finite field of size 5
Order(G) is  2^6 * 3^3 * 5^6 * 7^1 * 31^1
Order(W) is  2^2 * 3^1
...compute tori...
...compute sylows...
   2 (bad)  : 6 [ 4, 4, -4 ]
   3 (bad)  : 3 [ 6, 6, -3 ]
   5 (GOOD) : The unipotent subgroup of G
   7 (good) : 1 [ 21 ]
   31 (good) : 1 [ 31 ]
> SylowSubgroup(G,2);
[*
    [ 4, 4, -2, -2 ],
    [ (2 1) , (1 2) , n2 , n1 n2 n1 n2 n1 n2  ]
*]
```

note that the orders of the non-toral elements is not necessarily the corresponding integer in the first sequence:

```
> gens := $1[2];
> [ Order(g) : g in gens ];
[ 4, 4, 4, 4 ]
```

but, in this example, their squares are contained in the torus:

```
> gens[3]^2 eq gens[2]^2, gens[4]^2 eq gens[2]^2;
true true
```

103.14 Representations

This section describes basic functionality for Lie algebra representations: see Chapter 104 for more functions for highest weight representations and decompositions.

`StandardRepresentation(G)`

The standard (projective) representation of the semisimple group of Lie type G over an extension its base ring. In other words, the smallest dimension highest-weight representation. For the classical groups, this is the natural representation. If this is a projective representation rather than a linear representation, a warning is given. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

`AdjointRepresentation(G)`

The adjoint (projective) representation of the group of Lie type G over an extension of its base ring, i.e. the representation given by the action of G on its Lie algebra. The Lie algebra itself is the second returned value. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

`LieAlgebra(G)`

The Lie algebra of the group of Lie type G, together with the adjoint representation. If this is a projective representation rather than a linear representation, a warning is given.

`HighestWeightRepresentation(G, v)`

The highest weight (projective) representation with highest weight v of the group of Lie type G over an extension of its base ring. If this is a projective representation rather than a linear representation, a warning is given. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

Example H103E23

```
> G := GroupOfLieType("A2", Rationals() : Isogeny := "SC");
> rho := StandardRepresentation(G);
> rho(elt< G | 1 >);
[ 0 -1  0]
[ 1  0  0]
[ 0  0  1]
> rho(elt<G | <2,1/2> >);
[  1   0   0]
[  0   1   0]
[  0 1/2   1]
> rho(elt< G | VectorSpace(Rationals(),2)![3,5] >);
[  3   0   0]
[  0 5/3   0]
[  0   0 1/5]
>
> G := GroupOfLieType("A2", Rationals());
> Invariants(CoisogenyGroup(G));
[ 3 ]
> rho := StandardRepresentation(G);
Warning: Projective representation
> BaseRing(Codomain(rho));
Algebraically closed field with no variables
> rho(elt< G | VectorSpace(Rationals(),2)![3,1] >);
[r1  0  0]
[ 0 r2  0]
[ 0  0 r2]
> rho(elt< G | VectorSpace(Rationals(),2)![3,1] >)^3;
```

```
[  9   0   0]
[  0 1/3   0]
[  0   0 1/3]
```

`GeneralisedRowReduction(`ρ`)`

`RowReductionHomomorphism(`ρ`)`

`Inverse(`ρ`)`

Given a projective matrix representation $\rho : G \to \mathrm{GL}_m(k)$, return its inverse.

104 REPRESENTATIONS OF LIE GROUPS AND ALGEBRAS

Chapter 104
REPRESENTATIONS OF LIE GROUPS AND ALGEBRAS

104.1 Introduction

This chapter gives functionality for direct sums of *highest weight representations* (or modules). This is an important class of representations of (almost) semisimple Lie algebras (Chapter 100) and connected reductive algebraic groups (Chapter 103). This class includes all finite dimensional representations if the base field is the complex field.

The representations we are considering are in bijection with sets of dominant weights with multiplicities. Such sets are called *decomposition multisets*. Many interesting computations in representation theory can be done combinatorially with weight multisets, without the need to construct the module itself. Examples of the things we can compute include: module dimension, the multiset of all the weights, and decomposition multisets for symmetric powers, alternating powers, and tensor products. We can also restrict a decomposition multiset to a subgroup or induce it to a supergroup.

The code for such combinatorial computations is based on the LiE software package [vLCL92]. The algorithms for computing the actual representations are from [dG01] in the Lie algebra case, and from [CMT04] in the group case.

104.1.1 Highest Weight Modules

This introduction is inspired by the LiE manual [vLCL92].

First consider connected reductive Lie groups over the complex field. If G is a connected reductive complex Lie group, then it is a homomorphic image $G = \xi(G')$, where ξ is a Lie-group homomorphism with finite kernel and G' is the direct product of a simply connected group and a torus. Recall that a simply connected group is a direct product of *simple* simply connected groups. In particular, such groups are determined by their Cartan name and the dimension of the torus. For example, we denote the direct product of the group of type $A_4C_3B_2$ with a two dimensional torus by $A_4C_3B_2T_2$. Most of the code ported from LiE works only for groups of this form. Similar terminology is used for the root datum corresponding to a group.

Connected reductive complex Lie groups have a very pleasing representation theory:

– Every module decomposes as a direct sum of irreducible representations.

– The (finite dimensional) irreducible representations correspond to dominant weights.

It follows that representations correspond to finite sets of dominant weights with multiplicity. These multisets are called *decomposition multisets*. We can use this classification to do useful computations about representations, without having to explicitly construct them.

Multisets of weights can be used for other purposes as well: The multiset of all weights occurring in a module M is called the *character multiset*. Since the Weyl group permutes the weights occurring in the character of M, it suffices to consider only the dominant weights with their multiplicities. This is called the *dominant character multiset*. In the LiE system, multisets of weights are represented by polynomials: for example, the decomposition multiset is called a decomposition character.

When using the functions in this section, it is important to keep track of which kind of multiset you are using. For example, if you input a decomposition multiset to a function that expects a dominant character multiset, the output is meaningless.

We often abbreviate decomposition multiset to *decomposition*, and similarly for character multisets. Write R_D for the root datum of the group of the decomposition D. Denote the irreducible module for the group with root datum R with highest weight v by V_v^R, or to V_v if R is clear from the context.

It is often useful to define consider *virtual* multisets, which allow weights to have negative multiplicities. We call a virtual multiset *proper* if its weights all have nonnegative multiplicities. A decomposition corresponds to an actual module if and only if it is proper.

104.1.2 Toral Elements

Many functions use a special syntax for finite-order elements of the torus of a Lie group G (we are rarely interested in infinite-order elements). Recall that a weight is in fact a mapping from the torus T to $C^\star$, and thus a weight λ can be evaluated at an element $t \in T$. The resulting element is written t^λ. A set of fundamental weights $\omega_1, \ldots, \omega_r$ has the property that any element $t \in T$ is uniquely determined by the values $t^{\omega_1}, \ldots, t^{\omega_r}$. Therefore, we may represent t as a vector $(a_1, \ldots, a_r, n)$, with the property that $t^{\omega_i} = e^{2\pi i a_i/n} = \zeta_n^{a_i}$, where $\zeta_n = e^{2\pi i/n}$ is the canonical n-th root of unity. An example of a function which uses this syntax for toral elements is `Spectrum`. This function also provides a means to convert toral elements into a more natural form: see Example H104E10.

104.1.3 Other Highest Weight Representations

MAGMA can also construct highest weight representations for:

– (Almost) reductive Lie algebras (Chapter 100); and

– Split groups of Lie type (Chapter 103).

If the base field ha positive characteristic, highest weight representations are indecomposable, but not necessarily irreducible. In some cases there are irreducible representations which are not highest weight representations.

For groups of Lie type, we consider projective representations (i.e., homomorphisms to a projective general linear group). Suppose G is a split group of Lie type defined over the field k and r is the least common multiple of the nonzero abelian-group invariants of the coisogeny group of G (see Section 97.1.6). Let K be an extension of k containing at least one rth root of each element of k (i.e., K contains a Kummer extension). Then highest weight representations are projective representations defined over K, and are constructed using polynomial functions and rth roots.

If k already contains all rth roots, then no extension is needed and the representation will be linear rather than projective. This happens when $r = 1$, i.e., the coisogeny group is torsion free. This includes direct products of a simply connected group and a torus. The general linear group also has this property. It also happens when k is the complex field or field of algebraic numbers, when k is the real field and r is odd, and when k is finite and $|k| - 1$ is coprime to r.

The functions give a warning when the representation is not linear, but this can be avoided using the optional parameter `NoWarning`. Note that an appropriate extension K can be constructed for all fields other than rational function fields, fields of Laurent series, and local fields. In these cases, as well as for nonfields, the representations can only be computed when $r = 1$.

104.2 Constructing Weight Multisets

In this section, we describe how to construct weight multisets.

`TrivialLieRepresentationDecomposition(R)`

`LieRepresentationDecomposition(R)`

The decomposition multiset of the trivial representation. The root datum R must be weakly simply connected.

`LieRepresentationDecomposition(R, v)`

The decomposition multiset of the highest weight representation with weight v, i.e., the singleton multiset. The root datum R must be weakly simply connected. The weight v must be a sequence of length d or an element of $\mathbf{Z}^d$, where d is the dimension of the root datum R.

`LieRepresentationDecomposition(R, Wt, Mp)`

The decomposition multiset with weights given by the sequence Wt and multiplicities given by of the sequence Mp. The root datum R must be weakly simply connected. The weights must be a sequences of length d or elements of $\mathbf{Z}^d$, where d is the dimension of the root datum R.

`AdjointRepresentationDecomposition(R)`

The decomposition multiset of the adjoint representation. This has the highest root of R as its highest weight with multiplicity one. The root datum R must be weakly simply connected.

Example H104E1

The adjoint representation:

```
> R := RootDatum("D4" : Isogeny := "SC");
> D := AdjointRepresentationDecomposition(R);
> D:Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Dimension of weight space:4
     Weights:
          [
               (0 1 0 0)
          ]
     Multiplicities:
          [ 1 ]
> HighestRoot(R : Basis := "Weight");
(0 1 0 0)
```

104.3 Constructing Representations

104.3.1 Lie Algebras

The functions described in this section are applicable only to almost reductive structure constant Lie algebras.

If L has of large dimension, the step that calculates the information needed to compute preimages for these representations can be quite time consuming. So if there is no requirement for preimages, this step may be skipped by setting the optional argument `ComputePreImage` to `false`.

`TrivialRepresentation(L)`

The one-dimensional trivial representation of the Lie algebra L over its base ring.

`AdjointRepresentation(L)`

`ComputePreImage` BoolElt *Default :* `true`

The adjoint representation of the Lie algebra L acting on itself.

`StandardRepresentation(L)`

`ComputePreImage` BoolElt *Default :* `true`

The standard representation of the semisimple Lie algebra L over its base ring. This is the smallest dimensional faithful representation of G (with a few small exceptions). The Killing form of L must be nondegenerate.

Example H104E2

```
> R := RootDatum("A2");
> #CoisogenyGroup(R);
3
> L := LieAlgebra(R, GF(2));
> h := StandardRepresentation(L);
> h(L.1);
[0 0 1]
[0 0 0]
[0 0 0]
> L := LieAlgebra(R, GF(3));
> h := StandardRepresentation(L);
>> h := StandardRepresentation(L);
                               ^
Runtime error in 'StandardRepresentation': Cannot compute the standard
representation in characteristic  3
```

The coisogeny group of a simply connected root datum always has order one, so we can compute the standard representation in this case.

```
> R := RootDatum("A2" : Isogeny:="SC");
> L := LieAlgebra(R, GF(3));
> h := StandardRepresentation(L);
```

`HighestWeightRepresentation(L, w)`

The representation of the Lie algebra L with highest weight w (given either as a vector or as a sequence representing a vector). The result is a function, which for an element of L gives the corresponding matrix. The algorithm used is described in [dG01].

Example H104E3

```
> L:= LieAlgebra("G2", RationalField());
> DimensionOfHighestWeightModule(RootDatum(L), [1,0]);
7
> rho:= HighestWeightRepresentation(L, [1,0]);
> e, f, h := ChevalleyBasis(L);
> rho(e[1]+f[1]);
[ 0  1  0  0  0  0  0]
[ 1  0  0  0  0  0  0]
[ 0  0  0 -2  0  0  0]
[ 0  0 -1  0 -1  0  0]
[ 0  0  0 -2  0  0  0]
[ 0  0  0  0  0  0  1]
[ 0  0  0  0  0  1  0]
```

```
> Codomain(rho);
Full Matrix Lie Algebra of degree 7 over Rational Field
> N := sub<Codomain(rho) | [ rho(x) : x in e ]>;
> Dimension(N);
6
> IsSolvable(N);
true
```

`HighestWeightModule(L, w)`

Given a semisimple Lie algebra L corresponding to a root datum of rank r and a sequence w of non-negative integers of length r, this returns the irreducible L-module with highest weight w. The object returned is a left module over L. The algorithm used is described in [dG01].

`TensorProduct(Q)`

Given a sequence Q of left-modules over a Lie algebra, this function returns the module M that is the tensor product of the elements of Q. It also returns a map ϕ from the Cartesian product P of the modules in Q to M as the second return value. If t is an tuple whose i-th component is an element from the i-th module in Q then ϕ maps t to the element of M that corresponds to the tensor product of the elements of t.

`SymmetricPower(V, n)`

Given a left-module V over a Lie algebra, and an integer $n \geq 2$, this function returns the module M that is the n-th symmetric power of V. It also returns a map f from the n-fold Cartesian product of V to M. This map is multilinear and symmetric, i.e., if two of its arguments are interchanged then the image remains the same. Furthermore, f has the universal property, i.e., any multilinear symmetric map from the n-fold Cartesian product into a vector space W can be written as the composition of f with a map from M into W.

`ExteriorPower(V, n)`

Given a left-module V over a Lie algebra, and an integer $2 \leq n \leq \dim(V)$, this function returns the module M that is the n-th exterior power of V. It also returns a map f from the n-fold Cartesian product of V to M. This map is multilinear and antisymmetric, i.e., if two of its arguments are interchanged then the image is multiplied by -1. Furthermore, f has the universal property, i.e., any multilinear antisymmetric map from the n-fold Cartesian product into a vector space W can be written as the composition of f with a map from M into W.

Example H104E4

```
> L:= LieAlgebra("G2", Rationals());
> V1:= HighestWeightModule(L, [1,0]);
> V2:= HighestWeightModule(L, [0,1]);
> T,f:= TensorProduct([V1,V2]);
> HighestWeightsAndVectors(T);
[
    (1 1),
    (2 0),
    (1 0)
]
[
    [
        T: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ],
    [
        T: (0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 3 0 0 0 0 0 0 0 0 0 0 0 0 -3 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ],
    [
        T: (0 0 0 0 0 0 1 2 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 -1 0 0
            0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 -3 0 0 0 0 0 0 0 0 0 0
            0 0 -3 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ]
]
> DecomposeTensorProduct(RootDatum(L), [1,0], [0,1]);
[
    (1 1),
    (2 0),
    (1 0)
]
[ 1, 1, 1 ]
> f(<V1.2,V2.3>);
T: (0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
```

So we see that the tensor product T decomposes as a direct sum of three submodules. This information can also be computed by using `DecomposeTensorProduct`. However, in the former case, the corresponding highest-weight vectors are also given.

```
> E,h:= ExteriorPower(V1, 3);
> h(<V1.1,V1.3,V1.4>);
E: (0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> h(<V1.1,V1.4,V1.3>);
```

```
E: (0 0 0 0 0 -1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> DecomposeExteriorPower( RootDatum(L), 3, [1,0] );
[
    (2 0),
    (1 0),
    (0 0)
]
[ 1, 1, 1 ]
> HighestWeightsAndVectors(E);

    (2 0),
    (1 0),
    (0 0)
]
[
    [
        E: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
        0)
    ],
    [
        E: (0 0 0 1 0 0 1 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
        0)
    ],
    [
        E: (0 0 0 0 0 0 0 0 0 0 0 1 2 0 0 0 0 0 2 0 1 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0
        0)
    ]
]
```

104.3.2 Groups of Lie Type

`TrivialRepresentation(G)`

The one-dimensional trivial representation of the group of Lie type G over its base ring.

`StandardRepresentation(G)`

The standard (projective) representation of the semisimple group of Lie type G over an extension its base ring. In other words, the smallest dimension highest-weight representation. For the classical groups, this is the natural representation. If this is a projective representation rather than a linear representation, a warning is given. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

`AdjointRepresentation(G)`

The adjoint (projective) representation of the group of Lie type G over an extension of its base ring, ie. the representation given by the action of G on its Lie algebra. The Lie algebra itself is the second returned value. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

`LieAlgebra(G)`

The Lie algebra of the group of Lie type G, together with the adjoint representation. If this is a projective representation rather than a linear representation, a warning is given.

`HighestWeightRepresentation(G, v)`

The highest weight (projective) representation with highest weight v of the group of Lie type G over an extension of its base ring. If this is a projective representation rather than a linear representation, a warning is given. This is constructed from the corresponding Lie algebra representation, using the algorithm in [CMT04].

Example H104E5

```
> G := GroupOfLieType("A2", Rationals() : Isogeny := "SC");
> rho := StandardRepresentation(G);
> rho(elt< G | 1 >);
[ 0 -1  0]
[ 1  0  0]
[ 0  0  1]
> rho(elt<G | <2,1/2> >);
[  1   0   0]
[  0   1   0]
[  0 1/2   1]
> rho(elt< G | VectorSpace(Rationals(),2)![3,5] >);
[  3   0   0]
[  0 5/3   0]
[  0   0 1/5]
>
> G := GroupOfLieType("A2", Rationals());
> Invariants(CoisogenyGroup(G));
[ 3 ]
> rho := StandardRepresentation(G);
Warning: Projective representation
> BaseRing(Codomain(rho));
Algebraically closed field with no variables
> rho(elt< G | VectorSpace(Rationals(),2)![3,1] >);
[r1  0  0]
[ 0 r2  0]
[ 0  0 r2]
> rho(elt< G | VectorSpace(Rationals(),2)![3,1] >)^3;
```

```
[  9   0   0]
[  0 1/3   0]
[  0   0 1/3]
```

104.4 Operations on Weight Multisets

104.4.1 Basic Operations

In this section, basic access and arithmetic operations for weight multisets are described. Addition generally corresponds to direct sum of representations. The other arithmetic operations do not necessarily correspond to meaningful operations on the corresponding representation.

`RootDatum(D)`

The Root datum over which the weight multiset D is defined.

`Weights(D)`

`WeightsAndMultiplicities(D)`

The sequences of weights and multiplicities in the weight multiset D.

`Multiset(D)`

The weights and multiplicities of the weight multiset D as a normal multiset consisting of vectors.

`Multiplicity(D, v)`

The multiplicity of the weight v in the weight multiset D.

`D eq E`

Returns `true` if, and only if, the weight multisets D and E are identical, i.e. they are defined over identical root data, with equal weights and multiplicities.

`D + E`

The sum (union) of weight multisets D and E, i.e. this corresponds to the direct sum of the two decomposition multisets. The underlying root data must be the same.
Add V_v to D. The length of v must be equal to $\dim(R_D)$.

`D +:= E`

Add the weight multiset E to D. R_D must be equal to R_E.

`AddRepresentation(~D, E, c)`

`AddRepresentation(~D, E)`

Add c times the weight multiset E to D. The integer c may be omitted, in which case it is assumed to be equal to 1. The root data of D and E must be identical.

`D + v`

Add the weight v to the multiset D. The weight v must be a sequence of length d or an element of $\mathbf{Z}^d$, where d is the dimension of the root datum R.

`AddRepresentation(~D, v, c)`

`AddRepresentation(~D, v)`

Add c times the weight v to the multiset D. The integer c may be omitted, in which case it is assumed to be equal to 1. The length of v must be equal to the dimension of the root datum of D.

`D +:= v`

Add the weight v to the multiset D. The length of v must be equal to the dimension of the root datum of D.

`D * c`

The multiset whose weights are equal to those of D, and whose multiplicities are c times the multiplicities of D.

`D / c`

The multiset whose weights are equal to those of D, and whose multiplicities are the multiplicities of D divided by c. An error is flagged if any of the multiplicities of D is not divisible by c.

`D *:= c`

Multiply all multiplicities of the weight multiset D by c.

`D /:= c`

Divide all multiplicities of the weight multiset D by c. An error is flagged if a multiplicity of D is not divisible by c.

`D * E`

`ProductRepresentation(D, E)`

The product of the two weight multisets D and E, viewed as polynomials as in the LiE package [vLCL92]. The root datum of the resulting decomposition is the direct sum of the root data of D and E. Note that this is does not correspond to the direct sum or tensor product of representations.

`ProductRepresentation(D, E, R)`

The product of the two weight multisets D and E, viewed as polynomials as in the LiE package [vLCL92]. The product is interpreted as a weight multiset over the root datum R. An error is flagged if the dimension of R is not the sum of the dimensions of the root data of D and E.

`SubWeights(D, Q, S)`

Let k be the length of the sequence Q. The resulting decomposition E has Root datum S, and to each highest weight of D corresponds a highest weight w' of E, with $w'_i = w_{Q[i]}$, where $i = 1, \ldots, k$. The multiplicities of E are equal to the multiplicities of D, but one should note that E might in fact have fewer unique highest weights than D, especially if $k < \dim(R_D)$. The dimension of the root datum S must be equal to k.

`PermuteWeights(D, pi, S)`

Permute the components of the weights in the multiset D by the permutation π and interpret the result as a weight multiset over the root datum S. If the underlying root datum of D has dimension d, then S must also have dimension d and π must be an element of $\mathrm{Sym}(d)$.

Example H104E6

Arithmetic with decompositions:

```
> R := RootDatum("A2" : Isogeny := "SC");
> D := LieRepresentationDecomposition(R, [[2,3],[4,3]], [1,3]);
> D:Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 2 of type A2
     Dimension of weight space:2
     Weights:
          [
               (2 3),
               (4 3)
          ]
     Multiplicities:
          [ 1, 3 ]
> E := D + [5,2];
> E:Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 2 of type A2
     Dimension of weight space:2
     Weights:
          [
               (2 3),
               (4 3),
               (5 2)
```

```
          ]
     Multiplicities:
          [ 1, 3, 1 ]
> PermuteWeights(E, Sym(2)!(1,2), R):Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 2 of type A2
     Dimension of weight space:2
     Weights:
          [
               (3 2),
               (3 4),
               (2 5)
          ]
     Multiplicities:
          [ 1, 3, 1 ]
> S := RootDatum("A1" : Isogeny := "SC");
> SubWeights(E, [2], S):Maximal;
Highest weight decomposition of representation of:
     S: Simply connected root datum of dimension 1 of type A1
     Dimension of weight space:1
     Weights:
          [
               (3),
               (2)
          ]
     Multiplicities:
          [ 4, 1 ]
```

104.4.2 Conversion Functions

Functions for converting between different kinds of weight multiset (decomposition, character, and dominant character multisets). Note that it is the users responsibility to keep track of what kind of multiset they are using. If a function that expects one kind of set receives another, the output is likely to be meaningless.

`VirtualDecomposition(C)`

`VirtualDecomposition(R, v)`

The virtual decomposition multiset of the virtual module with dominant character multiset C. The second version is provided for convenience, and equivalent to `VirtualDecomposition(LieRepresentationDecomposition(R,v))`.

`DecomposeCharacter(C)`

The decomposition multiset of the module with dominant character multiset C. An error is flagged if D is virtual, i.e. if dominant weights occur with negative multiplicities.

`DominantCharacter(D)`

Returns the dominant character multiset with decomposition D.

104.4.3 Calculating with Representations

As described earlier, many operations on representations carry over naturally to operations on their decompositions. This section describes the various functions for this purpose that were ported from LiE.

Note that many functions in this sections have two variants: one that takes decompositions as an argument and one that takes a root datum and a highest weight.

`RepresentationDimension(D)`

The dimension of the module with decomposition polynomial D. The algorithm used is described in [vLCL92].

`RepresentationDimension(R, v)`

The dimension of the module with highest weight v over the root datum R. The algorithm used is described in [vLCL92].

`CasimirValue(R, w)`

The value of the quadratic Casimir on representation with highest weight w, normalised to take the value 2 on the highest weight of the adjoint representation. This function is due to Dr. Bruce Westbury, University of Warwick

`QuantumDimension(R, w)`

Two Multisets of positive integers, Num and Den, which should be read as follows. Take the product of the integers in Num and divide by the product of the integers in Den to get the ordinary dimension. Replacing each integer by the quantum integer will give the quantum dimension. This function is due to Dr. Bruce Westbury, University of Warwick

Example H104E7

Dimensions:

```
> R := RootDatum("D4" : Isogeny := "SC");
> D := AdjointRepresentationDecomposition(R);
> RepresentationDimension(D);
28
> wts, mps := WeightsAndMultiplicities(D); wts,mps;
[
    (0 1 0 0)
]
[ 1 ]
> num,den := QuantumDimension(R, wts[1]); num,den;
{* 4^^2, 7 *}
{* 1, 2^^2 *}
```

```
> &*num/&*den;
28
```

`Branch(FromGrp, ToGrp, v, M)`

`Virtual` BoolElt *Default :* `false`

The decomposition polynomial of the restriction to ToGrp of the irreducible module V_v with respect to the restriction matrix M. M must be a matrix with dim(FromGrp) rows and Dim(ToGrp) columns.

The matrix M is used in such a way that any weight v' (expressed on the basis of fundamental weights for g), when restricted to a torus of ToGrp, becomes the weight $v'M$ (expressed on the basis of fundamental weights for ToGrp). A suitable restriction matrix can often be obtained by use of `RestrictionMatrix`. The algorithm used is described in [vLCL92].

The optional argument `Virtual` may be set to `true` to allow occurrence of virtual weights.

`Branch(ToGrp, D, M)`

`Virtual` BoolElt *Default :* `false`

As `Branch(FromGrp, ToGrp, v, M)` but with the irreducible module v replaced by the module with decomposition D.

`Collect(R, D, M)`

This function attempts to perform the inverse operation of `Branch`, namely to reconstruct an R-module from its restriction to R_D.

Please note that in LiE one must supply the inverse of the matrix used in Branch. Magma, however, is able to compute inverses itself, so one needs to provide the matrix used in Branch, and not its inverse.

M must be a square matrix whose dimension is equal to the dimension of R_D. The dimension of R must be equal to the dimension of R_D as well. The algorithm used is described in [vLCL92].

Example H104E8

Branch and Collect:

```
> R := RootDatum("D4" : Isogeny := "SC");
> S := RootDatum("A3T1" : Isogeny := "SC");
> M := RestrictionMatrix(R, S);
> br := Branch(R, S, [1,0,0,0], M);
> br;
Highest weight decomposition of representation of:
     S: Simply connected root datum of dimension 4 of type A3
     Number of terms: 2
> cl := Collect(R, br, M);
```

```
> cl:Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Dimension of weight space:4
     Weights:
          [
               (1 0 0 0)
          ]
     Multiplicities:
          [ 1 ]
```

`TensorProduct(R, v, w)`

`Goal` ANY *Default :*

The decomposition multiset of the tensor product of the representations with highest weights v and w over the root datum R.

If the optional parameter `Goal` is set, only the multiplicity of the irreducible module with highest weight `Goal` is returned. This does not greatly speed up the process, as the same computational steps need to be made, but it will significantly reduce memory consumption. The algorithm used is described in [vLCL92].

`TensorProduct(D, E)`

`Goal` ANY *Default :*

The decomposition multiset of the tensor product of the representations with decomposition multisets D and E.

If the optional parameter `Goal` is set, only the multiplicity of the irreducible module with highest weight `Goal` is returned. This does not greatly speed up the process, as the same computational steps need to be made, but it will significantly reduce memory consumption. The algorithm used is described in [vLCL92].

`TensorProduct(Q)`

`Goal` ANY *Default :*

The decomposition multiset of the tensor product of the representations with decomposition multisets in the sequence Q.

If the optional parameter `Goal` is set, only the multiplicity of the irreducible module with highest weight `Goal` is returned. This does not greatly speed up the process, as the same computational steps need to be made, but it will significantly reduce memory consumption. The algorithm used is described in [vLCL92].

`TensorPower(R, n, v)`

`TensorPower(D, n)`

The decomposition of the n-th tensor power of V_v^R or D.

Example H104E9

Taking tensor powers nicely shows how rapidly the complexity of representations increases, especially if we have a reasonably high weight as highest weight:

```
> R := RootDatum("D4" : Isogeny := "SC");
> DAd := AdjointRepresentationDecomposition(R);
> pwrs := function(D, n)
>   Q := [D];
>   for i in [2..n] do
>     Q[i] := Tensor(Q[1], Q[i-1]);
>   end for;
>   return Q;
> end function;
> time Q := pwrs(DAd, 7);
Time: 4.900
> [ #q : q in Q ];
[ 1, 7, 15, 30, 54, 91, 143 ]
> DH := LieRepresentationDecomposition(R, [2,2,0,0]);
> time Q := pwrs(DH, 4); [ #q : q in Q ];
Time: 99.070
[ 1, 105, 390, 1017 ]
```

`AdamsOperator(R, n, v)`

`AdamsOperator(D, n)`

The decomposition polynomial of the virtual module obtained by applying the n-th Adams operator to V_v^R or D. The algorithm used is described in [vLCL92].

`SymmetricPower(R, n, v)`

`SymmetricPower(D, n)`

The decomposition polynomial of $S^n(V_v^R)$, the n-th symmetric tensor power of V_v^R.

In the second form the irreducible module V_v^R is replaced by the module with decomposition D. The algorithm used is described in [vLCL92].

`AlternatingPower(R, n, v)`

`AlternatingPower(D, n)`

The decomposition polynomial of $\mathrm{Alt}^n(V_v^R)$, the n-th alternating tensor power of V_v^R.

In the second form the irreducible module V_v^R is replaced by the module with decomposition D. The algorithm used is described in [vLCL92].

`Plethysm(R, lambda, v)`

`Plethysm(D, lambda)`

The decomposition multiset of the R_D-module of the plethysm of V_v^R corresponding to the partition λ. Here λ should be a partition of $d = \dim V_v^R$, i.e., a non-increasing sequence consisting of positive integers with sum d. The value returned is the decomposition multiset of the representation of R_D that is obtained by composing the representation of R_D afforded by V_v^R, with the representation of $\mathrm{GL}(V_v^R)$ corresponding to the partition λ. The classical Frobenius formula is used (see [And77] and [JK81]).

In the second form the irreducible module V_v^R is replaced by the module with decomposition D.

`Spectrum(R, v, t)`

`Spectrum(D, t)`

Let n be the last entry of the sequence t; the toral element $t \in T$ will act in any representation of R as a diagonalisable transformation, all of whose eigenvalues are n-th roots of unity. This function returns a sequence in which the i-th entry is the multiplicity of the eigenvalue ζ^i in the action of the toral element t on the irreducible module V_v^R (or the module with decomposition D, in the second case). Here ζ is the complex number $e^{2\pi i/n}$.

See Section 104.1.2 for a description of the format of t.

Example H104E10

Spectrum provides a means to recognise toral elements in a more natural form. [vLCL92, Section 5.7.3].

```
> R := RootDatum("A4" : Isogeny := "SC");
> stdrep := [1,0,0,0];
> t := [1,0,0,0,2];
> stdrep := [1,0,0,0];
> Spectrum(R, stdrep, t);
[ 3, 2 ]
/* Showing that t has 3 eigenvalues 1 (1st root of unity),
   and 2 eigenvalues -1 (2nd root of unity) */
/* We may use the following function for constructing
   toral elements of A_n in the LiE format: */
> mktoral := function(b, d)
>     r := [ (i eq 1)
>                 select b[i]
>                 else b[i-1]+b[i] mod d
>              : i in [1..(#b-1)]
>          ];
>     r[#b] := d;
>     return r;
```

```
> end function;
> t2 := mktoral([0,0,0,1,1], 2); t2;
[ 0, 0, 0, 1, 2 ]
/* We restrict to a one parameter subgroup */
> RM := Transpose(Matrix([[0,0,0,1]]));
> T1 := RootDatum("T1" : Isogeny := "SC");
> Branch(R, T1, stdrep, RM):Maximal;
Highest weight decomposition of representation of:
     T1: Toral root datum of dimension 1
     Dimension of weight space:1
     Weights:
          [
               (1),
               (0),
               (-1)
          ]
     Multiplicities:
          [ 1, 3, 1 ]
/* Indicating that the element of that one parameter
   subgroup parametrised by some complex number z has
   one eigenvalue z^-1, three eigenvalues 1, and one
   eigenvalue z in the standard representation. */
```

`Demazure(R, v, w)`

`Demazure(D, w)`

Starting with the highest weight v of R, or the decomposition D, repeatedly apply the Demazure operator M_{α_i}, taking for i the successive entries of the Weyl word w (viewed as product of simple reflections).

`Demazure(R, v)`

`Demazure(D)`

Equivalent to `Demazure(R, v, w)` or `Demazure(D, w)` where w is the longest word of the Coxeter group of R or R_D.

If D is a decomposition polynomial, then the result E is the character polynomial of this decomposition. This is not the most efficient way to compute characters, but it can be very useful in checking other algorithms, since only the most elementary manipulations are involved.

Example H104E11

The Demazure operator:

```
> R := RootDatum("D4" : Isogeny := "SC");
> DAd := AdjointRepresentationDecomposition(R);
> DAdCp := Demazure(DAd); DAdCp;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Number of terms: 25
> DAd2 := AlternatingDominant(DAdCp); DAd2;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Number of terms: 1
> DAd2 eq DAd;
true
```

`LittlewoodRichardsonTensor(p, q)`

`LittlewoodRichardsonTensor(P, M, Q, N)`

In the first form, p and q are interpreted as dominant weights for the group SL_n (of type A_{n-1}) expressed in partition coordinates. Here n is the number of elements of p (which must be equal to the number of elements of q).

The tensor product of the corresponding highest weight modules is computed using the Littlewood-Richardson rule, and the result is expressed again in partition coordinates. To be precise, two sequences P, M, are returned, meaning that the highest weight module with partition coordinates P[i] occurs in the tensor product with multiplicity M[i].

In the second form, instead of two irreducible modules, the tensor product of the module having partition coordinates P[i] with multiplicity M[i] and the module having partition coordinates Q[j] with multiplicity N[j] is computed.

`LittlewoodRichardsonTensor(R, v, w)`

`LittlewoodRichardsonTensor(D, E)`

In the first form, compute the tensor product of the irreducible A_n representations with highest weights v and w using the Littlewood-Richardson rule. In the second form, compute the tensor product of the representations with decompositions D and E.

This procedure converts the weights to partitions, computes the tensor product using the Littlewood-Richardson rule (as described above, see LittlewoodRichardsonTensor), and converts the result back to a weight multiset.

Example H104E12

We compare the Littlewood-Richardson tensor and the normal tensor:

```
> R := RootDatum("A2" : Isogeny := "SC");
> v := [1,2];
> w := [1,1];
> D1 := Tensor(R, v, w);
> D1;
Highest weight decomposition of representation of:
    R: Simply connected root datum of dimension 2 of type A2
    Weights:
        [
            (0 1),
            (2 0),
            (0 4),
            (3 1),
            (2 3),
            (1 2)
        ]
    Multiplicities:
        [ 1, 1, 1, 1, 1, 2 ]
> D2 := LittlewoodRichardsonTensor(R, v, w);
> D2;
Highest weight decomposition of representation of:
    R: Simply connected root datum of dimension 2 of type A2
    Weights:
        [
            (1 2),
            (2 3),
            (2 0),
            (0 4),
            (0 1),
            (3 1)
        ]
    Multiplicities:
        [ 2, 1, 1, 1, 1, 1 ]
> D1 eq D2;
true
```

So the results are identical, as they should be. We could also convert the weights to partitions by hand, directly compute the Littlewood- Richardson tensor, and compare that to the previous result:

```
> vp := WeightToPartition(v); wp := WeightToPartition(w);
> vp, wp;
[ 3, 2, 0 ]
[ 2, 1, 0 ]
> parts, mps := LittlewoodRichardsonTensor(vp, wp);
> parts, mps;
```

```
[
    (4 4 0),
    (4 3 1),
    (3 3 2),
    (5 3 0),
    (5 2 1),
    (4 2 2)
]
[ 1, 2, 1, 1, 1, 1 ]
> [ PartitionToWeight(p) : p in parts ];
[
    (0 4),
    (1 2),
    (0 1),
    (2 3),
    (3 1),
    (2 0)
]
```

So that again gives the same representation. Finally, note that in some cases computing tensor products using the Littlewood-Richardson rule may be faster than computing them in the normal way:

```
> R := RootDatum("A8" : Isogeny := "SC");
> v := [0,0,2,0,1,0,1,2];
> w := [0,2,1,2,0,0,1,0];
> time _ := Tensor(R, v, w);
Time: 2.630
> time _ := LittlewoodRichardsonTensor(R, v, w);
Time: 0.210
```

`AlternatingDominant(D, w)`

`AlternatingDominant(R, wt, w)`

Alternating Dominant of the representation with decomposition D or the irreducible representation V_{wt}, with respect to Weyl group element w. Starting with D, the following operation is repeatedly applied, taking for i the successive entries of w (viewed as reflection). For any (weight, multiplicity) pair (v, c) of D let $v_i = \langle v, \alpha_i \rangle$ be its coefficient of w_i; the term is

- unaltered if $v_i \geq 0$,
- removed if $v_i = -1$, and
- replaced by $((v + w_i)r_i - w_i, -c)$ if $v_i = -2$. As a result of the operation for i, the coefficient v_i is made non-negative without affecting the image $M_{\alpha_i}(D)$ under the Demazure operator, and hence also without changing the value of its alternating Weyl sum `AlternatingWeylSum`.

`AlternatingDominant(D)`

`AlternatingDominant(R, wt)`

Equivalent to (but somewhat faster than) the previous `AlternatingDominant`(D, w) and `AlternatingDominant`(R, wt, w), with w the longest element of the corresponding Weyl group. If D is interpreted as dominant weights with multiplicities, then the result E contains highest weights and multiplicities.

Example H104E13

Example of the alternating dominant:

```
> R := RootDatum("D4" : Isogeny := "SC");
> v := [1,5,2,1];
> Dec1 := LieRepresentationDecomposition(R, v);
> // First, we construct the character polynomial for the
> // module with highest weight lambda
> Dom := DominantCharacter(Dec1 : InBasis := "Weight"); Dom;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Number of terms: 176
> W := CoxeterGroup(R); #W; act := RootAction(W);
192
> domwts, dommps := WeightsAndMultiplicities(Dom);
> CP := LieRepresentationDecomposition(R);
> for i in [1..#domwts] do
>   wt := domwts[i]; mp := dommps[i];
>   wtor := WeightOrbit(W, wt : Basis := "Weight");
>   for wti in wtor do
>     AddRepresentation(~CP, wti, mp);
>   end for;
> end for;
> CP;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Number of terms: 17712
> time ad := AlternatingDominant(CP); ad:Maximal;
Time: 54.200
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 4 of type D4
     Dimension of weight space:4
     Weights:
          [
               (1 5 2 1)
          ]
     Multiplicities:
          [ 1 ]
> time adalt := AlternatingDominant(CP, LongestElement(W));
```

```
Time: 8.330
> ad eq adalt;
true
```

`AlternatingWeylSum(R, v)`

`AlternatingWeylSum(D)`

The alternating Weyl sum of V_v^R or D. Useful for demonstration purposes, but the fact that the number of terms in the result is a multiple of the order of the CoxeterGroup of R makes it impractical for most groups.

104.5 Operations on Representations

104.5.1 Lie Algebras

The functions described in this section are applicable only to modules of almost reductive structure constant Lie algebras.

`CharacterMultiset(V)`

`CharacterMultiset(ρ)`

The character multiset of the Lie-algebra module V or representation ρ.

`Weights(V)`

`WeightsAndVectors(V)`

For a module V over a semisimple Lie algebra this returns two sequences. The first sequence consists of the weights that occur in V. The second sequence is a sequence of sequences of elements of V, in bijection with the first sequence. The i-th element of the second sequence consists of a basis of the weight space of weight equal to the i-th weight of the first sequence.

`Weights(ρ)`

`WeightsAndVectors(ρ)`

For a representation ρ of a semisimple Lie algebra this returns two sequences. The first sequence consists of the weights of ρ. The second sequence is a sequence of sequences of elements of the underlying vector space, in bijection with the first sequence. The i-th element of the second sequence consists of a basis of the weight space of weight equal to the i-th weight of the first sequence.

`DecompositionMultiset(V)`

`DecompositionMultiset(ρ)`

The decomposition multiset of the Lie-algebra module V or representation ρ.

`HighestWeightsAndVectors(V)`

This function is analogous to the previous one. Except in this case the first sequence consists of highest weights, i.e., those weights which occur as highest weights of an irreducible constituent of V. The second sequence consists of sequences that contain the corresponding highest weight vectors. So the submodules generated by the vectors in the second sequence form a direct sum decomposition of V.

`DirectSum(U, V)`

The direct sum of the Lie algebra modules U and V.

`DirectSumDecomposition(V)`

`IndecomposableSummands(V)`

Given a Lie algebra module V, return the direct sum decomposition of V as a sequence of submodules whose sum is V and each of which cannot be further decomposed into a direct sum. If the Lie algebra is semisimple over a field of characteristic zero, the summands are known to be irreducible highest weight modules.

`DirectSum(`ρ`, `τ`)`

The direct sum of the Lie algebra representations ρ and τ.

`DirectSumDecomposition(`ρ`)`

`IndecomposableSummands(`ρ`)`

Given a Lie algebra representation ρ, return the direct sum decomposition of ρ as a sequence of indecomposable subrepresentation. If the Lie algebra is semisimple over a field of characteristic zero, the summands are known to be irreducible highest weight representations.

`TensorProduct(Q)`

Given a sequence Q of left-modules over a Lie algebra, this function returns the module M that is the tensor product of the elements of Q. Secondly it returns a map from the Cartesian product of the elements of Q to M. This maps a tuple t to the element of M that is formed by tensoring the elements of t.

`SymmetricPower(V, n)`

Given a left-module V over a Lie algebra, and an integer $n \geq 2$, this function returns the module M that is the n-th symmetric power of V. It also returns a map f from the n-fold Cartesian product of V to M. This map is multilinear and symmetric, i.e., if two of its arguments are interchanged then the image remains the same. Furthermore, f has the universal property, i.e., any multilinear symmetric map from the n-fold Cartesian product into a vector space W can be written as the composition of f with a map from M into W.

```
ExteriorPower(V, n)
```

Given a left-module V over a Lie algebra, and an integer $2 \le n \le \dim(V)$, this function returns the module M that is the n-th exterior power of V. It also returns a map f from the n-fold Cartesian product of V to M. This map is multilinear and antisymmetric, i.e., if two of its arguments are interchanged then the image is multiplied by -1. Furthermore, f has the universal property, i.e., any multilinear antisymmetric map from the n-fold Cartesian product into a vector space W can be written as the composition of f with a map from M into W.

Example H104E14

```
> L:= LieAlgebra("G2", Rationals());
> V1:= HighestWeightModule(L, [1,0]);
> V2:= HighestWeightModule(L, [0,1]);
> T,f:= TensorProduct([V1,V2]);
> HighestWeightsAndVectors(T);
[
    (1 1),
    (2 0),
    (1 0)
]
[
    [
        T: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ],
    [
        T: (0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 3 0 0 0 0 0 0 0 0 0 0 0 0 -3 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
            0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ],
    [
        T: (0 0 0 0 0 0 1 2 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 -1 0 0
            0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 -3 0 0 0 0 0 0 0 0 0 0
            0 0 -3 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
    ]
]
> DecomposeTensorProduct(RootDatum(L), [1,0], [0,1]);
[
    (1 1),
    (2 0),
    (1 0)
]
[ 1, 1, 1 ]
> f(<V1.2,V2.3>);
T: (0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
```

```
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
    0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
```

So we see that the tensor product T decomposes as a direct sum of three submodules. This information can also be computed by using `DecomposeTensorProduct`. However, in the former case, the corresponding highest-weight vectors are also given.

```
> E,h:= ExteriorPower(V1, 3);
> h(<V1.1,V1.3,V1.4>);
E: (0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> h(<V1.1,V1.4,V1.3>);
E: (0 0 0 0 0 -1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
> DecomposeExteriorPower( RootDatum(L), 3, [1,0] );
[
    (2 0),
    (1 0),
    (0 0)
]
[ 1, 1, 1 ]
> HighestWeightsAndVectors(E);
[
    (2 0),
    (1 0),
    (0 0)
]
[
    [
        E: (1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
        0)
    ],
    [
        E: (0 0 0 1 0 0 1 0 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
        0)
    ],
    [
        E: (0 0 0 0 0 0 0 0 0 0 0 1 2 0 0 0 0 0 2 0 1 0 0 0 0 1 0 0 0 0 0 0 0 0
        0)
    ]
]
```

104.5.2 Groups of Lie Type

These functions apply to projective representations of groups of Lie type. Note that modules have not yet been implemented for these groups.

`DirectSum(ρ, τ)`

The direct sum of the group of Lie type representations ρ and τ.

`DirectSumDecomposition(ρ)`
`IndecomposableSummands(ρ)`

Given a group of Lie type representation ρ, return the direct sum decomposition of ρ as a sequence of indecomposable subrepresentation. If the base field has characteristic zero, the summands are known to be irreducible highest weight representations.

`CharacterMultiset(V)`
`CharacterMultiset(ρ)`

The character weight multiset of the group of Lie type representation ρ.

`Weights(ρ)`
`WeightsAndVectors(ρ)`

The weights of the representation ρ, together with the corresponding weight vectors.

`WeightVectors(ρ)`

A basis of weight vectors of the representation ρ.

`Weight(ρ, v)`

The weight corresponding to the weight vector v of the representation ρ.

`DecompositionMultiset(V)`
`DecompositionMultiset(ρ)`

The decomposition multiset of the group of Lie type representation ρ.

`HighestWeights(ρ)`

The highest weights of the representation ρ, together with the corresponding highest weight vectors. This function may fail for small finite fields.

`HighestWeightVectors(ρ)`

The highest weight vectors of the representation ρ.

`GeneralisedRowReduction(ρ)`

Given a projective matrix representation $\rho : G \to \mathrm{GL}_m(k)$, return its inverse. This algorithm is based on [CMT04].

104.6 Other Functions for Representation Decompositions

In this section, we describe more complicated functions for dealing with representation decompositions.

`FundamentalClosure(R, S)`

A set of fundamental roots in the minimal subsystem (not necessarily closed!) of the root system R that contains all the roots in S. This function is equivalent to the `fundam` function in LiE.

The set S should contain either roots or root indices; the returned set will then contain objects of the same type.

`Closure(R, S)`

A set of fundamental roots in the minimal subsystem (not necessarily closed!) of the root system R that contains all the roots in S. This function is equivalent to the `closure` function in LiE.

The set S should contain either roots or root indices; the returned set will then contain objects of the same type.

`RestrictionMatrix(R, Q)`

For a simply connected root datum R and a sequence of roots Q forming a fundamental basis for a closed subdatum S of R, this function computes a restriction matrix for the fundamental Lie subgroup of type S of the Lie group corresponding to R.

The sequence Q may contain either integers (where i corresponds to the i-th root of R) or vectors (interpreted as root vectors written in the root basis of R).

Note that the result is not unique. Moreover, if the result is to be used by Branch or Collect the roots in Q must be positive roots, and their mutual inner products must be non-positive.

`RestrictionMatrix(R, S)`

Let S be a sub root datum of R, constructed for example (but not necessarily) using a call to `sub<...>`. Then the matrix M returned by this function maps the fundamental weights of R to those of S. Note that, if the rank of S is smaller than the rank of R, there will be more than one such matrix.

Example H104E15

Constructing a restriction matrix

```
> R := RootDatum("D4":  Isogeny := "SC");
> sub<R | [1,3,4]>;
Root datum of dimension 4 of type A1 A1 A1
[ 1, 3, 4, 13, 15, 16 ]
> S := RootDatum("A1A1A1T1" : Isogeny := "SC");
> M := RestrictionMatrix(R, S); M;
```

```
[ 1  0  0 -1]
[ 0  1  0 -2]
[ 0  0  1 -1]
[ 0  0  0  4]
> imgR := FundamentalWeights(R)*M; imgR;
[ 1  0  0 -1]
[ 0  1  0 -2]
[ 0  0  1 -1]
[ 0  0  0  4]
> FundamentalWeights(S);
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
/* M is of the required form, since: */
> [ BasisChange(S, BasisChange(S, imgR[i]
>     : InBasis := "Standard", OutBasis := "Weight")
>     : InBasis := "Weight", OutBasis := "Standard")
>   : i in [1..4]
> ];
[
    (1 0 0 0),
    (0 1 0 0),
    (0 0 1 0),
    (0 0 0 0)
]
```

`KLPolynomial(x, y)`

`Ring` RngUPol *Default :* **Z**[X]

The Kazhdan-Lusztig polynomial $P_{x,y}$. We use the recursion given originally by Kazhdan and Lusztig [KL79].

`RPolynomial(x, y)`

`Ring` RngUPol *Default :* **Z**[X]

The R-polynomial $R_{x,y}$.

Example H104E16

There is a relation between Kazhdan-Lusztig polynomials and R-polynomials. We should have, for any $x, w \in W$:

$$X^{l(w)-l(x)}\overline{P_{x,w}} - P_{x,w} = \sum_{x<y\leq w} R_{x,w}P_{y,w},$$

where the bar indicates a sign change of all the exponents. We need some fiddling around in order to implement this sign change, since MAGMA doesn't support negative exponents at the moment, but we can make it work:

```
> signchange := function(pol, pwr)
>     //returns X^pwr * bar(pol)
>     deg := Degree(pol);
>     P := Parent(pol);
>     if (deg gt pwr) then return "Failed: Can't do sign change"; end if;
>     return (P.1)^(pwr-deg)*P!Reverse(Eltseq(pol));
> end function;
> testKL := function(x, w)
>     W := Parent(x);
>     rng<X> := PolynomialRing(Integers());
>     lenw := CoxeterLength(W, w);
>     lenx := CoxeterLength(W, x);
>
>     if (lenx gt lenw) then
>         return "Failed: l(x) > l(w) gives zero R and KL polynomials.";
>     end if;
>
>     /* Left hand side */
>     Pxw := KLPolynomial(x, w : Ring := rng);
>     lhs := signchange(Pxw, lenw - lenx);
>     if (Type(lhs) eq MonStgElt) then return lhs; end if;
>     lhs -:= Pxw;
>
>     /* Right hand side */
>     rhs := rng!0;
>     lvl := {w};
>     lvllen := lenw;
>     while (lvllen gt lenx and #lvl gt 0) do
>         for y in lvl do
>             rhs +:= RPolynomial(x,y : Ring := rng)*
>                         KLPolynomial(y, w : Ring := rng);
>         end for;
>         lvl := BruhatDescendants(lvl : z := x);
>         lvllen -:= 1;
>     end while;
>
>     /* Done */
>     printf "LHS: %o\n", lhs;
```

```
>     printf "RHS: %o\n", rhs;
>     return lhs eq rhs;
> end function;
> W := CoxeterGroup("D4");
> x := W.1*W.2*W.1;
> w := W.1*W.2*W.3*W.4*W.1*W.2;
> testKL(x,w);
LHS: X^3 + X^2 - X - 1
RHS: X^3 + X^2 - X - 1
true
```

`Exponents(R)`

The exponents of a Root datum R form a sequence of numbers $e_1, \ldots, e_r$, where r is the rank of R, such that the polynomial $\sum_{w \in W} X^{l(w)}$ decomposes as a product $\prod_{i=1}^{r} \sum_{j=0}^{e_i} X^j$. They are given in weakly increasing order.

Example H104E17

Exponents of A_3:

```
> W := CoxeterGroup("A3"); #W;
24
> P<X> := PolynomialRing(Integers());
> f := &+[ X^(CoxeterLength(W, w)) : w in W ]; f;
X^6 + 3*X^5 + 5*X^4 + 6*X^3 + 5*X^2 + 3*X + 1
> R := RootDatum("A3" : Isogeny := "SC");
> exp := Exponents(R); exp;
[ 1, 2, 3 ]
> g := [ &+[ X^j : j in [0..e] ] : e in exp ]; g;
[
    X + 1,
    X^2 + X + 1,
    X^3 + X^2 + X + 1
]
> f eq &*g;
true
```

`ToLiE(D)`

The LiE equivalent of the decomposition D.

`FromLiE(R, p)`

The decomposition of the representation over R that is equivalent to p, where p is a polynomial in LiE-syntax.

Example H104E18

Conversion to and from LiE-syntax

```
> R := RootDatum("B3" : Isogeny := "SC");
> D := LieRepresentationDecomposition(R, [1,2,3]);
> s := ToLiE(D); s;
1X[1,2,3]
> FromLiE(R, s):Maximal;
Highest weight decomposition of representation of:
     R: Simply connected root datum of dimension 3 of type B3
     Dimension of weight space:3
     Weights:
          [
               (1 2 3)
          ]
     Multiplicities:
          [ 1 ]
```

104.6.1 Operations Related to the Symmetric Group

In this section, we describe some functions taken from LiE for dealing with the Symmetric group.

`ConjugationClassLength(l)`

The order of the conjugation class of S_n of permutations of cycle type l (for n the sum of the elements of l).

`PartitionToWeight(l)`

Let n be the number of parts of l, then the function returns the weight for a group of type A_{n-1} corresponding to λ, expressed on the basis of fundamental weights.

`WeightToPartition(v)`

Let n be the length of v, then v is interpreted as a weight for a group of type A_n, and the expression of that weight in $n+1$ partition coordinates is returned. When v is dominant, this is a partition with $n+1$ parts.

`TransposePartition(l)`

The transpose partition of l.

104.6.2 FusionRules

In this section, we describe a function for computing fusion rules using the Kac-Walton formular, as described in Section 16.2 of [FMS97].

`WZWFusion(R, v, w, k)`

`ReturnForm` MonStgElt *Default :* "*Auto*"

Compute the fusion rules for weights $v \times w$ of R at level k using the Kac-Walton formula. The weights v and w may be given either as finite weights (i.e. vectors or sequences with rank(R) entries) or as affine weights (i.e. vectors or sequences with rank(R)+1 entries).

The optional argument `ReturnForm` should be "Auto" (in which case the weights returned will be finite weights or affine weights depending on what v and w are; the default), "Finite" (in which case the weights returned are finite weights), or "Affine" (in which case the weights returned are affine weights).

Note that R should be a weakly simply connected root datum.

`WZWFusion(D, E, k)`

Compute the fusion rules for representations D and E at level k.

Example H104E19

Fusion rules at level 3 for B_3 (using finite weights first, affine weights second)

```
> R := RootDatum("B3" : Isogeny := "SC");
> WZWFusion(R, [0,0,1],[1,0,1], 3);
{*
    (2 0 0),
    (1 1 0),
    (0 0 2),
    (1 0 2),
    (1 0 0),
    (0 1 0)
*}
> WZWFusion(R, [0,0,1],[1,0,1], 3 : ReturnForm := "Affine");
{*
    (2 0 0 1),
    (1 0 2 0),
    (0 1 0 1),
    (1 0 0 2),
    (0 0 2 1),
    (1 1 0 0)
*}
```

104.7 Subgroups of Small Rank

LiE contains a small database with the types of the maximal proper subgroups of complex reductive simply connected Lie groups g, where g is simple and of rank at most 8. We copied this list into MAGMA, and it can be accessed using the following functions.

`LiEMaximalSubgroups()`

All maximal subgroups as described above, as a sequence of pairs. Each pair consists of a string denoting the simple group at hand, and a sequence of strings denoting its maximal subgroups.

`MaximalSubgroups(G)`

The maximal subgroups of the complex reductive simply connected simple Lie group whose Cartan type is the string G, represented as a sequence of strings.

`RestrictionMatrix(G, H)`

`Index` RNGINTELT *Default :* -1

The restriction matrix for the maximal proper subgroup of type H of G. If more than one maximal subgroup of G is of type H, the parameter *Index* must be set to indicate which one is required.

Example H104E20

Using the subgroup database:

```
> MaximalSubgroups("E7");
[ A2, A1, A1, A1F4, G2C3, A1G2, A1A1, D6A1, A7, A5A2 ]
> M := RestrictionMatrix("E7", "A1" : Index := 2); M;
[26]
[37]
[50]
[72]
[57]
[40]
[21]
> R := RootDatum("E7" : Isogeny := "SC");
> S := RootDatum("A1" : Isogeny := "SC");
> D := AdjointRepresentationDecomposition(R);
> RepresentationDimension(D);
133
> E := Branch(S, D, M); #E;
8
> RepresentationDimension(E);
133
```

104.8 Subalgebras of su(d)

This section describes functions for studying irreducible simple subalgebras of the Lie algebra $\mathfrak{su}(d)$ (cf. [Dyn57]). The verbose flag `"SubSU"` may be set to show details and progress of the various computations.

The algorithms and the implementation in this package are due to Robert Zeier. For more information about some of the algorithms used and the results obtained using this package we refer to [ZSH11].

`IrreducibleSimpleSubalgebrasOfSU(N)`

A list of all irreducible simple subalgebras occurring in the Lie algebra $\mathfrak{su}(d)$, for $2 \leq d \leq N$.

`IrreducibleSimpleSubalgebraTreeSU(Q, d)`

The subalgebra tree for degree d as a directed graph whose vertex labels describe subalgebras, derived from the list Q of irreducible subalgebras. The vertex labels are records with three fields: `algebra`, a string containing the Cartan type of this subalgebra; `weights`, a sequence of highest weights (as sparse vectors) corresponding to irreducible representations (they are related by an outer automorphism if there is more than one highest weight); and `type`, an integer with values -1, 1, or 0 corresponding to irreducible representations of quaternionic, real, or complex type, respectively (the Frobenius-Schur indicator).

`PrintTreesSU(Q, F)`

`FromDegree`	RngIntElt	*Default :* 2
`ToDegree`	RngIntElt	*Default :* $\|Q\|$
`IncludeTrivial`	BoolElt	*Default :* `true`

Print the tree of subalgebras in the sequence Q (as obtained by a call to IrreducibleSimpleSubalgebrasOfSU) to the file with filename F. The file F will be overwritten.

The resulting file will be a LaTeX document that may be typeset using `latex` followed by `dvipdf`, for instance. If the resulting file is large, the main memory allocated to TEX may have to be increased (the `main_memory` directive in `texmf.cnf`). Contact your system administrator in case of difficulty.

The optional arguments `FromDegree` and `ToDegree` limit which degrees are output; `IncludeTrivial` may be set to `false` to remove "trivial" cases (i.e. trivial trees) from the output. For $d \geq 5$ and d even, $\mathfrak{su}(d)$ is considered trivial if it contains only the (proper) irreducible simple subalgebras $C_{d/2}$ (i.e. $\mathfrak{sp}(d/2)$), $D_{d/2}$ (i.e. $\mathfrak{so}(d)$), and A_1 (i.e. $\mathfrak{su}(2)$); for $d \geq 5$ and d is odd, $\mathfrak{su}(d)$ is considered trivial if it contains only $B_{(d-1)/2}$ (i.e. $\mathfrak{so}(d)$) and A_1.

The Lie algebras in the output are coloured according to type: red for -1, blue for 1, and black for 0 (see IrreducibleSimpleSubalgebraTreeSU).

Example H104E21

We investigate subalgebras of $\mathfrak{su}(d)$ for d up to 2^{10}.

```
> Q := IrreducibleSimpleSubalgebrasOfSU(2^10);
> t := IrreducibleSimpleSubalgebraTreeSU(Q, 12);
> t;
Digraph
Vertex  Neighbours
1       2 4 ;
2       3 ;
3       ;
4       ;
> r := VertexLabel(t, 1); r`algebra;
rec<recformat<algebra: MonStgElt, weights, type: IntegerRing()> |
    algebra := A11,
    weights := [
        Sparse matrix with 1 row and 11 columns over Integer Ring,
        Sparse matrix with 1 row and 11 columns over Integer Ring
    ],
    type := 0>
> r := VertexLabel(t, 2); r;
rec<recformat<algebra: MonStgElt, weights, type: IntegerRing()> |
    algebra := C6,
    weights := [
        Sparse matrix with 1 row and 6 columns over Integer Ring
    ],
    type := -1>
> [ Matrix(w) : w in r`weights ];
[
    [1 0 0 0 0 0]
]
> RepresentationDimension(RootDatum("C6"),[1,0,0,0,0,0]);
12
> r := VertexLabel(t, 3); r`algebra;
A1
> [ Matrix(w) : w in r`weights ];
[
    [11]
]
> RepresentationDimension(RootDatum("A1"),[11]);
12
> r := VertexLabel(t, 4); r`algebra;
D6
```

In this manner we have used IrreducibleSimpleSubalgebraTreeSU to obtain information about irreducible simple subalgebras of $\mathfrak{su}(12)$: A_{11} ($\mathfrak{su}(12)$) is the root of the tree, C_6 corresponds to a proper subalgebra of A_{11}, and A_1 is a proper subalgebra of C_6. In addition, we have used RepresentationDimension to verify the dimensions of the representations. Let us use

RepresentationDimension to see what other $\mathfrak{su}(d)$ the Lie algebra of type C_6 should at the very least occur in:

```
> V := RSpace(Integers(), 6);
> [ RepresentationDimension(RootDatum("C6"), v) : v in Basis(V) ];
[ 12, 65, 208, 429, 572, 429 ]
```

We compare that to the list of $\mathfrak{su}(d)$ it does occur in using IrreducibleSimpleSubalgebraTreeSU and obtain the weights for the case $\mathfrak{su}(78)$.

```
> [ i : i in [2..2^10] | exists{r : r in VertexLabels(
>    IrreducibleSimpleSubalgebraTreeSU(Q, i)) | r`algebra eq "C6"} ];
[ 12, 65, 78, 208, 364, 429, 560, 572 ]
> t := IrreducibleSimpleSubalgebraTreeSU(Q, 78);
> l := VertexLabels(t);
> [ r`algebra : r in l ];
[ A77, C39, A1, D39, B6, C6, E6, A2, A11, A12 ]
> r := l[6];
> [ Matrix(x) : x in r`weights ];
[
    [2 0 0 0 0 0]
]
```

105 GRÖBNER BASES

Chapter 105
GRÖBNER BASES

105.1 Introduction

This chapter describes the basics for configuring MAGMA's powerful *Gröbner basis* machinery, which lies at the heart of computations with ideals and modules over multivariate polynomial rings. Later chapters will describe the many functions and operations available to the user for working with ideal and modules.

Gröbner bases were introduced by Bruno Buchberger [Buc65] and at the heart of the theory is the *Buchberger algorithm* which computes a Gröbner basis of an ideal starting from an arbitrary basis (generating set) of the ideal. The two books *Ideals, Varieties and Algorithms* [CLO96] and *Gröbner Bases* [BW93] have also inspired much of the design and presentation of ideals of multivariate polynomial rings in MAGMA.

Since V2.11 (May 2004), MAGMA also contains a highly optimized implementation of the Faugère F_4 algorithm [Fau99], based on sparse linear algebra techniques, which usually performs dramatically better than the Buchberger algorithm (see [Ste04]).

Chapter 24 deals with the basics of multivariate polynomial rings and their elements (for which there are very many functions), so it is recommended that that chapter be perused before reading this one.

Permutation and matrix groups have a natural action on multivariate polynomial rings. This leads to the subject of invariant rings of finite groups, which is covered in Chapter 110. See also the chapters on affine algebras (Chapter 108) and on modules over affine algebras (Chapter 109), and the chapter on algebraically closed fields (Chapter 40), which allows one to compute the variety of an ideal over the algebraic closure of the base field.

105.2 Representation and Monomial Orders

Let P be the polynomial ring $R[x_1, \ldots, x_n]$ of rank n over a ring R. A *monomial* (or *power product*) of P is a product of powers of the variables (or indeterminates) of P, that is, an expression of the form $x_1^{e_1} \cdots x_n^{e_n}$ with $e_i \geq 0$ for $1 \leq i \leq n$. Multivariate polynomials in MAGMA are stored efficiently in distributive form, using arrays of coefficient-monomial pairs, where the coefficient is in the base ring R. The word 'term' will always refer to a coefficient multiplied by a monomial.

Monomial orders are of critical importance when dealing with Gröbner bases. Let M be the set of all monomials of P. A *monomial ordering* on M is a total order $<$ on M such that $1 \leq s$ for all $s \in M$, $s \leq t$ implies $su \leq tu$ for all $s, t, u \in M$, and M is a well-ordering (every non-empty subset of M possesses a minimal element w.r.t. $<$). Monomial orders can be naturally specified in terms of *weight vectors*: a vector W from $\mathbf{Q}^n$ with non-negative entries is called a weight vector since it weights a monomial s by the product $s.W$ (defined to be the dot product of the exponent vector of s with W); any sequence of

n linearly-independent weight vectors determines a monomial order on M (see the weight order below [subsection 105.2.9]). All monomial orderings can in fact be represented in terms of weight vectors.

Multivariate polynomial rings are constructed in MAGMA such that the monomials of any polynomial are sorted with respect to a specified monomial order, with the greatest monomial first. Gröbner basis computations are dramatically affected by the choice of monomial order. MAGMA provides an extensive choice of monomial orders. Currently, the intrinsic functions `PolynomialRing` (or `PolynomialAlgebra`), `ChangeOrder` and `VariableExtension` expect a monomial order; it is specified by a string giving the name, optionally followed by extra arguments for that order.

We now describe each of the monomial orders available in MAGMA. We suppose that s and t are monomials from P which has rank n. Any order on the monomials is then fully defined by just specifying exactly when $s < t$ with respect to that order. In the following, the argument(s) are described for an order as a list of expressions; that means that the expressions (without the parentheses) should be appended to any base arguments when any particular intrinsic function is called which expects a monomial order. See also [CLO96, Chap. 2, §2] for more details about the first three orders.

105.2.1 Lexicographical: `lex`

Definition: $s < t$ iff there exists $1 \leq i \leq n$ such that the first $i-1$ exponents of s and t are equal but the i-th exponent of s is less than the i-th exponent of t. The order is specified by the argument (`"lex"`).

The order is called "lexicographical" since it orders the monomials as if they were words in a dictionary. The i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable. A Gröbner basis of an ideal with respect to the lexicographical order usually represents the most information about the ideal but can be hard to compute.

105.2.2 Graded Lexicographical: `glex`

Definition: $s < t$ iff the total degree of s is less than the total degree of t or the total degree of s is equal to the total degree of t and $s < t$ with respect to the lexicographical order. The order is specified by the argument (`"glex"`).

The order is called "graded lexicographical" since it first grades the monomials by total degree, and then decides ties by the lexicographical order. The i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable. This order is rarely used because the `grevlex` order below is usually a better degree order (i.e., yields smaller Gröbner bases).

105.2.3 Graded Reverse Lexicographical: `grevlex`

Definition: $s < t$ iff the total degree of s is less than the total degree of t or the total degree of s is equal to the total degree of t and $s > t$ with respect to the lexicographical order applied to the exponents of s and t in reverse order. The order is specified by the argument (`"grevlex"`).

The order is called "graded reverse lexicographical" since it first grades the monomials by total degree, and then decides ties by the negation of the lexicographical order applied to the variables in reverse order. Again, the i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable. A Gröbner basis of an ideal with respect to the graded reverse lexicographical order is usually the easiest to compute so it is recommended that this order be used when just any Gröbner basis for an ideal is desired.

105.2.4 Graded Reverse Lexicographical (Weighted): `grevlexw`

Definition (given a sequence W of n positive integer weights): $s < t$ iff the total weighted degree d_s of s w.r.t. W is less than the total degree d_t of t w.r.t. W or $d_s = d_t$ and $s > t$ with respect to the lexicographical order applied to the exponents of s and t in reverse order. The order is specified by the arguments (`"grevlexw", W`).

The order is called "graded reverse lexicographical (weighted)" since it first grades the monomials by weighted degree w.r.t. W, and then decides ties by the negation of the lexicographical order applied to the variables in reverse order. If $W = [1, 1, \ldots, 1]$, then this order is equal to the `grevlex` order. Again, the i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable.

This order is similar to the `grevlex` order, but is useful if an ideal is homogeneous with respect to the grading given by W, since the Gröbner basis of the ideal will tend to be smaller with this order.

105.2.5 Elimination (k): `elim`

Definition (given k with $1 \leq k \leq n-1$): $s < t$ iff $s_k < t_k$ with respect to the `grevlex` order or $s_k = t_k$ and $s_{k'} < t_{k'}$ with respect to the `grevlex` order where m_k denotes the monomial consisting of the first k exponents of m and $m_{k'}$ denotes the monomial consisting of the last $n-k$ exponents of m (this order is thus the concatenation of two block `grevlex` orders). The order is specified by the arguments (`"elim", k`).

The order is called "elimination" since the first k variables are "eliminated": if G is a Gröbner basis of an ideal I of the polynomial ring $K[x_1, \ldots, x_n]$ with respect to this order, then $G \cap K[x_{k+1}, \ldots, x_n]$ is a Gröbner basis of the k-th elimination ideal $I \cap K[x_{k+1}, \ldots, x_n]$. (It is usually easier to compute a Gröbner basis with respect to this order for any k than with respect to the full lexicographical order.) Again, the i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable.

105.2.6 Elimination List: `elim`

Definition (given sequences U and V such that U and V contain distinct integers in the range 1 to n and the sum of the lengths of U and V is n and U and V are disjoint): $s < t$ iff $s_U < t_U$ with respect to the `grevlex` order or $s_U = t_U$ and $s_V < t_V$ with respect to the `grevlex` order where m_L denotes the monomial consisting of the exponents of m corresponding to the entries of L in order. The order is specified by the arguments (`"elim", U, V`). V may be omitted if desired so the arguments are just (`"elim", U`); in this case V is chosen to be an appropriate sequence to complement U.

The order is called "elimination" since the variables in U are "eliminated". The order of the elements in U and V are significant since the ordering on the variables makes $U[1]$ greatest, then $U[2]$, etc., then $V[1]$, $V[2]$, etc.

105.2.7 Inverse Block: `invblock`

Definition (given sequences U and V such that U and V contain distinct integers in the range 1 to n and the sum of the lengths of U and V is n and U and V are disjoint): $s < t$ iff $s_V < t_V$ with respect to the `grevlex` order or $s_V = t_V$ and $s_U < t_U$ with respect to the `grevlex` order. The order is specified by the arguments (`"invblock", U, V`). V may be omitted if desired so the arguments are just (`"invblock", U`); in this case V is chosen to be an appropriate sequence to complement U.

The order is called "inverse block" since it applies a block ordering on the exponents on V then U which inverts the lists supplied to the elimination list order. Thus this is the same as the elimination order except that the lists U and V are swapped. See [BW93, p. 390] for the motivation for this order.

105.2.8 Univariate: `univ`

Definition (given i with $1 \leq i \leq n$): $s < t$ iff $s_L < t_L$ with respect to the `grevlex` order or $s_L = t_L$ and the i-th exponent of s is less than the i-th exponent of t, where L is the sequence `[1 .. n]` with i deleted. The order is specified by the arguments (`"univ", i`).

The order is called "univariate" since when monomials are compared, any monomial not containing the i-th variable is greater than any monomial containing the i-th variable. Thus all variables but the i-th are "eliminated" so that a Gröbner basis of a zero-dimensional ideal I with this ordering will contain the unique monic generator of the elimination ideal consisting of all the polynomials in I containing the i-th variable alone. The j-th variable is greater than the $(j+1)$-th variable for $1 \leq j < i$ and $i < j \leq n$ and the j-th variable is greater than the i-th variable for any $j \neq i$.

105.2.9 Weight: `weight`

Definition (given n weight vectors $W_1, \ldots W_n$ from $\mathbf{Q}^n$): $s < t$ iff there exists $1 \leq i \leq n$ such that $s.W_j = t.W_j$ for $1 \leq j < i$ and $s.W_i < t.W_i$. The order is specified by the arguments (`"weight", Q`) where Q is a sequence of n^2 non-negative integers or rationals describing the n weight vectors of length n (in row major order).

The n weight vectors must describe a vector space basis of $\mathbf{Q}^n$ (i.e., be linearly-independent), since otherwise this would not yield a total ordering on the monomials. The weight order allows one to specify any possible monomial order; any of the monomial orders mentioned above can be specified by an appropriate choice of weight vectors. However, using the in-built versions of the specialized orders above is much faster than constructing versions of them based on weight vectors. The next section contains an example in which a polynomial ring is constructed with a weight order for the monomials.

105.3 Polynomial Rings and Ideals

105.3.1 Creation of Polynomial Rings and Accessing their Monomial Orders

Multivariate polynomial rings are created from a coefficient ring, the number of variables, and a monomial order. If no order is specified, the monomial order is taken to be the lexicographical order. This section is briefly repeated from the section 24.2.1 in the multivariate polynomial rings chapter, so as to show how one can set up the polynomial ring in which to create an ideal.

Please note that the Gröbner basis of an ideal with respect to the lexicographical order is often much more complicated and difficult to compute than the Gröbner basis of the same ideal with respect to other monomial orders (e.g. the `grevlex` order), so it may be preferable to use another order if the Gröbner basis with respect to any order is desired (see also the function `EasyIdeal` below). Yet the lexicographical order is the most natural order and is often the desired order so that is why it is used by default if no specific order is given.

`PolynomialRing(R, n)`

`PolynomialAlgebra(R, n)`

`Global` BoolElt *Default :* `false`

Create a multivariate polynomial ring in $n > 0$ variables over the ring R. The ring is regarded as an R-algebra via the usual identification of elements of R and the constant polynomials. The lexicographical ordering on the monomials is used for this default construction (see next function).

By default, a *non-global* polynomial ring will be returned; if the parameter `Global` is set to `true`, then the unique global polynomial ring over R with n variables will be returned. This may be useful in some contexts, but a non-global result is returned by default since one often wishes to have several rings with the same numbers of variables but with different variable names (and create mappings between them, for example). Explicit coercion is always allowed between polynomial rings having the same number of variables (and suitable base rings), whether they are global or not, and the coercion maps the i-variable of one ring to the i-th variable of the other ring.

`PolynomialRing(R, n, order)`

`PolynomialAlgebra(R, n, order)`

Create a multivariate polynomial ring in $n > 0$ variables over the ring R with the given order *order* on the monomials. See the section on monomial orders for the valid values for the argument *order*.

`PolynomialRing(R, n, T)`

`PolynomialAlgebra(R, n, T)`

Create a multivariate polynomial ring in $n > 0$ variables over the ring R with the order given by the tuple T on the monomials. T must be a tuple whose components match the valid arguments for the monomial orders in Section 105.2 (or a tuple returned by the following function `MonomialOrder`).

`MonomialOrder(P)`

Given a polynomial ring P (or an ideal thereof), return a description of the monomial order of P. This is returned as a tuple which matches the relevant arguments listed for each possible order in Section 105.2, so may be passed as the third argument to the function `PolynomialRing` above.

`MonomialOrderWeightVectors(P)`

Given a polynomial ring P of rank n (or an ideal thereof), return the weight vectors of the underlying monomial order as a sequence of n sequences of n rationals. See, for example, [CLO98, p. 153] for more information.

Example H105E1

We show how one can construct different polynomial rings with different orders.

```
> Z := IntegerRing();
> // Construct polynomial ring with DEFAULT lex order
> P<a,b,c,d> := PolynomialRing(Z, 4);
> MonomialOrder(P);
<"lex">
> MonomialOrderWeightVectors(P);
[
    [ 1, 0, 0, 0 ],
    [ 0, 1, 0, 0 ],
    [ 0, 0, 1, 0 ],
    [ 0, 0, 0, 1 ]
]
> // Construct polynomial ring with grevlex order
> P<a,b,c,d> := PolynomialRing(Z, 4, "grevlex");
> MonomialOrder(P);
<"grevlex">
> MonomialOrderWeightVectors(P);
[
    [ 1, 1, 1, 1 ],
    [ 1, 1, 1, 0 ],
    [ 1, 1, 0, 0 ],
    [ 1, 0, 0, 0 ]
]
> // Construct polynomial ring with block elimination and a > d > b > c
```

```
> P<a,b,c,d> := PolynomialRing(Z, 4, "elim", [1, 4], [2, 3]);
> MonomialOrder(P);
<"elim", [ 1, 4 ], [ 2, 3 ]>
> MonomialOrderWeightVectors(P);
[
    [ 1, 0, 0, 1 ],
    [ 1, 0, 0, 0 ],
    [ 0, 1, 1, 0 ],
    [ 0, 1, 0, 0 ]
]
> a + b + c + d;
a + d + b + c
> a + d^10 + b + c^10;
d^10 + a + c^10 + b
> a + d^10 + b + c;
d^10 + a + b + c
> // Construct polynomial ring with weight order and x > y > z
> P<x, y, z> := PolynomialRing(Z, 3, "weight", [100,10,1, 1,10,100, 1,1,1]);
> MonomialOrder(P);

    4*y^2*z^9 + z^12
```

105.3.2 Creation of Graded Polynomial Rings

It is possible within MAGMA to assign weights to the variables of a multivariate polynomial ring. This means that monomials of the ring then have a *weighted degree* with respect to the weights of the variables. Such a multivariate polynomial ring is called *graded* or *weighted*. A polynomial of the ring whose monomials all have the same weighted degree is called *homogeneous*. The polynomial ring can be decomposed as the direct sum of graded homogeneous components.

Suppose a polynomial ring P has n variables $x_1, \ldots, x_n$ and the weights for the variables are $d_1, \ldots, d_n$ respectively. Then for a monomial $m = x_1^{e_1} \cdots x_n^{e_n}$ of P (with $e_i \geq 0$ for $1 \leq i \leq n$), the *weighted degree* of m is defined to be $\sum_{i=1}^{n} e_i d_i$.

A polynomial ring created without a specific weighting (using the default version of the PolynomialRing function or similar) has weight 1 for each variable so the weighted degree coincides with the total degree.

The following functions allow one to create and operate on elements of polynomial rings with specific weights for the variables.

```
PolynomialRing(R, Q)
```

```
PolynomialAlgebra(R, Q)
```

Given a ring R and a non-empty sequence Q of positive integers, create a multivariate polynomial ring in $n = \#Q$ variables over the ring R with the weighted degree of the i-th variable set to be $Q[i]$ for each i. The rank n of the polynomial is determined by the length of the sequence Q. (The angle bracket notation can be used to assign names to the variables, just like in the usual invocation of the `PolynomialRing` function.)

As of V2.15, the default monomial order chosen is the `grevlexw` order with weights given by Q, since the Gröbner basis of an ideal w.r.t. this order tends to be smaller if the ideal is homogeneous w.r.t. the grading.

```
Grading(P)
```

```
VariableWeights(P)
```

Given a graded polynomial ring P (or an ideal thereof), return the variable weights of P as a sequence of n integers where n is the rank of P. If P was constructed without specific weights, the sequence containing n copies of the integer 1 is returned.

105.3.3 Element Operations Using the Grading

```
Degree(f)
```

```
WeightedDegree(f)
```

Given a polynomial f of the graded polynomial ring P, this function returns the weighted degree of f, which is the maximum of the weighted degrees of all monomials that occur in f. The weighted degree of a monomial m depends on the weights assigned to the variables of the polynomial ring P — see the introduction of this section for details. Note that this is different from the natural total degree of f which ignores any weights.

```
LeadingWeightedDegree(f)
```

Given a polynomial f of the graded polynomial ring P, this function returns the leading weighted degree of f, which is the weighted degree of the leading monomial of f. The weighted degree of a monomial m depends on the weights assigned to the variables of the polynomial ring P — see the introduction of this section for details.

`IsHomogeneous(f)`

Given a polynomial f of the graded polynomial ring P, this function returns whether f is homogeneous with respect to the weights on the variables of P (i.e., whether the weighted degrees of the monomials of f are all equal).

`HomogeneousComponent(f, d)`

Given a polynomial f of the graded polynomial ring P, this function returns the *weighted* degree-d homogeneous component of f which is the sum of all the terms of f whose monomials have weighted degree d. d must be greater than or equal to 0. If f has no terms of weighted degree d, then the result is 0.

`HomogeneousComponents(f)`

Given a polynomial f of the graded polynomial ring P, this function returns the *weighted* degree-d homogeneous component of f which is the sum of all the terms of f whose monomials have weighted degree d. d must be greater than or equal to 0. If f has no terms of weighted degree d, then the result is 0.

`MonomialsOfDegree(P, d)`

Given a polynomial ring P and a non-negative integer d, return an indexed set consisting of all monomials in P with total degree d. If P is graded, the grading is ignored.

`MonomialsOfWeightedDegree(P, d)`

Given a graded polynomial ring P and a non-negative integer d, return an indexed set consisting of all monomials in P with weighted degree d. If P has the trivial grading, then this function is equivalent to the function `MonomialsOfDegree`.

Example H105E2

We create a simple graded polynomial ring and perform various simple operations on it.

```
> P<x, y, z> := PolynomialRing(RationalField(), [1, 2, 4]);
> P;
Graded Polynomial ring of rank 3 over Rational Field
Order: Grevlex with weights [1, 2, 4]
Variables: x, y, z
Variable weights: [1, 2, 4]
> VariableWeights(P);
[ 1, 2, 4 ]
> Degree(x);
1
> Degree(y);
2
> Degree(z);
4
> Degree(x^2*y*z^3); // Weighted total degree
```

```
16
> TotalDegree(x^2*y*z^3); // Natural total degree
6
> IsHomogeneous(x);
true
> IsHomogeneous(x + y);
false
> IsHomogeneous(x^2 + y);
true
> I := ideal<P | x^2*y + z, (x^4 + z)^2, y^2 + z>;
> IsHomogeneous(I);
true
> MonomialsOfDegree(P, 4);
{@
    x^4,
    x^3*y,
    x^3*z,
    x^2*y^2,
    x^2*y*z,
    x^2*z^2,
    x*y^3,
    x*y^2*z,
    x*y*z^2,
    x*z^3,
    y^4,
    y^3*z,
    y^2*z^2,
    y*z^3,
    z^4
@}
> MonomialsOfWeightedDegree(P, 4);
{@
    x^4,
    x^2*y,
    y^2,
    z
@}
```

105.3.4 Creation of Ideals and Accessing their Bases

Within the general context of ideals of polynomial rings, the term "basis" will refer to an *ordered* sequence of polynomials which generate an ideal. (Thus a basis can contain duplicates and zero elements so is not like a basis of a vector space.)

One normally creates an ideal by the `ideal` constructor or `Ideal` function, described below. But it is also possible to create an ideal with a specific basis U and then find the coordinates of polynomials from the polynomial ring with respect to U (see the function `Coordinates` below). This is done by specifying a *fixed basis* with the `IdealWithFixedBasis` intrinsic function. In this case, when MAGMA computes the Gröbner basis of the ideal (see below), extra information is stored so that polynomials of the ideal can be rewritten in terms of the original fixed basis. However, the use of this feature makes the Gröbner basis computation much more expensive so an ideal should usually **not** be created with a fixed basis.

`ideal< P | L >`

Given a multivariate polynomial ring P, return the ideal of P generated by the elements of P specified by the list L. Each term of the list L must be an expression defining an object of one of the following types:

(a) An element of P;

(b) A set or sequence of elements of P;

(c) An ideal of P;

(d) A set or sequence of ideals of P.

`Ideal(B)`

Given a set or sequence B of polynomials from a polynomial ring P, return the ideal of P generated by the elements of B with the given basis B. This is equivalent to the above `ideal` constructor, but is more convenient when one simply has a set or sequence of polynomials.

`Ideal(f)`

Given a polynomial f from a polynomial ring P, return the principal ideal of P generated by f.

`IdealWithFixedBasis(B)`

Given a sequence B of polynomials from a polynomial ring P, return the ideal of P generated by the elements of B with the given fixed basis B. When the function `Coordinates` is called, its result will be with respect to the entries of B instead of the Gröbner basis of I. **WARNING:** this function should *only* be used when it is desired to express polynomials of the ideal in terms of the elements of B, as the computation of the Gröbner basis in this case is *very* expensive, so it should be avoided if these expressions are not wanted.

`Basis(I)`

Given an ideal I, return the current basis of I. If I has a fixed basis, that is returned; otherwise the current basis of I (whether it has been converted to a Gröbner basis or not – see below) is returned.

`BasisElement(I, i)`

Given an ideal I together with an integer i, return the i-th element of the current basis of I. This the same as `Basis(I)[i]`.

105.4 Gröbner Bases

Computation in ideals of multivariate polynomial rings is possible because of the construction of Gröbner bases of such ideals. In MAGMA, it is possible to create ideals and compute their Gröbner bases for polynomial rings defined not only over fields but also over general Euclidean rings.

Different monomial orderings give different Gröbner bases for a fixed ideal. When an ideal I is created from a polynomial ring P or another ideal J, then the monomial order of I is taken to be the monomial order of P or J. Ideals can only be compatible if they have the same monomial order.

105.4.1 Gröbner Bases over Fields

Gröbner bases of ideals defined over fields have been studied for some time now, and there is a large literature concerning them.

For ideals defined over fields, a basis is called *minimal* if each polynomial in it is monic and not contained in the ideal generated by all the other polynomials [CLO96, Chap. 2, §7, Def. 4]. A basis is called *reduced* if each polynomial in it is monic and, for every monomial of each polynomial in the basis, that monomial is not divisible by the leading monomial of any other polynomial in the basis (equivalently, each leading monomial does not divide any monomial in any of the other polynomials) [CLO96, Chap. 2, §7, Def. 5].

For a given fixed monomial ordering, every ideal of a polynomial ring over a field possesses a **unique** sorted minimal reduced Gröbner basis (GB) [CLO96, Chap. 2, §7, Prop. 7]. This unique Gröbner basis (with respect to the order defined by the user) will be computed automatically when needed by MAGMA. Before this happens, an ideal will usually possess a basis which is not a Gröbner basis, but that will be changed into the unique Gröbner basis when needed. Thus the original basis will be discarded. See the procedure `Groebner` below for details on the algorithms available.

105.4.2 Gröbner Bases over Euclidean Rings

Since V2.8 (July 2001), MAGMA provides facilities for computing with Gröbner bases of ideals of polynomial rings over Euclidean rings (including the important case of the integer ring $\mathbf{Z}$). Such Gröbner bases are computed in MAGMA by an extension, due to Allan Steel (unpublished), of Jean-Charles Faugère's F_4 algorithm [Fau99], which uses sparse linear algebra.

The current Euclidean rings in MAGMA supported are: the integer ring $\mathbf{Z}$, the integer residue class rings $\mathbf{Z}_m$, the univariate polynomial rings $K[x]$ over any field K, Galois rings, p-adic quotient rings, and valuation rings.

We first outline some of the things which are peculiar to Gröbner bases defined over a Euclidean ring. Let I be an ideal of a polynomial ring defined over a Euclidean ring R. A subset G of I is called a *Gröbner basis* for I in MAGMA if, for every $f \in I$, there exists a $g \in G$ such that the leading **term** of g divides the leading **term** of f. Recall that "leading term" here means the leading coefficient times the leading monomial, so the leading coefficient of g must divide the leading coefficient of f in the base ring R. If R were a field, then obviously the leading coefficients would be insignificant and the Gröbner basis elements could be normalized (made monic) to yield an equivalent Gröbner basis. But if R is not a field, the leading coefficients are quite significant. For example, over the ring $\mathbf{Z}$, the set $\{x^2, 2x\}$ is a Gröbner basis and the polynomial x^2 is not redundant since 2 does not divide 1, but over $\mathbf{Q}$, the polynomial x^2 would be redundant.

Note that the definition here for a Gröbner basis in MAGMA is actually what some authors (e.g., [AL94, Def. 4.5.6]) call a *strong* Gröbner basis. *Weak* Gröbner bases have also been defined, but strong Gröbner bases satisfy stronger conditions, yield a simple effective normal form algorithm, provide more information about the ideal, are easier to get into a unique form, and are no more difficult to compute using the algorithm implemented in MAGMA. Thus MAGMA **always** computes a strong Gröbner basis, so the distinction between weak and strong is ignored. MAGMA also effectively computes a D-Gröbner basis as defined in [BW93, Def. 10.4, Table 10.1], although MAGMA also allows Euclidean rings which are not integral domains (i.e., which have zero divisors).

Over Euclidean rings, the definition of a minimal basis is practically the same as for fields (there must be no polynomial in the ideal generated by the others and each polynomial must be normalized), but the definition of a reduced basis is more subtle. A basis is called *reduced* if each polynomial in it is normalized and if, for every term $c \cdot s$ of every polynomial in the basis (where c is the coefficient and s is the monomial), then if some other polynomial in the basis has leading term $d \cdot t$, with t dividing s, then the Euclidean quotient of c by d must be zero (the remainder will be non-zero of course). Informally, this means that each polynomial is reduced modulo all the other polynomials, where each coefficient must be reduced modulo all other appropriate leading coefficients. As an example, suppose $f_1 = x^2 + 14xy$ and $f_2 = 5y + 9$ are in $\mathbf{Z}[x, y]$. Then $\{f_1, f_2\}$ is not reduced, since the second term of f_1 can be reduced by f_2 (y divides xy and the Euclidean quotient of 14 by 5 is 2, with remainder 4). But if we were to replace f_1 by $f_1 - 2xf_2 = x^2 + 4xy - 18x$, then $\{f_1, f_2\}$ would now be reduced.

MAGMA's extension of Faugère's algorithm depends on sparse linear algebra over Euclidean rings. (Note also that the advanced criteria for eliminating useless pairs in [Möl88]) are also implemented in this extension to work for general Euclidean rings as well.) MAGMA now contains an algorithm for computing a unique echelon form of a sparse matrix over such a ring; uniqueness is ensured because there is a unique Euclidean quotient-remainder algorithm for each Euclidean ring (and zero divisors are also handled properly). Consequently, based on this unique echelon form algorithm and some other techniques, MAGMA ensures that a Gröbner basis over a Euclidean ring is not only minimal (contains no re-

dundant polynomials), but it is also **reduced**, and **unique**.

Thus every ideal of a polynomial ring over a Euclidean ring possesses a **unique** sorted minimal reduced Gröbner basis (with respect to some fixed monomial ordering), just as for ideals defined over fields. Also, as for ideals defined over fields, this unique Gröbner basis will be computed automatically when needed by MAGMA, and before this happens, an ideal will usually possess a basis which is not a Gröbner basis, but that will be changed into the unique Gröbner basis when needed.

The uniqueness of the Gröbner basis also ensures that the normal form of an element with respect to an ideal for a fixed monomial order is always unique. All of this holds even for Euclidean rings which have zero divisors.

See the examples below for illustrations of the points made above, and also how one can effectively compute with Gröbner bases of ideals defined over rings which are not even Euclidean.

105.4.3 Construction of Gröbner Bases

The following functions and procedures allow one to construct Gröbner bases. Note that a Gröbner basis for an ideal will be automatically generated when necessary; the `Groebner` procedure below simply allows control of the algorithms used to compute the Gröbner basis.

NOTE: MAGMA applies a special monomial representation and a special variant of the F_4 algorithm if the ideal I is defined over $\mathbf{F}_2$ and the polynomials ${x_i}^2 + x_i$ for all i are present in the input basis of the ideal I. So if one wishes to solve a system of equations over $\mathbf{F}_2$, then one should include these polynomials in the input basis (they can be at any place and in any order; as long as there is at least one copy of ${x_i}^2 + x_i$ present for each i). Alternatively (since V2.15), one can create a boolean polynomial ring (via the function `BooleanPolynomialRing` below) and construct the ideal within this. See also Example H105E5 below.

`Groebner(I: parameters)`

(Procedure.) Explicitly force a Gröbner basis (GB) for the ideal I to be constructed. This procedure is normally not necessary, as MAGMA will automatically compute the GB when needed, but it does allow one to control how the GB is constructed by various parameters.

By default, the parameters are set to default values which tend to work best for the particular kinds of inputs which are given, but there exist many inputs for which setting at least one of the parameters to a non-default value will lead to a dramatic improvement. (A general strategy for the computation of GBs is very difficult to design.)

If I is defined over a Euclidean ring, then MAGMA always uses the extension of the Faugère algorithm directly, and of the parameters given below, only `Homogenize` is applicable. So the rest of this description assumes that I is defined over a field.

We call a GB algorithm **direct** if it takes the initial basis of the ideal I (with no structure) and computes the unique minimal reduced GB of I with respect to

some monomial order. Since V2.11 (May 2004), MAGMA has two direct algorithms for computing GBs over fields:

(1) The Faugère F_4 algorithm [Fau99], which works by specialized sparse linear algebra and is applicable to ideals defined over a finite field or the rational field;

(2) The Buchberger algorithm [CLO96, Chap. 2, §7] for ideals defined over any field.

Both direct algorithms use the advanced criteria for eliminating useless pairs in [Möl88]. MAGMA also uses two **order change** algorithms which both change the GB of an ideal with respect to one monomial order to the GB with respect to another monomial order:

(1) The FGLM algorithm [FGLM93], which works by efficient linear algebra and is only applicable if I is zero-dimensional;

(2) The Gröbner Walk algorithm [CKM97].

This parameter affects the main strategy:

`Al`	MonStgElt	*Default :* "*Default*"

The parameter `Al` may be set to one of: `"Default"`, `"Direct"`, `"FGLM"` or `"Walk"`. The value `"Direct"` specifies that MAGMA should compute the GB of I (with respect to the order of I) by a direct algorithm alone, so that an order-conversion algorithm is not used (the parameter `Faugere` below controls which direct algorithm is used).

The alternative strategy is to compute the GB first with respect to an "easy" order, and then to convert this to the GB with respect to the order of I. Setting `Al` to the values `"FGLM"` or `"Walk"` will cause this strategy to be used, where the order change algorithm will be the FGLM algorithm or Gröbner Walk algorithm, respectively.

If no algorithm is specified, or if `"Default"` is specified, an appropriate strategy is chosen by MAGMA, which is usually the FGLM method if the ideal is zero-dimensional and over a finite field or the rational field, and the Walk method otherwise.

The following parameters affect the direct algorithms:

`Faugere`	BoolElt	*Default :* `true`
`HomogeneousWeights`	BoolElt	*Default :* `true`
`Homogenize`	BoolElt	*Default :* `true`
`DegreeStart`	RngIntElt	*Default :* `true`

If the parameter `Faugere` is set to `true`, then the Faugère F_4 algorithm will be used (if the field is a finite field or the rational field); otherwise the Buchberger algorithm is used.

The current implementation of the Faugère algorithm is usually very much faster than the Buchberger algorithm and usually does not take much more memory, so that it is why it is now selected by default. However, there may be examples for

which it may be more desirable to use the Buchberger algorithm (particularly to save some memory).†

Since V2.12, if the input basis is not homogeneous, then MAGMA first attempts to find a weight vector W with respect to which the ideal is homogeneous; if such a W is found, then the "easy" order used internally for the direct algorithm (accessed by `EasyIdeal`) is taken to be the `grevlexw` order with respect to W (see subsection 105.2.4), since the GB is likely to be smaller with respect to this order. The selection of such an order may be suppressed by setting the parameter `HomogeneousWeights` to `false`.

If no appropriate `grevlexw` order is used, then setting `Homogenization` to `true` specifies that the ideal should first be *homogenized*: a GB of the homogenization of the ideal is computed and then the homogenization variable is removed and the final basis reduced. This parameter has the default value of `true` over the rational field and `false` over all other fields, since most computations are improved by these defaults.

If the parameter `DegreeStart` is set to an integer d, then any S-polynomial pairs of degree less than d will be ignored.

The following parameters affect the Faugère F_4 algorithm:

`AllPairs`	BOOLELT	*Default :* `false`
`PairsLimit`	BOOLELT	*Default :* 0
`ReversePairs`	BOOLELT	*Default :* `false`
`HFE`	BOOLELT	*Default :* `false`
`Boolean`	BOOLELT	*Default :* `false`
`Nthreads`	RNGINTELT	*Default :* 1

By default, the Faugère F_4 algorithm includes all pairs of the next degree at each step (see [Fau99, Sec.2.5]), since this usually produces the best performance. However, setting the parameter `AllPairs` to `true` will cause the algorithm to include *all* pairs currently in the queue at each new step; this generally makes the matrix larger and is usually less efficient, but for some inputs (e.g., inhomogeneous ideals where there are only a small number of pairs for each degree at each step) this option may yield a significant improvement.

Alternatively, setting the parameter `PairsLimit` to a positive integer n will cause the algorithm to include at most n pairs from the queue at each step; this will usually make the matrix smaller, thus saving memory, but will often also make the running time longer. Setting also the parameter `ReversePairs` to `true` will reverse the list of pairs of the current degree from which the restricted set of pairs is taken: this may help a lot for certain types of input, since this may lead to new polynomials of lower degree being found more quickly. (If there is no pairs limit, then the value

† If you encounter an example where the Faugère algorithm is significantly slower than the Buchberger algorithm, then please mail it to us (`magma@maths.usyd.edu.au`)!

of ReversePairs is irrelevant since all pairs of the current degree are taken at each step.)

If the input basis is an HFE system over $\mathbf{F}_2$ such that the secret degree d is less than or equal to 127, then one should set the HFE parameter to true. In this case, MAGMA can apply various optimizations which save memory and time (only pairs of degree of most 4 are considered, as this is sufficient for systems for which $d \leq 127$).

Since V2.18, if the base ring is the finite field $\mathbf{F}_p$, where p is a prime with $2 < p < 2^{23.5}$, then a multi-threaded version of the algorithm is available if POSIX threads are enabled in the current Magma version. In this case, setting the parameter Nthreads to a positive integer n will cause the F_4 algorithm to use n threads within the linear algebra phase of each step. One can alternatively use the procedure SetNthreads to set the global number of threads to a value n so that n threads are always used by default in this algorithm (unless overridden by the Nthreads parameter).

The following parameters affect the Buchberger algorithm:

ReduceInitial	BOOLELT	*Default :* true
RemoveRedundant	BOOLELT	*Default :* true
ReduceByNew	BOOLELT	*Default :* true

Setting ReduceInitial to true specifies that the basis of the ideal should be first reduced (see the function Reduce) before any S-polynomial pairs are considered. Setting RemoveRedundant to true specifies that redundant polynomials in the input (which reduce to zero with respect to the other polynomials) should first be removed. Setting ReduceByNew to true specifies that when a new polynomial f is inserted into the current GB being constructed, the current basis should be reduced by f (thus the basis stays close to being fully reduced throughout the algorithm).

Each of these control parameters usually have the default values of true (it depends on the coefficient ring).

The following parameters affect the Walk algorithm:

SigmaEpsilon	FLDRATELT	*Default :* $1/2$
TauEpsilon	FLDRATELT	*Default :* $1/n$
SigmaVectors	RNGINTELT	*Default :* n
TauVectors	RNGINTELT	*Default :* $\lceil n/2 \rceil$

The parameters SigmaEpsilon and TauEpsilon control the factor ϵ which is used in the Walk algorithm to perturb the initial weight vector σ and the final weight vector τ respectively. The parameters SigmaVectors and TauVectors determine how many weight vectors of the initial and final orders are used to perturb the initial weight vector σ and the final weight vector τ respectively. By default, the ϵ factor and number of weight vectors for σ are determined dynamically to be "optimal", while the ϵ factor for τ is taken to be $1/n$ and the number of weight vectors for τ is taken to be $\lceil n/2 \rceil$, where n is the rank of I.

`GroebnerBasis(I: parameters)`

Given an ideal I, force the Gröbner basis of I to be computed, and then return that. The parameters are the same as those for the procedure `Groebner`.

See also the function `GroebnerBasis(S,d)` below, which creates a truncated degree-d Gröbner basis.

`GroebnerBasis(S: parameters)`

Given a set or sequence S of polynomials, return the unique Gröbner basis of the ideal generated by S as a sorted sequence. This function is useful for computing Gröbner bases without the need to construct ideals. The parameters are the same as those for the procedure `Groebner`.

See also the function `GroebnerBasis(S,d)` below, which creates a truncated degree-d Gröbner basis.

`GroebnerBasisUnreduced(S: parameters)`

`Homogenize`	BoolElt	*Default :* `true`
`ReduceInitial`	BoolElt	*Default :* `true`
`ReduceByNew`	BoolElt	*Default :* `true`

Given a set or sequence S of polynomials, return an unreduced Gröbner basis of the ideal generated by S as a sorted sequence. This function is useful for computing Gröbner bases without the need to construct ideals and when the reduction of the Gröbner basis is very expensive. The parameters behave the same as for the procedure `Groebner`.

`GroebnerBasis(S, d: parameters)`

Given a set or sequence S of polynomials, return the degree-d Gröbner basis of the ideal generated by S, which is the truncated Gröbner basis obtained by ignoring S-polynomial pairs whose total degree is greater than d.

If the ideal is homogeneous, then it is guaranteed that the result G_d is equal to the set of all polynomials in the full Gröbner basis of the ideal whose total degree is less than or equal to d, and thus a polynomial whose total degree is less than or equal to d is in the ideal iff its normal form with respect to the degree-d Gröbner basis G_d is zero. But if the ideal is not homogeneous, these last properties may not hold, but it may be still useful to construct the truncated basis.

The parameters are the same as those for the procedure `Groebner`. See the section on graded polynomial rings below for an example. See also [BW93, section 10.2], for further discussion.

105.4.4 Related Functions

The following functions and procedures perform operations related to Gröbner bases.

`HasGroebnerBasis(I)`

Given an ideal I, return whether the Gröbner basis of I can be computed. This depends on the type of base ring of I: the base ring must currently be a field or a Euclidean ring.

`EasyIdeal(I)`

Given an ideal I, return the ideal E which is mathematically equal to I but whose basis is the Gröbner basis of I with respect to an "easy" order, together with an isomorphism f from I onto E. The easy order is usually the `grevlex` order or `grevlexw` order with suitable weights, and the easy basis (the Gröbner basis of the easy ideal) of I is used extensively by MAGMA in many of its internal algorithms; this function allows one to access this "easy" Gröbner basis directly.

`EasyBasis(I)`

Given an ideal I, return the Gröebner basis of the easy ideal of I.

`SmallBasis(I)`

Given an ideal I, return the basis of I with shortest length which is currently known. This may be the original basis with which I was constructed, or a Gröbner basis, but the result is always has the the same monomial order as the main monomial order of I.

`MarkGroebner(I)`

(Procedure.) Given an ideal I, mark the current basis of I to be *the* Gröbner basis of the ideal w.r.t. the monomial order of the ideal. Note that the current basis must exactly equal the unique (reverse) sorted minimal reduced Gröbner basis for the ideal, as returned by the function `GroebnerBasis`. This procedure is useful when one creates an ideal with a basis known to be the Gröbner basis of the ideal from a previous computation or for other reasons. If the basis is not the unique Gröbner basis, the results are unpredictable.

`IsGroebner(S)`
`IsGroebner(S)`

Given a set or sequence S of polynomials describing a basis of an ideal, return whether the basis is itself a (not necessarily minimal or reduced) Gröbner basis of the ideal.

`Coordinates(I, f)`

Given an ideal I of a polynomial ring P, together with a polynomial f in I, and supposing that I has basis $b_1, \ldots, b_k$, return a sequence $[g_1, \ldots, g_k]$ of elements of P so that $f = g_1 * b_1 + \ldots + g_k * b_k$. If I was created by `IdealWithFixedBasis`(B), then the fixed basis B is used as the basis $b_1, \ldots, b_k$; otherwise the (unique) Gröbner basis of I is used as the basis $b_1, \ldots, b_k$. The resulting sequence is not necessarily unique.

`CoordinateMatrix(I)`

Given an ideal I such that I has a fixed basis (i.e., such that I was created via the function `IdealWithFixedBasis`), return the coordinate matrix C of I. The i-th row of C gives the coordinates of the i-th element of the Gröebner basis of I w.r.t. the fixed basis of I. The Gröebner basis of I is first computed if it has not been already.

`NormalForm(f, I)`

Given a polynomial f from a polynomial ring P, together with an ideal I of P, return the unique normal form of f with respect to (the Gröbner basis of) I. The normal form of f is zero if and only if f is in I.

`NormalForm(f, S)`

Given a polynomial f from a polynomial ring P, together with a set or sequence S of polynomials from P, return a normal form g of f with respect to S. (This is not unique in general. If the normal form of f is zero then f is in the ideal generated by S, but the converse is false in general. In fact, the normal form is unique if and only if S forms a Gröbner basis.) If S is a sequence, one may also assign a second return value C which gives the coordinates of the reduction, so that $C[i] \cdot S[i]$ is subtracted from f for each i to yield g.

`SPolynomial(f, g)`

Given elements f and g from a polynomial ring P, return the S-polynomial of f and g.

`Reduce(S)`

Given a set or sequence S of polynomials, return the sequence consisting of the reduction of S. The reduction is obtained by reducing to normal form each element of S with respect to the other elements and sorting the resulting non-zero elements left. Note that all Gröbner bases returned by MAGMA are automatically reduced so that this function would usually only be used just to simplify a set or sequence of polynomials which is not a Gröbner basis.

`ReduceGroebnerBasis(S)`

Given a set or sequence S of polynomials which is assumed to be a (not necessarily minimal or reduced) Gröbner basis for an ideal, return the sequence consisting of the reduction of S. The reduction is obtained by first removing each redundant polynomial whose leading term is a multiple of another leading term and then reducing the remaining polynomials as in the function `Reduce`. This function would usually only be used to reduce a set or sequence of polynomials which is known to be a non-reduced Gröbner basis (created in some way other than by one of MAGMA's internal Gröbner basis construction algorithms).

105.4.5 Gröbner Bases of Boolean Polynomial Rings

Since V2.15, a special type of polynomial ring is available: the **boolean polynomial ring** in n variables. Such a ring is a multivariate polynomial ring defined over $\mathbf{F}_2$ but such that all monomials are reduced modulo the *field relations* $x_i^2 = x_i$ for each i (so a bit vector representation can be used for monomials). Technically, the ring is thus the quotient algebra

$$\mathbf{F}_2[x_1, \ldots, x_n]/\langle x_1^2 + x_1, \ldots, x_n^2 + x_n \rangle.$$

Besides the basic creation and access functions for elements and ideals of such a ring, the main interest is to compute and examine a Gröbner basis of an ideal. Since the field relations are always present, an ideal represents a zero-dimensional system of multivariate polynomial equations over $\mathbf{F}_2$ with the solution components always lying in $\mathbf{F}_2$; these are particularly of interest for algebraic attacks on cryptosystems. Otherwise, there are not many other operations applicable to such rings and their elements.

Note that if one creates an ideal I of $\mathbf{F}_2[x_1, \ldots, x_n]$ such that the basis of I includes the *field polynomials* ($x_i^2 + x_i$ for each i), then MAGMA automatically uses the boolean polynomial ring representation internally, so this is basically equivalent to using the boolean polynomial ring type, except that MAGMA will have to move back to the original ring $\mathbf{F}_2[x_1, \ldots, x_n]$ at the end, and this may take much more time and memory. So it is preferable to use the boolean polynomial ring from the outset if one wishes to create the Gröbner basis of such an ideal and examine it (particularly if it does not collapse down to a sequence of linear polynomials).

See example H105E5 below for simple uses of boolean polynomial rings.

`BooleanPolynomialRing(n)`

Create the boolean polynomial ring with n variables (whose coefficients lie in $\mathbf{F}_2$). The default monomial order chosen is the lexicographical (`lex`) order.

`BooleanPolynomialRing(n, order)`

Create the boolean polynomial ring with n variables (whose coefficients lie in $\mathbf{F}_2$) and with the given order *order* on the monomials. Currently, *order* must be one of the following strings: `"lex"`, `"grevlex"`, `"glex"`.

`BooleanPolynomialRing(B, Q)`

Given a boolean polynomial ring B of rank n and a sequence Q of integers, create the boolean polynomial in B whose monomials are given by the entries of Q: each integer must be in the range $[0 \dots 2^n-1]$ and its binary expansion gives the exponents of the monomial in order (the resulting monomials are sorted w.r.t. the monomial order of B, so may be given in any order and duplicate monomials are added).

This function is simply provided so that boolean polynomials may be stored and read back in a compact form; otherwise, one can create a boolean polynomial in the usual way from the generators of B after B is created. Note also that if one prints B, an ideal of B, or an element of B with the `Magma` print level, then this function will be used to print the elements in a compact form.

105.4.6 Verbosity

This subsection describes the verbose flags available for the Gröbner basis algorithms. There are separate verbose flags for each algorithm (`Buchberger`, etc.), but the all-encompassing verbose flag `Groebner` includes all these flags implicitly.

For each procedure provided for setting one of these flags, the value `false` is equivalent to level 0 (nothing), and `true` is equivalent to level 1 (minimal verbosity). For each `Set-` procedure, there is also a corresponding `Get-` function to return the value of the corresponding flag.

`SetVerbose("Groebner", v)`

(Procedure.) Change the verbose printing level for all Gröbner basis algorithms to be v. This includes all of the algorithms whose verbosity is controlled by flags subsequently listed, as well as some other minor related algorithms. Currently the legal levels are 0, 1, 2, 3, or 4. One would normally set this flag to 1 for minimal verbosity for Gröbner basis-type computations, and possibly also set one or more of the following flags to levels higher than 1 for more verbosity.

`SetVerbose("Buchberger", v)`

(Procedure.) Change the verbose printing level for the Buchberger algorithm to be v. Currently the legal levels are 0, 1, 2, 3, or 4. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

`SetVerbose("Faugere", v)`

(Procedure.) Change the verbose printing level for the Faugère algorithm to be v. Currently the legal levels are 0, 1, 2, or 3. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

`SetVerbose("FGLM", v)`

(Procedure.) Change the verbose printing level for the FGLM order change algorithm to be v. Currently the legal levels are 0, 1, 2, or 3. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

`SetVerbose("GroebnerWalk", v)`

(Procedure.) Change verbose printing for the Gröbner Walk order change algorithm to be v. Currently the legal levels are 0, 1, 2, or 3. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

Example H105E3

We compute the Gröbner basis of the "Cyclic-6" ideal with respect to the lexicographical order. The ideal is an ideal of the polynomial ring $\mathbf{Q}(x, y, z, t, u, v)$. We also note that the last polynomial in the Gröbner basis is univariate (since, in fact, the ideal is zero-dimensional and the monomial order is lexicographical) and observe that it has a nice factorization. Note especially that in this example, homogenizing at first and keeping the Gröbner basis reduced makes this computation very fast; without using these features (i.e., if the parameters `Homogenize := false` or `ReduceByNew := false` are given), the computation is much more expensive (takes hundreds of seconds on the same computer).

```
> Q := RationalField();
> P<x, y, z, t, u, v> := PolynomialRing(Q, 6);
> I := ideal<P |
>     x + y + z + t + u + v,
>     x*y + y*z + z*t + t*u + u*v + v*x,
>     x*y*z + y*z*t + z*t*u + t*u*v + u*v*x + v*x*y,
>     x*y*z*t + y*z*t*u + z*t*u*v + t*u*v*x + u*v*x*y + v*x*y*z,
>     x*y*z*t*u + y*z*t*u*v + z*t*u*v*x + t*u*v*x*y + u*v*x*y*z + v*x*y*z*t,
>     x*y*z*t*u*v - 1>;
> time B := GroebnerBasis(I);

Example H105E4

We solve the system of equations Runge-Kutta 2 from the paper "Some Examples for Solving Systems of Algebraic Equations by Calculating Groebner Bases" by Boege, Gebauer, and Kredel (J. Symbolic Computation (1986) **1**, 83–98). The coefficient field K is the rational function field $\mathbf{Q}(c2, c3)$, and the polynomial ring $K[c4, b4, b3, b2, b1, a21, a31, a32, a41, a42, a43]$ has 11 variables with the lexicographical ordering on monomials. The resulting Gröbner basis contains a linear polynomial for each variable so there is exactly one solution to the system.

```
> K<c2, c3> := FunctionField(IntegerRing(), 2);
> P<c4, b4, b3, b2, b1, a21, a31, a32, a41, a42, a43> := PolynomialRing(K, 11);
> I := ideal<P |
>    b1 + b2 + b3 + b4 - 1,
>    b2*c2 + b3*c3 + b4*c4 - 1/2,
>    b2*c2^2 + b3*c3^2 + b4*c4^2 - 1/3,
>    b3*a32*c2 + b4*a42*c2 + b4*a43*c3 - 1/6,
>    b2*c2^3 + b3*c3^3 + b4*c4^3 - 1/4,
>    b3*c3*a32*c2 + b4*c4*a42*c2 + b4*c4*a43*c3 - 1/8,
>    b3*a32*c2^2 + b4*a42*c2^2 + b4*a43*c3^2 - 1/12,
>    b4*a43*a32*c2 - 1/24,
>    c2 - a21,
>    c3 - a31 - a32,
>    c4 - a41 - a42 - a43>;
> time Groebner(I);
Time: 0.110
> I;

    a42 + (-c2^2 + 4*c2*c3^2 - 5*c2*c3 + 3*c2 - 4*c3^2 + 5*c3 - 2)/(12*c2^3*c3 -
```

```
        8*c2^3 - 12*c2^2*c3^2 + 6*c2^2 + 8*c2*c3^2 - 6*c2*c3),
    a43 + (-2*c2^2*c3 + 2*c2^2 + 3*c2*c3 - 3*c2 - c3 + 1)/(6*c2^2*c3^2 -
        4*c2^2*c3 - 6*c2*c3^3 + 3*c2*c3 + 4*c3^3 - 3*c3^2)
]
```

Example H105E5

We demonstrate how one can solve a system of multivariate equations over $\mathbf{F}_2$. We construct a sequence B of 4 polynomials in 5 variables, and note that the Gröbner basis of B contains monomials having degrees greater than 1.

```
> P<a,b,c,d,e> := PolynomialRing(GF(2), 5);
> B := [a*b + c*d + 1, a*c*e + d*e, a*b*e + c*e, b*c + c*d*e + 1];
> GroebnerBasis(B);
[
    a + c^2*d + c + d^2*e,
    b*c + d^3*e^2 + d^3*e + d^2*e^2 + d*e + e + 1,
    b*e + d*e^2 + d*e + e,
    c*e + d^3*e^2 + d^3*e + d^2*e^2 + d*e,
    d^4*e^2 + d^4*e + d^3*e + d^2*e^2 + d^2*e + d*e + e
]
```

If one wanted to consider solutions over an algebraic closure of $\mathbf{F}_2$, then one would have to work with this ideal. But to solve over $\mathbf{F}_2$ itself, one can add the *field polynomials* $a^2 + a$, $b^2 + b$, etc. MAGMA recognizes these extra polynomials and uses an optimized representation; this makes the computation much faster for larger examples. The resulting polynomials (besides any remaining field polynomials) will always have degree at most 1 in each variable. In this example, we see that there are 2 solutions over $\mathbf{F}_2$ for the system.

```
> L := [P.i^2 + P.i: i in [1 .. Rank(P)]];
> BB := B cat L;
> BB;
[
    a*b + c*d + 1,
    a*c*e + d*e,
    a*b*e + c*e,
    b*c + c*d*e + 1,
    a^2 + a,
    b^2 + b,
    c^2 + c,
    d^2 + d,
    e^2 + e
]
> GroebnerBasis(BB);
[
    a + d + 1,
    b + 1,
    c + 1,
    d^2 + d,
```

```
    e
]
> I := ideal<P|BB>;
> Variety(I);
[ <0, 1, 1, 1, 0>, <1, 1, 1, 0, 0> ]
```

Since V2.15, an alternative way to solve the system over $\mathbf{F}_2$ is to use the boolean polynomial ring type as follows.

```
> P<a,b,c,d,e> := BooleanPolynomialRing(5, "grevlex");
> B := [a*b + c*d + 1, a*c*e + d*e, a*b*e + c*e, b*c + c*d*e + 1];
> I := Ideal(B);
> I;
Ideal of Boolean polynomial ring of rank 5 over GF(2)
Order: Graded Reverse Lexicographical (bit vector word)
Variables: a, b, c, d, e
Basis:
[
    a*b + c*d + 1,
    a*c*e + d*e,
    a*b*e + c*e,
    c*d*e + b*c + 1
]
> GroebnerBasis(I);
[
    a + d + 1,
    b + 1,
    c + 1,
    e
]
> Variety(I);
[ <0, 1, 1, 1, 0>, <1, 1, 1, 0, 0> ]
```

In general, if one wishes to solve a system over $\mathbf{F}_2$ from the outset, it is best to use the boolean polynomial ring type so as to save memory (and to avoid internal conversion to and from the bit vector representation for monomials). Note also that because of the implicit field relations, the Gröbner basis of an ideal generated by only one polynomial may have several polynomials. In the following example, the Gröbner basis of an ideal generated by just one polynomial has linear polynomials alone.

```
> R<[x]> := BooleanPolynomialRing(10, "grevlex");
> R;
Boolean polynomial ring of rank 10 over GF(2)
Order: Graded Reverse Lexicographical (bit vector word)
Variables: x[1], x[2], x[3], x[4], x[5], x[6], x[7], x[8], x[9], x[10]
> f := x[2]*x[3]*x[5]*x[7] + x[2]*x[4]*x[5]*x[8] + x[3]*x[4]*x[5]*x[9] +
>    x[3]*x[6]*x[7]*x[9] + x[2]*x[3]*x[5] + x[2]*x[4]*x[5] + x[2]*x[3]*x[7] +
>    x[2]*x[5]*x[7] + x[3]*x[5]*x[7] + x[3]*x[6]*x[7] + x[2]*x[4]*x[8] +
>    x[2]*x[5]*x[8] + x[4]*x[5]*x[8] + x[3]*x[6]*x[9] + x[3]*x[7]*x[9] +
>    x[6]*x[7]*x[9] + x[2]*x[3] + x[2]*x[4] + x[3]*x[5] + x[4]*x[5] +
```

```
>    x[3]*x[6] + x[2]*x[7] + x[5]*x[7] + x[6]*x[7] + x[2]*x[8] + x[4]*x[8] +
>    x[5]*x[8] + x[3]*x[9] + x[6]*x[9] + x[7]*x[9] + x[1]*x[10] + x[1] + x[4]
>    + x[6] + x[8] + x[9] + x[10];
> I := Ideal([f]);
> G := GroebnerBasis(I);
> #G;
38
> [Length(f): f in G];
[ 188, 50, 80, 82, 26, 22, 20, 26, 20, 20, 26, 32, 8, 8, 8, 8, 32, 32, 8, 8, 8,
8, 8, 8, 8, 8, 8, 32, 8, 8, 8, 8, 40, 5, 8, 8, 8, 8 ]
> G[38];
x[1]*x[4]*x[7]*x[10] + x[1]*x[5]*x[7]*x[10] + x[1]*x[4]*x[7] + x[1]*x[5]*x[7] +
    x[4]*x[7]*x[10] + x[5]*x[7]*x[10] + x[4]*x[7] + x[5]*x[7]
```

Example H105E6

This simple example illustrates some of the peculiarities of Gröbner bases over Euclidean rings. We first create a simple ideal I in $\mathbf{Z}[x, y, z]$ and compute its Gröbner basis.

```
> P<x, y, z> := PolynomialRing(IntegerRing(), 3);
> I := ideal<P| x^2 - 1, y^2 - 1, 2*x*y - z>;
> GroebnerBasis(I);
[
    x^2 - 1,
    x*z - 2*y,
    2*x - y*z,
    y^2 - 1,
    z^2 - 4
]
```

Notice that the Gröbner basis contains polynomials whose leading terms are x^2, xz and $2x$, but the third cannot eliminate the first two since the leading coefficient 2 does not divide the other leading coefficients 1 and 1.

When we compute normal forms modulo I, x is clearly not reducible by any polynomial, while $2x$ can be reduced by the $2x - yz$ polynomial.

```
> NormalForm(x, I);
x
> NormalForm(2*x, I);
y*z
```

If we compute the normal form of $(-x)$ modulo I, then even though the x monomial cannot be reduced, the result is NOT the negative of the normal form of x, since one can use the $2x - yz$ polynomial and the fact that $((-1) \bmod 2)$ is 1 to reduce the polynomial to a unique normal form. This behaviour differs from that for ideals defined over fields, where the normal form of $-f$ will always be the negative of the normal form of f.

```
> NormalForm(-x, I);
```

```
x - y*z
```

If we reduce the Gröbner basis modulo various primes, we obtain familiar Gröbner bases over fields:

```
> GroebnerBasis(ChangeRing(I, GF(2)));
[
    x^2 + 1,
    y^2 + 1,
    z
]
> GroebnerBasis(ChangeRing(I, GF(3)));
[
    x + y*z,
    y^2 + 2,
    z^2 + 2
]
```

But if we reduce modulo 4, using the ring of integers modulo 4, then the Gröbner basis still has a structure not encountered when working over fields:

```
> GroebnerBasis(ChangeRing(I, IntegerRing(4)));
[
    x^2 + 3,
    x*z + 2*y,
    2*x + y*z,
    y^2 + 3,
    z^2,
    2*z
]
```

In fact, the new polynomial $2z$ has been included in this Gröbner basis.

Example H105E7

This example shows how one can use Gröbner bases over the integers to find the primes modulo which a system of equations has a solution, when the system has no solutions over the rationals.

We first form a certain ideal I in $\mathbf{Z}[x, y, z]$, and note that the Gröbner basis of I over $\mathbf{Q}$ contains 1, so there are no solutions over $\mathbf{Q}$ or an algebraic closure of it (this is not surprising as there are 4 equations in 3 unknowns).

```
> P<x, y, z> := PolynomialRing(IntegerRing(), 3);
> I := ideal<P | x^2 - 3*y, y^3 - x*y, z^3 - x, x^4 - y*z + 1>;
> GroebnerBasis(ChangeRing(I, RationalField()));
[
    1
]
```

However, when we compute the Gröbner basis of I (defined over $\mathbf{Z}$), we note that there is a certain integer in the ideal which is not 1.

```
> GroebnerBasis(I);
```

```
[
    x + 170269749119,
    y + 2149906854,
    z + 170335012540,
    282687803443
]
```

Now for each prime p dividing this integer 282687803443, the Gröbner basis of I modulo p will be non-trivial and will thus give a solution of the original system modulo p.

```
> Factorization(282687803443);
[ <101, 1>, <103, 1>, <27173681, 1> ]
> GroebnerBasis(ChangeRing(I, GF(101)));
[
    x + 19,
    y + 48,
    z + 68
]
> GroebnerBasis(ChangeRing(I, GF(103)));
[
    x + 39,
    y + 8,
    z + 85
]
> GroebnerBasis(ChangeRing(I, GF(27173681)));
[
    x + 26637654,
    y + 3186055,
    z + 10380032
]
```

Of course, modulo any other prime the Gröbner basis is trivial so there are no other solutions. For example:

```
> GroebnerBasis(ChangeRing(I, GF(3)));
[
    1
]
```

Note that the problem can also be solved by using resultants, but this may yield many extraneous potential primes, while the Gröbner basis technique yields the exact list of primes for which there are modular solutions.

Example H105E8

This example shows how one can effectively compute in MAGMA with Gröbner bases over a ring which is not Euclidean (and may not even be a principal ideal ring), by starting with **Z** and adding appropriate defining relations. The input for this example is based on [AL94, Ex. 4.2.13].

Let $R = \mathbf{Z}[\sqrt{-5}]$. R is the maximal order of $\mathbf{Q}(\sqrt{-5})$ and is **NOT** a PIR. We consider the ideal I of $R[x, y]$ generated by $f_1 = 2xy + \sqrt{-5}y$ and $f_2 = (1 + \sqrt{-5})x^2 - xy$. To work over R, we

simply compute over $\mathbf{Z}$, introduce a new variable S to represent $\sqrt{-5}$, make sure that S is less than both x and y in the monomial order, and include the polynomial (S^2+5) in the ideal I. We then print out the Gröbner basis of I.

```
> P<x, y, S> := PolynomialRing(IntegerRing(), 3);
> f1 := 2*x*y + S*y;
> f2 := (1 + S)*x^2 - x*y;
> I := ideal<P | f1, f2, S^2 + 5>;
> GroebnerBasis(I);
[
    x^2*S + x^2 + 5*y^3 + 13*y*S - 25*y,
    6*x^2 + 5*y^2 + 3*y*S - 10*y,
    x*y + 5*y^3 + 13*y*S - 25*y,
    y^2*S + 5*y^2 - 15*y,
    10*y^2 + 5*y*S - 25*y,
    S^2 + 5
]
```

In [AL94, p. 224], a (weak) Gröbner basis for the ideal is given as $\{f_2, f_5, f_7, f_9\}$, where $f_5 = (5+\sqrt{-5})y^2 - 15y$, $f_7 = -2\sqrt{-5}y^2 + 5(1+\sqrt{-5})y$, and $f_9 = xy + \sqrt{-5}y^3 - 5\sqrt{-5}y^2 + 8\sqrt{-5}y$. We can easily verify that the ideal J generated by these 4 polynomials describes the same ideal as I (and so has the same Gröbner basis in MAGMA).

```
> f5 := (5 + S)*y^2 - 15*y;
> f7 := -2*S*y^2 + (5 + 5*S)*y;
> f9 := x*y + S*y^3 - 5*S*y^2 + 8*S*y;
> J := ideal<P |  f2, f5, f7, f9, S^2 + 5>;
> I eq J;
true
> GroebnerBasis(I) eq GroebnerBasis(J);
true
```

We can even write f_5, f_7 and f_9 as combinations of the Gröbner basis elements of I, as follows.

```
> Coordinates(I, f5);
[
    0, 0, 0, 1, 0, 0
]
> Coordinates(I, f7);
[
    0, 0, 0, -2, 1, 0
]
> Coordinates(I, f9);
[
    0, 0, 1, y, -y - 1, 0
]
```

We can see that these elements are fairly trivially derived from the Gröbner basis which MAGMA computes for I. But if we now create J again using the `IdealWithFixedBasis` function and the sequence $Q = [f_2, f_5, f_7, f_9, S^2+5]$, then we can see the coordinates of any element of $I = J$ as a

linear combination of the elements of Q. We find the coordinates of the second element of MAGMA's original Gröbner basis of I with respect to Q. The resulting coordinates are rather non-trivial.

```
> Q := [f2, f5, f7, f9, S^2 + 5];
> J := IdealWithFixedBasis(Q);
> J eq I;
true
> g := GroebnerBasis(I)[2];
> g;
6*x^2 + 5*y^2 + 3*y*S - 10*y
> C := Coordinates(J, g);
> C;
[
    -S + 1,
    -5*y + 1,
    -x - y^2*S + 7*y*S - 2*y - 7*S - 2,
    -2*y*S + 4*S + 6,
    x^2 + 5*y^3 - 13*y^2 + 3*y
]
```

We check that multiplying out the expression recovers g.

```
> &+[C[i]*Q[i]: i in [1 .. #C]] eq g;
true
```

Note that in the terminology of Adams and Loustaunau, MAGMA is here computing a "strong" Gröbner basis (for this representation which uses an extra variable for $\sqrt{-5}$), while these authors show that $\{f_2, f_5, f_7, f_9\}$ constitutes a "weak" Gröbner basis for I over the ring $\mathbf{Z}[\sqrt{-5}]$. The fact that the coordinates of g with respect to Q are rather non-trivial shows that MAGMA's strong Gröbner basis computation has computed a lot more information than the weak Gröbner basis (i.e., g, which must be included in the strong Gröbner basis, is not trivially derived from Q).

Most importantly of all, the fact that we have done all this by defining things over $\mathbf{Z}$ with the extra variable S has been no less powerful: we can still do full membership testing, normal forms, coordinate computations, etc. with this representation. Also, see below for an elimination computation which continues this example.

Gröbner bases over very many other general rings can be effectively handled in just the same way as that presented in this example! For example, if we need $\alpha = (1 + \sqrt{5})/2$, we can introduce a variable new A and the polynomial $(2A - 1)^2 - 5$.

Example H105E9

We construct an ideal I of the polynomial ring $P = \mathbf{Q}[x, y]$ with a specific fixed basis S, determine that I is the full polynomial ring P, and then find coordinates of the polynomial 1 of P with respect to S. Note that we use the function `IdealWithFixedBasis` to construct the ideal so that the fixed basis will be remembered.

```
> P<x, y> := PolynomialRing(RationalField(), 2);
> S := [x^2 - y, x^3 + y^2, x*y^3 - 1];
> I := IdealWithFixedBasis(S);
```

```
> 1 in I;
true
> C := Coordinates(I, P!1);
> C;
[
    -1/2*x^2*y^3 - 1/2*x^2*y^2 + 1/2*x^2*y + 1/2*x^2 + 1/2*x*y^3 +
        1/2*x*y^2 - 1/2*x*y - 1/2*y^4 - 1/2*y^3 + 1/2*y^2 + 1/2*y,
    1/2*x*y^3 + 1/2*x*y^2 - 1/2*x*y - 1/2*x - 1/2*y^3 - 1/2*y^2 + 1/2*y,
    -1/2*y^2 + 1
]
```

Now we check that multiplying out by the coordinates gives 1.

```
> C[1]*S[1] + C[2]*S[2] + C[3]*S[3];
1
```

Now we move the problem to being over the integer ring $\mathbf{Z}$.

```
> P<x, y> := PolynomialRing(IntegerRing(), 2);
> S := [x^2 - y, x^3 + y^2, x*y^3 - 1];
> I := IdealWithFixedBasis(S);
> 1 in I;
false
> GroebnerBasis(I);
[
    x + 1,
    y + 1,
    2
]
```

We note that 1 is not in the ideal this time, but 2 is! So we compute the coordinates of 2 with respect to I this time.

```
> C := Coordinates(I, P!2);
> C;
[
    x^2*y^2 - x^2*y - x^2 - x*y^2 + x*y + x + y^4 + y^3 - y^2 - y - 1,
    -x*y^2 + x*y + x + y^3 + y^2 - y - 1,
    -x^2 - x*y + y - 2
]
```

Note that C is the same as above, except that each polynomial has been scaled by 2 to make it integral. Finally we check again that multiplying out by the coordinates gives 2.

```
> C[1]*S[1] + C[2]*S[2] + C[3]*S[3];
2
```

Incidentally, we can see from the Gröbner basis of I over $\mathbf{Z}$ that the only solution to the system of equations described by S is the local solution $x = y = 1$ over $\mathbf{F}_2$.

Example H105E10

Gröbner bases can be constructed over any exact Euclidean ring in MAGMA, not just the ring of integers and its residue class rings.
We construct an ideal I of the polynomial ring $P = \mathbf{Q}[x, y]$ with a specific fixed basis S, determine that I is the full polynomial ring P, and then find coordinates of the polynomial 1 of P with respect to S. Note that we use the function `IdealWithFixedBasis` to construct the ideal so that the fixed basis will be remembered.

```
> P<x, y> := PolynomialRing(RationalField(), 2);
> S := [x^2 - y, x^3 + y^2, x*y^3 - 1];
> I := IdealWithFixedBasis(S);
> 1 in I;
true
> C := Coordinates(I, P!1);
> C;
[
    -1/2*x^2*y^3 - 1/2*x^2*y^2 + 1/2*x^2*y + 1/2*x^2 + 1/2*x*y^3 +
        1/2*x*y^2 - 1/2*x*y - 1/2*y^4 - 1/2*y^3 + 1/2*y^2 + 1/2*y,
    1/2*x*y^3 + 1/2*x*y^2 - 1/2*x*y - 1/2*x - 1/2*y^3 - 1/2*y^2 + 1/2*y,
    -1/2*y^2 + 1
]
```

Now we check that multiplying out by the coordinates gives 1.

```
> C[1]*S[1] + C[2]*S[2] + C[3]*S[3];
1
```

Now we move the problem to being over the integer ring $\mathbf{Z}$.

```
> P<x, y> := PolynomialRing(IntegerRing(), 2);
> S := [x^2 - y, x^3 + y^2, x*y^3 - 1];
> I := IdealWithFixedBasis(S);
> 1 in I;
false
> GroebnerBasis(I);
[
    x + 1,
    y + 1,
    2
]
```

We note that 1 is not in the ideal this time, but 2 is! So we compute the coordinates of 2 with respect to I this time.

```
> C := Coordinates(I, P!2);
> C;
[
    x^2*y^2 - x^2*y - x^2 - x*y^2 + x*y + x + y^4 + y^3 - y^2 - y - 1,
    -x*y^2 + x*y + x + y^3 + y^2 - y - 1,
    -x^2 - x*y + y - 2
```

```
]
```

Note that C is the same as above, except that each polynomial has been scaled by 2 to make it integral. Finally we check again that multiplying out by the coordinates gives 2.

```
> C[1]*S[1] + C[2]*S[2] + C[3]*S[3];
2
```

Incidentally, we can see from the Gröbner basis of I over $\mathbf{Z}$ that the only solution to the system of equations described by S is the local solution $x = y = 1$ over $\mathbf{F}_2$.

105.4.7 Degree-d Gröbner Bases

`GroebnerBasis(S, d : parameters)`

Given a set or sequence S of polynomials from a graded polynomial ring P, return the weighted degree-d Gröbner basis of the ideal generated by S, which is the truncated Gröbner basis obtained by ignoring S-polynomial pairs whose weighted degree (with respect to the grading on P) is greater than d.

If the ideal is homogeneous, then it is guaranteed that the result is equal to the set of all polynomials in the full Gröbner basis of the ideal whose weighted degree is less than or equal to d, and a polynomial whose weighted degree is less than or equal to d is in the ideal iff its normal form with respect to this truncated basis is zero. But if the ideal is not homogeneous, these last properties may not hold, but it may be still useful to construct the truncated basis.

The parameters are the same as those for the procedure `Groebner`. See also [BW93, section 10.2] for further discussion. Note that the base ring may be a field or Euclidean ring.

Example H105E11

We create a graded polynomial ring and compute the degree-d Gröbner basis of a sequence L of homogeneous polynomials for various d. Since the polynomials are homogeneous (with respect to the grading), we check that the result for each d contains the set of all polynomials in the full Gröbner basis of L having weighted degree less than or equal to d.

```
> P<a,b,c,d> := PolynomialRing(RationalField(), [4,3,2,1]);
> L := [a*b - c^2*d^3, b*c*d + c^3, c^2*d - d^5, a*d - b*c];
> [IsHomogeneous(f): f in L];
[ true, true, true, true ]
> [Degree(f): f in L];
[ 7, 6, 5, 5 ]
> G:=GroebnerBasis(L);
> G;
[
    a*b - d^7,
    a*c^3 + d^10,
    a*d - b*c,
```

```
    b^2*c - d^8,
    b*c^3 + d^9,
    b*c*d + c^3,
    b*d^5 + c^4,
    c^5 - d^10,
    c^2*d - d^5,
    c*d^7 - d^9
]
> #G;
10
> [Degree(f): f in G];
[ 7, 10, 5, 8, 9, 6, 8, 10, 5, 9 ]
> for D := 1 to 10 do
>     T := GroebnerBasis(L, D);
>     printf "D = %o, #GB = %o, contains all degree-D polynomials: %o\n",
>         D, #T, {f: f in G | Degree(f) le D} subset T;
> end for;
D = 1, #GB = 4, contains all degree-D polynomials: true
D = 2, #GB = 4, contains all degree-D polynomials: true
D = 3, #GB = 4, contains all degree-D polynomials: true
D = 4, #GB = 4, contains all degree-D polynomials: true
D = 5, #GB = 4, contains all degree-D polynomials: true
D = 6, #GB = 4, contains all degree-D polynomials: true
D = 7, #GB = 4, contains all degree-D polynomials: true
D = 8, #GB = 6, contains all degree-D polynomials: true
D = 9, #GB = 8, contains all degree-D polynomials: true
D = 10, #GB = 10, contains all degree-D polynomials: true
> GroebnerBasis(L, 5);
[
    a*b - d^7,
    a*d - b*c,
    b*c*d + c^3,
    c^2*d - d^5
]
> GroebnerBasis(L, 8);
[
    a*b - d^7,
    a*d - b*c,
    b^2*c - d^8,
    b*c*d + c^3,
    b*d^5 + c^4,
    c^2*d - d^5
]
```

105.5 Changing Coefficient Ring

The `ChangeRing` function enables the changing of the coefficient ring of a polynomial ring or ideal.

`ChangeRing(I, S)`

Given an ideal I of a polynomial ring $P = R[x_1, \ldots, x_n]$ of rank n with coefficient ring R, together with a ring S, construct the ideal J of the polynomial ring $Q = S[x_1, \ldots, x_n]$ obtained by coercing the coefficients of the elements of the basis of I into S. It is necessary that all elements of the old coefficient ring R can be automatically coerced into the new coefficient ring S. If R and S are fields and R is known to be a subfield of S and the current basis of I is a Gröbner basis, then the basis of J is marked automatically to be a Gröbner basis of J.

Example H105E12

It is better to find the Gröbner basis of an ideal over the smallest subfield possible (e.g. **Q**), then use `ChangeRing` to create the equivalent ideal over a splitting field to find the variety.

```
> P<x, y, z, t, u> := PolynomialRing(RationalField(), 5);
> I := ideal<P |
>     x + y + z + t + u,
>     x*y + y*z + z*t + t*u + u*x,
>     x*y*z + y*z*t + z*t*u + t*u*x + u*x*y,
>     x*y*z*t + y*z*t*u + z*t*u*x + t*u*x*y + u*x*y*z,
>     x*y*z*t*u - 1>;
> Groebner(I);
> K<W> := CyclotomicField(5);
> J := ChangeRing(I, K);
> V := Variety(J);
> #V;
70
```

105.6 Changing Monomial Order

Often one wishes to change the monomial order of an ideal. MAGMA allows one to do this by use of the `ChangeOrder` function.

`ChangeOrder(I, Q)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, together with a polynomial ring Q of rank n (with possibly a different order to that of P), return the ideal J of Q corresponding to I and the isomorphism f from P to Q. The map f simply maps $P.i$ to $Q.i$ for each i.

The point of the function is that one can change the order on monomials of I to be that of Q. When a Gröbner basis of J is needed to be calculated, MAGMA uses a conversion algorithm starting from a Gröbner basis of I if possible—this usually

makes order conversion much more efficient than by computing a Gröbner basis of J from scratch.

`ChangeOrder(I, order)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, together with a monomial order *order* (see Section 105.2), construct the polynomial ring $Q = R[x_1, \ldots, x_n]$ with order *order*, and then return the ideal J of Q corresponding to I and the isomorphism f from P to Q. See the section on monomial orders for the valid values for the argument *order*. The map f simply maps $P.i$ to $Q.i$ for each i.

`ChangeOrder(I, T)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, together with a tuple T, construct the polynomial ring $Q = R[x_1, \ldots, x_n]$ with the monomial order given by the tuple T on the monomials, and then return the ideal J of Q corresponding to I and the isomorphism f from P to Q. T must be a tuple whose components match the valid arguments for the monomial orders in Section 105.2 (or a tuple returned by the function `MonomialOrder`).

Example H105E13

We write a function `univgen` which, given a zero-dimensional ideal defined over a field, computes the univariate elimination ideal generator for a particular variable by changing order to the appropriate univariate order. Note that this function is the same as (and is in fact implemented in exactly the same way as) the intrinsic function `UnivariateEliminationIdealGenerator`. We then find the appropriate univariate polynomials for a particular ideal.

```
> function univgen(I, i)
>    // Make sure I has a Groebner basis so that
>    // the conversion algorithm will be used when
>    // constructing a Groebner basis of J
>    Groebner(I);
>    J := ChangeOrder(I, "univ", i);
>    Groebner(J);
>    return rep{f: f in Basis(J) | IsUnivariate(f, i)};
> end function;
>
> P<x, y, z> := PolynomialRing(RationalField(), 3, "grevlex");
> I := ideal<P |
>     1 - x + x*y^2 - x*z^2,
>     1 - y + y*x^2 + y*z^2,
>     1 - z - z*x^2 + z*y^2 >;
>
> univgen(I, 1);
x^21 - x^20 - 2*x^19 + 4*x^18 - 5/2*x^17 - 5/2*x^16 + 4*x^15 -
    15/2*x^14 + 129/16*x^13 + 11/16*x^12 - 103/8*x^11 +
    131/8*x^10 - 49/16*x^9 - 171/16*x^8 + 12*x^7 - 3*x^6 -
    29/8*x^5 + 15/4*x^4 - 17/16*x^3 - 5/16*x^2 + 5/16*x - 1/16
```

```
> univgen(I, 2);
y^14 - y^13 - 13/2*y^12 + 8*y^11 + 53/4*y^10 - 97/4*y^9 -
    45/8*y^8 + 33*y^7 - 25/2*y^6 - 18*y^5 + 107/8*y^4 + 5/8*y^3 -
    27/8*y^2 + 9/8*y - 1/8
> univgen(I, 3);
z^21 - z^20 - 2*z^19 + 4*z^18 - 5/2*z^17 - 5/2*z^16 + 4*z^15 -
    15/2*z^14 + 129/16*z^13 + 11/16*z^12 - 103/8*z^11 +
    131/8*z^10 - 49/16*z^9 - 171/16*z^8 + 12*z^7 - 3*z^6 -
    29/8*z^5 + 15/4*z^4 - 17/16*z^3 - 5/16*z^2 + 5/16*z - 1/16
```

105.7 Hilbert-driven Gröbner Basis Construction

MAGMA incorporates an implementation of the *Hilbert-driven Buchberger Algorithm* [Tra96]. This algorithm constructs the Gröbner basis of an homogeneous ideal I whose Hilbert series is known. The algorithm is often much more efficient than the conventional Buchberger algorithm since knowledge of the Hilbert series eliminates many unnecessary reductions of S-polynomials. The algorithm can also be used as an alternative to the Gröbner Walk algorithm for changing order since one can compute the Hilbert series of the ideal with respect to an easy monomial order, and then start again with the Hilbert-driven algorithm to compute the Gröbner basis with respect to the desired final order. Furthermore, the algorithm can sometimes be used to test whether an ideal has a particular Hilbert series and abort early if this is proven to be false. The algorithm is also used extensively internally in the Invariant Theory algorithms of MAGMA.

`HilbertGroebnerBasis(S, H)`

`HilbertGroebnerBasis(S, N)`

Let S be a set or sequence of homogeneous polynomials from the multivariate polynomial ring $P = K[x_1, \ldots, x_n]$, where K is a field, and let I be the ideal of P generated by S. Let either H be the Hilbert series $H_{P/I}(t)$ of I (as a rational function in $\mathbf{Z}(t)$) or let $N \in \mathbf{Z}[t]$ be a univariate integer polynomial such that the weighted numerator of the Hilbert series of I is N. This function attempts to construct the (reduced) Gröbner basis of I using the given Hilbert series. The weighted numerator of the Hilbert series of I is the Hilbert series $H_{P/I}(t)$ of I, multiplied by the denominator $\prod_{i=1}^{n} 1 - t^{d_i}$, where d_i is the weighted degree of the i-th variable x_i (this denominator is thus $(1-t)^n$ if P has the default grading).

If the function returns `false`, then H (or N) cannot be the correct Hilbert series (or weighted numerator of the Hilbert series) of I. Otherwise, the function returns `true` and a sequence B of polynomials which generates the same ideal as S; if H or N is correct, B will be the (reduced) Gröbner basis of I.

In more detail, let f_H be the power series corresponding to the true Hilbert series of I and let f_N be the power series corresponding to $N/(\prod_{i=1}^{n} 1 - t^{d_i})$. If $f_H = f_N$, then the function returns `true` and the correct (reduced) Gröbner basis of I. Otherwise, consider the first term at which f_N and f_H differ: if the coefficient

of f_N is greater than that of f_H, then the function returns `false` (since it will not be able to construct the extra Gröbner basis polynomials needed), otherwise the function will return `true` with a partial Gröbner basis (since it concludes that it has enough Gröbner basis polynomials when it hasn't). Consequently, the algorithm is usually used when the correct Hilbert series or weighted numerator of the Hilbert series is known, or when there is a weighted numerator which is known to be greater than or equal to the correct weighted numerator of the Hilbert series.

`SetVerbose("HilbertGroebner", v)`

Change verbose printing for the Hilbert-driven Buchberger algorithm to be v. Currently the legal values for v are `true`, `false`, 0, or 1.

Example H105E14

We illustrate a subalgorithm of the Invariant Theory module of MAGMA which uses the Hilbert-driven Buchberger Algorithm.
Let R be the invariant ring of the (permutation) cyclic group G of order 4 over the field $K = \mathbf{F}_2$. Suppose we have a sequence L of 4 homogeneous invariants of degrees $1, 2, 2$, and 4 respectively. We wish to determine efficiently whether the polynomials of L constitute primary invariants for R. To check this, the ideal generated by L must be zero-dimensional and the elements of L must be algebraically independent. This is equivalent to the condition that the weighted numerator of the Hilbert series of the ideal is the product $(1-t)(1-t^2)^2(1-t^4)$. If that is not the correct weighted numerator, it will be less than the correct weighted numerator so the algorithm will return whether the polynomials L do constitute primary invariants for R.

```
> K := GF(2);
> P<a,b,c,d> := PolynomialRing(K, 4);
> L := [
>     a + b + c + d,
>     a*b + a*d + b*c + c*d,
>     a*c + b*d,
>     a*b*c*d
> ];
> // Form potential Hilbert series weighted numerator
> T<t> := PolynomialRing(IntegerRing());
> N := &*[1 - t^Degree(f): f in L];
> N;
t^9 - t^8 - 2*t^7 + 2*t^6 + 2*t^3 - 2*t^2 - t + 1
> time l, B := HilbertGroebnerBasis(L, N);
Time: 0.000
> l;
true
> // Examine Groebner basis B of L:
> B;
[
    a + b + c + d,
    b^2 + d^2,
    b*c + b*d + c^2 + c*d,
```

```
    c^3 + c^2*d + c*d^2 + d^3,
    d^4
]
```

105.8 SAT solver

MAGMA V2.16 contains an interface to the *MiniSat* satisfiability (SAT) solver. Such a solver is given a system of boolean expressions in conjunctive normal form and determines whether there is an assignment in the variables such that all the expressions are satisfied. MAGMA supplies a function by which one may transform a system of boolean polynomial equations into an equivalent boolean system, and solve this via the SAT solver.

To use the interface function, the *MiniSat* program must currently be installed as a command external to MAGMA. At the time of writing (November 2009), the latest version of *MiniSat* can be installed as follows on most Unix/Linux systems:

(1) Download `http://minisat.se/downloads/minisat2-070721.zip` from the *MiniSat* website (`minisat.se`).

(2) Use the command `unzip minisat2-070721.zip` or equivalent to unzip the files.

(3) Change directory into `minisat/core` and run `make` there.

(4) Copy the produced executable `minisat` into a place which is in the current path when MAGMA is run.

`SAT(B)`

`Exclude`	[RngMPolElt]	*Default :* []
`Verbose`	BoolElt	*Default :* `true`

Given a sequence B of boolean polynomials in a rank-n boolean polynomial ring (or a rank-n polynomial ring over $\mathbf{F}_2$), call *MiniSat* on the associated boolean system and return whether the system is satisfiable, and if so, return also a solution S as a length-n sequence of elements of $\mathbf{F}_2$. (This assumes that *MiniSat* is in the executable path of external commands; see above for instructions for installing *MiniSat*).

The parameter `Exclude` may be set to a sequence $[e_1, \ldots e_k]$, where each e_i is a sequence of n elements of $\mathbf{F}_2$, specifying that the potential solutions in e_i are to be excluded (this is done by adding new relations to the system to exclude the e_i). The verbose information printed by *MiniSat* may be controlled by the parameter `Verbose`.

Example H105E15

In Example H105E5, we solved a boolean polynomial system via the standard Gröbner basis method (which the function `Variety` uses). Here we solve the same system via the SAT solver. Each time we obtain a solution, we can call the function again, but excluding the solution(s) already found. We can thus find all the solutions to the system. Of course, this is not worth doing when there are large numbers of solutions, but it may be of interest to find all solutions when it is expected there is a small number of solutions.

```
> P<a,b,c,d,e> := BooleanPolynomialRing(5, "grevlex");
> B := [a*b + c*d + 1, a*c*e + d*e, a*b*e + c*e, b*c + c*d*e + 1];
> l, S := SAT(B);
> l;
true
> S;
[ 1, 1, 1, 0, 0 ]
> Universe(S);
Finite field of size 2
> [Evaluate(f, S): f in B];
[ 0, 0, 0, 0 ]
> l, S2 := SAT(B: Exclude := [S]);
> l;
true
> S2;
[ 0, 1, 1, 1, 0 ]
> [Evaluate(f, S2): f in B];
[ 0, 0, 0, 0 ]
> l, S3 := SAT(B: Exclude := [S, S2]);
> l;
false
```

106 POLYNOMIAL RING IDEAL OPERATIONS

Chapter 106
POLYNOMIAL RING IDEAL OPERATIONS

106.1 Introduction

This chapter describes the MAGMA functionality for ideals over polynomial rings. For the basics on multivariate polynomial rings and their elements, see Chapter 24. Most of the significant operations with ideals construct or utilise a previously-constructed Gröbner basis. The monomial ordering used for this basis can greatly affect the speed and memory usage of these operations. This ordering is attached to the polynomial ring in which the ideals are created. For information on Gröbner bases and the creation of polynomial rings with specified orders, see Chapter 105. That chapter also tells the user how to compute and return a Gröbner basis, or just to compute it internally for later use in the operations described below, with many additional configuration parameters to optimise the computation. Users may ignore the issue when creating the ambient polynomial rings by allowing MAGMA to make default choices. It is, however, highly recommended that users who wish to work with complicated ideals thoroughly acquaint themselves with the options available. MAGMA has an extremely powerful Gröbner basis engine and often makes sophisticated choices internally of alternative monomial orders for particular computations. Ultimately, however, the user may significantly speed up his work by a judicious choice of order. We note here that the default order is the lexicographical one, a total elimination order well suited to finding solutions of zero-dimensional systems of polynomial equations but tending to produce very large bases that can take much time and memory to compute. For homogeneous ideals of rings with the standard weighting (all variables have weight one), the grevlex order is usually the best in practise and there is theoretical justification for this. In the case that the ring has a different weighting and the ideal is homogeneous with respect to that, the weighted grevlex order is the best choice. In any case, the `EasyIdeal` and `EasyBasis` intrinsics of the Gröbner basis chapter return to the user a basis for an internally chosen good order and these "easy" bases are used in many internal functions if a basis with respect to the polynomial ring order has not already been computed and stored.

The functions and operations described here cover a wide range of commutative algebra functionality. This includes sums and intersections, colon ideals and saturations, elimination, radicals and primary decompositions, Noether normalisations and computation of Hilbert polynomials and Hilbert series.

Related chapters including other polynomial ring functionality relying on Gröbner bases are the chapter on invariant rings of finite group actions, Chapter 110, and the chapters on affine algebras (Chapter 108) and on modules over affine algebras (Chapter 109). The chapter on algebraically closed fields (Chapter 40) describes functions that allows one to compute the variety of an ideal over the algebraic closure of the base field. And, of course, the Algebraic Geometry component of MAGMA and parts of the Arithmetic Geometry are built upon the commutative algebra here.

106.2 Creation of Polynomial Rings and their Ideals

As noted in the introduction, for the basics on multivariate polynomial rings and their elements, including their creation, the user should refer to Chapter 24. For creation of polynomial rings with non-default (currently lexicographic) monomial ordering, the user should refer to Chapter 105. Similarly, the basic creation functions for ideals and additional basis options are described in Chapter 105. The commonest creation methods are the `ideal` constructor and the `Ideal` function.

106.3 First Operations on Ideals

In the following, note that since ideals of a full polynomial ring P are regarded as subrings of P, the ring P itself is a valid ideal as well (the ideal containing 1).

106.3.1 Simple Ideal Constructions

The following basic constructions involve no Gröbner basis computation.

`I + J`

Given ideals I and J of the same polynomial ring P, return the sum of I and J, which is the ideal generated by the generators of I and those of J.

`I * J`

Given ideals I and J of the same polynomial ring P, return the product of I and J, which is the ideal generated by the products of the generators of I and those of J.

`I ^ k`

Given an ideal I of the polynomial ring P, and an integer k, return the k-th power of I.

`I / J`

Given an ideal I of a polynomial ring P over a field and an ideal J of P, such that $J \subset I$, return the affine algebra I/J.

106.3.2 Basic Commutative Algebra Operations

The following important basic operations on ideals involve Gröbner basis computation and use the standard algorithms as described in Chapter 1.8 of [GP02], for example, unless otherwise stated.

`QuotientDimension(I)`

Given an ideal I of a polynomial ring P over a field K, return the dimension of P/I as a K-vector space. Note that this is quite different from the function `Dimension` below (which returns the Krull dimension of an ideal). If I is not of Krull dimension 0 then the vector space is infinite and `Infinity` is returned.

`ColonIdeal(I, J)`

`IdealQuotient(I, J)`

Given ideals I and J of the same polynomial ring P, return the colon ideal $I : J$ (or ideal quotient of I by J), consisting of the polynomials f of P such that $f * g$ is in I for all g in J.

`ColonIdeal(I, f)`

`IdealQuotient(I, f)`

Given an ideal I and an element f of a polynomial ring P, return the saturation (colon) ideal $I : f^\infty$, consisting of the polynomials g of P such that there exists an $i \geq 1$ with $f^i * g \in I$. An integer s with $s \geq 1$ is also returned such that $I : f^\infty = I : f^s$. Note that if s is not needed, only one return value of the function should be expected which increases the efficiency enormously. Note also that this function is *not* equivalent to taking the ideal quotient of I by the ideal of P generated by f. It is in some ways a more natural operation mathematically, corresponding to taking the full inverse image of the localised ideal I_f under the localisation map $P \to P_f$, and can be faster than the $I : f$ computation, if s is not required. In this case, the computation goes by the elimination of extra variable t from the ideal $< I, 1 - f * t >$.

`ColonIdealEquivalent(I, f)`

`Saturation(I, f)`

Given an ideal I and an element f of a polynomial ring P, return the saturation (colon) ideal $C = I : f^\infty$, and a polynomial $g \in P$ such that $C = I : \langle g \rangle$ and g is of minimal degree. The irreducible factors of g will be a subset of the irreducible factors of f (and the corresponding multiplicities may be greater or lesser, depending on how often an irreducible factor divides the ideal I).

`Saturation(I, J)`

Given ideals I and J of some polynomial ring P, return the saturation $(I : J^\infty)$: that is, the ideal $\{f \in P : \exists n > 0, f^n J \subseteq I\}$.

`Saturation(I)`

Given an ideal I of a polynomial ring P, return the saturation of I with respect to the irrelevant ideal of P – that is, the ideal of all elements of P having positive degree.

`Generic(I)`

Given an ideal I of a generic polynomial ring P, return P.

`LeadingMonomialIdeal(I)`

Given an ideal I, return the leading monomial ideal of I; that is, the ideal generated by all the leading monomials of I.

`I meet J`

Given ideals I and J of the same polynomial ring P, return the intersection of I and J.

`&meet S`

Given a set or sequence S of ideals of the same polynomial ring P, return the intersection of all the ideals of S.

`RegularSequence(I)`

`Homogeneous` BoolElt *Default :* `true`

Given an ideal I of a polynomial ring P over a field, computes and returns a maximal regular sequence in I. The algorithm used is that of Eisenbud and Sturmfels ([ES94]) that tries to construct a regular sequence of fairly sparse polynomials. If parameter `Homogeneous` is `true` (the default), and I is a homogeneous ideal with respect to the variable weights, then the regular sequence constructed will also consist of homogeneous polynomials.

`ReesIdeal(P, I)`

`ReesIdeal(P, J, I)`

`a` RngMPolElt *Default :* 1

`ReesIdeal(R, I)`

`a` RngMPolElt *Default :* 1

In each case P is a multivariate polynomial ring and I is an ideal of P. In the third case R is an affine quotient algebra of the form P/J. In the second case J is another ideal of P and we write R for the affine algebra P/J. In the first case, let $R = P$.

The Rees algebra $R(I)$ is the finitely-generated, graded polynomial algebra isomorphic to the algebra

$$R \oplus I \oplus I^2 \oplus I^3 \oplus \dots$$

where I gives the first graded part, I^2 the second etc. and the multiplication is the obvious one. Here I is thought of as an ideal of R, rather than P for the second and third signatures. *Proj* of this algebra represents the blow-up of the affine scheme $Spec(R)$ along the closed subscheme defined by I (see Chapter 2, Section 7 of [Har77]).

The function returns the *Rees ideal*, K, such that, if R_1 is the generic polynomial ring of K, then R_1/K is an affine algebra isomorphic to $R(I)/ < a - torsion >$, where a is an element of P (or R in the third case) that gives a non-zero divisor in R and is 1 by default. In the first case, any such a remains a non-zero divisor in $R(I)$, so is redundant. However, in the second and third cases, a can be specified to be not equal to 1 by use of the `a` parameter. Geometrically, dividing out by a-torsion gives the coordinate ring of the maximal closed subscheme of the blow-up that is flat over the generic point and the codimension one points defined by the vanishing of a, if these points are regular.

106.3.3 Ideal Predicates

`I eq J`

Given two ideals I and J of the same polynomial ring P, return whether I and J are equal. Involves the use of a Gröbner basis for each ideal.

`I ne J`

Given two ideals I and J of the same polynomial ring P, return whether I and J are not equal. Involves the use of a Gröbner basis for each ideal.

`I notsubset J`

Given two ideals I and J in the same polynomial ring P return whether I is not contained in J. Involves the use of a Gröbner basis for J.

`I subset J`

Given two ideals I and J in the same polynomial ring P return whether I is contained in J. Involves the use of a Gröbner basis for J.

`IsZero(I)`

Given an ideal I of the polynomial ring P, return whether I is the zero ideal (contains zero alone).

`IsProper(I)`

Given an ideal I of the polynomial ring P, return whether I is proper; that is, whether I is strictly contained in P, or whether the Gröbner basis of I does not contain 1 alone.

`IsHomogeneous(I)`

Given an ideal I of the polynomial ring P, this function returns whether I is homogeneous with respect to the weights on the variables of P (i.e., whether I possesses a basis consisting of homogeneous polynomials alone). Checks whether the current basis of I consists of homogeneous polynomials and, if not and the current basis isn't Gröbner, then whether an easy Gröbner basis consists of homogeneous elements.

`IsPrincipal(I)`

Given an ideal I of the polynomial ring P, return whether I is principal, and if so, return also a generator of I. This will be true if and only if an arbitrary Gröbner basis consists of a single (generating) element.

`IsPrimary(I)`

Given an ideal I of the polynomial ring P, return whether I is primary. An ideal I is primary if and only if for all $ab \in I$, either $a \in I$ or $b^n \in I$ for some $n \geq 1$. The restrictions on I are the same as for the function `PrimaryDecomposition`—see the description of that function. In general, this function computes or retrieves the primary decomposition and checks whether it has a unique element.

`IsPrime(I)`

Given an ideal I of the polynomial ring P, return whether I is prime. An ideal I is prime if and only if for all $ab \in I$, either $a \in I$ or $b \in I$. The restrictions on I are the same as for the function `PrimaryDecomposition`—see the description of that function. Again, this function computes the primary decomposition or uses the already stored one.

`IsMaximal(I)`

Given an ideal I of the polynomial ring P, return whether I is maximal. The restrictions on I are the same as for the function `PrimaryDecomposition`—see the description of that function. Checks first whether I is zero-dimensional (see below) and, if so, then checks whether it is prime. NB: given that I is of dimension 0, the prime/primary decomposition computation is relatively fast.

`IsRadical(I)`

Given an ideal I of the polynomial ring P, return whether I is radical; that is, whether the radical of I is I itself. The restrictions on I are the same as for the function `Radical`—see the description of that function. The function computes the radical or uses the already stored one.

`IsZeroDimensional(I)`

Given an ideal I of the polynomial ring P, defined over a field, return whether I is zero-dimensional (so the quotient of P by I has non-zero finite dimension as a vector space over the coefficient field – see the section on dimension for further details). Note that the full polynomial ring P as an ideal of itself has dimension -1, so it is not zero-dimensional.

`HasGrevlexOrder(I)`

Given an ideal I of the polynomial ring P, return whether the monomial order of I is the `grevlex` order.

Example H106E1

We construct some ideals in $\mathbf{Q}[x, y, z]$ and perform basic arithmetic on them.

```
> P<x,y,z> := PolynomialRing(RationalField(), 3);
> I := ideal<P | x*y - 1, x^3*z^2 - y^2, x*z^3 - x - 1>;
> J := ideal<P | x*y - 1, x^2*z - y, x*z^3 - x - 1>;
> A := I * J;
> A;
Ideal of Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: x, y, z
Basis:
[
    x^2*y^2 - 2*x*y + 1,
```

```
    x^3*y*z - x^2*z - x*y^2 + y,
    x^2*y*z^3 - x^2*y - x*y - x*z^3 + x + 1,
    x^4*y*z^2 - x^3*z^2 - x*y^3 + y^2,
    x^5*z^3 - x^3*y*z^2 - x^2*y^2*z + y^3,
    x^4*z^5 - x^4*z^2 - x^3*z^2 - x*y^2*z^3 + x*y^2 + y^2,
    x^2*y*z^3 - x^2*y - x*y - x*z^3 + x + 1,
    x^3*z^4 - x^3*z - x^2*z - x*y*z^3 + x*y + y,
    x^2*z^6 - 2*x^2*z^3 + x^2 - 2*x*z^3 + 2*x + 1
]
> M := I meet J;
> M;
Ideal of Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: x, y, z
Basis:
[
    x^4 + x^3 - x*z^2 + z^12 - 4*z^9 + 6*z^6 - z^4 - 4*z^3 + z + 1,
    x^5 + x^4 - x^2*z^2 + z^9 - 3*z^6 + 3*z^3 - z - 1,
    x*z^3 - x - 1,
    y - z^3 + 1
]
> A eq M;
true
> QuotientDimension(A);
24
> ColonIdeal(I, J);
Ideal of Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: x, y, z
Inhomogeneous, Dimension 0
Basis:
[
    x*y - 1,
    x^3*z^2 - y^2,
    x*z^3 - x - 1
]
```

106.3.4 Element Operations with Ideals

`f in I`

Given a polynomial f from a polynomial ring P, together with an ideal I of P, return whether f is in I. The function computes the normal form of f relative to some Gröbner basis of I and checks if this is zero.

`f notin I`

Given a polynomial f from a polynomial ring P, together with an ideal I of P, return whether f is not in I. As with `in`, this performs a normal form computation.

`IsInRadical(f, I)`

Given a polynomial f from a polynomial ring P, together with an ideal I of P, return whether f is in the radical of I. Note that using this function is much quicker in general than actually computing the radical of I. It uses the algorithm described in section 1.8.6 of [GP02].

`JacobianIdeal(f)`

Return the ideal generated by all first partial derivatives of the polynomial f.

Example H106E2

We demonstrate the element operations with respect to an ideal of $\mathbf{Q}[x, y, z]$.

```
> P<x, y, z> := PolynomialRing(RationalField(), 3);
> I := ideal<P | (x + y)^3, (y - z)^2, y^2*z + z>;
> NormalForm(y^2*z + z, I);
0
> NormalForm(x^3, I);
-3*x^2*y - 3*x*z^4 - 6*x*z^2 + 1/2*z^3 + 3/2*z
> NormalForm(z^4 + y^2, I);
2*z^4 + 2*z^2
> x + y in I;
false
> IsInRadical(x + y, I);
true
> IsInRadical((x + y)^2, I);
true
> IsInRadical(z, I);
false
> SPolynomial(x^4 + y - z, x^2 + y - z);
-x^2*y + x^2*z + y - z
```

106.4 Computation of Varieties

The slightly non-standard term variety in this section refers to the (finite) solution set of the system of polynomials that make up a zero-dimensional ideal. It can also be thought of as the set of points of a zero-dimensional affine scheme over a specified field extension of the polynomial ring base field. For more general functionality for schemes of arbitrary dimension, see the chapters on Algebraic and Arithmetic Geometry. The functions here also work for higher-dimensional ideals if the base field is finite, when the solution set is again finite (over the base or a finite extension of the base).

The functions compute solutions over the base field of the polynomial ring or over an extension field L. MAGMA's algebraically closed fields (see Chapter 40) may be used to get all solutions if so desired when an explicit splitting field is not known for the system. L should be an exact field over which MAGMA has a root-finding algorithm for univariate polynomials or a real or complex field.

For the corresponding functions with argument a zero-dimensional scheme which may not be affine, see the Section 112.7 in the Schemes chapter.

`Variety(I)`

`Variety(I, L)`

`Digits` RNGINTELT *Default :* 38

Given a zero-dimensional ideal I of a polynomial ring P, return the variety of I over its coefficient field K as a sequence of tuples. Each tuple is of length n, where n is the rank of P, and corresponds to an assignment of the n variables of P (in order) such that all polynomials in I vanish with this assignment.

If K is not a finite field then the ideal must be the full polynomial ring or be zero-dimensional so that the variety is known to be finite. If a superfield L of K is also given, the variety is computed over L instead, so the entries of the tuples lie in L.

If the field over which the variety is computed is the free complex field, MAGMA uses a special root finding algorithm to ensure the precision of the results; in this case, the parameter `Digits` may be given (see the `Roots` function in the Real and Complex Fields chapter (Chapter 25)).

The function works in the zero-dimensional case by first computing a triangular or radical decomposition of I (see Section 106.11). This reduces the problem to successively computing roots of univariate polynomials.

`VarietySequence(I)`

`VarietySequence(I, L)`

`Digits` RNGINTELT *Default :* 38

Given a zero-dimensional ideal I of a polynomial ring P whose order is of lexicographic type, return the variety of I over its coefficient field K as a sequence of sequences of elements of K. Each inner sequence is of length n, where n is the rank of P, and corresponds to an assignment of the n variables of P (in order) such that all polynomials in I vanish with this assignment.

If K is not a finite field then the ideal must be the full polynomial ring or be zero-dimensional so that the variety is known to be finite. If a superfield L of K is also given, the variety is computed over L instead, so the entries of the sequences lie in L.

If the field over which the variety is computed is the free complex field, MAGMA uses a special root finding algorithm to ensure the precision of the results; in this case, the parameter `Digits` may be given (see the `Roots` intrinsic function in the Real and Complex Fields chapter (Chapter 25)).

The function works in the zero-dimensional case by first computing a triangular or radical decomposition of I (see Section 106.11). This reduces the problem to successively computing roots of univariate polynomials.

`VarietySizeOverAlgebraicClosure(I)`

Given a zero-dimensional ideal I of a polynomial ring P over a field K, return the size of the variety of I over the algebraic closure K' of K. The size is determined by finding the (prime) radical decomposition of I and placing each component of the decomposition into normal position so the size of the variety of the component over K' can be read off. Note that this function will usually be much faster than actually computing the variety of I over a suitable extension field of K.

Example H106E3

We construct an ideal I of the polynomial ring $\mathbf{F}_{27}[x, y]$, and then find the variety $V = V(I)$. We then check that I vanishes on V.

```
> K<w> := GF(27);
> P<x, y> := PolynomialRing(K, 2);
> I := ideal<P | x^8 + y + 2, y^6 + x*y^5 + x^2>;
> Groebner(I);
> I;
Ideal of Polynomial ring of rank 2 over GF(3^3)
Order: Lexicographical
Variables: x, y
Inhomogeneous, Dimension 0
Groebner basis:
[
    x + 2*y^47 + 2*y^45 + y^44 + 2*y^43 + y^41 + 2*y^39 + 2*y^38 + 2*y^37 +
        2*y^36 + y^35 + 2*y^34 + 2*y^33 + y^32 + 2*y^31 + y^30 + y^28 + y^27 +
        y^26 + y^25 + 2*y^23 + y^22 + y^21 + 2*y^19 + 2*y^18 + 2*y^16 + y^15 +
        y^13 + y^12 + 2*y^10 + y^9 + y^8 + y^7 + 2*y^6 + y^4 + y^3 + y^2 + y +
        2,
    y^48 + y^41 + 2*y^40 + y^37 + 2*y^36 + 2*y^33 + y^32 + 2*y^29 + y^28 +
        2*y^25 + y^24 + y^2 + y + 1
]
> V := Variety(I);
> V;
[ <w^14, w^12>, <w^16, w^10>, <w^22, w^4> ]
```

```
> // Check that the original polynomials vanish:
> [
>    <x^8 + y + 2, y^6 + x*y^5 + x^2> where x is v[1] where y is v[2]: v in V
> ];
[ <0, 0>, <0, 0>, <0, 0> ]
> // Note that the variety of I would be larger over an extension field of K:
> VarietySizeOverAlgebraicClosure(I);
48
```

106.5 Multiplicities

This section contains some useful invariants for an isolated singularity at the origin of a hypersurface given by a multivariate polynomial f.

`MilnorNumber(f)`

Given a polynomial $f \in K[x_1, \ldots, x_n]$, where K is a field, return the Milnor number of f at the origin. This is the dimension of the quotient by the ideal generated by the partials of f in the localization of $K[x_1, \ldots, x_n]$ at the origin. See [CLO98, p. 147] or [DL06, Remark 9.37].

`TjurinaNumber(f)`

Given a polynomial $f \in K[x_1, \ldots, x_n]$, where K is a field, return the Tjurina number of f at the origin. This is the dimension of the quotient by the ideal generated by f and the partials of f in the localization of $K[x_1, \ldots, x_n]$ at the origin. See [CLO98, p. 148] or [DL06, Def. 9.35].

Example H106E4

We compute some Milnor and Tjurina numbers, based on Exercise 12 of [CLO98, p. 177].

```
> P<x,y> := PolynomialRing(RationalField(), 2);
> MilnorNumber((x^2 + y^2)^3 - 4*x^2*y^2); // 4-leaved rose
13
> [MilnorNumber(y^2 - x^n): n in [1 .. 5]];
[ 0, 1, 2, 3, 4 ]
> P<x,y,z> := PolynomialRing(RationalField(), 3);
> [MilnorNumber(x*y*z + x^n + y^n + z^n): n in [1 .. 10]];
[ 0, 1, 8, 11, 14, 17, 20, 23, 26, 29 ]
> [TjurinaNumber(x*y*z + x^n + y^n + z^n): n in [1 .. 10]];
[ 0, 1, 8, 10, 13, 16, 19, 22, 25, 28 ]
```

A much larger example is given in [DL06, p. 254].

```
> f := y^2 - 2*x^28*y - 4*x^21*y^17 + 4*x^14*y^33 - 8*x^7*y^49 +
>      x^56 + 20*y^65 + 4*x^49*y^16;
> time TjurinaNumber(f);
2260
```

```
Time: 0.010
```

106.6 Elimination

Elimination theory plays an important role when working with ideals of multivariate polynomial rings. MAGMA provides an assortment of functions to perform various kinds of elimination easily. Elimination of variables is accomplished by computing a Gröbner basis with respect to a suitable elimination order (for more information about elimination orders, see Section 105.2 as well as comments in the function descriptions below).

All of the functions in this section may be applied to ideals over general Euclidean rings, not just over fields.

106.6.1 Construction of Elimination Ideals

`EliminationIdeal(I, k: parameters)`

Given an ideal I of a polynomial ring P of rank n with $P = R[x_1, \ldots, x_n]$, together with an integer k with $0 \leq k \leq n$, return the k-th elimination ideal I_k of I, which is defined to be $I \cap R[x_{k+1}, \ldots, x_n]$. Thus I_k consists of all polynomials of I which have the first k variables eliminated. If the elimination ideals I_k are to be computed for several different k, it is recommended first that a Gröbner basis with respect to lexicographical order for I first be computed as then the elimination ideals can be determined trivially. If I does not have a Gröbner basis stored with respect to lexicographical order, then a Gröbner basis computation will be necessary each time an elimination ideal is desired.

If $k = n$, then $I \cap R$ is returned, which, if R is a field, is always the full ring P or the empty ideal, according to whether I is the full polynomial ring or not. But if R is not a field, then this intersection will yield the ideal generated by the normalized smallest element of R which is in I (according to the Euclidean norm), which could be neither 0 nor 1.

The parameters are as for the `Groebner` procedure. Note that setting `Al := "Direct"` occasionally produces much better performance since the relevant elimination order may yield a better Gröbner basis than the default method of going via the `grevlex` order.

`EliminationIdeal(I, S)`

`EliminationIdeal(I, S)`

Given an ideal I of a polynomial ring P of rank n with $P = R[x_1, \ldots, x_n]$, together with a set S describing a subset U of the variables $\{x_1, \ldots x_n\}$, return the elimination ideal I_U of I, which is defined to be $I \cap R[U]$. Thus I_U consists of all polynomials of I which contain variables only found in U. U can be specified in two ways: either as a set S of integers in the range $1 \ldots n$ such the integer i corresponds to the i-th variable x_i, or as a set S of variables lying in P. S may be the empty set, in which case this is equivalent to `EliminationIdeal(I, n)`; see above.

Example H106E5

This example continues the example above which computed a Gröbner basis over a ring which was not even a PIR.

As before, $R = \mathbf{Z}[\sqrt{-5}]$ and I is the ideal of $R[x, y]$ generated by $f_1 = 2xy + \sqrt{-5}y$ and $f_2 = (1+\sqrt{-5})x^2 - xy$. As before, we compute over $\mathbf{Z}$, introduce a new variable S and include (S^2+5) in I, so we can effectively work over R.

```
> P<x, y, S> := PolynomialRing(IntegerRing(), 3);
> f1 := 2*x*y + S*y;
> f2 := (1 + S)*x^2 - x*y;
> I := ideal<P | f1, f2, S^2 + 5>;
> GroebnerBasis(I);
[
    x^2*S + x^2 + 5*y^3 + 13*y*S - 25*y,
    6*x^2 + 5*y^2 + 3*y*S - 10*y,
    x*y + 5*y^3 + 13*y*S - 25*y,
    y^2*S + 5*y^2 - 15*y,
    10*y^2 + 5*y*S - 25*y,
    S^2 + 5
]
```

In [AL94, Ex. 4.3.8], the elimination ideal $E_y = I \cap (\mathbf{Z}[\sqrt{-5}])[y]$ is shown to be generated by $f_5 = (5 + \sqrt{-5})y^2 - 15y$ and $f_7 = -2\sqrt{-5}y^2 + 5(1 + \sqrt{-5})y$. We can compute E_y in MAGMA easily using `EliminationIdeal`. We must be careful to include S in the second argument (the set of variables which we want), since S should be considered a 'constant' (member of R) in this context.

```
> Ey := EliminationIdeal(I, {y, S});
> GroebnerBasis(Ey);
[
    y^2*S + 5*y^2 - 15*y,
    10*y^2 + 5*y*S - 25*y,
    S^2 + 5
]
```

Obviously, the polynomials yielded are simply the last 3 polynomials of the full Gröbner basis given above. We check also that the ideal generated by f_5 and f_7 over R is the same as that given by MAGMA.

```
> f_5 := y^2*S + 5*y^2 - 15*y;
> f_7 := -2*y^2*S + 5*y*S + 5*y;
> E := ideal<P | f_5, f_7, S^2 + 5>;
> E eq Ey;
true
```

Finally, we also compute $E_x = I \cap (\mathbf{Z}[\sqrt{-5}])[x]$, which requires more effort this time, since it cannot be read off the Gröbner basis.

```
> Ex := EliminationIdeal(I, {x, S});
> GroebnerBasis(Ex);
```

```
[
    2*x^3*S + 2*x^3 + x^2*S - 5*x^2,
    12*x^3 + 6*x^2*S,
    S^2 + 5
]
```

From this, we see that E_x is generated by $(2+2\sqrt{-5})x^3+(-5+\sqrt{-5})x^2$ and $12x^3+6\sqrt{-5}x^2$.

106.6.2 Univariate Elimination Ideal Generators

`UnivariateEliminationIdealGenerator(I, i)`

Given a zero-dimensional ideal I of a polynomial ring P of rank n with $P = K[x_1,\ldots,x_n]$, together with an integer i with $1 \le i \le n$, return the unique monic generator of the univariate elimination ideal $I \cap K[x_i]$.

`UnivariateEliminationIdealGenerators(I)`

Given a zero-dimensional ideal I of a polynomial ring P of rank n with $P = K[x_1,\ldots,x_n]$, return the sequence of length n whose i-th element is the unique monic generator of the univariate elimination ideal $I \cap K[x_i]$.

Example H106E6

We construct an ideal I (derived from Neural networks theory) of the polynomial ring $\mathbf{Q}[x,y,z]$, and then find various elimination ideals of I.

```
> P<x, y, z> := PolynomialRing(RationalField(), 3);
> I := ideal<P |
>     1 - x + x*y^2 - x*z^2,
>     1 - y + y*x^2 + y*z^2,
>     1 - z - z*x^2 + z*y^2 >;
> UnivariateEliminationIdealGenerator(I, 1);
x^21 - x^20 - 2*x^19 + 4*x^18 - 5/2*x^17 - 5/2*x^16 + 4*x^15 - 15/2*x^14 +
    129/16*x^13 + 11/16*x^12 - 103/8*x^11 + 131/8*x^10 - 49/16*x^9 -
    171/16*x^8 + 12*x^7 - 3*x^6 - 29/8*x^5 + 15/4*x^4 - 17/16*x^3 - 5/16*x^2
    + 5/16*x - 1/16
> UnivariateEliminationIdealGenerator(I, 2);
y^14 - y^13 - 13/2*y^12 + 8*y^11 + 53/4*y^10 - 97/4*y^9 - 45/8*y^8 + 33*y^7 -
    25/2*y^6 - 18*y^5 + 107/8*y^4 + 5/8*y^3 - 27/8*y^2 + 9/8*y - 1/8
> E :=  EliminationIdeal(I, {y, z});
> E;
Ideal of Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: x, y, z
Basis:
[
    z^21 - z^20 - 2*z^19 + 4*z^18 - 5/2*z^17 - 5/2*z^16 + 4*z^15 - 15/2*z^14 +
        129/16*z^13 + 11/16*z^12 - 103/8*z^11 + 131/8*z^10 - 49/16*z^9 -
```

```
        171/16*z^8 + 12*z^7 - 3*z^6 - 29/8*z^5 + 15/4*z^4 - 17/16*z^3 - 5/16*z^2
        + 5/16*z - 1/16,
    y + 141944208/7806653*z^20 - 42803108/7806653*z^19 - 290535348/7806653*z^18
        + 309392460/7806653*z^17 - 164881460/7806653*z^16 -
        331099258/7806653*z^15 + 203830442/7806653*z^14 - 894960798/7806653*z^13
        + 622205873/7806653*z^12 + 1352184655/31226612*z^11 -
        4746138097/31226612*z^10 + 5122044359/31226612*z^9 +
        991547639/31226612*z^8 - 830598655/7806653*z^7 + 1472712995/15613306*z^6
        - 59983627/15613306*z^5 - 486698319/15613306*z^4 + 174173263/7806653*z^3
        - 30672252/7806653*z^2 - 735083/664396*z + 30093391/31226612
]
```

Example H106E7

We write a simple function ZRadical to compute the radical of a zero dimensional ideal defined over a field using the univariate elimination ideal generators. See [BW93, p. 345].

```
> function ZRadical(I)
>     // Find radical of zero dimensional ideal I
>     P := Generic(I);
>     n := Rank(P);
>     G := UnivariateEliminationIdealGenerators(I);
>     N := {};
>
>     for i := 1 to n do
>         // Set FF to square-free part of the i-th univariate
>         // elimination ideal generator
>         F := G[i];
>         FF := F;
>         while true do
>             D := GCD(FF, Derivative(FF, 1, i));
>             if D eq 1 then
>                 break;
>             end if;
>             FF := FF div D;
>         end while;
>         // Include FF in N if FF is a proper divisor of F
>         if FF ne F then
>             Include(~N, FF);
>         end if;
>     end for;
>
>     // Return the sum of I and N
>     if #N eq 0 then
>       return I;
>     else
>       return ideal<P | I, N>;
>     end if;
```

```
> end function;
```

We now apply ZRadical to an ideal of $\mathbf{Q}[x, y, z]$.

```
> P<x, y, z> := PolynomialRing(RationalField(), 3);
> I := ideal<P | (x+1)^3*y^4, x*(y-z)^2+1, z^3-z^2>;
> R := ZRadical(I);
> Groebner(I);
> Groebner(R);
> I;
Ideal of Polynomial ring of rank 3 over Rational Field

> IsInRadical(x + 1, I);
true
```

106.6.3 Relation Ideals

`RelationIdeal(Q)`

`RelationIdeal(Q, T)`

Given a sequence Q of k polynomials of a polynomial ring P over a ring S (not necessarily a field), return the relation ideal U of Q which is an ideal of the polynomial ring of rank k over S containing all algebraic relations between the elements of Q. That is, U consists of all polynomials $r \in S[y_1, \ldots, y_k]$ such that $r(Q[1], \ldots, Q[k]) = 0$. If U is desired to be an ideal of a particular polynomial ring T of rank k (to obtain predetermined names of variables, for example), then T may be passed as a second argument.

The computation is the same as that for the image of an affine polynomial map, which this basically is, thinking of the polynomials in Q as giving a map from n-dimensional affine space (n = rank of P) to k-dimensional affine space. k new variables y_i and relations $y_i - Q[i]$ are added and then the original variables x_i of P are eliminated in the usual way.

Example H106E8

We construct an ideal I of the polynomial ring $\mathbf{F}_2[x, y, z]$, and discover that the ideal is the full polynomial ring. Suppose we then wish to write $1 \in I$ as an (algebraic) expression in terms of the original generators. We use `RelationIdeal` to find that expression.

```
> P<x, y, z> := PolynomialRing(GF(2), 3, "grevlex");
> S := [(x + y + z)^2, (x^2 + y^2 + z^2)^3 + x + y + z + 1];
> I := ideal<P | S>;
> Groebner(I);
> I;
Ideal of Polynomial ring of rank 3 over GF(2)
Graded Reverse Lexicographical Order
Variables: x, y, z
Groebner basis:
[
    1
]
> Q<a, b> := PolynomialRing(GF(2), 2);
> U := RelationIdeal(S, Q);
> U;
Ideal of Polynomial ring of rank 2 over GF(2)
Order: Lexicographical
Variables: a, b
Inhomogeneous, Dimension >0
Basis:
[
    a^6 + a + b^2 + 1
```

```
]
```

Finally, we check the algebraic expression, evaluating it at the original polynomials:

```
> S[1]^6 + S[1] + S[2]^2;
1
```

106.7 Variable Extension of Ideals

Often one wishes to introduce new variables temporarily to a polynomial ring. MAGMA allows one to do this by use of the `VariableExtension` function, and also to restrict again to the original ring with elimination performed automatically.

`VariableExtension(I, k, b)`

`VariableExtension(I, k, b, order)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, create a polynomial ring Q as a k-variable extension of P, the ideal J of Q corresponding to I, and the embedding map $f : P \to Q$, and return J and f.

If the argument b (standing for "before") is `true`, the k variables are inserted before the current variables of P, so Q is defined to be $R[y_1, \ldots, y_k, x_1, \ldots, x_n]$ and f maps $P.i$ to $Q.(k+i)$ (so the x_i variables of P are mapped to the x_i variables of Q).

If the argument b is `false`, the k variables are inserted after the current variables of P, so Q is defined to be $R[x_1, \ldots, x_n, y_1, \ldots, y_k]$ and f maps $P.i$ to $Q.i$ (so the x_i variables of P are mapped to the x_i variables of Q).

If the argument *order* is given, then Q is constructed with the specified order; otherwise, the `grevlex` order is used for Q by default. See the section on monomial orders (Section 105.2) for the valid values for the argument *order*.

The image under f of a polynomial of P is the corresponding polynomial of Q, while the image under f of an ideal of P is the corresponding ideal of Q. The inverse image under f of a polynomial of Q is only defined if none of the extension variables of Q occur in that polynomial, in which case the inverse image is just the restriction back to P, while the inverse image under f of an ideal H of Q is always defined and is the restriction back to P of the elimination ideal $H \cap R[x_1, \ldots, x_n]$.

106.8 Homogenization of Ideals

MAGMA allows one to homogenize a polynomial ring or ideal by use of the `Homogenization` function, and also to restrict again to the original ring with elimination performed automatically.

`Homogenization(I, b)`

`Homogenization(I, b, order)`

`Homogenization(I)`

`Homogenization(I, order)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, create a polynomial ring H as a single variable extension of P, the homogenized ideal J of H corresponding to I, and the homogenization map $f : P \to H$, and return J and f.

If the argument b (standing for "before") is `true`, the homogenization variable is inserted before the current variables of P, so H is defined to be $R[h, x_1, \ldots, x_n]$ and f maps $P.i$ to $H.(k+i)$ (so the x_i variables of P are mapped to the x_i variables of H).

If the argument b is `false`, the homogenization variable is inserted after the current variables of P, so H is defined to be $R[x_1, \ldots, x_n, h]$ and f maps $P.i$ to $H.i$ (so the x_i variables of P are mapped to the x_i variables of H).

If the argument b is omitted, it is taken to be `false`, so the homogenization variable is introduced after the current variables of P.

If the argument *order* is given, then H is constructed with the specified order; otherwise, the `grevlex` order is used for H by default. See the section on monomial orders (Section 105.2) for the valid values for the argument *order*.

The image under f of a polynomial of P is the homogenization of f in H, while the image under f of an ideal of P is the homogenization ideal I^h in H. The inverse image under f of a polynomial of H is the restriction back to P (obtained by setting the homogenization variable to 1), while the inverse image under f of an ideal J of H is the restriction back to P of the ideal obtained by setting the homogenization variable to 1.

106.9 Extension and Contraction of Ideals

MAGMA allows the extension to and contraction from the ring of quotients of an ideal, defined over a field, with respect to certain variables. See [BW93, pp. 54–58 and 388–397] for the relevant definitions and theory.

`Extension(I, U)`

Given an ideal I of the polynomial ring $P = K[x_1, \ldots, x_n]$, where K is a field, together with a sequence U of integers each between 1 and n, create the (ring of quotients) extension Q of P, and return the ideal J of Q, together with the map $f : P \to Q$.

If U has length k and the values (in order) of U are $u_1, \ldots, u_k$, then first the rational function field $F = K(x_{u_1}, \ldots, x_{u_k})$ is constructed, then the list $v_1, \ldots, v_{n-k}$ is constructed as the list $1, \ldots, n$ with the u_i removed, and finally the extension Q of P is defined to be the polynomial ring $F[x_{v_1}, \ldots, x_{v_{n-k}}] = K(x_{u_1}, \ldots, x_{u_k})[x_{v_1}, \ldots, x_{v_{n-k}}]$.

The map f is constructed in the obvious way so that x_i is mapped to the appropriate variable in F if i is in U, or the appropriate variable in Q otherwise. The image under f of an ideal of P is just the appropriate ideal of Q whose basis is obtained by taking the image under f of each of the polynomials in the basis of I.

The inverse image under f of a polynomial of Q is obtained by first making the polynomial monic, then multiplying by the LCM of the denominators ("clearing the denominators"), then mapping each variable back to the appropriate one in P—this is possible since there are no proper denominators. The inverse image under f of an ideal H of Q is defined to be the ideal of P generated by the inverse images under f of the polynomials in the basis of H (note that this is not always equal to the contraction of H—see [BW93, p. 389], for a simple algorithm to compute the contraction of an ideal of Q).

106.10 Dimension of Ideals

Let I be an ideal of the polynomial ring $P = K[x_1, \ldots, x_n]$, where K is a field. Let X be the set $\{x_1, \ldots, x_n\}$ of variables of P. A subset U of X is called *independent modulo* I if $I \cap K[U] = \emptyset$. A subset U of X is called *maximally independent modulo* I if U is independent modulo I, and no proper superset of U is independent modulo I. The *dimension* of I is defined to be the maximum of the cardinalities of all the independent sets modulo I. It is not too hard to see in this case that this coincides with the more abstract commutative algebra definition of the Krull dimension of the *quotient algebra* P/I as the maximal length of a chain of prime ideals.

Note that the definition given above of zero-dimensionality (as the case when the quotient of P by I has finite dimension as a vector space over the coefficient field) coincides with the definition of zero-dimensionality as dimension 0.

`Dimension(I)`

Given an ideal I of a polynomial ring P defined over a field, return the dimension d of I, together with a (sorted) sequence U of integers of length d such that the variables of P corresponding to the integers of U constitute a maximally independent set modulo I. If I is the full polynomial ring P, the dimension is defined to be -1, and the second return value is not set. The algorithm implemented is that given in [BW93, p. 449].

106.11 Radical and Decomposition of Ideals

MAGMA has algorithms for computing the full radical and the primary decomposition of ideals. See [BW93, chapter 8], for the relevant definitions and theory. The implementation of the algorithms presented here in MAGMA was based on the algorithms presented in that chapter. Currently these algorithms work only for ideals of polynomial rings over fields (Euclidean rings will be supported in the future).

There are also functions for some easier decompositions than the full primary decomposition: radical decompositions, equidimensional decompositions and triangular decompositions for zero-dimensional ideals. The theory behind these is discussed in the relevant function description.

106.11.1 Radical

`Radical(I)`

Given an ideal I of a polynomial ring P over a field, return the radical of I. The radical R of I is defined to be the set of all polynomials $f \in P$ such that $f^n \in I$ for some $n \geq 1$. The radical R is also an ideal of P, containing I. The function works for an ideal defined over any field over which polynomial factorization is available.

Example H106E9

We compute the radical of an ideal of $\mathbf{Q}[x, y, z, t, u]$ (which is not zero-dimensional).

```
> P<x, y, z, t, u> := PolynomialRing(RationalField(), 5);
> I := ideal<P |
> x + y + z + t + u,
> x*y + y*z + z*t + t*u + u*x,
> x*y*z + y*z*t + z*t*u + t*u*x + u*x*y,

106.11.2 Primary Decomposition

`PrimaryDecomposition(I)`

Given an ideal I of a polynomial ring over a field, return the primary decomposition of I, and also the sequence of associated prime ideals. See IsPrimary for the definition of a primary ideal. The primary decomposition of I is returned as two parallel sequences Q and P of ideals, both of length k, having the following properties:

(a) The ideals of Q are primary.

(b) The intersection of the ideals of Q is I.

(c) The ideals of P are the associated primes of Q; i.e., $P[i]$ is the radical of $Q[i]$ (so $P[i]$ is prime) for $1 \leq i \leq k$.

(d) Q is minimal: no ideal of Q contains the intersection of the rest of the ideals of Q and the associated prime ideals in P are distinct.

(e) Q and P are sorted so that P is always unique and Q is unique if I is zero-dimensional. If I is not zero-dimensional, then an embedded component of Q (one whose associated prime contains another associated prime from P) will not be unique in general. Yet MAGMA will always return the same values for Q and P, given the same I.

The function works for an ideal defined over any field over which polynomial factorization is available (inseparable field extensions are handled by an algorithm due to Allan Steel [Ste05]).

NB: if one only wishes to compute the prime components P, then the next function RadicalDecomposition should be used, since this may be much more efficient.

`RadicalDecomposition(I)`

Given an ideal I of a polynomial ring over a field, return the prime decomposition of the radical of I. This is equivalent to applying the function PrimaryDecomposition to the radical of I, but may be a much more efficient than using that method. The (prime) radical decomposition of I is returned as a sequence P of ideals of length k having the following properties:

(a) The ideals of P are prime.

(b) The intersection of the ideals of P is the radical of I.

(c) P is minimal: no ideal of P contains the intersection of the rest of the ideals of P.

(e) P is sorted so that P is always unique. Thus MAGMA will always return the same values for P, given the same I.

The function works for an ideal defined over any field over which polynomial factorization is available.

`ProbableRadicalDecomposition(I)`

Given an ideal I of a polynomial ring P over a field, return a probabilistic prime decomposition of the radical of I as a sequence of ideals of P. This function is like the function `RadicalDecomposition` except that the ideals returned may not be prime, but the time taken may be much less.

`MinimalDecomposition(S)`

Given a set or sequence S of ideals of a polynomial ring over a field, with $I = \cap_{J \in S} J$ (so that S describes a decomposition of I), return a minimal decomposition M of I as a subset of S such that $I = \cap_{J \in M} J$ also (so none of the ideals in the decomposition M are redundant).

`SetVerbose("Decomposition", v)`

Change verbose printing for the (Primary/Radical) Decomposition algorithm to be v. Currently the legal values for v are `true`, `false`, 0, 1, or 2.

Example H106E10

We compute the primary decomposition of the same ideal of $\mathbf{Q}[x, y, z, t, u]$ (which is not zero-dimensional).

```
> P<x, y, z, t, u> := PolynomialRing(RationalField(), 5);
> I := ideal<P |
> x + y + z + t + u,
> x*y + y*z + z*t + t*u + u*x,
> x*y*z + y*z*t + z*t*u + t*u*x + u*x*y,
> x*y*z*t + y*z*t*u + z*t*u*x + t*u*x*y + u*x*y*z,
> x*y*z*t*u>;
> IsZeroDimensional(I);
false
> Q, P := PrimaryDecomposition(I);
```

We next print out the primary components Q and associated primes P.

```

Notice that $P[6]$ contains other ideals of P so $Q[6]$ is an embedded primary component of I. Thus the first 5 ideals of Q would the same be in any primary decomposition of I, while $Q[6]$ could be different in another primary decomposition of I. Finally, notice that the prime decomposition of the radical of I is the same as P except for the removal of $P[6]$ to satisfy the uniqueness condition.

The structure of the variety of I can be easily understood by examining the prime decomposition of the radical.

```
> RP := RadicalDecomposition(I);
> #RP;
5
> Set(RP) eq { P[i]: i in [1 .. 5] };
true
```

106.11.3 Triangular Decomposition

Let T be a zero-dimensional ideal of the polynomial ring $K[x_1, \ldots, x_n]$, where K is a field. T is called *triangular* if its Gröbner basis G has length n and the initial term of the i-th polynomial of G is of the form $x_i^{e_i}$ for each i. Any *radical* zero-dimensional ideal has a decomposition as an intersection of triangular ideals. The algorithm in MAGMA for primary decomposition now (since V2.4) first computes a triangular decomposition and then decomposes each triangular component to primary ideals since the computation of a triangular decomposition is usually fast. See [Laz92] for further discussion of triangular ideals.

`TriangularDecomposition(I)`

Given a zero-dimensional ideal I of a polynomial ring over a field with *lexicographical* order, return a triangular decomposition of I as a sequence Q of ideals such that the intersection of the ideals of Q equals I and for each ideal J of Q which is radical, J is triangular (see above for the definition of a triangular ideal). A second return value indicates whether I is proven to be radical. If I is radical, all entries of Q are triangular. Computing a triangular decomposition will often be faster than computing the full primary decomposition and may yield sufficient information for a specific problem. The algorithm implemented is that given in [Laz92].

Example H106E11

We compute the triangular decomposition of the (radical) Cyclic-5 roots ideal and compare it with the full primary decomposition of the same ideal.

```
> R<x, y, z, t, u> := PolynomialRing(RationalField(), 5);
> I := ideal<R |
>     x + y + z + t + u,
>     x*y + y*z + z*t + t*u + u*x,
>     x*y*z + y*z*t + z*t*u + t*u*x + u*x*y,
>     x*y*z*t + y*z*t*u + z*t*u*x + t*u*x*y + u*x*y*z,
>     x*y*z*t*u - 1>;
> IsRadical(I);
true
> time T := TriangularDecomposition(I);
Time: 0.000
```

```
> time Q, P := PrimaryDecomposition(I);
Time: 0.010
> #T;
9
> #Q;
20
```

So we notice that although I decomposes into 9 triangular ideals, some of these ideals must decompose further since the primary decomposition consists of 20 prime ideals. We examine the first entry of T. Notice that it is at least triangular (it has 5 polynomials and for each variable there is a polynomial whose leading monomial is a power of that variable).

```

    ]
]
```

106.11.4 Equidimensional Decomposition

`EquidimensionalPart(I)`

`EquidimensionalDecomposition(I)`

`FineEquidimensionalDecomposition(I)`

Let I be an ideal of a polynomial ring P over a field. Currently for the two decomposition functions, it is *assumed* that I has no embedded associated primes (e.g., when I is radical). In this case, it can be much faster to compute an equidimensional decomposition rather than a full primary or radical one. The equidimensional decomposition is the set of ideals which are the intersections of all primary components of I associated to primes of the same dimension. This decomposition (often trivial) is useful for certain constructions involving the Jacobian ideal.

The first function just computes the highest-dimensional decomposition component. The second performs the straight decomposition. The third gives a slightly finer decomposition for the convenience of some applications. In it, each equidimensional component is possibly further split so that, for each final equidimensional factor there is a single set of variables which constitute a maximally independent set of every primary component of the factor (*cf* `Dimension` on page 3244). A sequence of pairs consisting of each factor and the indices of its set of variables is returned.

The algorithm from [GP02] is used in the general case. When I is homogeneous, a faster, more module-theoretic method is employed for the first two functions. This involves first expressing P/I as a finite module M over a linear Noether Normalisation (described in the next section) S of I. Then if $E(I)$ is the equidimensional part of I, $E(I)/I$ as a submodule of M is equal to the kernel of the natural map of M to its double dual over S, $Hom_S(Hom_S(M,S),S)$. Working with modules over S rather than over P here allows the "reduction to dimension 0". We could directly over P, doing a similar computation but with Hom_S replaced by some Ext^i_P (see [EHV92]).

Example H106E12

```
> P<x, y, z> := PolynomialRing(RationalField(), 3);
> P1 := ideal<P|x*y+y*z+z*x>; // dimension 2 prime
> P2 := ideal<P|x^2+y,y*z+2>; // dimension 1 prime
> P3 := ideal<P|x*y-1,y+z>;   // dimension 1 prime
> I := P1 meet P2 meet P3;
> time rd := RadicalDecomposition(I);
Time: 3.720
> time ed := EquidimensionalDecomposition(I);
Time: 0.070
> #ed;
2
> ed[1] eq P1;
true
> ed[2] eq (P2 meet P3);

106.12 Normalisation and Noether Normalisation

Suppose I is an ideal of $P = K[x_1, \ldots, x_n]$ with K a field, and I has dimension d.

A Noether normalisation of I is given by a set of d polynomials $f_1, \ldots, f_d$ of P, algebraically independent over K, for which $K[f_1, \ldots, f_d] \cap I = 0$ and $K[f_1, \ldots, f_d] \to P/I$ is an integral extension. These always exist and if K is an infinite field, the f_i can be chosen to be linear expressions in the x_i.

If I is radical, then the normalisation of I here will refer to the integral closure of the affine ring P/I in its total ring of fractions. If $I = \bigcap P_i$ with P_i prime, then the normalisation is equal to the finite direct product of the normalisations of the P_i as affine rings. It will be specified by a list of pairs (I_i, ϕ_i) where I_i is a prime ideal with generic ring G_i, a multivariate polynomial ring over K, and ϕ_i a homomorphism from P to G_i. The pairs represent the normalisation of each P_i and the inclusion $P/I \to \prod G_i/I_i$ induced by the ϕ_i makes the RHS the integral closure of P/I.

106.12.1 Noether Normalisation

`NoetherNormalisation(I)`

`NoetherNormalization(I)`

This function attempts to compute a Noether Normalisation for I, as described above, using *linear* combinations of the variables. The function is guaranteed to work if K has characteristic zero but may fail in unlucky cases in small characteristic.

The algorithm followed is basically that given in [GP02] but with a simpler test for homogeneous ideals I, which gives a speed-up in that case. Also, subsets of the full sets of variables are considered before more general linear combinations.

The return values are

1) the sequence $[f_1, \ldots, f_d]$.
2) h, an automorphism $P \to P$ given by a linear change of variables which maps the f_i to the last d variables of P. Thus $x_{n-d+1}, \ldots, x_n$ are a corresponding Noether normalising set of polynomials for $h(I)$.
3) the inverse of h.

Example H106E13

```
> P<x,y> := PolynomialRing(RationalField(),2);
> I := ideal<P | x*y+x+2>;
> fs,h,hinv := NoetherNormalisation(I);
> fs;
[
    x + y
]
> J := ideal<P | [h(b) : b in Basis(I)]>; J;
Ideal of Polynomial ring of rank 2 over Rational Field
Order: Lexicographical
Variables: x, y
Basis:
[
    -x^2 + x*y + x + 2
]
> // clearly x is integral over the last variable y in P/J
```

106.12.2 Normalisation

`Normalisation(I)`

`Normalization(I)`

`UseFF`	BoolElt	*Default :* `true`
`FFMin`	BoolElt	*Default :* `true`
`UseMax`	BoolElt	*Default :* `false`

This function computes the normalisation of the ideal I and returns the result as a list of pairs as described above. The ideal I must be radical - this is not checked in the function. Also the base field K must be perfect.

There are several options. The general algorithm used is that of De Jong as described in [GP02]. However, if the generic polynomial ring P of I has rank 2 then Magma's powerful function field machinery can be applied to give a generally much faster algorithm. This is the default behaviour but can be bypassed by setting the parameter `UseFF` to `false`.

When the function field machinery is used, a correct result can be obtained extremely quickly, but the generic spaces of the solution ideals can be of quite high

dimension. The default behaviour, controlled by the parameter `FFMin`, is to use a filtration by Riemann-Roch spaces to try to find a roughly minimal number of generators of the algebras G_i/I_i and return the corresponding ideal in the smaller number of variables as a more optimal presentation of the solution. This takes more time but is still usually faster than the general algorithm and tends to produce much nicer results. In some cases, the minimised solution is the same as the basic one but takes longer to generate. The minimising stage can be cut out by setting `FFMin` to `false`.

The general algorithm can avoid doing some work if it is known that certain conditions on I hold. One standard condition is that $I \subseteq M =< x_1, \ldots, x_n >$ and that P/I is locally normal away from M. This holds, for example, if the affine variety defined by I in K^n is non-singular except at the origin. If this is known, then parameter `UseMax` can be set to `true` which will usually speed up the general algorithm (it has no effect if the function field method is used). However, if P/I is locally non-normal at other primes then this will produce an incorrect result.

Example H106E14

```
> P<x,y> := PolynomialRing(RationalField(),2);
> // we begin with a very simple example (prime ideal)
> I := Ideal((x - y^2)^2 - x*y^3);

106.13 Hilbert Series and Hilbert Polynomial

Let I be a *homogeneous* ideal of the graded polynomial ring $P = K[x_1, \ldots, x_n]$, where K is a field. Then the quotient ring P/I is a *graded* vector space in the following way: P/I is the direct sum of the vector spaces V_d for $d = 0, 1, \ldots$ where V_d is the K-vector space consisting of all homogeneous polynomials in P/I (i.e., reduced residues of polynomials of P with respect to I) of weighted degree d. The *Hilbert Series* of the graded vector space P/I is the generating function

$$H_{P/I}(t) = \sum_{d=0}^{\infty} \dim(V_d) t^d.$$

The Hilbert series can be written as a rational function in the variable t.

If the weights on the variables of P are all 1, then there also exists the Hilbert polynomial $F_{P/I}(d)$ corresponding to the Hilbert series $H_{P/I}(t)$ which is a univariate polynomial in $\mathbf{Q}[d]$ such that $F_{P/I}(i)$ is equal to the coefficient of t^i in the Hilbert series for all $i \geq k$ for some fixed k.

`HilbertSeries(I)`

Given an homogeneous ideal I of a polynomial ring P over a field, return the Hilbert series $H_{P/I}(t)$ of the quotient ring P/I as an element of the univariate function field $\mathbf{Z}(t)$ over the ring of integers. The algorithm implemented is that given in [BS92].

Note that this is equivalent to `HilbertSeries(QuotientModule(I))`, while if one wishes the Hilbert series of I considered as a P-module, one should call `HilbertSeries(Submodule(I))`.

`HilbertSeries(I, p)`

Given an homogeneous ideal I of a polynomial ring P over a field, return the Hilbert series $H_{P/I}(t)$ of the quotient ring P/I as a power series to precision p.

`HilbertDenominator(I)`

Given an homogeneous ideal I of a polynomial ring P over a field, return the unreduced Hilbert denominator D of P/I (as a univariate polynomial over the ring of integers). The denominator D equals

$$\prod_{i=1}^{n}(1 - t^{w_i}),$$

where n is the rank of P and w_i is the weight of the i-th variable (1 by default).

`HilbertNumerator(I)`

Given an homogeneous ideal I of a polynomial ring P over a field, return the unreduced Hilbert numerator N of P/I (as a univariate polynomial over the ring of integers). The numerator N equals $D \times \times H_{P/I}(t)$, where D is the unreduced Hilbert denominator above. Computing with the unreduced numerator is often more convenient.

`HilbertPolynomial(I)`

Given an homogeneous ideal I of a polynomial ring P over a field with weight 1 for each variable, return the Hilbert polynomial $H(d)$ of the quotient ring P/I as an element of the univariate polynomial ring $Q[d]$, together with the index of regularity of P/I (the minimal integer $k \geq 0$ such that $H(d)$ agrees with the Hilbert function of P/I at d for all $d \geq k$).

Example H106E15

We compute the Hilbert series and Hilbert polynomial for an ideal corresponding to the square of a matrix (see [BS92]).

```
> MatSquare := function(n)
>     P := PolynomialRing(RationalField(), n * n, "grevlex");
>     AssignNames(
>         ~P,
>         ["x" cat IntegerToString(i) cat IntegerToString(j): i, j in [1..n]]
>     );
>     M := MatrixRing(P, n);
>     X := M ! [P.((i - 1) * n + j): i, j in [1 .. n]];
>     Y := X^2;
>     return ideal<P | [Y[i][j]: i, j in [1 .. n]]>;
> end function;
> I := MatSquare(4);
> I;

106.14 Syzygies

The main functions to compute syzygies work with or return modules. See Chapter 109 for these. This section contains a variant that returns a basis of syzygies of a polynomial sequence as rows of a matrix.

`SyzygyMatrix(Q)`

Given a sequence Q of polynomials from a multivariate polynomial ring P, return the module of syzygies of Q as a matrix S. This an r by k matrix, where k is the length of Q, whose rows span the space of all vectors v such that the sum of $v[i] * Q[i]$ for $i = 1, \ldots k$ is zero. The algorithm used is the standard one, computing a module Gröbner basis with respect to a particular elimination order (see section 2.5 of [GP02], for example). The base ring may be a field or Euclidean ring.

Example H106E16

```
> P<x, y, z> := PolynomialRing(RationalField(), 3);
> SyzygyMatrix([x + y, x - y, x*z + y*z]);
[             z              0             -1]
[ 1/2*x - 1/2*y -1/2*x - 1/2*y              0]
```

106.15 Maps between Rings

MAGMA includes functions for working with maps between multivariate polynomial rings. Let $R = K_1[x_1, \ldots, x_n]$ and $S = K_2[y_1, \ldots, y_m]$ be a polynomial rings over the fields K_1, K_2, and $f : R \to S$ a ring homomorphism.

`PolyMapKernel(f)`

Return the kernel of the map f as an ideal in the domain R, i.e., the set $\{a \in R | f(a) = 0\}$. This is basically the computation of the relation ideal for the polynomials defining the map and is as described in `RelationIdeal`.

`IsInImage(f, p)`

Given an polynomial p in S, return whether p is in the image of the map f. The algorithm is the one described on p. 82 of [AL94].

`IsSurjective(f)`

Return whether the map f is surjective. Uses the function above to check whether each codomain variable lies in the image.

`Extension(phi, I)`

The extension of the ideal I by ϕ, where ϕ is a homomorphism from the generic of I. That is, the ideal generated by the image of I under ϕ.

`Implicitization(phi)`

Suppose the polynomial map $\phi : K^n \to K^m$ is a parametrization of a variety V, i.e., V is the image of ϕ in K^m. This function constructs the ideal of S corresponding to V.

The map ϕ maps $(z_1, \ldots, z_n) \mapsto (f_1(z_1), \ldots, f_m(z_m))$ where the z_i are the coordinates of K^n. Let $f : S \to R$ be the map of polynomial rings defined by $(y_1, \ldots, y_m) \mapsto (f_1(y_1), \ldots, f_m(y_m))$. Then `Implicitization(f)` is the ideal of S corresponding to V.

If V is not a true variety, the function returns the smallest variety containing V (the Zariski closure of V).

The algorithm used is given on p. 97 of [CLO96]

Example H106E17

We demonstrate the use of the function `Implicitization` for the variety defined by $\phi : Q[x, y] \to Q[r, u, v, w]$, $(x, y) \mapsto (x^4, x^3y, xy^3, y^4)$. This example is taken from [AL94, Ex. 2.5.4].

```
> R<x, y> := PolynomialRing(Rationals(), 2);
> S<r, u, v, w> := PolynomialRing(Rationals(), 4);
> f := hom<S -> R |x^4, x^3*y, x*y^3, y^4>;
> Implicitization(f);
Ideal of Polynomial ring of rank 4 over Rational Field
Lexicographical Order
Variables: r, u, v, w
```

```
Basis:
[
    -r^2*v + u^3,
    r*v^2 - u^2*w,
    -u*w^2 + v^3,
    -r*w + u*v
]
```

106.16 Symmetric Polynomials

MAGMA includes functions for working with symmetric polynomials.

`ElementarySymmetricPolynomial(P, k)`

Given a polynomial ring P of rank n, and an integer k with $1 \leq k \leq n$, return the k-th elementary symmetric polynomial of P.

`IsSymmetric(f)`

`IsSymmetric(f, S)`

Given a polynomial f from a polynomial ring P of rank n, return whether f is a symmetric polynomial of P (i.e., is symmetric in all the n variables of P). If the answer is true, a polynomial g from a new polynomial ring of rank n is returned such that $f = g(e_1, \ldots, e_n)$, where e_i is the i-th elementary symmetric polynomial of P. If g is desired to be a member of a particular polynomial ring S of rank n (to obtain predetermined names of variables, for example), then S may also be passed.

Example H106E18

We create a symmetric polynomial from $\mathbf{Q}[a, b, c, d]$ and express it in terms of the elementary symmetric polynomials.

```
> P<a, b, c, d> := PolynomialRing(RationalField(), 4, "grevlex");
> f :=
> a^2*b^2*c*d + a^2*b*c^2*d + a*b^2*c^2*d + a^2*b*c*d^2 + a*b^2*c*d^2 +
>     a*b*c^2*d^2 - a^2*b^2*c - a^2*b*c^2 - a*b^2*c^2 - a^2*b^2*d -
>     3*a^2*b*c*d - 3*a*b^2*c*d - a^2*c^2*d - 3*a*b*c^2*d - b^2*c^2*d -
>     a^2*b*d^2 - a*b^2*d^2 - a^2*c*d^2 - 3*a*b*c*d^2 - b^2*c*d^2 -
>     a*c^2*d^2 - b*c^2*d^2 + a + b + c + d;
> // Check orbit under Sym(4) has size one:
> #(f^Sym(4));
1
> Q<e1, e2, e3, e4> := PolynomialRing(RationalField(), 4);
> l, E := IsSymmetric(f, Q);
> l;
true
> E;
```

```
e1 - e2*e3 + e2*e4
```

In the following example, we use a rational function field to define parameters a and b which occur as coefficients of the symmetric polynomial f.

```
> F<a,b> := FunctionField(RationalField(), 2);
> P<x1,x2,x3,x4,x5> := PolynomialRing(F, 5, "grevlex");
> y1 := x1^4 + x1^2*a + x1*b;
> y2 := x2^4 + x2^2*a + x2*b;
> y3 := x3^4 + x3^2*a + x3*b;
> y4 := x4^4 + x4^2*a + x4*b;
> y5 := x5^4 + x5^2*a + x5*b;
> f := y1*y2 + y1*y3 + y1*y4 + y1*y5 + y2*y3 + y2*y4 +
>      y2*y5 + y3*y4 + y3*y5 + y4*y5;
> Q<e1,e2,e3,e4,e5> := PolynomialRing(F,  5);
> l,E := IsSymmetric(f, Q);
> l, E;
true b*e1^3*e2 - 2*a*e1^3*e3 - 4*e1^3*e5 + a*e1^2*e2^2 +
    4*e1^2*e2*e4 + 2*e1^2*e3^2 - b*e1^2*e3 + 2*a*e1^2*e4 -
    4*e1*e2^2*e3 - 3*b*e1*e2^2 + 4*a*e1*e2*e3 + 8*e1*e2*e5 +
    a*b*e1*e2 - 8*e1*e3*e4 - 2*a^2*e1*e3 + b*e1*e4 - 6*a*e1*e5 +
    e2^4 - 2*a*e2^3 - 4*e2^2*e4 + a^2*e2^2 + 4*e2*e3^2 +
    5*b*e2*e3 + 2*a*e2*e4 + b^2*e2 - 3*a*e3^2 - 4*e3*e5 -
    3*a*b*e3 + 6*e4^2 + 2*a^2*e4 - 5*b*e5
```

106.17 Functions for Polynomial Algebra and Module Generators

The following functions work with collections of polynomials which are considered as generators for subalgebras or submodules of a polynomial ring. They have particular use in invariant theory.

`MinimalAlgebraGenerators(L)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose L is a set or sequence of k polynomials $f_1, \ldots, f_k$ in R. Let $A = K[f_1, \ldots, f_k]$ be the subalgebra (*not* ideal) of R generated by L. This function returns a minimal generating set of the algebra A as a (sorted) sequence of elements taken from L.

`HomogeneousModuleTest(P, S, F)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose P is a sequence of k homogeneous polynomials $p_1, \ldots, p_k$ in R and suppose S is a sequence of r homogeneous polynomials $s_1, \ldots, s_r$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by P and let $M = A[s_1, \ldots, s_r]$ be the A-module generated by S over A. Finally, suppose F is an element of R. This function returns whether F is in the module M (considered as a submodule of R).

If the result is `true`, the function also returns a sequence $C = [c_1, \ldots, c_r]$ of length r with $c_i \in K[t_1, \ldots, t_k]$ such that $F = \sum_{i=1}^{r} c_i(p_1, \ldots, p_k) \cdot s_i$. (The polynomial ring $K[t_1, \ldots, t_r]$ is constructed separately but automatically with the print names `t1`, `t2`, etc.)

The grading of the polynomial ring R is used to determine the (weighted) degrees of all the polynomials in P, S and the polynomial F.

The function works as follows: it first splits F into its homogeneous components, and then, for each homogeneous component of (weighted) degree d, it constructs a basis for the K-space of all polynomials of the module M of degree d and then determines by linear algebra whether the component lies in that space.

The function is most often used with an invariant ring: P is the sequence of primary invariants, S is the sequence of secondary invariants, and F is a general invariant which one wishes to express in terms of the module generators S over the algebra generated by P. Also, if one wishes to test only for membership in the algebra $A = K[p_1, \ldots, p_k]$, then the sequence `[R!1]` should be passed for S.

`HomogeneousModuleTest(P, S, L)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose P is a sequence of k homogeneous polynomials $p_1, \ldots, p_k$ in R and suppose S is a sequence of r homogeneous polynomials $s_1, \ldots, s_r$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by P and let $M = A[s_1, \ldots, s_r]$ be the A-module generated by S over A. Finally, suppose L is a sequence of length l of elements of R which are all homogeneous of (weighted) degree d. This function returns parallel sequences B and V with the following properties:

(a) B is sequence of length l of booleans such that for $1 \leq i \leq l$, $B[i]$ is true iff $L[i]$ is in the module M.

(b) V is a sequence of length l consisting of sequences of length r and consisting of polynomials in the polynomial ring $T = K[t_1, \ldots, t_r]$. (The polynomial ring $T = K[t_1, \ldots, t_r]$ is constructed separately but automatically with the print names `t1`, `t2`, etc.) If $B[i]$ is false (so $L[i]$ is not in M), $V[i]$ is a sequence of r zero polynomials. Otherwise $V[i]$ is a sequence of r polynomials $c_{i,1}, \ldots, c_{i,r}$ in T such that that $L[i] = \sum_{j=1}^{r} c_{i,j}(p_1, \ldots, p_k) \cdot s_j$.

The grading of the polynomial ring R is used to determine the (weighted) degrees of all the polynomials in P, S and L.

The function works as follows: it constructs a basis for the K-space of all polynomials of the module M of degree d and then, for each i with $1 \leq i \leq l$, determines by linear algebra whether $L[i]$ lies in the space. Only one echelonization of the space is needed to determine all the values of B and V so it is *much* more efficient to use this function if possible with many polynomials in L of the same homogeneous degree instead of calling the previous function separately for each polynomial since that will need to construct the basis for the homogeneous space and perform an echelonization each time.

Again, this function is most often used with an invariant ring: P is the sequence of primary invariants, S is the sequence of secondary invariants, and L is a sequence of general invariants which one wishes to express in terms of the module generators S over the algebra generated by P. Also, if one wishes to test only for membership in the algebra $A = K[p_1, \ldots, p_k]$, then the sequence $[R!1]$ should be passed for S.

`HomogeneousModuleTestBasis(P, S, L)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose P is a sequence of k homogeneous polynomials $p_1, \ldots, p_k$ in R and suppose S is a sequence of r homogeneous polynomials $s_1, \ldots, s_r$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by P and let $M = A[s_1, \ldots, s_r]$ be the A-module generated by S over A. Finally, suppose L is a sequence of length l of elements of R which are all homogeneous of (weighted) degree d. Let U be the K-subspace of R consisting of all polynomials of the module M of (weighted) degree d and let V be the K-subspace of R generated by the elements of L. This function returns a sequence I of integer indices such that the sequence elements of L corresponding to the indices in I forms a basis for a K-subspace W of R such that $U + V = U \oplus W$. That is, I selects a subsequence of L which yields an *extension* of any basis of U to a basis of $U + V$.

Using this function, one can extend a minimal module generating set in S to include new elements of increasing degree, while ensuring that the module generators are minimalized (i.e., there is no redundancy amongst them).

The grading of the polynomial ring R is used to determine the (weighted) degrees of all the polynomials in P, S and L.

Example H106E19

We demonstrate simple uses of the function `HomogeneousModuleTest`. See also the example `HomogeneousModuleTest2` in the Invariant Rings chapter which demonstrates the use of the function `HomogeneousModuleTest` in invariant theory.

```
> R<x, y, z> := PolynomialRing(RationalField(), 3);
> P := [x^2 + y^2, z];
> S := [1, x + y + z];
> L := [x^2 + y^2, (x+y+z)^2-z^2-2*x*y, x*y];
> B, V := HomogeneousModuleTest(P, S, L);
> B;
[ true, true, false ]
```

```
> V;
[
    [
        t1,
        0
    ],
    [
        t1 - 2*t2^2,
        2*t2
    ],
    [
        0,
        0
    ]
]
> // Thus L[1] is P[1]*S[1] and
> // L[2] is (P[1] - 2*P[2]^2)*S[1] + 2*P[2]*S[2].
> L[1] eq P[1]*S[1];
true
> (P[1] - 2*P[2]^2)*S[1] + 2*P[2]*S[2] eq L[2];
true
> // Determine subsequence of [x^3, y^3, z^3] which forms
> // extension basis of module generated by P and S.
> L := [x^3, y^3, z^3];
> HomogeneousModuleTestBasis(P, S, L);
[ 1, 2 ]
> // Thus x^2 and y^2 could be appended to S to preserve
> // minimality.
```

107 LOCAL POLYNOMIAL RINGS

Chapter 107
LOCAL POLYNOMIAL RINGS

107.1 Introduction

This chapter describes local polynomial rings. Let R be the multivariate polynomial ring $K[x_1, \ldots, x_n]$, where K is a field. We denote by

$$K[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$$

the collection of all rational functions f/g of $x_1, \ldots, x_n$ with $g(p) \neq 0$, where $p = (0, \ldots, 0)$. Such a ring is **local** (has a unique maximal ideal) and we will call it a **local polynomial ring** in MAGMA. Such a ring is always multivariate and is related to the corresponding multivariate polynomial ring $K[x_1, \ldots, x_n]$ which will we will call **global** (when distinguishing it from the local case). We will also call $K[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$ the **localization** of $K[x_1, \ldots, x_n]$ (this is always understood to be at the prime ideal generated by $x_1, \ldots, x_n$, corresponding to the origin).

Much of the theory for multivariate polynomial rings and their ideals carry over to local polynomial rings, so the reader should first be familiar with multivariate polynomial rings and their ideals (see Chapters 24 and 105).

Corresponding to a Gröbner basis of an ideal of a global multivariate ring is a **standard basis** of an ideal of a local polynomial ring. See [CLO98, Chapter 4] or [GP02, Chapter 1] for the basics of the theory and algorithms.

The other facilities are currently basic but will be expanded in coming versions. But note that computations with $R-$modules, where R is a local polynomial ring, are fully supported: see Chapter 109.

107.2 Elements and Local Monomial Orders

Elements of a local polynomial ring are multivariate polynomials just like the usual (global) multivariate polynomials, except that the monomials are sorted (again with the greatest first) with respect to a **local monomial order**, which is in general the negation of a standard global monomial order. Thus the monomial 1 is less than all other monomials and the polynomials are like multivariate formal power series (written, for example, as $1 + x + x^2y + y^4$). But most arithmetic-like operations allowed for global polynomials also carry over automatically for elements of a local polynomials so we will not list them in detail in this chapter (see Chapter 24).

Note that in the strict mathematical definition of $R = K[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$, elements of R may have non-trivial denominators, but this is currently not supported in MAGMA: the elements in MAGMA must always be strict polynomials. The main purpose of supporting

such rings is for standard bases of ideals (see below), and this restriction does not matter there, since units are automatically removed from the elements of a standard basis.

We now describe the current local monomial orders available in MAGMA. First the reader should see Section 105.2 for the fundamental points about (global) monomial orders for multivariate polynomial rings.

The fundamental difference in the local case is that for a local polynomial ring R of rank n, the monomial order is the negation of a global monomial order. More precisely, let M be the monomials of R. A **local monomial ordering** on M is a total order $<$ on M such that $s \leq 1$ for all $s \in M$, $s \leq t$ implies $su \leq tu$ for all $s, t, u \in M$, and M is a well-ordering (every non-empty subset of M possesses a minimal element w.r.t. $<$). See [CLO98, Sec. 4.3], [DL06, Sec. 9.1], or [GP02, Sec. 1.2] for more information.

We now list each of the monomial orders available in MAGMA (these will be expanded in future versions). As in the global case, we suppose that s and t are monomials from a ring R of rank n. Any order on the monomials is then fully defined by just specifying exactly when $s < t$ with respect to that order. In the following, the argument(s) are described for an order as a list of expressions; that means that the expressions (without the parentheses) should be appended to any base arguments when any particular intrinsic function is called which expects a monomial order.

107.2.1 Local Lexicographical: `llex`

Definition: $s < t$ iff there exists $1 \leq i \leq n$ such that all of the j-th exponents of s and t are equal for $i < j \leq n$, but the i-th exponent of s is greater than the i-th exponent of t. The order is specified by the argument (`"llex"`).

This order is the negation of the global lexicographical order, but with the reverse order for the variables. Thus the i-th variable is greater than the $(i+1)$-th variable for $1 \leq i < n$ so the first variable is the greatest variable.

107.2.2 Local Graded Lexicographical: `lglex`

Definition: $s < t$ iff the total degree of s is greater than the total degree of t or the total degree of s is equal to the total degree of t and $s > t$ with respect to the (glocal) lexicographical order. The order is specified by the argument (`"lglex"`).

This order is the negation of the global `glex` order.

107.2.3 Local Graded Reverse Lexicographical: `lgrevlex`

Definition: $s < t$ iff the total degree of s is greater than the total degree of t or the total degree of s is equal to the total degree of t and $s < t$ with respect to the (global) lexicographical order applied to the exponents of s and t in reverse order. The order is specified by the argument (`"grevlex"`).

This order is the negation of the global `grevlex` order.

107.3 Local Polynomial Rings and Ideals

107.3.1 Creation of Local Polynomial Rings and Accessing their Monomial Orders

Local polynomial rings are created from a coefficient field, the number of variables, and a monomial order. If no order is specified, the monomial order is taken to be the local lexicographical order.

`LocalPolynomialRing(K, n)`

Create a local polynomial ring in $n > 0$ variables over the field K. The *local lexicographical* ordering on the monomials is used for this default construction.

`LocalPolynomialRing(K, n, order)`

`LocalPolynomialAlgebra(K, n, order)`

Create a local polynomial ring in $n > 0$ variables over the ring R with the given order *order* on the monomials. See the above section on local monomial orders for the valid values for the argument *order*.

`LocalPolynomialRing(K, n, T)`

Create a local polynomial ring in $n > 0$ variables over the field K with the order given by the tuple T on the monomials. T must be a tuple whose components match the valid arguments for the monomial orders in Section 107.2. Such a tuple is also returned by the next function.

`MonomialOrder(R)`

Given a local polynomial ring R (or an ideal thereof), return a description of the monomial order of R. This is returned as a tuple which matches the relevant arguments listed for each possible order in Section 107.2, so may be passed as the third argument to the function `LocalPolynomialRing` above.

`MonomialOrderWeightVectors(R)`

Given a polynomial ring R of rank n (or an ideal thereof), return the weight vectors of the underlying monomial order as a sequence of n sequences of n rationals. See, for example, [CLO98, p. 153] for more information.

`Localization(R)`

Given a (global) multivariate polynomial ring $R = K[x_1, \ldots, x_n]$ (or an ideal I of such an R), return the localization $K[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$ of R (or the ideal of the localization of R which corresponds to I). The print names for the variables of R are carried over.

Example H107E1

We show how one can construct local polynomial rings with different orders. Note the order on the monomials for elements of the rings.

```
> K := RationalField();
> R<x,y,z> := LocalPolynomialRing(K, 3);
> R;
Localization of Polynomial Ring of rank 3 over Rational Field
Order: Local Lexicographical
Variables: x, y, z
> MonomialOrder(R);
<"llex">
> MonomialOrderWeightVectors(R);
[
    [ 0, 0, -1 ],
    [ 0, -1, 0 ],
    [ -1, 0, 0 ]
]
> 1 + x + y + z + x^7 + x^8*y^7 + y^5 + z^10;
1 + x + x^7 + y + y^5 + x^8*y^7 + z + z^10
> R<x,y,z> := LocalPolynomialRing(K, 3, "lgrevlex");
> R;
Localization of Polynomial Ring of rank 3 over Rational Field
Order: Local Graded Reverse Lexicographical
Variables: x, y, z
> MonomialOrder(R);
<"lgrevlex">
> MonomialOrderWeightVectors(R);
[
    [ -1, -1, -1 ],
    [ -1, -1, 0 ],
    [ -1, 0, 0 ]
]
> 1 + x + y + z + x^7 + x^8*y^7 + y^5 + z^10;
1 + z + y + x + y^5 + x^7 + z^10 + x^8*y^7
```

107.3.2 Creation of Ideals and Accessing their Bases

As for global polynomial rings, within the general context of ideals of local polynomial rings, the term "basis" will refer to an *ordered* sequence of polynomials which generate an ideal. (Thus a basis can contain duplicates and zero elements so is not like a basis of a vector space.)

`ideal< R | L >`

Given a local polynomial ring R, return the ideal of R generated by the elements of R specified by the list L. Each term of the list L must be an expression defining an object of one of the following types:

(a) An element of R;

(b) A set or sequence of elements of R;

(c) An ideal of R;

(d) A set or sequence of ideals of R.

`Ideal(B)`

Given a set or sequence B of polynomials from a local polynomial ring R, return the ideal of R generated by the elements of B with the given basis B. This is equivalent to the above `ideal` constructor, but is more convenient when one simply has a set or sequence of polynomials.

`Ideal(f)`

Given a polynomial f from a local polynomial ring R, return the principal ideal of R generated by f.

`Basis(I)`

Given an ideal I, return the current basis of I. This will be the standard basis of I if it is computed; otherwise it will be the original basis.

`BasisElement(I, i)`

Given an ideal I together with an integer i, return the i-th element of the current basis of I. This the same as `Basis(I)[i]`.

107.4 Standard Bases

Computation in ideals of local polynomial rings is possible because of the construction of **standard bases** of such ideals. These are the counterpart to Gröbner bases for ideals of global polynomial rings. Currently, standard bases may only be computed for ideals defined over fields.

MAGMA computes a standard basis of an ideal using the Mora normal form and standard basis algorithms (with the homogenization technique): see [CLO98, Sec. 4.4] for an overview.

In contrast to the global case, for a given fixed monomial ordering a standard basis of an ideal is not unique in general because it can be difficult to get the lower order terms of polynomials in the standard basis into a unique form. But the **leading monomials** of a standard basis are always sorted in MAGMA and **are unique**.

107.4.1 Construction of Standard Bases

The following functions and procedures allow one to construct standard bases. Note that a standard basis for an ideal will be automatically generated when necessary; the `Groebner` procedure below simply allows control of the algorithms used to compute the standard basis. The verbose flags are shared with those for global Gröbner basis construction (since the standard basis algorithms reduce to those), so see Section 105.4.6 for details on these.

`StandardBasis(I)`

Given an ideal I, force the standard basis of I to be computed, and then return that.

`StandardBasis(S)`

Given a set or sequence S of polynomials of a local polynomial ring R, return a standard basis of the ideal generated by S as a sorted sequence.

Example H107E2

We compute the standard basis of the ideal given in [CLO98, p.167].

```
> Q := RationalField();
> R<x,y,z> := LocalPolynomialRing(Q, 3);
> I := Ideal([x^5 - x*y^6 + z^7, x*y + y^3 + z^3, x^2 + y^2 - z^2]);
> I;
Ideal of Localization of Polynomial Ring of rank 3 over Rational Field
Order: Local Lexicographical
Variables: x, y, z
Basis:
[
    x^5 - x*y^6 + z^7,
    x*y + y^3 + z^3,
    x^2 + y^2 - z^2
]
> StandardBasis(I);
[
    x^2 + y^2 - z^2,
    x*y + y^3 + z^3,
    y^3 - x*y^3 - y*z^2 - x*z^3,
    x*z^4 + 3*y^2*z^4 + 4*x*y^4*z^4 + y*z^5 + 5*x*y^3*z^5 - 2*z^6 + 4*y^2*z^6 +
        x*y^2*z^6 + z^7 - 2*x*z^7 + 7*y*z^7 + 4*x*y*z^7 - y^2*z^7 + 3*z^8 +
        4*x*z^8,
    y^2*z^4 + 3*y^5*z^5 - z^6 + 3/2*x*z^6 + 2*y^2*z^6 + y^4*z^6 - x*z^7 +
        7/2*y*z^7 - x*y^2*z^7 - y^3*z^7 + 3/2*z^8 - 3/2*x*z^8 - 2*y*z^8 +
        2*x*y*z^8 + 3/2*y^2*z^8,
    y*z^7 + 1/2*x*z^8 + 23/4*y*z^8 - 9/4*x*y^3*z^8 + 3/2*y^4*z^8,
    z^9
```

```
]
```

We note that no elements of the standard basis have factors which are units in R.

```
> [Factorization(f): f in $1];
[
    [
        <x^2 + y^2 - z^2, 1>
    ],
    [
        <x*y + y^3 + z^3, 1>
    ],
    [
        <y^2 - x*y^2 - y*z + x*y*z - x*z^2, 1>,
        <y + z, 1>
    ],
    [
        <z, 4>,
        <x + 3*y^2 + 4*x*y^4 + y*z + 5*x*y^3*z - 2*z^2 + 4*y^2*z^2 + x*y^2*z^2 +
            z^3 - 2*x*z^3 + 7*y*z^3 + 4*x*y*z^3 - y^2*z^3 + 3*z^4 + 4*x*z^4, 1>
    ],
    [
        <z, 4>,
        <y^2 + 3*y^5*z - z^2 + 3/2*x*z^2 + 2*y^2*z^2 + y^4*z^2 - x*z^3 +
            7/2*y*z^3 - x*y^2*z^3 - y^3*z^3 + 3/2*z^4 - 3/2*x*z^4 - 2*y*z^4 +
            2*x*y*z^4 + 3/2*y^2*z^4, 1>
    ],
    [
        <z, 7>,
        <y + 1/2*x*z + 23/4*y*z - 9/4*x*y^3*z + 3/2*y^4*z, 1>
    ],
    [
        <z, 9>
    ]
]
```

Example H107E3

We note that starting from an ideal I of a global polynomial ring, the standard basis of the localization of I may be much simpler than the Gröbner basis of I.

```
> Q := RationalField();
> R<x,y,z> := PolynomialRing(Q, 3);
> I := Ideal([x^2 - x*y^3 + z^3, x*y + y^2 + z, x + y^2 - z^2]);
> Groebner(I); I;
Ideal of Polynomial ring of rank 3 over Rational Field
Order: Lexicographical
Variables: x, y, z
Inhomogeneous, Dimension 0
```

```
Groebner basis:
[
    x - y*z + 127/1052*z^9 + 585/1052*z^8 + 233/263*z^7 + 1273/1052*z^6 +
        695/526*z^5 + 223/1052*z^4 + 569/526*z^3 + 35/1052*z^2 - z,
    y^2 + y*z - 127/1052*z^9 - 585/1052*z^8 - 233/263*z^7 - 1273/1052*z^6 -
        695/526*z^5 - 223/1052*z^4 - 569/526*z^3 - 1087/1052*z^2 + z,
    y*z^2 + 51/263*z^9 + 208/263*z^8 + 308/263*z^7 + 476/263*z^6 + 465/263*z^5 +
        278/263*z^4 + 691/263*z^3 + 217/263*z^2,
    z^10 + 5*z^9 + 10*z^8 + 15*z^7 + 16*z^6 + 9*z^5 + 12*z^4 + 13*z^3 + 2*z^2
]
> QuotientDimension(I);
12
>
> IL := Localization(I);
> StandardBasis(IL);
[
    x + y^2,
    y^2 - y^3 + z,
    z^2
]
> QuotientDimension(IL);
4
```

107.5 Operations on Ideals

In the following, note that since ideals of a full polynomial ring P are regarded as subrings of P, the ring P itself is a valid ideal as well (the ideal containing 1).

107.5.1 Basic Operations

`I + J`

Given ideals I and J of the same polynomial ring P, return the sum of I and J, which is the ideal generated by the generators of I and those of J.

`I * J`

Given ideals I and J of the same polynomial ring P, return the product of I and J, which is the ideal generated by the products of the generators of I and those of J.

`I ^ k`

Given an ideal I of the polynomial ring P, and an integer k, return the k-th power of I.

`QuotientDimension(I)`

Given an ideal I of a local polynomial ring R over a field K, return the dimension of P/I as a K-vector space. Note that this is quite different from the function `Dimension` below (which returns the Krull dimension of an ideal).

`Generic(I)`

Given an ideal I of a generic local polynomial ring R, return R.

`LeadingMonomialIdeal(I)`

Given an ideal I, return the leading monomial ideal of I; that is, the ideal generated by all the leading monomials of I.

`I meet J`

Given ideals I and J of the same polynomial ring P, return the intersection of I and J.

`&meet S`

Given a set or sequence S of ideals of the same local polynomial ring R, return the intersection of all the ideals of S.

107.5.2 Ideal Predicates

`I eq J`

Given two ideals I and J of the same polynomial ring P, return whether I and J are equal.

`I ne J`

Given two ideals I and J of the same polynomial ring P, return whether I and J are not equal.

`I notsubset J`

Given two ideals I and J in the same polynomial ring P return whether I is not contained in J.

`I subset J`

Given two ideals I and J in the same polynomial ring P return whether I is contained in J.

`IsZero(I)`

Given an ideal I of the local polynomial ring R, return whether I is the zero ideal (contains zero alone).

`IsProper(I)`

Given an ideal I of the local polynomial ring R, return whether I is proper; that is, whether I is strictly contained in R (or whether the standard basis of I does not contain 1 alone).

`IsZeroDimensional(I)`

Given an ideal I of the local polynomial ring R, return whether I is zero-dimensional (so the quotient of P by I has non-zero finite dimension as a vector space over the coefficient field – see the section on dimension for further details). Note that the ring R has dimension -1, so it is not zero-dimensional.

Example H107E4

We construct some ideals in $\mathbf{Q}[x, y, z]$ and perform basic arithmetic on them.

```
> R<x,y,z> := LocalPolynomialRing(RationalField(), 3);
> I := ideal<R | x*y - z, x^3*z^2 - y^2, x*z^3 - x - y>;
> J := ideal<R | x*y - z, x^2*z - y, x*z^3 - x - y>;
> A := I * J;
> _ := StandardBasis(A);
> A;
Ideal of Localization of Polynomial Ring of rank 3 over Rational Field
Order: Local Lexicographical
Variables: x, y, z
Inhomogeneous, Dimension 0
Standard basis:
[
    x^2 - y^2 + 2*x^3*z,
    x*y + y^2 - x^3*z,
    y^3,
    x*z + y*z,
    y*z,
    z^2
]
> M := I meet J;
> M;
Ideal of Localization of Polynomial Ring of rank 3 over Rational Field
Order: Local Lexicographical
Variables: x, y, z
Homogeneous
Basis:
[
    x + y,
    y^2,
    z
]
> A eq M;
```

```
false
> A subset M;
true
```

107.5.3 Operations on Elements of Ideals

`f in I`

Given a polynomial f from a local polynomial ring R, together with an ideal I of R, return whether f is in I.

`NormalForm(f, I)`

Given a polynomial f from a local polynomial ring R, together with an ideal I of R, return a normal form of f with respect to (the standard basis of) I. The normal form of f is zero if and only if f is in I.

`f notin I`

Given a polynomial f from a polynomial ring P, together with an ideal I of P, return whether f is not in I.

Example H107E5

We demonstrate the element operations with respect to an ideal of the localization of $\mathbf{Q}[x, y, z]$.

```
> R<x,y,z> := LocalPolynomialRing(RationalField(), 3);
> I := ideal<R | (x + y)^3, (y - z)^2, y^2*z + z>;
> NormalForm(y^2*z + z, I);
0
> NormalForm(x^3, I);
-3*x^2*y
> x + y in I;
false
```

107.6 Changing Coefficient Ring

The `ChangeRing` function enables the changing of the coefficient ring of a local polynomial ring or ideal.

`ChangeRing(I, L)`

Given an ideal I of a local polynomial ring $R = K[x_1, \ldots, x_n]$ of rank n with coefficient ring K, together with a field L, construct the ideal J of the polynomial field $S = L[x_1, \ldots, x_n]$ obtained by coercing the coefficients of the elements of the basis of I into L. It is necessary that all elements of the old coefficient field K can be automatically coerced into the new coefficient field L. If K and L are fields and K is known to be a subfield of L and the current basis of I is a standard basis, then the basis of J is marked automatically to be a standard basis of J.

107.7 Changing Monomial Order

Often one wishes to change the monomial order of an ideal. MAGMA allows one to do this by use of the `ChangeOrder` function.

`ChangeOrder(I, Q)`

Given an ideal I of the local polynomial ring $R = K[x_1, \ldots, x_n]$, together with a local polynomial ring S of rank n (with possibly a different order to that of R), return the ideal J of S corresponding to J and the isomorphism f from R to S. The map f simply maps $R.i$ to $S.i$ for each i.

`ChangeOrder(I, order)`

Given an ideal I of the polynomial ring $P = R[x_1, \ldots, x_n]$, together with a monomial order *order* (see Section 107.2), construct the polynomial ring $Q = R[x_1, \ldots, x_n]$ with order *order*, and then return the ideal J of Q corresponding to I and the isomorphism f from P to Q. See the section on monomial orders for the valid values for the argument *order*. The map f simply maps $P.i$ to $Q.i$ for each i.

107.8 Dimension of Ideals

Let I be an ideal of the local polynomial ring $K[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$, where K is a field. As for polynomial rings, the dimension of the ideal I can be defined as the the maximum of the cardinalities of all the independent sets modulo I (see Section 107.8 for details).

`Dimension(I)`

Given an ideal I of a local polynomial ring R defined over a field, return the dimension d of I, together with a (sorted) sequence U of integers of length d such that the variables of P corresponding to the integers of U constitute a maximally independent set modulo I. If I is the full local polynomial ring R, the dimension is defined to be -1, and the second return value is not set. The algorithm implemented is that given in [BW93, p. 449].

108 AFFINE ALGEBRAS

Chapter 108
AFFINE ALGEBRAS

108.1 Introduction

An affine algebra in MAGMA is simply the quotient ring of a multivariate polynomial ring $P = R[x_1, \ldots, x_n]$ by an ideal J of P. Such rings arise commonly in commutative algebra and algebraic geometry. They can also be viewed as generalizations of number fields and algebraic function fields, when R is a field.

The elements of affine algebras are simply multivariate polynomials which are always kept reduced to normal form modulo the ideal J of "relations". Practically all operations which are applicable to multivariate polynomials are also applicable in MAGMA to elements of affine algebras (when meaningful).

If the ideal J of relations defining an affine algebra $A = R[x_1, \ldots, x_n]/J$ is *maximal* and R is a field, then A is a field and may be used with any algorithms in MAGMA which work over fields. Factorization of polynomials over such affine algebras is also supported (including fields of small characteristic, since V2.10).

If an affine algebra defined over a field has finite dimension considered as a vector space over the coefficient field, extra special operations are available on its elements.

Currently the base ring R may be a field or a Euclidean ring. Further operations for affine algebras over Euclidean rings will be supported in the future.

An affine algebra has type `RngMPolRes` and its elements type `RngMPolResElt`.

108.2 Creation of Affine Algebras

One can create an affine algebra simply by forming the quotient of a multivariate polynomial ring by an ideal (`quo` constructor or `/` function). A special constructor `AffineAlgebra` is also provided to remove the need to create the base polynomial ring.

`quo< P | J >`

`quo< P | a`$_1$`, ..., a`$_r$ `>`

Given a multivariate polynomial ring P and an ideal J of P, return the quotient ring P/J. The ideal J may either be specified as an ideal or by a list a_1, a_2, ..., a_r, of generators which all lie in P. The angle bracket notation can be used to assign names to the indeterminates: `Q<q, r> := quo< I | I.1 + I.2, I.2^2 - 2, I.3^2 + I.4 >;`.

`P / J`

Given a multivariate polynomial ring P and an ideal J of P, return the quotient affine algebra P/J.

`AffineAlgebra< R, X | L >`

Given a ring R, a list X of n identifiers, and a list L of polynomials (relations) in the n variables X, create the affine algebra of rank n with base ring R with given quotient relations; i.e., return $R[X]/\langle L\rangle$. The angle bracket notation can be used to assign names to the indeterminates.

Example H108E1

One can create a relative extension of an algebraic number field as an affine algebra. The multivariate representation will often be more efficient than an absolute representation because of the sparsity of the elements in the field.

```
> Q := RationalField();
> A<x, y> := AffineAlgebra<Q, x, y | x^2 - y^2 + 2, y^3 - 5>;
> A;
Affine Algebra of rank 2 over Rational Field
Lexicographical Order
Variables: x, y
Quotient relations:
[
    x^2 - y^2 + 2,
    y^3 - 5
]
> x^2;
y^2 - 2
> x^-1;
2/17*x*y^2 + 5/17*x*y + 4/17*x
> P<z> := PolynomialRing(Q);
> MinimalPolynomial(x);
z^6 + 6*z^4 + 12*z^2 - 17
> MinimalPolynomial(x^-1);
z^6 - 12/17*z^4 - 6/17*z^2 - 1/17
> MinimalPolynomial(y);
z^3 - 5
```

Another important construction is to create an affine algebra over a rational function field to obtain an algebraic function field:

```
> F<t> := FunctionField(IntegerRing());
> A<x, y> := AffineAlgebra<F, x, y | t*x^2 - y^2 + t + 1, y^3 - t>;
> P<z> := PolynomialRing(F);
> x^-1;
(-t^2 - t)/(t^3 + 2*t^2 + 3*t + 1)*x*y^2 - t^2/(t^3 + 2*t^2 + 3*t + 1)*x*y
    + (-t^3 - 2*t^2 - t)/(t^3 + 2*t^2 + 3*t + 1)*x
> MinimalPolynomial(x);
z^6 + (3*t + 3)/t*z^4 + (3*t^2 + 6*t + 3)/t^2*z^2 + (t^3 + 2*t^2 + 3*t +
    1)/t^3
> MinimalPolynomial(x^-1);
z^6 + (3*t^3 + 6*t^2 + 3*t)/(t^3 + 2*t^2 + 3*t + 1)*z^4 + (3*t^3 +
```

```
3*t^2)/(t^3 + 2*t^2 + 3*t + 1)*z^2 + t^3/(t^3 + 2*t^2 + 3*t + 1)
```

In this example we can consider y as a cube root of the transcendental indeterminate t.
Note that in general the (Krull) dimension of the ideal defining the relations may be anything; it need not be 0 or 1 as it is in these examples.

108.3 Operations on Affine Algebras

This section describes operations on affine algebras. Most of the operations are very similar to those for multivariate polynomial rings; such operations are done by mapping the computation to the preimage ideal and then by mapping the result back into the affine algebra. See the corresponding functions for the multivariate polynomial rings for details.

`Q . i`

Given an affine algebra Q, return the i-th indeterminate of Q as an element of Q.

`CoefficientRing(Q)`

Return the coefficient ring of the affine algebra Q.

`Rank(Q)`

Return the rank of the affine algebra Q (the number of indeterminates of Q).

`DivisorIdeal(I)`

Given an ideal I of an affine algebra Q which is the quotient ring P/J, where P is a polynomial ring and J an ideal of P, return the ideal J.

`PreimageIdeal(I)`

Given an ideal I of an affine algebra Q which is the quotient ring P/J, where P is a polynomial ring and J an ideal of P, return the ideal I' of P such that the image of I' under the natural epimorphism $P \to Q$ is I.

`PreimageRing(Q)`

Given an affine algebra Q which is the quotient ring P/J, where P is a polynomial ring and J an ideal of P, return the polynomial ring P.

`OriginalRing(Q)`

Return the generic polynomial ring P such that Q is P/J for some ideal J of P.

`I eq J`

Given two ideals I and J of the same affine algebra Q, return `true` if and only if I and J are equal.

`I subset J`

Given two ideals I and J of the same affine algebra Q, return `true` if and only if I is contained in J.

`I + J`

Given two ideals I and J of the same affine algebra Q, return the sum $I + J$.

`I * J`

Given two ideals I and J of the same affine algebra Q, return the product $I * J$.

`I ^ n`

Given an ideal I of an affine algebra Q and an integer n, return the power I^n.

`I meet J`

Given two ideals I and J of the same affine algebra Q, return the intersection $I \cap J$.

`IsProper(I)`

Given an ideal I of the affine algebra Q, return whether I is proper; that is, whether I is strictly contained in Q.

`IsZero(I)`

Given an ideal I of the affine algebra Q, return whether I is the zero ideal. Note that this is equivalent to whether the preimage ideal of I is the divisor ideal of Q.

`IsPrime(I)`

Given an ideal I of the affine algebra Q, return whether I is a prime ideal.

`IsPrimary(I)`

Given an ideal I of the affine algebra Q, return whether I is a primary ideal.

`IsRadical(I)`

Given an ideal I of the affine algebra Q, return whether I is a radical ideal.

`PrimaryDecomposition(I)`

Given an ideal I of the affine algebra Q, return the primary decomposition of I, together with the associated primes.

`RadicalDecomposition(I)`

Given an ideal I of the affine algebra Q, return the (prime) decomposition of the radical of I.

Example H108E2

We illustrate the operations on ideals of affine algebras.

```
> Q := RationalField();
> A<x,y,z> := AffineAlgebra<Q,x,y,z | x^2 - y + 1, y^3 + z - 1>;
> A;
Affine Algebra of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
Quotient relations:
[
    x^2 - y + 1,
    y^3 + z - 1
]
> I := ideal<A | x^3*y*z^2>;
> IsRadical(I);
false
> Radical(I);
Affine Algebra of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
Quotient relations:
[
    x^2 - y + 1,
    y^3 + z - 1
]
Generating basis:
[
    x*y^2 + x*y - x*z + x,
    y*z,
    z^2 - z
]
> PQ, PP := PrimaryDecomposition(I);
> #PQ;
3
> PQ[1];
Affine Algebra of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
Quotient relations:
[
    x^2 - y + 1,
    y^3 + z - 1
]
Generating basis:
[
    y + 5/81*z^3 + 1/9*z^2 + 1/3*z - 1,
    x*z^3,
```

```
    y + 5/81*z^3 + 1/9*z^2 + 1/3*z - 1,
    z^4
]
> PP[1];
Affine Algebra of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
Quotient relations:
[
    x^2 - y + 1,
    y^3 + z - 1
]
Generating basis:
[
    x,
    y - 1,
    z
]
```

108.4 Maps between Affine Algebras

MAGMA includes functions for working with maps between affine algebras.

`AffineAlgebraMapKernel(phi)`

Return the kernel of the homomorphism ϕ of affine algebras.

108.5 Finite Dimensional Affine Algebras

If an affine algebra is defined over a field and has finite dimension considered as a vector space over its coefficient field, extra special operations are available on its elements.

Similar operations for affine algebras defined over general Euclidean rings will be supported in the future.

`HasFiniteDimension(Q)`

Given an affine algebra Q defined over a field, return whether Q has finite dimension.

`Dimension(Q)`

Given a finite dimensional affine algebra Q defined over a field, return the dimension of Q.

`VectorSpace(Q)`

Given a finite dimensional affine algebra Q defined over a field, construct the vector space V isomorphic to Q, and return V together with the isomorphism f from Q onto V.

`MonomialBasis(Q)`

Given a finite dimensional affine algebra Q defined over a field, return the basis B of monomials of Q. This is a sequence of monomials in Q of length d, such that that the image $f(B[i]) = V.i$ where V and f are the return values of `VectorSpace` above.

`MatrixAlgebra(Q)`

Given a finite dimensional affine algebra Q defined over a field, construct the matrix algebra A isomorphic to Q, and return A together with the isomorphism f from Q onto A.

`RepresentationMatrix(f)`

Given an element f of a finite dimensional affine algebra Q defined over a field, return the representation matrix of f, which is a d by d matrix over the coefficient field of Q (where d is the dimension of Q) which represents f.

`IsUnit(f)`

Given an element f of a finite dimensional affine algebra Q defined over a field, return whether f is a unit.

`IsNilpotent(f)`

Given an element f of a finite dimensional affine algebra Q defined over a field, return whether f is nilpotent, and if so, return also the smallest q such that $f^q = 0$.

`MinimalPolynomial(f)`

Given an element f of a finite dimensional affine algebra Q defined over a field, return the minimal polynomial of f as a univariate polynomial over the coefficient field of Q.

Example H108E3

Suppose we wish to find the minimal polynomial of $\theta = \sqrt{2} + \sqrt[3]{5}$ over $\mathbf{Q}$. To do this we can just compute the minimal polynomial of (the coset of) $x + y$ over $\mathbf{Q}$ in the affine algebra $Q[x, y]/(x^2 - 2, y^3 - 5)$.

```
> Q := RationalField();
> A<x, y> := AffineAlgebra<Q, x, y | x^2 - 2, y^3 - 5>;
> UP<z> := PolynomialRing(Q);
> MinimalPolynomial(x + y);
z^6 - 6*z^4 - 10*z^3 + 12*z^2 - 60*z + 17
```

108.6 Affine Algebras which are Fields

If the ideal J of relations defining an affine algebra $A = K[x_1, \ldots, x_n]/J$, where K is a field, is *maximal*, then A is a field and may be used with any algorithms in MAGMA which work over fields. Factorization of polynomials over such affine algebras is also supported (in any characteristic, since V2.10). The examples below will demonstrate some of the applications available.

Note that an affine algebra defined over a field which itself is a field also has finite dimension when considered as a vector space over its coefficient field, so all of the operations in the previous section are also available.

Example H108E4

We create the function field $F = \mathbf{Q}(a, b, x)$ and then the affine algebra $A = F[y]/ < y^2 - (x^3 + ax + b) >$ (which is also equivalent to an algebraic function field). This then allows us to create a generic elliptic curve E over A and compute the coordinates of multiples of a generic point easily.

```
> Q := RationalField();
> F<x, a, b> := FunctionField(Q, 3);
> A<y> := AffineAlgebra<F, y | y^2 - (x^3 + a*x + b)>;
> IsField(A);
true
> y^2;
x^3 + x*a + b
> y^-1;
1/(x^3 + x*a + b)*y
> E := EllipticCurve([A | a, b]);
> E;
Elliptic Curve defined by y^2 = x^3 + a*x + b over Affine Algebra of rank 1 over
    Rational function field of rank 3 over Rational Field
    Variables: x, a, b
> p := E ! [x, y];
> p;
(x : y : 1)
> q := 2*p;
> q;
((1/4*x^4 - 1/2*x^2*a - 2*x*b + 1/4*a^2)/(x^3 + x*a + b) : (1/8*x^6 +
5/8*x^4*a + 5/2*x^3*b - 5/8*x^2*a^2 - 1/2*x*a*b - 1/8*a^3 - b^2)/(x^6
+ 2*x^4*a + 2*x^3*b + x^2*a^2 + 2*x*a*b + b^2)*y : 1)
> c := LeadingCoefficient(q[2]);
> Denominator(c);
x^6 + 2*x^4*a + 2*x^3*b + x^2*a^2 + 2*x*a*b + b^2
> Factorization($1);
[
    <x^3 + x*a + b, 2>
]
```

Example H108E5

Starting with the same affine algebra $A = \mathbf{Q}(a, b, x)F[y]/ < y^2 - (x^3 + ax + b) >$ as in the last example, we factor some univariate polynomials over A. A is of course isomorphic to an absolute field, but the presentation given may be much more convenient to the user.

```
> Q := RationalField();
> F<x, a, b> := FunctionField(Q, 3);
> A<y> := AffineAlgebra<F, y | y^2 - (x^3 + a*x + b)>;
> P<z> := PolynomialRing(A);
> f := z^2 - (x^3 + a*x + b);
> f;
z^2 + -x^3 - x*a - b
> time Factorization(f);
[
    <z - y, 1>,
    <z + y, 1>
]
Time: 0.019
```

Example H108E6

In this final example, A is isomorphic to an algebraic number field, but its presentation may be more convenient than an absolute presentation (and may lead to sparser expressions for elements).

```
> Q := RationalField();
> A<a,b,c> := AffineAlgebra<Q, a,b,c | a^2 - b*c + 1, b^2 - c + 1, c^2 + 2>;
> P<x> := PolynomialRing(A);
> time Factorization(x^2 + 2);
[
    <x - c, 1>,
    <x + c, 1>
]
Time: 0.080
> time Factorization(x^2 - b*c + 1);
[
    <x - a, 1>,
    <x + a, 1>
]
Time: 0.090
> MinimalPolynomial(a);
x^8 + 4*x^6 + 2*x^4 - 4*x^2 + 9
> time Factorization(P ! $1);
[
    <x - a, 1>,
    <x + a, 1>,
    <x - 1/3*a*b*c - 2/3*a*b + 1/3*a*c - 1/3*a, 1>,
    <x + 1/3*a*b*c + 2/3*a*b - 1/3*a*c + 1/3*a, 1>,
    <x^4 + 2*x^2 - 2*c - 1, 1>
```

```
]
Time: 2.809
```

108.7 Rings and Fields of Fractions of Affine Algebras

Given any affine algebra $Q = K[x_1, \ldots, x_n]/J$, where K is a field, one may create the *ring of fractions* R of Q. This is the set of fractions a/b, where $a, b \in Q$ and b is invertible, and it forms a ring.

The defining ideal J does not need to be zero-dimensional. The ring of fractions R is itself represented internally by an affine algebra over an appropriate rational function field, but has the appearance to the user of the set of fractions, so one may access the numerator and denominator of elements of R, for example.

If the ideal J is prime, then R is the field of fractions of A and may be used with any algorithms in MAGMA which work over fields. For example, factorization of polynomials over such fields of fractions is supported (in any characteristic).

Rings of fractions have type `RngFunFrac` and their elements `RngFunFracElt`.

`RingOfFractions(Q)`

`FieldOfFractions(Q)`

Given an affine algebra Q over a field K, return the ring of fractions of Q. The only difference between the two functions is that for `FieldOfFractions`, the defining ideal of Q must be prime.

`Numerator(a)`

`Denominator(a)`

Given an element a from the ring of fractions of an affine algebra Q, return the numerator (resp. denominator) of a as an element of Q.

Example H108E7

We create the field of fractions of an affine algebra and note the basic operations.

```
> A<x,y> := AffineAlgebra<RationalField(), x,y | y^2 - x^3 - 1>;
> IsField(A);
false
> F<a,b> := FieldOfFractions(A);
> F;
Ring of Fractions of Affine Algebra of rank 2 over Rational Field
Lexicographical Order
Variables: x, y
Quotient relations:
[
    x^3 - y^2 + 1
]
```

```
> a;
a
> b;
b
> a^-1;
> a^-1;
1/(b^2 - 1)*a^2
> b^-1;
1/b
> c := b/a;
> c;
b/(b^2 - 1)*a^2
> Numerator(c);
x^2*y
> Denominator(c);
y^2 - 1
> P<X> := PolynomialRing(F);
> time Factorization(X^3 - b^2 + 1);
[
    <X - a, 1>,
    <X^2 + a*X + a^2, 1>
]
Time: 0.000
> P<X,Y> := PolynomialRing(F, 2);
> time Factorization((X + Y)^3 - b^2 + 1);
[
    <X + Y - a, 1>,
    <X^2 + 2*X*Y + a*X + Y^2 + a*Y + a^2, 1>
]
Time: 0.030
> time Factorization((b*X^2 - a)*(a*Y^3 - b + 1)*(X^3 - b^2 + 1));
[

Example H108E8

This example shows the internal operations underlying the method of constructing the field of fractions. If the ideal of relations has dimension d, then the sequence L of d maximally independent variables is passed to the extension/contraction construction, which creates a rational function field with d variables such that the ideal of relations over this field now becomes zero dimensional. Appropriate maps are set up, too.

```
> Q := RationalField();
```

109 MODULES OVER MULTIVARIATE RINGS

Chapter 109
MODULES OVER MULTIVARIATE RINGS

109.1 Introduction

This chapter describes modules over multivariate polynomial rings and related rings. The fundamental tool for computing with such modules is the construction of Gröbner bases for modules, since these rings are not principal ideal rings in general (so standard matrix echelonization algorithms are not applicable).

In this chapter, unless otherwise indicated, a **ring** R will refer to one of the following:

(a) **Multivariate Polynomial Ring** (Chapters 24 and 105). Currently the coefficient ring of such a ring may be a field or Euclidean ring (even operations such as syzygy modules or free resolutions work over modules whose coefficient rings are Euclidean but not fields).

(b) **Local Polynomial Ring** (Localization of a Multivariate Polynomial Ring: Chapter 107; new in V2.15). Currently the coefficient ring of such a ring must be a field.

(c) **Affine Algebra** (Chapter 108). Currently the coefficient ring of such a ring must be a field.

(d) **Exterior Algebra** (Chapter 82; new in V2.15). Currently the coefficient ring of such a ring must be a field. Strictly speaking, this is a skew-commutative ring, so is not a commutative ring, and the associated modules are left R-modules, but the operations on R-modules in this chapter are practically all applicable if R is such an algebra also, so the term 'a ring R' will include such an algebra in this chapter.

In this chapter, the term "**module**" will always refer to an R-module, where R is one of the above types of ring, and such a module will have type `ModMPol` (or may have type `ModMPolGrd` if graded; see below). So we assume that the reader is generally familiar with such base rings and their ideals in MAGMA; see the relevant chapters for background. Many of the concepts and tools of Gröbner basis theory carry over from these types of rings.

109.2 Module Basics: Embedded and Reduced Modules

All of the modules considered in this chapter are ambient modules or embedded in such a module. We call an R-module **ambient** if it has the **explicit** presentational form $R^k/\langle relations\rangle$, where the relations are elements of R^k (and they may be zero or not even determined, initially). Elements of an ambient R-module M are represented explicitly as vectors in R^k, and M is always generated by the k unit vectors. The **degree** of M is k.

An arbitrary module S may have a representation as a submodule of such an ambient A, which is referred to as its **ambient module**. Hence the most general definition of a module is as a sub-quotient of a free module. If A has no relations then S is just a

submodule of a free module (namely, A). However, in this case, S will often also have an *internal* representation in presentational form that is essential for much of its fundamental functionality. In any case, the primary representation of elements of such an embedded module S is as vectors in the ambient.

As with vector spaces, there are two basic ways that modules can be defined in MAGMA: as embedded or reduced modules. A general subquotient as described above is in embedded form, but ambients may also be defined of either reduced or embedded type. The type primarily affects the way submodules and quotient modules are created. Briefly, submodules and quotient modules of embedded modules stay in embedded form (as generally proper submodules of an ambient) whereas submodules or quotients of reduced modules are always returned in presentational form as ambients, with connecting homomorphisms to link them explicitly to the original module. The two types are described in a bit more detail below. For illustration, see the examples at the end of Section 109.6.

Embedded modules are created in general via the function `EModule`, which returns a free embedded module, and in principle mimic the embedded R-spaces (as created by the function `RSpace(R, k)` in Chapter 54). Such modules are always presented with their elements and bases lying in an ambient module $R^k/\langle relations\rangle$. The modules are basically implemented as extensions of the multivariate polynomial ideal type (or affine algebra type if non-zero relations are present), where columns are internally added to monomials in a polynomial to represent a vector. Many operations applicable to ideals, including various Gröbner basis operations, naturally extend to such modules.

Starting with an ambient embedded module $M = R^k/\langle relations\rangle$, when a submodule S of M is created, the ambient module of S is still M, so the elements of S are represented as elements of R^k (modulo the relations if present); this therefore also applies to elements of any basis of S, including the Gröbner basis of S. Thus S itself may be not ambient and this is the only situation in which non-ambients can occur. Similarly, when a quotient module Q of M is constructed, the elements of Q appear as elements of R^k, while Q simply gains more relations than M, but its generators are usually not minimally reduced.

Reduced modules are created in general via the function `RModule`, which returns a free reduced module, and are more abstract and mimic the reduced modules with action over fields and Euclidean rings (as created by the function `RModule(R, k)` in Chapter 54). Such modules are **always ambient**, so always have the abstract form $R^n/\langle relations\rangle$, and the relationships between such modules are managed by **morphisms** lying in the background. The Gröbner basis techniques and properties are also hidden from the user in general.

Starting from a reduced module $M = R^k/\langle relations\rangle$, when a submodule S (having s generators $v_1, \ldots, v_s$) of M is created, S is generally created as $R^s/\langle relations_S\rangle$ (where the relations for S are initially unknown and are only computed when needed) and a morphism is stored from S to M, which maps the i-th unit vector of S to v_i in M. Similarly, a quotient module Q of M is constructed as another ambient module, usually with minimal generators, and a morphism from M onto Q is stored in the background. All morphisms between modules can be accessed via the function `Morphism`.

For any module M, there exists an isomorphic reduced **presentation module** P, which is always ambient, since P is reduced. If M is embedded, then P is a reduced

module equivalent to M (and morphisms in the background allow automatic coercion between M and P). Otherwise, M is already reduced so P is simply identical to M. Some functions (such as `FreeResolution`) always move to the presentation of M, since it is more natural to work only with ambient modules in that context.

Embedded modules are generally preferable when one wishes to work explicitly with Gröbner bases at a very low level, while reduced modules are generally preferable for homological computations since the ambient presentation form is more convenient (particularly for the relevant maps).

Technically, there is little difference in practice between an ambient embedded module and a reduced module, if each module is considered in isolation. The concepts basically refer to how submodules and quotient modules are derived from a given module (and the fact that embedded modules allow non-ambient submodules).

Finally, there is a subclass of reduced modules with the special type `ModMPolGrd`: these are **graded**, which means that they are always generated by homogeneous elements (with respect to the relevant grading). The main distinctive of this type is simply that when one creates a submodule or quotient module of a module of type `ModMPolGrd`, then the generators must be homogeneous, thus ensuring that the new derived module is also graded so will be of type `ModMPolGrd` also. In the future, more functions will be developed which will take modules of type `ModMPolGrd` explicitly. Note also that since the type `ModMPolGrd` ISA `ModMPol` via the type 'ISA' relation, any operation applicable to a module of type `ModMPol` is also applicable to a module of type `ModMPolGrd`.

109.3 Monomial Orders

In this section we describe each of the **module monomial orders** available in MAGMA. If the user wishes to work with reduced modules only (particularly for homology computations), then the underlying monomial orders and Gröbner bases will probably be rarely of interest to the user, so this section may be skipped. The monomial orders are mostly of interest if one wishes to work with embedded modules with special orders so that the relevant Gröbner bases have special properties. In either case, elements of the module are represented by vectors in an ambient and we refer to the vector component positions as *columns* in analogy to matrix terminology: a presentational module is often just defined by a matrix of relations, the rows giving vectors generating the relation module and the column numbering labelling the components of the vectors. For our modules there can be a non-trivial column weighting, which we think of as applying a shift to the degree of a homogeneous polynomial that occurs as the corresponding vector component of the module element. This is used to define homogeneity and degree of the overall vector.

Given an R-module M, suppose that the underlying monomial order of R is $<_R$. A **module monomial** of M is a monomial-column pair consisting of a monomial s of R and a column number c (with $c \geq 1$), written as $s[c]$ in the following. Monomial-column pairs give an (infinite) basis for the elements in a free module R^k and a vector representing an element of M can be decomposed into a sum of scalar multiples of monomial-column pairs just as elements of the polynomial ring R can be written as a sum of scalar multiples of plain monomials.

Now suppose that $s_1[c_1]$ and $s_2[c_2]$ are module monomials from M. Any order on the pairs is then fully defined by just specifying exactly when $s_1[c_1] < s_2[c_2]$ with respect to that order. As for multivariate polynomial rings, in the following the argument(s) are described for an order as a list of expressions; that means that the expressions (without the parentheses) should be appended to any base arguments when any particular intrinsic function is called which expects a module monomial order. See [AL94, Sec. 3.5] and [CLO98, Def. 2.4] for motivation and further discussion.

109.3.1 Term Over Position: `TOP`

Definition: $s_1[c_1] < s_2[c_2]$ iff $s_1 <_R s_2$ or $s_1 = s_2$ and $c_2 > c_1$. The order is specified by the argument (`"top"`).

This order is called "TOP" (term over position) since it first compares the underlying monomials (terms with the coefficients ignored†) and then compares the columns (the positions). The column comparison is ordered so that the first column is the greatest. A Gröbner basis of a module with respect to the `TOP` order is usually the easiest to compute, and corresponds to the `grevlex` order for polynomial rings in a certain way (i.e., the order favours the 'size' of monomials and only gives priority to the columns in a secondary way).

109.3.2 Term Over Position (Weighted): `TOPW`

Definition (given a sequence W of k integer weights, where k is the degree of the ambient module): write $d_i = \text{Degree}_W(s_i[c_i]) = \text{Degree}(s_i) + W[c_i]$; then $s_1[c_1] < s_2[c_2]$ iff $d_1 < d_2$ or $d_1 = d_2$ and $s_1 <_R s_2$ or $d_1 = d_2$, $s_1 = s_2$ and $c_2 > c_1$. The order is specified by the arguments (`"topw", W`). The weights need not be positive (but must be small integers).

This order first compares the degrees of the monomial-coefficient pairs using both the weights of the underlying ring R and the weights on the columns given by W and then proceeds as for the `TOP` order. If there is a natural grading W on the columns of the module, then it is preferable to use this order with W, particularly if submodules of interest are homogeneous or graded w.r.t. W, since then the GB w.r.t. this order will tend to be smaller and easier to compute. Normally one would also make the base order $<_R$ to be one of the `grevlex` or `grevlexw` degree orders (see Subsections 105.2.3, 105.2.3), so that the order $<$ extends the degree order $<_R$ to a degree order on the module.

109.3.3 Position Over Term: `POT`

Definition: $s_1[c_1] < s_2[c_2]$ iff $c_2 > c_1$ or $c_1 = c_2$ and $s_1 <_R s_2$. The order is specified by the argument (`"pot"`).

This order is called "POT" (position over term) since it first compares the columns and then compares the underlying monomials. The column comparison is ordered so that the first column is the greatest. A Gröbner basis of a module with respect to the `POT` order is like an echelon form of a matrix, since the order gives priority to the columns but this is in general rather harder to compute than the GB w.r.t. the `TOP` order.

---

† Some authors apply the terms 'monomial' and 'term' in opposite senses to how we do here, so that is why there are the established names 'TOP' and 'POT'; we follow this instead of using 'MOP' and 'POM'!

109.3.4 Position Over Term (Permutation): POTPERM

Definition (given a sequence P of k integers describing a permutation of $[1..k]$, where k is the degree of the ambient module): $s_1[c_1] < s_2[c_2]$ iff $P[c_2] > P[c_1]$ or $c_1 = c_2$ and $s_1 <_R s_2$. The order is specified by the arguments ("potperm", P).

This order first compares the columns using the given permutation, and then compares the underlying monomials.

109.3.5 Block TOP-TOP: TOPTOP

Definition (given a integer k): say that a column c is in the 1st block if $c \leq k$ and in the 2nd block if $c > k$; then $s_1[c_1] < s_2[c_2]$ iff c_2 is in the 1st block and c_1 is in the 2nd block, or if the columns are in the same block and $s_1[c_1] < s_2[c_2]$ w.r.t. the TOP order.

This order is a block order, like an elimination order for polynomial rings: comparison is first made on the blocks in which the columns lie, and then the TOP order is applied within each block. A GB w.r.t. this order is easier in general to compute than the POT order and so is useful when one wishes to 'eliminate' the first k columns only in a GB.

109.3.6 Block TOP-POT: TOPPOT

Definition (given a integer k): say that a column c is in the 1st block if $c \leq k$ and in the 2nd block if $c > k$; then $s_1[c_1] < s_2[c_2]$ iff c_2 is in the 1st block and c_1 is in the 2nd block, or if the columns are in the same block and $s_1[c_1] < s_2[c_2]$ w.r.t. the TOP/POT order (respective to the 1st/2nd blocks).

This order is a block order, like an elimination order for polynomial rings: comparison is first made on the blocks in which the columns lie, and then the TOP order is applied within the 1st block and the POT order is applied within the 2nd block. This is similar to the TOPTOP order, but it may be preferable to order the 2nd block w.r.t. the POT order. Note: POTPOT would equal to POT, and POTTOP does not seem to be useful.

109.4 Basic Creation and Access

An ambient free module $M = R^k$ is created by giving the base ring R (see introduction above), the degree r or a sequence W of r integers for the column weights, and, optionally, an argument specifying the type of module monomial order.

109.4.1 Creation of Ambient Embedded Modules

The following functions create ambient embedded modules.

`EModule(R, k)`

Given a ring R, create the ambient embedded module R^k with the default TOP module monomial order.

`EModule(R, k, order)`

Given a ring R, create the ambient embedded module R^k with the module monomial order described by the given order *order*. See Section 109.3 for the valid values for *order*.

`EModule(R, W)`

Given a ring R and a sequence W of k integers, create the ambient embedded module R^k with column weights given by W and with the `TOPW` module monomial order with weights W.

`EModule(R, W, order)`

Given a ring R and a sequence W of k integers, create the ambient embedded module R^k with column weights given by W and with the module monomial order described by the given order *order*. See Section 109.3 for the valid values for *order*.

109.4.2 Creation of Reduced Modules

The following functions create reduced modules, which are always ambient.

`RModule(R, k)`

Given a ring R, create the reduced module R^k with zero column weights.

`RModule(R, W)`

Given a ring R and a sequence W of k integers, create the reduced module R^k with column weights given by W.

`GradedModule(R, k)`

Given a ring R, create the reduced graded module R^k with zero column weights. The resulting module has type `ModMPolGrd`, so submodules and quotient modules of it may only be generated by homogeneous elements.

Note also that in general it is preferable if possible that the base ring R has a degree ordering (such as the `grevlex` or `grevlexw` orders) so that associated Gröbner bases of derived modules will be easier to compute.

`GradedModule(R, W)`

Given a ring R and a sequence W of k integers, create the reduced graded module R^k with column weights given by W. The resulting module has type `ModMPolGrd`, so submodules and quotient modules of it may only be generated by homogeneous elements.

109.4.3 Localization

`Localization(M)`

Given an R-module M, where $R = K[x_1, \ldots, x_n]$ for a field K, return the corresponding S-module $M_{\langle x_1,\ldots,x_n\rangle}$, where $S = K[x_1, \ldots, x_n]_{\langle x_1,\ldots,x_n\rangle}$ is the localization of R. See Chapter 107 for more information.

109.4.4 Basic Invariants

The following functions access simple defining invariants of a module M.

`Ambient(M)`
`Generic(M)`

Given a module M, return the ambient (or generic) module A in which M is embedded. The only case in which A differs from M is when M is a proper submodule of an ambient embedded module. So if M is reduced, A will always equal M.

`IsAmbient(M)`

Given a module M, return whether M is ambient.

`IsEmbedded(M)`

Given a module M, return whether M is embedded.

`IsReduced(M)`

Given a module M, return whether M is reduced.

`IsRoot(M)`

Given a module M, return whether M is a root (an independent module, not derived via sub- or quotient constructions from another module).

`CoefficientRing(M)`
`BaseRing(M)`

Given an R-module M, return the base ring R over which M is defined. Note that one can then call `BaseRing(R)` to obtain the underlying ring S in which the base coefficients of elements R lie.

`Degree(M)`

Given an R-module M, return the degree of M, which is the k such that the ambient module of M equals $R^k/\langle relations \rangle$. Note that if M is free and ambient, then the degree of M equals the rank of M, but otherwise in general the rank of M may be less than the degree of M (see the function `Rank` below).

`ColumnWeights(M)`
`Grading(M)`

Given a module M of degree k, return the grading of M, which is a sequence of k integers giving the grading on the columns of M.

`RelationModule(M)`

Given an R-module M of degree k, return the submodule of the embedded module R^k which is generated by the defining relations of M.

`Relations(M)`

Given an R-module M of degree k, return the defining relations of M as a sorted sequence of elements of the embedded module R^k.

`RelationMatrix(M)`

Given a module M, return the relation matrix of M, which is the matrix whose rows are the defining relations of M.

`Presentation(M)`

Given an R-module M, return the presentation module P of M. This is a reduced module isomorphic to M (and such that automatic coercion between M and P is allowed). If M is reduced, then P is identical to M.

`IsGraded(M)`

`IsHomogeneous(M)`

Given a module M, return whether M is graded (or equivalently, homogeneous), w.r.t. the grading of M (given by the weights on the columns of M and the variables of the base ring of M). This is true iff the Gröbner basis of M consists of homogeneous elements only (always true if M is reduced) and the Gröbner basis of the relation module of M consists of homogeneous elements alone. Note that a module of type `ModMPolGrd` is always graded.

109.4.5 Creation of Module Elements

Module elements (internally, multivariate polynomials with columns attached to the monomials) are constructed in general by giving a sequence or vector of elements from the coefficient ring R.

`M ! Q`

Suppose M is an R-module of degree r. Given a sequence $Q = [a_1, \ldots, a_r]$ of ring elements such that the a_i are coercible into R, construct the element of M corresponding to Q.

`M ! v`

Suppose M is an R-module of degree r. Given a vector v from the R-space R^r, construct the element of M corresponding to v.

`M ! 0`

`Zero(M)`

Create the zero element of the module M.

`UnitVector(M, i)`

Suppose M is an R-module of degree r. Given an integer i in the range $[1..r]$, construct the i-th unit vector of M (the vector with 1 in the i-th column and 0 elsewhere) whose parent is the ambient module of M (since it may not lie in M itself). Note that this *not* the same as the function `BasisElement` (below) which depends on the current basis of M.

109.4.6 Element Operations

The following functions allow simple access and operations on module elements. Some of them use the module structure and refer to the column structure of an element; others use the polynomial structure and ignore the column structure.

109.4.6.1 Access

`Eltseq(f)`

Given an element f of the R-module of degree r, return the sequence $[f_1, \ldots, f_r]$ of r elements from R corresponding to f.

`Vector(f)`

Given an element f of the module M over R and of degree r, return the element of the R-space of degree r over R corresponding to f.

`f[i]`

Given an element f of the R-module of degree r, together with an integer i in the range $[1..r]$, return the i-th component of f as an element of R.

109.4.6.2 Arithmetic

The following functions act on elements of R-modules. The operations are similar to those for multivariate polynomials or vectors, whenever meaningful. For the binary operations, the elements must be **compatible**; that is, their parents must have the same ambient module. Note that if quotient relations for M are present, then the result is reduced to the unique normal form modulo the quotient relations, but if the determination of the relations is delayed, then an element may have a non-unique representation, but all the predicates on elements below do not depend on the representation.

`f + g` `f - g` `- f` `r * f` `f * r`

Basic arithmetic operations. The element r lies in the base ring R.

`f div s`

Given a scalar ring element s and an element f of the module M, such that s is coercible into R s divides all components of f, return the quotient of f by s.

`SPolynomial(f, g)`

Given elements f and g of the module M such that the leading module monomials of f and g have the same column, return the S-polynomial of f and g. Note that the result is always reduced to the unique normal form modulo the quotient relations of M.

`Normalize(f)`

Given an element f of the module M, return the normalized form of f (so that the leading module monomial of f is normalized).

`NormalForm(f, S)`

Given an element f of the module M, together with a compatible module S, return the normal form of f with respect to S. This is unique if the base ring R is not local. In general, S will be a non-ambient embedded module for this to be useful (otherwise any f would already be in S so the result would always be zero).

`Coordinates(f, M)`

Given an element f of the R-module S, together with a compatible R-module M such that f is in M, return the coordinates of f with respect to the basis of M (whose components lie in R).

109.4.6.3 Accessing the Underlying Representation

The following functions access simple properties of module elements which are to do with the underlying representation.

`Coefficients(f)` `Monomials(f)` `Terms(f)`
`LeadingCoefficient(f)` `LeadingMonomial(f)`
`LeadingTerm(f)`
`CoefficientsAndMonomials(f)`

These functions are equivalent to the access functions for multivariate polynomials and access the underlying distributed polynomial representation (with columns added to the monomials); see Section 24.4.4 for details.

`Column(f)`

Given a single-term element f of a module M, return the column c of the single monomial-column pair (module monomial) $s[c]$ which f has.

`Degree(f)`
`WeightedDegree(f)`

Given an element f of a module M, return the weighted degree (abbreviated to 'degree' in this chapter) of f, which is the maximum of the weighted degrees of the monomial-column pairs of f. The weighted degree of a monomial-column $s[c]$ is the weighted degree of s (in the base ring R) plus the degree of column c in the grading of M.

`IsHomogeneous(f)`

Given an element f of a module M, return whether f is homogeneous; that is, whether the weighted degrees of all the monomial-columns of f are equal. (Note that the grading of M is thus significant.)

109.4.6.4 Predicates

`IsZero(f)`

Given an element f of the module M, return whether f is the zero element of M. Note that if the relations of M are non-zero this operation may be non-trivial (especially if the relations are not yet computed, but they will be automatically computed if needed).

`f eq g`

Given elements f and g of the module M, return whether f and g are equal. Note that this may be non-trivial (see the remarks above).

`f lt g`

Given elements f and g of the module M, return whether $f < g$ w.r.t. the underlying module monomial order. The operators `le`, `gt`, `ge` are similarly defined.

`f in M`

Given an element f of a module S together with a compatible module M, return whether f is in M.

Example H109E1

We illustrate simple modules over a multivariate polynomial ring. We construct simple ambient embedded modules over $\mathbf{Q}[x, y, z]$. The first module has default weights 0 on its columns, while the second has weights 1, 2, and 3 respectively on its columns.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3, "grevlex");
> M := EModule(R, 3);
> M;
Free Embedded Module R^3
Order: Module TOP: Graded Reverse Lexicographical
> f := M![x, y, z^2];
> g := M![z, y^3, x + 1];
> f;
[x, y, z^2]
> g;
[z, y^3, x + 1]
> f + g;
[x + z, y^3 + y, z^2 + x + 1]
> Terms(f);
[
    [0, 0, z^2],
    [x, 0, 0],
    [0, y, 0]
]
> Degree(f);
2
> [Degree(m): m in Monomials(f)];
```

```
[ 2, 1, 1 ]
> LeadingMonomial(f);
[0, 0, z^2]
> M2 := EModule(R, [10, 5, 1]);
Free Embedded Module R^3 with grading [10, 5, 1]
Order: Module TOP with column weights [10, 5, 1]: Graded Reverse Lexicographical
> f := M2![x, y, z^2];
> f;
[x, y, z^2]
> Terms(f);
[
    [x, 0, 0],
    [0, y, 0],
    [0, 0, z^2]
]
> Degree(f);
11
> [Degree(m): m in Monomials(f)];
[ 11, 6, 3 ]
```

Similar operations can be done with reduced modules. There is no difference for the elements.

```
> M := RModule(R, 3);
> M;
Free RModule R^3
> M := GradedModule(R, [10, 5, 1]);
> M;
Free Graded Module R^3 with grading [10, 5, 1]
> Grading(M);
[ 10, 5, 1 ]

109.5 The Homomorphism Type

Magma has a special type for a homomorphism between two R-modules. The type of such a homomorphism is `ModMPolHom`. In general, functions such as `Morphism` return a homomorphism of type `ModMPolHom`, while the boundary maps of complexes are also of type `ModMPolHom` (see the function `FreeResolution`).

A homomorphism $f : M \to N$ is represented by a matrix A. There are two ways in which A can be defined:

(a) A is an **ambient** matrix: in this case, A gives the explicit map on the *ambient* modules of M and N. Thus A is $m \times n$, where $m =$`Degree(M)`, $n =$`Degree(N)`.

(b) A is a **presentation** matrix: in this case, A gives the explicit map on the *presentation* modules of M and N. Thus A is $m \times n$, where $m =$`Degree(Presentation(M))`, $n =$`Degree(Presentation(N))`.

If M and N are reduced (a common case), then they equal their respective presentation modules, so there is no difference between the above two cases (the ambient matrix and the presentation matrix are identical). So the only difference between (a) and (b) occurs when at least one of M and N is a non-ambient (proper) submodule of an embedded module.

When M and N are graded - that is, generated by elements homogeneous with respect to the ambient column weightings and with a relation module that is also generated by homogeneous elements - all homomorphisms as non-graded modules are still allowed. However there are functions to test if a given homomorphism preserves the gradings on the domain and codomain up to a constant degree shift. See `IsHomogeneous` and `Degree` below.

`Homomorphism(M, N, A)`

`Presentation` BoolElt *Default :* `true`

Given R-modules M and N and an $m \times n$ matrix A over R, construct the homomorphism $f : M \to N$ (with type `ModMPolHom`) defined by A.

By default, A is assumed to be a presentation matrix (see the comments above), in which case m and n must equal the degrees of the presentation modules of M and N, respectively. Alternatively, setting the parameter `Presentation` to `false` specifies that A is an ambient matrix; in this case, m and n must equal the degrees of M and N, respectively.

`Domain(f)`

Given a module homomorphism $f : M \to N$, return the domain M.

`Codomain(f)`

Given a module homomorphism $f : M \to N$, return the codomain N.

`PresentationMatrix(f)`

`Matrix(f)`

Given a module homomorphism $f : M \to N$, return the presentation matrix A_P of f as an $m \times n$ matrix corresponding to the presentation modules of M and N, respectively. This presentation matrix is always well-defined and computed, even if f is constructed via an ambient matrix.

`AmbientMatrix(f)`

`Matrix(f)`

Given a module homomorphism $f : M \to N$, return the ambient matrix A_A of f as an $m \times n$ corresponding to the ambient modules of M and N, respectively. If M and N are reduced (as commonly happens), this will be the same as the presentation matrix above. But if M and N are not reduced and f is constructed via a presentation matrix, then an error may result (since it may be impossible to give a matrix over the base ring R which gives the mapping for the ambient modules).

`f(v)`

`v * f`

Given a module homomorphism $f : M \to N$ and an element v of M, return the image of v under f, as an element of N.

`f[i]`

Given a module homomorphism $f : M \to N$ and an integer i, return the element of N corresponding to the i-th row of the ambient matrix of f.

`Image(f)`

Given a module homomorphism $f : M \to N$, return the image of f as a submodule of N (which will be reduced iff N is).

`Kernel(f)`

Given a module homomorphism $f : M \to N$, return the kernel of f as a submodule of M (which will be reduced iff M is).

`Cokernel(f)`

Given a module homomorphism $f : M \to N$, return the cokernel of f as a quotient module of N (which will be reduced iff N is).

`IsZero(f)`

Given a module homomorphism $f : M \to N$, return whether f is the zero map. Note that f may be the zero map even if the presentation or ambient matrices of f are non-zero.

`IsInjective(f)`

Given a module homomorphism $f : M \to N$, return whether f is injective (whether the kernel of f is the zero module).

`IsSurjective(f)`

Given a module homomorphism $f : M \to N$, return whether f is surjective (whether the image of f equals N).

`IsBijective(f)`

Given a module homomorphism $f : M \to N$, return whether f is bijective (injective and surjective).

`IsGraded(f)`
`IsHomogeneous(f)`

Given a module homomorphism $f : M \to N$, where M and N are graded modules, return whether f is homogeneous of some degree d; that is, whether for every pure degree element $v \in M$, $f(v) = 0$ or `Degree`$(f(v))$ equals `Degree`$(v) + d$.

`Degree(f)`

Given a module homomorphism $f : M \to N$, return the degree of f, which is the maximum d such that an element of M of degree e is mapped via f to zero or an element of degree $e + d$. If f is homogeneous, then the 'maximum' concept is unnecessary, since the degree will be consistent for all elements of M (see the previous function).

Example H109E2

We illustrate some homomorphism functionality by looking at the explicit inclusion homomorphism between two submodules of a rank 3 free module over $\mathbf{Q}[x, y]$. We define this in non-presentational form by the identity matrix. Then we can retrieve the corresponding defining matrix for the map between the internal presentations of the two submodules. The two submodules being graded submodules, we check that the inclusion is indeed homogeneous of degree 0 (as it must be, obviously preserving degrees of elements).

```
> R<x,y> := PolynomialRing(RationalField(), 2, "grevlex");
> F := EModule(R, 3);
> // get a submodule M1 generated by a single non-zero element of F
> M1 := sub<F|[x^2,y^2,x*y]>;
> // and a second submodule M2 containing M1
> M2 := sub<F|[x,0,y],[0,y,0]>;
> incl_hm :=  Homomorphism(M1,M2,IdentityMatrix(R,3) :
>               Presentation := false);
> incl_hm;
Module homomorphism (3 by 3)
Ambient matrix:
[1 0 0]
```

```
[0 1 0]
[0 0 1]
```

Now the corresponding presentation matrix of the inclusion map is the obvious one coming from the expression of the natural generator of M1 in terms of the two natural generators of M2

```
>  PresentationMatrix(incl_hm);
[y x]
> // check homogeneity of incl_hm
> IsHomogeneous(incl_hm);
true
> Degree(incl_hm);
0
```

109.6 Submodules and Quotient Modules

The following functions allow the construction of submodules and quotient modules and access to essential properties.

109.6.1 Creation

`sub< M | L >`

Given a module M over a ring R, return the submodule of M (with the same quotient relations as M) generated by the elements of M specified by the list L. Each term of the list L must be an expression defining an object of one of the following types:

(a) An element of M;

(b) A set or sequence of elements of M;

(c) A submodule of M;

(d) A set or sequence of submodules of M.

A morphism is stored from the resulting submodule S into M, such that $S.i$ is mapped to the i-th generator given in the above list.

`quo< M | L >`

Given a module M over a ring R, return the quotient module of M by the elements of M specified by the list L. Each term of the list L must be an expression defining an object of one of the following types:

(a) An element of M;

(b) A set or sequence of elements of M;

(c) A submodule of M;

(d) A set or sequence of submodules of M.

A morphism is stored from M onto the resulting quotient module Q.

`Morphism(M, N)`

Given modules M and N, related by a chain of stored sub and quo morphisms as mentioned above, returns the resulting morphism matrix map from M to N. If no known sub/quo relationship chain exists between M and N then an error is returned.

`Submodule(I)`

Given an ideal I of a polynomial ring R, return the submodule of R^1 generated by I.

`QuotientModule(I)`

Given an ideal I of a polynomial ring R, return the quotient module R^1/I.

`GradedModule(I)`

Given a homogeneous ideal I of a ring R, return the graded quotient module R^1/I.

109.6.2 Module Bases

The following functions allow one to manipulate the bases of modules. Note that a Gröbner basis for a module will be automatically generated when necessary; the `Groebner` procedure just allows explicit immediate construction of the Gröbner basis.

`Basis(M)`

Given a module M, return the current basis (whether it has been converted to a Gröbner basis or not) of M.

`BasisElement(M, i)`

Given a module M together with an integer i, return the i-th element of the current basis of M. Note that this is *not* the same as $M.i$.

`BasisMatrix(M)`

Given a module M, return the basis matrix of M, which is a k by r matrix over R, where k is the length of the basis of M and r is the degree of M.

`Groebner(M)`

(Procedure.) Explicitly force a Gröbner basis for the module M to be constructed.

Example H109E3

We construct simple submodules and quotient modules of an embedded module and consider some of their basic properties.

```
> R<x, y, z> := PolynomialRing(RationalField(), 3);
> M := EModule(R, 3);
> S := sub<M | [1, x, x^2+y], [z, y, x*y^2+1],
>              [y, z, x+z]>;
> Groebner(S);
> S;
Embedded Submodule of R^3
Order: Module TOP: Lexicographical
Groebner basis:
[ -x*z + y^2 + y, x*y^2 - x*y + z,         y^3 + z],
[  x*y - y*z - 1,   x*z - x - z^2,        -y - z^2],
[             y,               z,           x + z],
[       y^3 - z,       y^2*z - y,       y^2*z - 1]
> a := M ! [y, z, x+z];
> a;
[y, z, x + z]
> a in S;
true
> BasisElement(S, 1);
[-x*z + y^2 + y, x*y^2 - x*y + z, y^3 + z]
> Q := quo<M | [x, y, z]>;
> Q;
Embedded Module R^3/<relations>
Order: Module TOP: Lexicographical
Relations (Groebner basis):
[x, y, z]
> a := Q![x, y, 0];
> b := Q![0, 0, z];
> a;
[0, 0, -z]
> b;
[0, 0, z]
> a+b;
[0, 0, 0]
> Q ! [x,y,z];
[0, 0, 0]
> QQ := quo<Q | [x^2, 0, y+z]>;
> QQ;
Embedded Module R^3/<relations>
Order: Module TOP: Lexicographical
Relations (Groebner basis):
[          0,         x*y, x*z - y - z],
[          x,           y,           z]
> SL := Localization(S);
```

```
> SL;
Embedded Submodule of R^3 (local)
Order: Module TOP: Local Lexicographical
Basis:
[        1,         x,   x^2 + y],
[        z,         y, 1 + x*y^2],
[        y,         z,     x + z]
```

Example H109E4

We construct simple submodules and quotient modules of a reduced module and consider some of their basic properties.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3);
> M := RModule(R, 3);
> S := sub<M | [1, x, x^2+y], [z, y, x*y^2+1]>;
> M;
Free Reduced Module R^3
> S;
Reduced Module R^2/<relations>
> Morphism(S, M);
Module homomorphism (2 by 3)
Ambient matrix:
[        1         x   x^2 + y]
[        z         y x*y^2 + 1]
> RelationMatrix(S);
Matrix with 0 rows and 2 columns
> S;
Free Reduced Module R^2
> M.1;
[1, 0, 0]
> M!S.1;
[1, x, x^2 + y]
> M!S.2;
[z, y, x*y^2 + 1]
> M.1 in S;
false
> Q := quo<M | [1, x^2, y]>;
> Q;
Free Reduced Module R^2
> RelationMatrix(Q);
Matrix with 0 rows and 2 columns
> Morphism(M, Q);
Module homomorphism (3 by 2)
Ambient matrix:
[-x^2   -y]
[   1    0]
[   0    1]
```

```
> Morphism(S, Q);
Module homomorphism (2 by 2)
Ambient matrix:
[       -x^2 + x             x^2]
[     -x^2*z + y x*y^2 - y*z + 1]
> Q!M.1;
[-x^2, -y]
> M!Q.1;
[0, 1, 0]
> M!Q.2;
[0, 0, 1]
> Q!M!Q.2;
[0, 1]
```

109.7 Basic Module Constructions

The following functions give some fundamental basic constructions with modules.

`M + N`

Given compatible modules M and N (ie, embedded in the same ambient module), return the sum of M and N; that is, the submodule of the ambient generated by M and N.

`M meet N`

Given compatible modules M and N (ie, embedded in the same ambient module), return the intersection of M and N in the ambient. This uses the standard algorithm for intersecting two modules of a free module (see Section 2.8.3 of [GP02]). If the ambient is the quotient of a free module F by non-trivial relations, the intersection performed is effectively that of the inverse images of M and N in F.

`f * M`
`M * f`

Given an R-module M and an element $f \in R$, return the submodule of M generated by $\{f \cdot v : v \in M\}$ or $\{v \cdot f : v \in M\}$, respectively.

`I * M`
`M * I`

Given an R-module M and an ideal I of R, return the submodule of M generated by $\{f \cdot v : f \in I, v \in M\}$ or $\{v \cdot f : f \in I, v \in M\}$, respectively.

`M / N`

Given compatible modules M and N (ie, embedded in the same ambient module), return the quotient module $M/(M \cap N)$. This has the same effect as using the `quo` constructor.

`DirectSum(M, N)`

Given R-modules M and N, return the direct sum $D = M \oplus N$ and two sequences of corresponding homomorphisms giving the injections into and projections from D, respectively.

`DirectSum(S)`

A sequence or list L of R-modules, return their direct sum D and two sequences of corresponding homomorphisms giving the injections into and projections from D, respectively.

`Twist(M, d)`

Given a graded module M, and an integer d, return the Serre twist $M(d)$ and an isomorphism $f : M \to M(d)$. The twisted module is simply an isomorphic copy of M, but with the grading twisted by d (so d is subtracted from each weight of M). f has degree $-d$.

109.8 Predicates

`IsZero(M)`

Given a module M, return whether M is the zero module.

`M subset N`

Given compatible modules M and N (ie, embedded in the same ambient module), return whether M is a submodule of N. This will generally involve module Gröbner basis and normal form computations to check that the generators of M lie in N.

`M eq N`

Given compatible modules M and N (ie, embedded in the same ambient module), return whether M equals N. The function checks that appropriate module Gröbner bases of M and N are equal.

`IsFree(M)`

Given an R-module M, return whether M is free. M is free iff M is isomorphic to the module R^k for some k. Such a k need not equal the degree of M but will equal the rank of M (as defined in the next section) if M is free. The function checks whether a minimised presentation of M has trivial relations or not.

109.9 Module Operations

The following functions perform some fundamental module operations.

`MinimalBasis(M)`

Given an R-module M, return a minimal basis B of M. If M is graded, or if R is a local ring, then the cardinality of B (the rank) is guaranteed to be unique (so is the absolutely minimal number of elements needed to generate M).

Otherwise the cardinality of B is not unique: B will only satisfy the rule that the i-th element of B is not in the submodule generated by elements 1 to $i-1$ of B.

In the graded case or local cases, a minimal basis is computed in the usual way starting from any basis B consisting of homogeneous elements. B gives a particular presentation whose relation matrix R consists of homogeneous polynomials. If R contains a non-zero constant term (or more generally a unit in the local case), an element of B can be eliminated and R recalculated. This can be continued until all non-zero terms of R have positive degree.

`MinimalBasis(S)`

Given a set or sequence S of homogeneous module elements from a module M, return a minimal basis of the submodule of M generated by S.

`Rank(M)`

Given an R-module M, return the rank of M. This is simply defined to be the cardinality of the minimal basis of M, returned by the function `MinimalBasis`. Thus if M is graded, or if R is a local ring, then the rank is guaranteed to be unique (and is the absolutely minimal number of elements needed to generate M). Otherwise the result is not an invariant of M, but simply reflects the minimum as found by the `MinimalBasis` algorithm.

`ColonModule(M, J)`

Given an R-module M and an ideal J of R, return the colon module $M : J$ which is the submodule of the ambient module A of M consisting of all $f \in A$ such that $f \cdot g \in M$ for all $g \in J$. When J is generated by a single element, this easily reduces to a syzygy computation in A and in the general case, we intersect the colon modules for a set of generators of J.

`ColonIdeal(M, N)`

Given an R-modules M and N which are both submodules of a common supermodule, return the colon ideal $M : N$, which is the ideal of R consisting of all $f \in R$ such that $f \cdot N \subset M$. The algorithm used is as described in section 2.8.4 of [GP02].

`Annihilator(M)`

Given an R-module M, return the annihilator ideal of M. This is the ideal I of R consisting of all $f \in R$ such that $f \cdot M = 0$ (which can be seen to equal the ideal $0_M : M$, where 0_M is the zero submodule of M, so is a special case of `ColonIdeal`).

`FittingIdeal(M, i)`

Given an R-module M of degree r and an integer $i \geq 0$, return the i-th Fitting ideal of M, which is the ideal of R generated by the $(r-i)$-th minors of the presentation matrix of M, where r is the degree of M. See [CLO98, p.229] or [Eis95, Sec. 20.2].

`FittingIdeals(M)`

Given an R-module M of degree r, return the Fitting ideals (for from 0 to r) as a sequence of ideals of R.

`SyzygyModule(M)`

Given a module M, return the syzygy module S of M. If the basis B of M has length k, the syzygy module S has degree k and elements of S express a syzygy amongst the k elements of the basis B. Note that the degree of the resulting module thus depends on the current basis of M.

`MinimalSyzygyModule(M)`

Given a homogeneous module M, return the syzygy module S of the minimal basis of M. If the minimal basis B of M has length k, the syzygy module S has degree k and elements of S express a syzygy amongst the k elements of the minimal basis B.

`SyzygyModule(Q)`

Given a sequence Q of polynomials from a multivariate polynomial ring P, return the module of syzygies of Q. This is a module over P of degree k, where k is the length of Q, consisting of all vectors v such that the sum of $v[i] * Q[i]$ for $i = 1, \ldots k$ is zero.

Example H109E5

In this example we note that a certain module M has rank 3 (equal to its degree 3), since no generator is redundant. If we move to the localization of M, then $(1 + x - z)$ becomes a unit, so the first generator becomes redundant.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3, "grevlex");
> F := RModule(R, 3);
> M := quo<F | [x + 1, y, z], [z, y, 0]>;
> M;
Reduced Module R^3/<relations>
Relations:
[x + 1,     y,     z],
[    z,     y,     0]
> Degree(M);
3
> Rank(M);
3
> ML := Localization(M);
> ML;
```

```
Reduced Module R^3/<relations> (local)
Relations:
[1 + x - z,         0,         z],
[        z,         y,         0]
> Rank(ML);
2
> MinimalBasis(ML);
[
    [0, 1, 0],
    [0, 0, 1]
]
```

109.10 Changing Ring

The `ChangeRing` function enables the changing of the polynomial ring over which a module is defined.

`ChangeRing(M, S)`

Given an R-module M, where R is a polynomial ring, and another polynomial ring S, construct the S-module N obtained by coercing the coefficients of the elements of the basis and relations of M into S. It is necessary that all elements of the old coefficient ring R can be automatically coerced into the new coefficient ring S. Note that S itself must be polynomial ring having the same rank as R, so S does not specify the new ring for the underlying coefficients (one can use `ChangeRing` for polynomial rings to do that first).

109.11 Hilbert Series

The following functions compute the Hilbert series information of graded or (homogeneous) modules. This depends on the column weights, just as in graded polynomial rings.

`HilbertSeries(M)`

Given a graded R-module M, return the Hilbert series $H_M(t)$ of M (as a univariate function field over the ring of integers. The i-th coefficient of the series gives the vector-space dimension of the degree-i graded piece of M. The algorithm implemented is that given in [BS92].

Note that if I is an ideal of the ring R, then the corresponding function for ideals `HilbertSeries` applied to I gives the Hilbert series of the affine algebra (quotient) R/I, so this is equivalent to `HilbertSeries(QuotientModule(I))`.

`HilbertSeries(M, p)`

Given a graded R-module M, return the Hilbert series $H_M(t)$ of M as a Laurent series to precision p. (A Laurent series is required in general, since negative powers may occur when there are negative values in the grading of M.)

`HilbertDenominator(M)`

Given a graded R-module M, return the unreduced Hilbert denominator D of the Hilbert series $H_M(t)$ of M (as a univariate polynomial over the ring of integers). The denominator D equals `HilbertDenominator(R)` which is simply

$$\prod_{i=1}^{n}(1-t^{w_i}),$$

where n is the rank of R and w_i is the weight of the i-th variable (1 by default).

`HilbertNumerator(M)`

Given a graded R-module M, return the unreduced Hilbert numerator N of the Hilbert series $H_M(t)$ of M (as a univariate polynomial over the ring of integers) and a valuation shift s. The numerator N equals $D \times t^s \times H_M(t)$, where D is the unreduced Hilbert denominator above. Computing with the unreduced numerator is often more convenient. Note that s will only be non-zero when M has negative weights in its grading.

`HilbertPolynomial(I)`

Given a graded R-module M, return the Hilbert polynomial $H(d)$ of M as an element of the univariate polynomial ring $\mathbf{Q}[d]$, together with the index of regularity of M (the minimal integer $k \geq 0$ such that $H(d)$ agrees with the Hilbert function of M at d for all $d \geq k$).

Example H109E6

We apply the Hilbert series functions to a simple quotient module.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3);
> F := GradedModule(R, 3);
> M := quo<F | [x,0,0], [0,y^2,0]>;
> M;
Graded Module R^3/<relations>
Relations:
[  x,   0,   0],
[  0, y^2,   0]
> HilbertSeries(M);
(t^2 + t - 3)/(t^3 - 3*t^2 + 3*t - 1)
> HilbertSeries(M, 10);
3 + 8*s + 14*s^2 + 21*s^3 + 29*s^4 + 38*s^5 + 48*s^6 + 59*s^7 + 71*s^8 + 84*s^9
    + O(s^10)
> HilbertNumerator(M);
-x^2 - x + 3
0
> HilbertDenominator(M);
-x^3 + 3*x^2 - 3*x + 1
```

```
> HilbertPolynomial(M);
1/2*x^2 + 9/2*x + 3
0
> [Evaluate(HilbertPolynomial(F), i): i in [0..10]];
[ 3, 9, 18, 30, 45, 63, 84, 108, 135, 165, 198 ]
```

If the module has negative weights, then denominator may include extra powers of t, so the shift for the numerator will be non-zero.

```
> F := GradedModule(R, [-1]);
> F;
Free Graded Module R^1 with grading [-1]
> HilbertSeries(F);
-1/(t^4 - 3*t^3 + 3*t^2 - t)
> HilbertSeries(F, 10);
s^-1 + 3 + 6*s + 10*s^2 + 15*s^3 + 21*s^4 + 28*s^5 + 36*s^6 + 45*s^7 + O(s^8)
> HilbertNumerator(F);
1
1
> HilbertDenominator(F);
-x^3 + 3*x^2 - 3*x + 1
> HilbertPolynomial(F);
1/2*x^2 + 5/2*x + 3
-1
> [Evaluate(HilbertPolynomial(F), i): i in [-1..10]];
[ 1, 3, 6, 10, 15, 21, 28, 36, 45, 55, 66, 78 ]
```

109.12 Free Resolutions

The functions in this section deal with free resolutions and associated properties. Free resolutions are returned as chain complexes (see Chapter 56).

109.12.1 Constructing Free Resolutions

`FreeResolution(M)`

`Minimal`	BoolElt	*Default :* `true`
`Limit`	RngIntElt	*Default :* 0
`Homogenize`	BoolElt	*Default :* `true`
`Al`	MonStgElt	*Default :* "*LaScala*"

Given an R-module M, return a free resolution M as a complex C, and a comparison homomorphism $f : C_0 \to M$ (where C_0 is the term of C of degree 0).

By default, the free resolution will be **minimal**. Setting the parameter `Minimal` to `false` will construct a non-minimal resolution (which is constructed via a sequence of successive syzygy modules, with no minimization).

Magma has two algorithms for computing resolutions:

(1) The **La Scala** (LS) [SS98] algorithm, which works with a homogeneous module. The Magma implementation involves an extension of this algorithm which uses techniques from the Faugère F_4 [Fau99] algorithm to compute many normal forms together in a block.

(2) The **Iterative** algorithm, which simply computes successive syzygy modules progressively (minimizing as it goes if and only a minimal resolution is desired).

By default the LS algorithm is used if M is homogeneous and the coefficient ring of R is a finite field or the rational field, since this tends to be faster in general. But for some inputs the iterative algorithm may be significantly faster, particularly for some modules over the rationals. So one may set the parameter `Al` to `"Iterative"` to select the iterative algorithm. Uniqueness of the terms in the resolution is as follows.

(1) If M is homogeneous or defined over a local ring R, then the resulting complex C is guaranteed to be minimal, so the ranks of the terms in C and the associated Betti numbers will be unique.

(2) If M is non-homogeneous and over a global ring R, then the boundary maps of C will not have any entries which are units, but C cannot be guaranteed to be an absolutely minimal free resolution, so the ranks of the terms and the associated Betti numbers will not be unique in general. Also, Magma may choose to compute C by computing the free resolution C_H of a homogenization M_H of M, and then specializing C_H to yield C, since this method is usually faster (since the LS algorithm can then be used). One may set the parameter `Homogenize` to `true` or `false` to force Magma to use this homogenization technique or not.

If the parameter `Limit` is set to a non-zero value l, then at most l terms (plus the term corresponding to the free module) are computed. If R is an affine algebra or exterior algebra of rank n, then by default the limit is set to n, since the resolution is not finite in general.

`SetVerbose("Resolution", v)`

(Procedure.) Change the verbose printing level for the free resolution algorithm and related functions to be v.

Example H109E7

We construct the module $M = R^1/I$ where I is the ideal of the twisted cubic and then construct a minimal free resolution of M and note simple properties of this.

```
> R<x,y,z,t> := PolynomialRing(RationalField(), 4, "grevlex");
> B := [
>     -x^2 + y*t, -y*z + x*t, x*z - t^2,
>     x*y - t^2, -y*z + x*t, -x^2 + z*t
> ];
> M := GradedModule(Ideal(B));
```

```
> M;
Graded Module R^1/<relations>
Relations:
[-x^2 + y*t],
[-y*z + x*t],
[ x*z - t^2],
[ x*y - t^2],
[-y*z + x*t],
[-x^2 + z*t]
> C := FreeResolution(M);
> C;
Chain complex with terms of degree 4 down to -1

> Image(B[3]) eq Kernel(B[4]);
true
```

Example H109E8

Following [CLO98, p.248], we compute the ideal I of $\mathbf{Q}[x, y]$ whose affine variety is a certain list of 6 pairs.

```
> R<x,y> := PolynomialRing(RationalField(), 2, "grevlex");
> L := [<0, 0>, <1, 0>, <0, 1>, <2, 1>, <1, 2>, <3, 3>];
> I := Ideal(L, R);
> I;
Ideal of Polynomial ring of rank 2 over Rational Field
Graded Reverse Lexicographical Order
Variables: x, y
Inhomogeneous, Dimension 0
Groebner basis:
[
    x^3 - 5*x^2 + 2*x*y - 2*y^2 + 4*x + 2*y,
    x^2*y - 5*x^2 + 3*x*y - 4*y^2 + 5*x + 4*y,
    x*y^2 - 4*x^2 + 3*x*y - 5*y^2 + 4*x + 5*y,
    y^3 - 2*x^2 + 2*x*y - 5*y^2 + 2*x + 4*y
]
```

I is not homogeneous, and we compute a non-minimal free resolution of the module R/I.

```
> M := QuotientModule(I);
> M;
Reduced Module R^1/<relations>
Relations:
[  x^3 - 5*x^2 + 2*x*y - 2*y^2 + 4*x + 2*y],
[x^2*y - 5*x^2 + 3*x*y - 4*y^2 + 5*x + 4*y],
[x*y^2 - 4*x^2 + 3*x*y - 5*y^2 + 4*x + 5*y],
[  y^3 - 2*x^2 + 2*x*y - 5*y^2 + 2*x + 4*y]
> C := FreeResolution(M: Minimal := false);
> C;
Chain complex with terms of degree 3 down to -1
Dimensions of terms: 0 3 4 1 0
> B := BoundaryMaps(C);
> B;
```

```
[*
    Module homomorphism (0 by 3),
    Module homomorphism (3 by 4)
    Ambient matrix:
    [-y + 5  x - 8      6     -2]
    [     4 -y - 8  x + 8     -4]
    [     2     -6 -y + 8  x - 5],
    Module homomorphism (4 by 1)
    Ambient matrix:
    [  x^3 - 5*x^2 + 2*x*y - 2*y^2 + 4*x + 2*y]
    [x^2*y - 5*x^2 + 3*x*y - 4*y^2 + 5*x + 4*y]
    [x*y^2 - 4*x^2 + 3*x*y - 5*y^2 + 4*x + 5*y]
    [  y^3 - 2*x^2 + 2*x*y - 5*y^2 + 2*x + 4*y],
    Module homomorphism (1 by 0)
*]
> IsZero(B[2]*B[3]);
true
```

As noted in [CLO98], the 3 by 3 minors of the boundary map from R^3 to R^4 generate the ideal I again, and this is due to the Hilbert-Burch Theorem.

```
> U := Minors(Matrix(B[2]), 3);
> U;
[
    y^3 - 2*x^2 + 2*x*y - 5*y^2 + 2*x + 4*y,
    x*y^2 - 4*x^2 + 3*x*y - 5*y^2 + 4*x + 5*y,
    x^2*y - 5*x^2 + 3*x*y - 4*y^2 + 5*x + 4*y,
    x^3 - 5*x^2 + 2*x*y - 2*y^2 + 4*x + 2*y
]
> Ideal(U) eq I;
true
```

109.12.2 Betti Numbers and Related Invariants

Each of the functions in this section compute numerical properties of a free resolution of a module M. Each function takes the same parameters as the function `FreeResolution` (not repeated here), thus allowing control of the construction of the underlying resolution.

In particular, by default the **minimal** free resolution of M is used (so the Betti numbers correspond to that), so the relevant invariant is guaranteed to be unique if M is graded or over a local ring R. Otherwise, one may set the parameter `Minimal` to `false` to give the Betti numbers for a non-minimal resolution.

Note: If M is graded and the LS algorithm is used (which will be the case by default), then computing any of the invariants to do with Betti numbers in this section may be quicker than computing the full resolution (since minimization of the actual resolution is needed for the latter). Thus it is preferable just to use one of the following functions instead of `FreeResolution` if only the numerical invariants are desired.

`BettiNumbers(M)`

Given a module M, return the Betti numbers of M, which is simply the sequence of integers consisting of the degrees of the non-zero terms of the free resolution of M. See the discussion above concerning the parameters. Since the underlying resolution is minimal by default, if M is graded or over a local ring, then the result is unique.

`BettiNumber(M, i, j)`

Given a module M and integers $i, j \geq 0$, return the graded Betti number $\beta_{i,j}$ of M as an integer. This is the number of generators of degree j in the i-th term F_i of the free resolution of M.

`MaximumBettiDegree(M, i)`

Given a module M and an integer $i \geq 0$, return the maximum degree of the generators in the i-th term of the free resolution of M. Equivalently, this is the maximum j such that `BettiNumber(M, i, j)` is non-zero.

`BettiTable(M)`

Given a module M, return the Betti table of M as a sequence S of sequences of integers, and a shift s. This is designed so that if M is non-zero, then `S[1, 1]` is always non-zero and `S[i, j]` equals `BettiNumber(M, i, j - i + s)`. (So the degrees are shifted by s.)

`Regularity(M)`

Given an R-module M which is either graded or over a local ring, return the Castelnuovo-Mumford regularity. This is the least r such that in a minimal free resolution of M, the maximum of the degrees of the generators of the i-th term F_i is at most $i + r$. A simple consequence of this is that M is generated by elements of degree at most r. See [Eis95, Sec. 20.5] or [DL06, p. 167].

`HomologicalDimension(M)`

Given a module M, return the homological dimension of M. This is just the length of a minimal free resolution of M (the number of non-zero boundary maps).

Example H109E9

For an integer n, we can construct a Koszul complex as the free resolution of R/I, where I is the ideal of $R = K[x_1, \ldots, x_n]$ generated by the n variables.

```
> Q := RationalField();
> n := 3;
> R<[x]> := PolynomialRing(Q, n);
> I := Ideal([R.i: i in [1 .. n]]);
> M := QuotientModule(I);
> M;
Graded Module R^1/<relations>
Relations:
```

```
[x[1]],
[x[2]],
[x[3]]
> C := FreeResolution(M);
> C;
Chain complex with terms of degree 4 down to -1
Dimensions of terms: 0 1 3 3 1 0
> BoundaryMaps(C);
[*
    Module homomorphism (0 by 1),
    Module homomorphism (1 by 3)
    Ambient matrix:
    [ x[3] -x[2]  x[1]],
    Module homomorphism (3 by 3)
    Ambient matrix:
    [-x[2]  x[1]     0]
    [-x[3]     0  x[1]]
    [    0 -x[3]  x[2]],
    Module homomorphism (3 by 1)
    Ambient matrix:
    [x[1]]
    [x[2]]
    [x[3]],
    Module homomorphism (1 by 0)
*]
```

In general, the i-th Betti number is $\binom{n}{i}$. We can see this for $n = 10$. Each boundary map consists of linear relations alone, so the regularity is zero.

```
> n := 10;
> R<[x]> := PolynomialRing(Q, n);
> I := Ideal([R.i: i in [1 .. n]]);
> M := QuotientModule(I);
> time C := FreeResolution(M);
Time: 0.060
> C;

    [ 1, 10, 45, 120, 210, 252, 210, 120, 45, 10, 1 ]
]
> $1 eq [[Binomial(n, i): i in [0 .. n]]];
true
> Regularity(M);
0
```

Example H109E10

We can construct the same type of ideal and module as in the last example for $n = 3$, but over an exterior algebra. The free resolution is infinite here, but we can construct the resolution partially (by default, a bound is set on the number of terms). In this general construction, the i-th Betti number will be $\binom{i}{n-1}$.

```
> Q := RationalField();
> n := 3;
> R<[x]> := ExteriorAlgebra(Q, n);
> I := Ideal([R.i: i in [1 .. n]]);
> M := QuotientModule(I);
> M;
Reduced Module R^1/<relations>
Relations:
[x[1]],
```

```
[x[2]],
[x[3]]
> BettiNumbers(M);
[ 1, 3, 6, 10, 15 ]
> [Binomial(i + n - 1, n - 1): i in [0..4]];
[ 1, 3, 6, 10, 15 ]
> C := FreeResolution(M);
> C;
Chain complex with terms of degree 5 down to -1
Dimensions of terms: 0 15 10 6 3 1 0
> BoundaryMaps(C);
[*
    Graded module homomorphism (0 by 15),
    Graded module homomorphism (15 by 10) of degree 0
    Ambient matrix:
    [x[3]    0    0    0    0    0    0    0    0    0]

    Ambient matrix:
    [x[3]]
    [x[2]]
    [x[1]],
    Graded module homomorphism (1 by 0)
*]
```

Example H109E11

We construct a non-homogeneous quotient module M of $\mathbf{Q}^3$. As expected, the Betti numbers of the localization of M are smaller than the Betti numbers of M.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3, "grevlex");
> R3 := RModule(R, 3);
> B := [R3 | [x*y, x^2, z], [x*z^3, x^3, y], [y*z, z, x],
>       [z, y*z, x], [y, z, x]];
> M := quo<R3 | B>;
> M;
Reduced Module R^3/<relations>
Relations:
[  x*y,   x^2,     z],
[x*z^3,   x^3,     y],
[  y*z,     z,     x],
[    z,   y*z,     x],
[    y,     z,     x]
> BettiNumbers(M);
[ 3, 5, 4, 2 ]
> BettiNumbers(Localization(M));
[ 3, 5, 3, 1 ]
```

Since M is non-homogeneous, the Betti numbers are not unique. If we create a second module M_2 which is equivalent to M and compute the Betti numbers this time without homogenization (in the internal free resolution algorithm), then we obtain different Betti numbers for M_2. But since the Betti numbers over a local ring are unique, we get the same result for the localization of M_2.

```
> M2 := quo<R3 | B>;
> BettiNumbers(M2: Homogenize :=false);
[ 3, 6, 5, 2 ]
> BettiNumbers(Localization(M2): Homogenize:=false);
[ 3, 5, 3, 1 ]
```

Example H109E12

Suppose M is a graded R-module. Given the graded Betti numbers $\beta_{i,j}$ of M, one can compute the Hilbert series $H_M(t)$ of M via the formula ([Eis95, Thm. 1.13] or [DL06, Thm. 1.22]):

$$H_M(t) = \frac{\sum_{i,j}(-1)^i \beta_{i,j} t^j}{D},$$

where D is the Hilbert denominator of M: this depends on the underlying ring R and equals

$$\prod_{i=1}^{n}(1 - t^{w_i}),$$

where n is the rank of R and w_i is the weight of the i-th variable (1 by default). We can thus write a simple function to compute the Hilbert series numerator via this formula.

```
> function HilbertNumeratorBetti(M)
>    P<t> := PolynomialRing(IntegerRing());
>    return &+[
>        (-1)^i*BettiNumber(M, i, j)*t^j:
>           j in [0 .. MaximumBettiDegree(M, i)],
>           i in [0 .. #BettiNumbers(M)]
>    ];
> end function;
```

We then check that this function agrees with the MAGMA internal function `HilbertNumerator` for some modules. (Since the modules do not have negative gradings, we do not have to worry about the denominator shift which is 0 for these modules.) First we try the Twisted Cubic.

```
> Q := RationalField();
> R<x,y,z,t> := PolynomialRing(Q, 4, "grevlex");
> B := [
>     -x^2 + y*t, -y*z + x*t, x*z - t^2,
>     x*y - t^2, -y*z + x*t, -x^2 + z*t
> ];
> M := GradedModule(Ideal(B));
> HilbertNumeratorBetti(M);
-t^5 + 5*t^3 - 5*t^2 + 1
> HilbertNumerator(M);
-t^5 + 5*t^3 - 5*t^2 + 1
0
```

Now we apply the function to the module $M = R^1/I$ where I is the ideal generated by the 2×2 minors of a generic 4×4 matrix. Computing the Hilbert series numerator via the Betti numbers takes a little time since the resolution is non-trivial. Note the components of the Betti table which contribute to the terms of the Hilbert series numerator.

```
> n := 4;
> R<[x]> := PolynomialRing(Q, n^2, "grevlex");
> A := Matrix(n, [R.i: i in [1 .. n^2]]);
```

```
> A;
[ x[1]  x[2]  x[3]  x[4]]
[ x[5]  x[6]  x[7]  x[8]]
[ x[9] x[10] x[11] x[12]]
[x[13] x[14] x[15] x[16]]
> I := Ideal(Minors(A, 2));
> #Basis(I);
36
> M := QuotientModule(I);
> time HilbertNumeratorBetti(M);
-t^12 + 36*t^10 - 160*t^9 + 315*t^8 - 288*t^7 + 288*t^5 - 315*t^4 + 160*t^3 -
    36*t^2 + 1

```

Example H109E13

Given a graded module $M = R^1/I$, one can obtain an upper bound on the regularity of M by computing the regularity of $M_L = R^1/I_L$, where I_L is the leading monomial ideal of I. This will be faster in general (since the associated free resolution will be easier to compute).

```
> wts := [ 1, 5, 9, 13, 17, 5, 1, 1, 1 ];
> K := GF(32003);
> R<x0,x1,x2,x3,x4,y0,y1,u,t> := PolynomialRing(K, wts);
> I := Ideal([
>     x0*y0 - y1^3*u^3 - x1*t,
>     x1*y1 - x0*u^5 - t^6,

Example H109E14

The following example shows how to explicitly use the resolution and syzygy functions to compute the ideal of a random space curve (in P^3) of genus 11. The construction is described in Section 1.2 of [ST02] and an equivalent form of the following computation is used by MAGMA's `RandomCurveByGenus` function to produce such curves.

We work over the field $GF(101)$, which will be referred to as K and the polynomial ring R will be the 4 variable polynomial ring over K. The construction begins by choosing a random 8 x 3 matrix with entries given by random linear and quadratic polynomials of R in appropriate positions. The minimal free resolution of the reduced module having this as the matrix of relations is computed. The image of the second boundary map of the resolution is the module referred to as $\mathcal{G}^*$ in the above reference. Taking the submatrix of rows of a certain weighting of the matrix defining this map, we multiply by a 6 x 8 matrix with random entries in K. The resulting matrix represents a map from a free module F of rank 6 to $\mathcal{G}^*$, whose kernel is isomorphic to R as a submodule of F. The 6 coordinates of a generator of the kernel generate the desired ideal I. This kernel is computed with a syzygy computation (note: we could also use `Kernel` for the matrix giving the map). We also check that the quotient module of I has a minimal free resolution of the right form.

```
> K := GF(101);
> R<x,y,z,t> := PolynomialRing(GF(101),4,"grevlex");
> v := [1,1,1,1,1,1,2,2];
> // generate the base random relations with appropriate linear and quadratic
> // entries using the Random function for multivariate polynomials.
> rels := [[Random(i,R,0): j in [1..3]] : i in v];
> Matrix(8,3,[TotalDegree(e) : e in &cat(rels)]);
```

```
[1 1 1]
[1 1 1]
[1 1 1]
[1 1 1]
[1 1 1]
[1 1 1]
[2 2 2]
[2 2 2]
> // get the quotient module
> F := RModule(R,3);
> M := quo<F|rels>;
```

Get the minimal free resolution and check that it has the correct Betti table.

```
> res := MinimalFreeResolution(M);
> BettiTable(res);
[
    [ 3, 6, 0, 0, 0 ],
    [ 0, 2, 8, 0, 0 ],
    [ 0, 0, 3, 10, 4 ]
]
0
```

Get the 2nd boundary map matrix and then the 8 x 8 submatrix of linear and quadratic entry rows.

```
> mat :=  Matrix(BoundaryMap(res,2));
> Nrows(mat); Ncols(mat);
11
8
> u := [1,1,2,2,2,2,2,2];
> mat := Matrix(R,[ri : i in [1..11] |
>          &and[(ri[j] eq 0) or (TotalDegree(ri[j]) eq u[j]):
>             j in [1..8]] where ri is Eltseq(mat[i])]);
> Nrows(mat); Ncols(mat);
8
8
> Matrix(8,8,[TotalDegree(m) :m in Eltseq(mat)]);
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
[1 1 2 2 2 2 2 2]
```

Now generate the random 6 x 8 matrix over K, compute the kernel of the composition via syzygies and generate the matrix I.

```
> mat1 := Matrix(R,6,8,[Random(K) : i in [1..48]]);
```

```
> matc := mat1*mat;
> F1 := EModule(R,[2-x : x in u]);
> syz := SyzygyModule(sub<F1|RowSequence(matc)>);
> B := MinimalBasis(syz);
> #B;
1
> I := ideal<R|Eltseq(B[1])>;
```

Finally, check I has the right dimension (2) and degree (12) and that R/I has the correct minimal free resolution with Betti table as given in [ST02].

```
> Dimension(I); Degree(I);
2 [ 3, 4 ]
12
> OC := QuotientModule(I);
> BettiTable(MinimalFreeResolution(OC));
[
    [ 1, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 0, 0, 0 ],
    [ 0, 6, 2, 0 ],
    [ 0, 0, 6, 3 ]
]
0
```

109.13 The Hom Module and Ext

`Hom(M, N)`

Given $R-$modules M and N, return $H = \mathrm{Hom}_R(M, N)$ as an abstract reduced module and a transfer map $f : H \to S$, where S is the set of all homomorphisms (of type `ModMPolHom`) from M to N.

Thus H is a module representing the set of all homomorphisms from M to N, while f maps an element $h \in H$ to an actual homomorphism from M to N (and the inverse image of an element of S under f gives a corresponding element of H).

If M and N are graded, then H is graded also, and the degree d_f of an element $f \in H$ is the degree of the corresponding homomorphism (so an element in M of degree d will be mapped by f to zero or an element of degree $d_f + d$ in N).

`Hom(C, N)`

Given a complex C of R-modules and an R-module N, return $\mathrm{Hom}_R(C, N)$. This is a new complex whose i-th term is $\mathrm{Hom}_R(C_i, N)$ (where C_i is the i-th term of C); the boundary maps are also derived from those of C in the natural way via the functor $\mathrm{Hom}_R(-, N)$ (see [Eis95, p.63]). Note that the direction of arrows in this complex is opposite to that of C.

`Ext(i, M, N)`

Given an integer $i \geq 0$ and R-modules M and N, return $\mathrm{Ext}^i(M, N)$. This is the homology at the i-th term of the complex $\mathrm{Hom}_R(C, N)$ where C is a free resolution of M.

Example H109E15

We construct a Hom module and explicit homomorphisms derived from it.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3);
> M := quo<GradedModule(R, 3) |
>     [x*y, x*z, y*z], [y, x, y],
>     [0, x^3 - x^2*z, x^2*y - x*y*z], [y*z, x^2, x*y]>;
> N := quo<GradedModule(R, 2) |
>     [x^2, y^2], [x^2, y*z], [x^2*z, x*y^2]>;
> M;

    [    0     0]
    [    0     0]
```

```
]
```

109.14 Tensor Products and Tor

`TensorProduct(M, N)`

Given $R-$modules M and N, return the tensor product $M \otimes_R N$ as an ambient module T, together with the associated map $f : M \times N \to T$. If M and N are graded, then T is graded also.

`TensorProduct(C, N)`

Given a complex C of R-modules and an R-module N, return $C \otimes_R N$. This is a new complex whose i-th term is $C_i \otimes_R N$ (where C_i is the i-th term of C); the boundary maps are also derived from those of C in the natural way via the functor $- \otimes_R N$ (see [Eis95, p.64]).

`Tor(i, M, N)`

Given an integer $i \geq 0$ and R-modules M and N, return $\mathrm{Tor}^i(M, N)$. This is the homology at the i-th term of the complex $C \otimes_R N$ where C is a free resolution of M.

Example H109E16

We construct a tensor product and some Tor modules for the same modules from the previous example.

```
> R<x,y,z> := PolynomialRing(RationalField(), 3);
> M := quo<GradedModule(R, 3) |
>     [x*y, x*z, y*z], [y, x, y],
>     [0, x^3 - x^2*z, x^2*y - x*y*z], [y*z, x^2, x*y]>;
> N := quo<GradedModule(R, 2) |
>     [x^2, y^2], [x^2, y*z], [x^2*z, x*y^2]>;
> T, f := TensorProduct(M, N);
> T;
Graded Module R^6/<relations>
Relations (Groebner basis):
[x^2, y*z, 0, 0, 0, 0],
[0, 0, 0, 0, x^2, y*z],
[0, 0, 0, 0, 0, x*y*z - y*z^2],
[x*y - y*z, 0, 0, 0, 0, 0],
[0, x*y - y*z, 0, 0, 0, 0],
[y*z, 0, 0, -y*z, x*y, 0],
[y, 0, x, 0, y, 0],
[0, y, 0, x, 0, y],
[0, y^2 - y*z, 0, 0, 0, 0],
[0, 0, 0, y^2 - y*z, 0, 0],
```

```
[0, 0, 0, 0, 0, y^2 - y*z],
[y*z^2, 0, 0, -y*z^2, 0, -y*z^2],
[0, y*z^2, 0, y*z^2, 0, y*z^2]
```

Note that f maps the cartesian product of M and N into T.

```
> f(<M.1, N.1>);
[1, 0, 0, 0, 0, 0]
> [f(<m, n>): n in Basis(N), m in Basis(M)];
[
    [1, 0, 0, 0, 0, 0],
    [0, 1, 0, 0, 0, 0],
    [0, 0, 1, 0, 0, 0],
    [0, 0, 0, 1, 0, 0],
    [0, 0, 0, 0, 1, 0],
    [0, 0, 0, 0, 0, 1]
]
```

Finally we construct associated Tor modules.

```
> Tor(0, M, N);
Graded Module R^6/<relations>
Relations:
[y, 0, x, 0, y, 0],
[0, y, 0, x, 0, y],
[0, 0, 0, 0, x*y - y*z, 0],
[0, 0, 0, 0, 0, x*y - y*z],
[y*z, x^2, 0, 0, 0, 0],
[x*y*z - y*z^2, 0, 0, 0, 0, 0],
[y^2 - y*z, 0, 0, 0, 0, 0],
[0, 0, y*z, x^2, 0, 0],
[0, 0, x*y*z - y*z^2, 0, 0, 0],
[0, 0, y^2 - y*z, 0, 0, 0],
[0, 0, 0, 0, y*z, x^2],
[0, 0, 0, 0, y^2 - y*z, 0],
[0, 0, 0, 0, x*y*z - y*z^2, 0]
> Tor(1, M, N);
Graded Module R^2/<relations> with grading [3, 3]
Relations:
[y - z,     0],
[    z,    -y],
[  z^2,  -x*y],
[    0,     0]
> Tor(2, M, N);
Free Reduced Module R^0
```

109.15 Cohomology Of Coherent Sheaves

We have implemented functions to compute the dimensions of cohomology groups of coherent sheaves on ordinary projective space over an (exact) field. The sheaves are represented by graded modules over the coordinate ring of the ambient projective space. The sheaf may arise naturally as one supported on a particular closed subscheme (*eg*, the structure sheaf of a projective variety) but it is a matter of indifference whether the sheaf is considered as lying on the subscheme or the entire ambient space (equivalently, whether the representing module is considered as a module over the coordinate ring of the ambient or the quotient coordinate ring of the subscheme) because the cohomology groups are naturally isomorphic. We plan to add a fuller package of functionality for coherent sheaves, but it is convenient to add the cohomology function now as the algorithm we use works equally efficiently (roughly speaking) when applied to any two graded modules that represent the same coherent sheaf.

The algorithm we have implemented is that of Decker, Eisenbud, Floystad and Schreyer which uses the Beilinson-Gelfand-Gelfand (BGG) correspondence to reduce the computation of the cohomology groups of the sheaf and its Serre twists to that of various graded free modules in the projective resolution of a module over a finite exterior (alternating) algebra.

`CohomologyDimension(M,r,n)`

Verbose `Cohom` *Maximum :* 1

M is a graded module over $P = k[x_0, .., x_m]$ with k an exact field. Let $\tilde{M}$ be the corresponding coherent sheaf on $Proj(P) = \mathbf{P}_k^m$. The function returns the k-dimension of the cohomology group $H^r(\mathbf{P}_k^m, \tilde{M}(n))$ where $\tilde{M}(n)$ is the nth Serre twist of $\tilde{M}$. n can be any integer and r a non-negative integer.

The algorithm used is based on the BGG correspondence. Details can be found in [EFS03] or see [DE02] for a slightly more computational description. Let A be the finite exterior algebra with $m+1$ generators, which is of dimension 2^{m+1} over k. The *Tate resolution* of $\tilde{M}$ is a doubly infinite exact sequence of graded free A-modules. Each cohomology group of a twist of $\tilde{M}$ is isomorphic as a k vector space to a particular graded piece of a particular term in the Tate resolution. In fact, we never need to explicitly compute the terms of the resolution of index $\geq reg(M)$ (the regularity of M) because they are pure graded of dimension given by the Hilbert polynomial of M.

The algorithm computes two consecutive terms in the Tate resolution at indices $\geq reg(M)$, and the A-homomorphism between them, from two corresponding graded pieces of M and the linear maps between them coming from multiplication by the base variables. Then the resolution is extended backwards as far as necessary by computing the A-projective resolution of the kernel of this A-homomorphism. The projective resolution is efficiently determined by non-commutative Gröbner basis computations. This uses the new MAGMA machinery for exterior algebras and their modules. The projective resolution information is cached so that repeated calls to the function for the same module M will require either no extra work or only an

extension to the part of the resolution already computed.

Example H109E17

We consider a random surface X in a family of Enriques surfaces of degree 9 in $\mathbf{P}^4$. It is defined by 15 degree 5 polynomials and we work over $\mathbf{F}_{17}$ to keep the input of reasonable size (it is still fairly large!).
The surface is non-singular with arithmetic genus (p_a), geometric genus (g) and irregularity q all zero. These are related generally for a non-singular surface by $g = p_a + q$ and p_a can be computed without cohomology machinery (from Hilbert polynomials). But cohomology of the structure sheaf of X and Serre duality is the easiest way to get g or q.

```
> R<x,y,z,t,u> := PolynomialRing(GF(17),5,"grevlex");
> I := ideal<R |[

>   14*x*y*z*u^2 + 10*x*z^2*u^2 + 11*x^2*t*u^2 + 11*x*z*t*u^2 + 3*x*z*u^3]>;
> X := Scheme(Proj(R),I); // define the surface
> // The structure sheaf O_X of X is represented by graded module R/I
> O_X := GradedModule(I); // R/I
```

We first compute the dimension of $H^0(O_X)$. This is fairly uninteresting (it's just 1) but after this computation, the cached data will allow the following cohomology calls to execute practically instantaneously.

```
> CohomologyDimension(O_X,0,0);  // dim H^0(O_X)
1
> // get the geometric genus and irregularity
> time CohomologyDimension(O_X,2,0); // dim H^2(O_X) = g
0
Time: 0.000
> time CohomologyDimension(O_X,1,0); // dim H^1(O_X) = q
0
Time: 0.000
> // => p_a(X)=0. Verify this.
> ArithmeticGenus(X);
0
```

We now compute a module representative of the canonical sheaf K_X of X. We can just take $Ext^2_R(M, R(-5))$. Then we check again that $H^0(K_X) = g$ is 0. Note that here the module representing K_X is maximal so that $H^0(K_X(n))$ is just the dimension of its nth graded part for any n. However, in other cases (where X is again *not* arithmetically Cohen-Macaulay) the Ext computation for K_X may not give the maximal representing module, so its 0th graded piece might have dimension less than g.

```
> K_X := Ext(2,O_X,RModule(R,[5]));
> K_X;
Reduced Module R^6/<relations> with grading [1, 1, 1, 1, 1, 1]
Quotient Relations:

110 INVARIANT THEORY

Chapter 110
INVARIANT THEORY

110.1 Introduction

MAGMA contains a powerful module for computing with invariant rings and fields of finite groups and algebraic groups. The algorithms for invariant theory of finite groups in MAGMA are based on those in the *Invar* package written in Maple, implemented by G. Kemper [Kem96], but also include many new ideas and improvements which are described in detail in a subsequent paper [KS97]. Since a detailed understanding of the latter paper is useful for better understanding of many of the functions in the chapter, it is recommended the paper be perused by anyone wishing to make serious applications of the functions.

Since V2.14, MAGMA also has algorithms for invariant theory of linear algebraic groups. In particular, Derksen's algorithm [Der99] and the algorithm by Beth and Müller-Quade [MQB99] have been implemented. These additions use code written by G. Kemper.

The primary goal of invariant theory in MAGMA is the computation of generators of the invariant ring or field of a given group, which may be finite or algebraic. The ground field may have arbitrary characteristic. In invariant theory of finite groups, the *modular case*, i.e., the case where the characteristic of the ground field K divides the group order, is of particular interest, since in that case there are still many theoretical questions unanswered. MAGMA also contains easy algorithms to calculate properties of modular invariant rings, such as the Hilbert series, the Cohen-Macaulay property, depth, and free resolutions.

The approach to calculating the invariant ring of a finite group is broken up into two major steps: first a system of *primary invariants* is constructed, i.e., homogeneous invariants $f_1, \ldots, f_n$ which are algebraically independent, such that the invariant ring is a finitely generated module over $A = K[f_1, \ldots, f_n]$. In the next step we calculate *secondary invariants*, which are generators of the invariant ring as an A-module.

Throughout this chapter, K will be a field and G is a group acting linearly on the n-dimensional vector space $V \cong K^n$ with basis $x_1, \ldots, x_n$. G may be a linear algebraic group, in which case K is assumed to be algebraically closed, or a finite matrix group, or a permutation group. G also acts on the symmetric algebra $K[V] = S(V)$, which is the multivariate polynomial ring $K[x_1, \ldots, x_n]$ in the variables $x_1, \ldots, x_n$. The invariant ring $R = \{f \in K[V] \mid f^\sigma = f \ \forall \sigma \in G\}$ is denoted by $K[V]^G$. The G-action extends naturally to the rational function field $K(V)$ on V, leading to the analogous definition of the invariants field $K(V)^G$.

Sections 110.2.1 through 110.7 describe the general setup of invariant theory in MAGMA. Section 110.8 is about computing invariants of specified degree. Sections 110.9 through 110.16 deal with functions for invariant rings of finite groups. The following Sections 110.17 and 110.18 present some functions whose scope is not limited to the context of invariant theory. Sections 110.20 and 110.21.3 are about functions for invariant rings

of algebraic groups and for invariant fields, respectively. The Section 110.19 gives information about some low-level control of the data structures associated to invariant theory. Finally, since V2.14, the Section 110.20 deals with invariant rings of algebraic groups and the Section 110.21.3 deals with invariant fields.

110.2 Invariant Rings of Finite Groups

110.2.1 Creation

Let G be a finite matrix or permutation group acting on the polynomial ring $P = K[x_1, \ldots, x_n]$ over the field K. MAGMA allows the construction of the invariant ring $R = K[V]^G$. The invariant ring R is a special structure which contains references to the group G and polynomial ring P. When the invariant ring R is created using the `InvariantRing` function, no explicit calculations are done until specifically invoked (e.g., by the `PrimaryInvariants` function). The elements of R are the polynomials of P which are invariant under the action of G. Note that the parent of such polynomials is still P – the invariant ring R is just a special structure which contains all the information about the invariant ring. The category of invariant rings is `RngInvar`.

`InvariantRing(G)`

`InvariantRing(G, K)`

Construct the invariant ring $R = K[V]^G$ of the finite matrix or permutation group G over the field K. For a matrix group G, G alone should be supplied, while for a permutation group G, G should be supplied, together with the field K. The appropriate multivariate polynomial ring P is automatically constructed. No other explicit calculations are done (e.g. computation of primary invariants).

110.2.2 Access

The following functions allow simple access to basic properties of invariant rings.

`Group(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return the group G.

`CoefficientRing(R)`

`CoefficientField(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return the coefficient field K.

`PolynomialRing(R)`

Given an invariant ring $R = K[V]^G$ of the group G of degree n over the field K, return the polynomial ring $P = K[x_1, \ldots, x_n]$ in which the invariants of R lie. P has the print names `"x1", "x2"`, etc. – the angle bracket notation or the . operator should be used to assign the variables of P to actual MAGMA variables.

`f in R`

Return whether the polynomial f is in $R = K[V]^G$. Note that the parent of f is always the polynomial ring P, never R, so a `true` result does not mean that the parent of f is R.

110.3 Group Actions on Polynomials

This section describes in detail the actions which groups have on multivariate polynomial rings.

110.4 Permutation Group Actions on Polynomials

If P is a polynomial ring in n indeterminates $x_1, \ldots, x_n$, over any coefficient ring, $\mathrm{Sym}(n)$ acts on P by permuting the indices of the indeterminates. Thus, the polynomial $f(x_1, \ldots, x_n)$ is mapped into the polynomial $f(x_{g(1)}, \ldots, x_{g(n)})$.

`f ^ g`

Given a polynomial f belonging to a polynomial ring having n indeterminates, and a permutation g belonging to a subgroup of $\mathrm{Sym}(\{1, \ldots, n\})$, return the image of f under g.

`f ^ G`

Given a polynomial f belonging to a polynomial ring having n indeterminates, and a permutation group G contained in $\mathrm{Sym}(\{1, \ldots, n\})$, return the orbit of f under G.

`IsInvariant(f, g)`

Given a polynomial f belonging to a polynomial ring having n indeterminates, and a permutation g of degree n or an element of a matrix group of degree n whose coefficient ring is the same as that of f, return whether f is an invariant of g, i.e., whether $f^g = f$.

`IsInvariant(f, G)`

Given a polynomial f belonging to a polynomial ring having n indeterminates, and a permutation group G of degree n or a matrix group of degree n whose coefficient ring is the same as that of f, return whether f is an invariant of G, i.e., whether $f^g = f$ for all $g \in G$.

110.5 Matrix Group Actions on Polynomials

If P is a polynomial ring in n indeterminates $x_1, \ldots, x_n$, over the ring S, then $\mathrm{GL}(n, S)$ acts on P as follows: Let $\mathbf{x}$ denote the vector $(x_1, \ldots, x_n)$. Then the image g of a polynomial f of P under the action of a matrix a of $\mathrm{GL}(n, S)$ is defined by $g(\mathbf{x}) = f(\mathbf{x} * a)$.

`f ^ a`

Given a polynomial f belonging to a polynomial ring having n indeterminates and coefficient ring S, and a matrix a belonging subgroup G of $\mathrm{GL}(n, S)$, return the image of f under a.

`f ^ G`

Given a polynomial f belonging to a polynomial ring having n indeterminates and coefficient ring S, and a to a subgroup of $\mathrm{GL}(n, S)$, return the orbit of f under G.

Example H110E1

We act on the polynomial ring in two indeterminates over the field $K = Q(\sqrt{2})$, by a cyclic subgroup of $\mathrm{GL}(2, K)$.

```
> K := QuadraticField(2);
> Aq := [ x / K.1 : x in [1, 1, -1, 1]];
> G := MatrixGroup<2, K | Aq>;
> P<x, y> := PolynomialRing(K, 2);
> f := x^2 + x * y + y^2;
> g := f^G.1;
> g;
1/2*x^2 + 3/2*y^2
> f^G;
{
   1/2*x^2 + 3/2*y^2,
   x^2 - x*y + y^2,
   x^2 + x*y + y^2,
   3/2*x^2 + 1/2*y^2
}
```

110.6 Algebraic Group Actions on Polynomials

In the invariant theory package of MAGMA, a linear algebraic group G is given by polynomials, say in variables $t_1, \ldots, t_m$, defined over some field K that is representable in MAGMA, as the affine variety over the algebraic closure $\bar{K}$ of K given by these polynomials. A G-module is given by a matrix $A \in K[t_1, \ldots, t_m]^{n \times n}$ such that a group element $(\eta_1, \ldots, \eta_m) \in G$ acts on $\bar{K}^n$ by the matrix obtained by substituting $(\eta_1, \ldots, \eta_m)$ into the polynomials occurring in the matrix A.

G then also acts on the ring of polynomials on $\bar{K}^n$ by

$$\sigma(f) = f \circ \sigma^{-1}$$

for $\sigma \in G$ and $f \in \bar{K}[x_1, \ldots, x_n]$. Since the algorithms in MAGMA do not work with the algebraic closure, single group elements are never dealt with. In fact, all relevant algorithms ony involve field elements of K, the field of definition.

110.7 Verbosity

The following procedure allows verbose information for the Invariant Theory algorithms to be displayed.

```
SetVerbose("Invariants", v)
```

(Procedure.) Set the verbose printing level for the Invariant Theory algorithms of MAGMA to be v. Currently the legal values for v are `true`, `false`, 0, 1, 2, 3, or 4 (`false` has the same effect as 0, and `true` has the same effect as 1). Level 1 gives a minimal amount of useful information during the running of all the algorithms while higher levels give more detailed information. For the primary invariants computation, the verbose output displays each possible degree list (degrees of the potential primary invariants) before and then tries to find primary invariants corresponding to this degree list. For the secondary invariants computation, in the non-modular case the algorithm loops over the necessary degrees in increasing order and computes the relevant new invariants; in the modular case the algorithm finds secondary invariants with respect to a subgroup and then performs a module syzygy computation. Full details of the algorithms are found in [KS97].

110.8 Construction of Invariants of Specified Degree

Let $R = K[V]^G$ be the invariant ring of the group G over the field K. Let $d \geq 0$ be a fixed integer. The homogeneous invariants in R of degree d form a vector space R_d over K.

There are two ways of explicitly constructing homogeneous invariants in R of degree d: the *Reynolds operator* method and the *linear algebra* method. Both methods are described in detail in [KS97].

The Reynolds operator method only works fro finite groups in the non-modular case. It takes a monomial of degree d and yields either the zero polynomial or a non-zero invariant of degree d. By applying it to several different monomials, a complete basis of R_d can be

constructed. If G is a permutation group, a simplified version of the Reynolds operator can always be used which is independent of the field K (and thus whether we are in the modular case or not).

The linear algebra method works in both the modular and non-modular cases and, with appropriate modifications, also for linear algebraic groups. It simply finds a basis for R_d in one step – it is not possible to find a single invariant alone by this method.

MAGMA provides the function `InvariantsOfDegree` to automatically compute a basis of R_d by a default appropriate method – the method can also be selected by a parameter. The function `InvariantsOfDegree` can also be given a positive integer k which is less than or equal to the dimension of R_d: in such a case, only k linearly independent invariants are computed. See also the functions `MonomialsOfDegree` and `MonomialsOfWeightedDegree` in the Ideal Theory chapter.

```
ReynoldsOperator(f, G)
```

Given a polynomial f and a matrix group G such that G can act on f, return the application of the Reynolds operator of G to f. (f need not be a monomial but may be a non-homogeneous polynomial.)

```
InvariantsOfDegree(R, d)
InvariantsOfDegree(G, d)
InvariantsOfDegree(G, K, d)
InvariantsOfDegree(G, P, d)
```

`Invariants` MONSTGELT *Default :* "*Both*"

Construct a K-basis of the space R_d of the homogeneous invariants of degree d in the invariant ring $R = K[V]^G$ of the group G over the field K as a sequence of polynomials. Either the invariant ring R, the group G (if a matrix group), or the group G (if a permutation group) together with the field K may be passed. A specific polynomial ring P compatible with G and K may be passed so that the returned invariants lie in P. The parameter `Invariants` may be supplied to select the method of the construction of the invariants: `"Reynolds"` (use the Reynolds operator), `"Linear"` (use the linear algebra method), or `"Both"` (use an appropriate combination of both methods). The default is `"Both"`.

```
InvariantsOfDegree(R, d, k)
InvariantsOfDegree(G, d, k)
InvariantsOfDegree(G, K, d, k)
InvariantsOfDegree(G, P, d, k)
```

`Invariants` MONSTGELT *Default :* "*Both*"

Construct k linearly independent homogeneous invariants of degree d in the invariant ring $R = K[V]^G$ of the group G over the field K as a sequence of polynomials, where k must be greater than or equal to 1 and less than or equal to the dimension of the

space R_d. Either the invariant ring R, the group G (if a matrix group), or the group G (if a permutation group) together with the field K may be passed. A specific polynomial ring P compatible with G and K may be passed so that the returned invariants lie in P. The parameter `Invariants` may be supplied to select the method of the construction of the invariants – see the last function.

Example H110E2

We demonstrate elementary uses of `ReynoldsOperator` and `InvariantsOfDegree`.

```
> K<z> := CyclotomicField(5);
> w := -z^3 - z^2;
> G := MatrixGroup<3,K |
>    [1,0,-w, 0,0,-1, 0,1,-w],
>    [-1,-1,w, -w,0,w, -w,0,1]>;
> P<x1,x2,x3> := PolynomialRing(K, 3);
> time ReynoldsOperator(x1^4, G);
(-z^3 - z^2 + 1)*x1^4 + (12/5*z^3 + 12/5*z^2 -
    4/5)*x1^3*x2 + (12/5*z^3 + 12/5*z^2 - 4/5)*x1^3*x3
    + (-14/5*z^3 - 14/5*z^2 + 14/5)*x1^2*x2^2 +
    (4/5*z^3 + 4/5*z^2 + 4/5)*x1^2*x2*x3 + (-14/5*z^3 -
    14/5*z^2 + 14/5)*x1^2*x3^2 + (12/5*z^3 + 12/5*z^2 -
    4/5)*x1*x2^3 + (4/5*z^3 + 4/5*z^2 + 4/5)*x1*x2^2*x3
    + (4/5*z^3 + 4/5*z^2 + 4/5)*x1*x2*x3^2 + (12/5*z^3
    + 12/5*z^2 - 4/5)*x1*x3^3 + (-z^3 - z^2 + 1)*x2^4 +
    (12/5*z^3 + 12/5*z^2 - 4/5)*x2^3*x3 + (-14/5*z^3 -
    14/5*z^2 + 14/5)*x2^2*x3^2 + (12/5*z^3 + 12/5*z^2 -
    4/5)*x2*x3^3 + (-z^3 - z^2 + 1)*x3^4
Time: 0.090
> time I20_1 := InvariantsOfDegree(G, 20, 1);

```
    x1^3*x2 + x1*x4^3 + x2^3*x3 + x3^3*x4,
    x1^3*x3 + x1*x3^3 + x2^3*x4 + x2*x4^3,
    x1^3*x4 + x1*x2^3 + x2*x3^3 + x3*x4^3,
    x1^2*x2^2 + x1^2*x4^2 + x2^2*x3^2 + x3^2*x4^2,
    x1^2*x2*x3 + x1*x2*x4^2 + x1*x3^2*x4 + x2^2*x3*x4,
    x1^2*x2*x4 + x1*x2^2*x3 + x1*x3*x4^2 + x2*x3^2*x4,
    x1^2*x3^2 + x2^2*x4^2,
    x1^2*x3*x4 + x1*x2^2*x4 + x1*x2*x3^2 + x2*x3*x4^2,
    x1*x2*x3*x4
]
```

`SetAllInvariantsOfDegree(R, d, Q)`

(Procedure.) Given an invariant ring $R = K[V]^G$, an integer $d \geq 0$, and a sequence Q consisting of k degree-d homogeneous invariants of G, set the internal list of all linearly-independent homogeneous invariants of degree d of R to be Q. Thus the elements of Q must describe a basis of the space of all homogeneous invariants of degree d of R. If the Hilbert Series of R is known, it will be used to check that the length of Q (the dimension of the basis) is correct.

Example H110E3

We demonstrate a simple use of `SetAllInvariantsOfDegree`.

```
> R := InvariantRing(CyclicGroup(4), GF(2));
> P<x1,x2,x3,x4> := PolynomialRing(R);
> L := [
>     x1^2 + x2^2 + x3^2 + x4^2,
>     x1*x2 + x1*x4 + x2*x3 + x3*x4,
>     x1*x3 + x2*x4
> ];
> SetAllInvariantsOfDegree(R, 2, L);
> InvariantsOfDegree(R, 2);
[
    x1^2 + x2^2 + x3^2 + x4^2,
    x1*x2 + x1*x4 + x2*x3 + x3*x4,
    x1*x3 + x2*x4
]
> PrimaryInvariants(R);
[
    x1 + x2 + x3 + x4,
    x1*x2 + x1*x4 + x2*x3 + x3*x4,
    x1*x3 + x2*x4,
    x1*x2*x3*x4
]
```

The following sections 110.9 through 110.16 all deal with invariant rings of finite groups.

110.9 Construction of G-modules

This section describes how one can create a finite-dimensional G-module corresponding to the action of a finite group G on a polynomial ring P. There are two ways one can create a finite-dimensional action: the action on the space of homogeneous polynomials of a fixed degree, or the action on the quotient space of polynomials by a zero-dimensional ideal (so the quotient has finite-dimension as a vector space). The functions in this section are also found in the chapter on general modules but are also included here since they are useful in Invariant Theory.

`GModule(G, P, d)`

Given a finite permutation or matrix group G of degree n, a polynomial ring $P = K[x_1, \ldots, x_n]$ over a field K, and a non-negative integer d, create the $K[G]$-module M corresponding to the action of G on the space of homogeneous polynomials of degree d of the polynomial ring P. The function also returns the isomorphism f between the space of homogeneous polynomials of degree d of P and M, together with an indexed set of monomials of degree d of P which correspond to the columns of M.

`GModule(G, I, J)`

Given a finite permutation or matrix group G of degree n, an ideal I of a multivariate polynomial ring $P = K[x_1, \ldots, x_n]$ over a field K, and a zero-dimensional subideal J of I, create the $K[G]$-module M corresponding to the action of G on the finite-dimensional quotient I/J. The function also returns the isomorphism f between the quotient space I/J and M, together with an indexed set of monomials of P, forming a (vector space) basis of I/J, and which correspond to the columns of M.

`GModule(G, Q)`

Given a finite permutation or matrix group G of degree n, and a finite-dimensional quotient ring $Q = I/J$ of a multivariate polynomial ring $P = K[x_1, \ldots, x_n]$ over a field K, create the $K[G]$-module M corresponding to the action of G on the finite-dimensional quotient Q. The function also returns the isomorphism f between the quotient ring Q and M, together with an indexed set of monomials of P, forming a (vector space) basis of Q, and which correspond to the columns of M.

Example H110E4

We demonstrate simple uses of the `GModule` function.

```
> q := 5;
> K := GF(q);
> G := GL(3, K);
> P<x, y, z> := PolynomialRing(K, 3);
> I := ideal< P | x^5 - x,y^5 - y, z^5 - z >;
> Q, rho := quo< P | I >;
> f := x^3 + x^2*y + y^3;
> M, phi:= GModule(G, P, I);
```

```
> Constituents(M);
[
    GModule of dimension 1 over GF(5),
    GModule of dimension 3 over GF(5),
    GModule of dimension 3 over GF(5),
    GModule of dimension 6 over GF(5),
    GModule of dimension 6 over GF(5),
    GModule of dimension 10 over GF(5),
    GModule of dimension 10 over GF(5),
    GModule of dimension 15 over GF(5),
    GModule of dimension 15 over GF(5),
    GModule of dimension 18 over GF(5),
    GModule of dimension 18 over GF(5),
    GModule of dimension 19 over GF(5)
]
> N := sub<M | phi(f)>;
> N;
GModule N of dimension 10 over GF(5)
> M5 := GModule(G, P, 5);
> M5;
GModule M5 of dimension 21 over GF(5)
> Constituents(M5);
[
    GModule of dimension 3 over GF(5),
    GModule of dimension 18 over GF(5)
]
```

110.10 Molien Series

Let $R = K[V]^G$ be the invariant ring of the finite group G over the field K. If G is a finite matrix group in the non-modular case or a permutation group (in *either* the modular or non-modular case) then the Molien series of G yields the Hilbert Series of R.

`MolienSeries(G)`

The Molien series of G, returned as an element of the rational function field $\mathbf{Z}(t)$. If G is a permutation group, the Molien series always exists and equals the Hilbert series of the invariant ring of G for any field. If G is a matrix group, the characteristic of the coefficient field of G must be coprime with the order of G.

`MolienSeriesApproximation(G, n)`

The Molien series of a permutation group G, or more precisely, an approximation to it, as a Laurent series with n known coefficients. In contrast to the `MolienSeries` function above, approximations can be computed for far larger groups.

Example H110E5

We compute the Molien series of a matrix G and verify that the coefficients of the corresponding power series match the number of independent invariants for each degree.

```
> K<z> := CyclotomicField(5);
> w := -z^3 - z^2;
> G := MatrixGroup<3,K |
>    [1,0,-w, 0,0,-1, 0,1,-w],
>    [-1,-1,w, -w,0,w, -w,0,1]>;
> M<t> := MolienSeries(G);
> M;
(-t^8 - t^7 + t^5 + t^4 + t^3 - t - 1)/(t^11 + t^10 -
    t^9 - 2*t^8 - t^7 + t^4 + 2*t^3 + t^2 - t - 1)
> P<u> := PowerSeriesRing(IntegerRing());
> P ! M;
1 + u^2 + u^4 + 2*u^6 + 2*u^8 + 3*u^10 + 4*u^12 +
    4*u^14 + u^15 + 5*u^16 + u^17 + 6*u^18 + u^19 +
    O(u^20)
> Coefficients(P ! M);
[ 1, 0, 1, 0, 1, 0, 2, 0, 2, 0, 3, 0, 4, 0, 4, 1, 5, 1,
6, 1 ]
> time [#InvariantsOfDegree(G, i): i in [0 .. 19]];
[ 1, 0, 1, 0, 1, 0, 2, 0, 2, 0, 3, 0, 4, 0, 4, 1, 5, 1,
6, 1 ]
```

110.11 Primary Invariants

Let $R = K[V]^G$ be the invariant ring of a finite group G over the field K and suppose the degree of G is n. A set of *primary invariants* of R is a set $\{f_1, \ldots, f_n\}$ of n algebraically independent homogeneous invariants of R such that the invariant ring R is a finitely generated module over $A = K[f_1, \ldots, f_n]$. A set of primary invariants always exists for any invariant ring R. The invocation `PrimaryInvariants(R)` allows automatic construction of primary invariants of R. The primary invariants are stored in R and recalled as necessary in subsequent computations.

The latest algorithm in MAGMA to compute primary invariants, due to G. Kemper [Kem99], now guarantees that the degrees of the primary invariants found by the algorithm are optimal (with respect to their product and then their sum).

`PrimaryInvariants(R)`

Construct optimal primary invariants for the invariant ring $R = K[V]^G$ as a sorted sequence (with increasing degrees) of n polynomials of R where n is the degree of G.

Example H110E6

We compute primary invariants for the "first A_5 in $\mathrm{SL}(\mathbf{F}_2)$", discussed in [AM94, p. 116]. The resulting degrees $3, 5, 8$, and 12 are necessarily optimal (see [Kem96]).

```
> K := GF(2);
> G := MatrixGroup<4, K |
>     [0,1,0,0, 1,1,0,0, 0,0,1,1, 0,0,1,0],
>     [1,0,0,0, 0,1,0,0, 1,0,1,0, 0,1,0,1],
>     [1,0,1,0, 0,1,0,1, 0,0,1,0, 0,0,0,1]>;
> R := InvariantRing(G);
> time p := PrimaryInvariants(R);
Time: 1.399
> [TotalDegree(f): f in p];
[ 3, 5, 8, 12 ]
```

110.12 Secondary Invariants

Let $R = K[V]^G$ be the invariant ring of a finite group G over the field K and suppose the degree of G is n. If $\{f_1, \ldots, f_n\}$ is a set of primary invariants for R then R can be viewed as a finitely generated module over the algebra $A = K[f_1, \ldots, f_n]$. A set of *secondary invariants* for R with respect to these primary invariants is set of module generators over A. The invocation `SecondaryInvariants(R)` allows automatic construction of secondary invariants of R. The secondary invariants are stored in R and recalled as necessary in subsequent computations. Different algorithms are needed for the modular and non-modular cases – see [KS97] for details.

`SecondaryInvariants(R)`

Construct secondary invariants for the invariant ring $R = K[V]^G$ (with respect to the current primary invariants of R, constructed automatically first if necessary) as a sorted sequence (with increasing degrees) of polynomials of R. The secondary invariants are *minimal*; i.e. they are a minimal generating set for R considered as a module over the algebra generated by the primary invariants.

`SecondaryInvariants(R, H)`

Construct secondary invariants for the *modular* invariant ring $R = K[V]^G$ (with respect to the current primary invariants of R), using the subgroup H. This function can only be used if R is a modular invariant ring. H must be a subgroup of the group G; first, secondary invariants are computed for $K[V]^H$ using the current primary invariants for G and then these secondary invariants are used in the manner described in [KS97]. The function `SecondaryInvariants(R)` (taking just the invariant ring R) follows a default strategy in which it tries to use this function with the best subgroup H appropriate. Thus usually using this function to specify a particular subgroup is not more helpful than the one-argument function but occasionally it may be.

`IrreducibleSecondaryInvariants(R)`

Return the irreducible secondary invariants of the invariant ring $R = K[V]^G$ (with respect to the current primary invariants of R, constructed automatically first if necessary) as a sequence of polynomials of R. These, together with the primary invariants of R, generate R as an algebra over K. In the modular case, these will be the same as the secondary invariants of R (excluding the polynomial 1) but in the non-modular case they may form a proper subsequence of the secondary invariants. Note that the expression of the secondary invariants in terms of the irreducible secondary invariants is given as the second return value of the function `Algebra` (see the section on the algebra of an invariant ring and algebraic relations below).

Example H110E7

We construct primary and then secondary invariants for the invariant ring R of the group G over $\mathbf{F}_2$, where G is the (permutation) cyclic group of order 4. Note that in this example Noether's degree bound (which holds for characteristic 0) is violated.

```
> K := GF(2);
> G := CyclicGroup(4);
> R := InvariantRing(G, K);
> time PrimaryInvariants(R);
[
    x1 + x2 + x3 + x4,
    x1*x2 + x1*x4 + x2*x3 + x3*x4,
    x1*x3 + x2*x4,
    x1*x2*x3*x4
]
Time: 0.040
> time SecondaryInvariants(R);

```

110.13 Fundamental Invariants

Let $R = K[V]^G$ be the invariant ring of the group G over the field K and suppose the degree of G is n. A set of *fundamental invariants* for R is a generating set of R as an algebra over K.

`FundamentalInvariants(R)`

`Al`	MonStgElt	*Default :* "*King*"
`MaxDegree`	RngIntElt	*Default :* 0

Construct fundamental invariants for the invariant ring $R = K[V]^G$ as a sorted sequence (with increasing degrees) of polynomials of R.

As of V2.15, if R is non-modular, then by default the fundamental invariants are computed via the algorithm of S.King [Kin07]; the alternative algorithm (always used in the modular case), which computes the fundamental invariants by minimalizing the union of the primary and secondary invariants of R, may be selected by setting the parameter `Al` to `"MinPrimSec"`.

If the fundamental invariants are known to be bounded by degree d, then the parameter `MaxDegree` may be set to d to assist the King algorithm with an early stopping condition in the non-modular case.

Example H110E8

We construct fundamental invariants for the invariant ring R of the group G over $\mathbf{Q}$, where G is permutation group consisting of two parallel copies of S_3 in degree 6. Notice that the sequence of fundamental invariants is shorter and simpler than the sequence consisting of the primary invariants combined with the secondary invariants.

```
> K := RationalField();
> G := PermutationGroup<6 | (1,2,3)(4,5,6), (1,2)(4,5)>;
> R := InvariantRing(G, K);
> PrimaryInvariants(R);
[
    x1 + x2 + x3,
    x4 + x5 + x6,
    x1^2 + x2^2 + x3^2,
    x4^2 + x5^2 + x6^2,
    x1^3 + x2^3 + x3^3,
    x4^3 + x5^3 + x6^3
]
> SecondaryInvariants(R);
[
    1,
    x1*x4 + x2*x5 + x3*x6,
    x1^2*x4 + x2^2*x5 + x3^2*x6,
    x1*x4^2 + x2*x5^2 + x3*x6^2,
    x1^2*x4^2 + 2*x1*x2*x4*x5 + 2*x1*x3*x4*x6 + x2^2*x5^2 + 2*x2*x3*x5*x6 +
        x3^2*x6^2,
```

```
    x1^3*x4^3 + x1^2*x2*x4*x5^2 + x1^2*x3*x4*x6^2 + x1*x2^2*x4^2*x5 +
        x1*x3^2*x4^2*x6 + x2^3*x5^3 + x2^2*x3*x5*x6^2 + x2*x3^2*x5^2*x6 +
        x3^3*x6^3
]
> FundamentalInvariants(R);
[
    x1 + x2 + x3,
    x4 + x5 + x6,
    x1^2 + x2^2 + x3^2,

    x4^2 + x5^2 + x6^2,
    x1^3 + x2^3 + x3^3,
    x1^2*x4 + x2^2*x5 + x3^2*x6,
    x1*x4^2 + x2*x5^2 + x3*x6^2,
    x4^3 + x5^3 + x6^3
]
```

Example H110E9

As in [Kin07], we compute fundamental invariants for the invariant rings for all transitive groups of degree 7 (in characteristic zero). For each group, we print its order and a summary of the degrees (where the i-th element of the sequence gives the number of fundamental invariants of degree i).

```
> function deg_summary(B)
>     degs := [TotalDegree(f): f in B];
>     return [#[j: j in degs | j eq d]: d in [1 .. Max(degs)]];
> end function;
>
> d := 7;
> time for i := 1 to NumberOfTransitiveGroups(d) do
>     G := TransitiveGroup(d, i);
>     R := InvariantRing(G, RationalField());
>     F := FundamentalInvariants(R);
>     printf "%o: Order: %o, Degrees: %o\n", i, #G, deg_summary(F);
> end for;
1: Order: 7, Degrees: [ 1, 3, 8, 12, 12, 6, 6 ]
2: Order: 14, Degrees: [ 1, 3, 4, 6, 6, 3, 3 ]
3: Order: 21, Degrees: [ 1, 1, 4, 5, 8, 8, 6 ]
4: Order: 42, Degrees: [ 1, 1, 2, 3, 4, 7, 7, 5, 1 ]
5: Order: 168, Degrees: [ 1, 1, 2, 2, 2, 2, 2 ]
6: Order: 2520, Degrees: [ 1, 1, 1, 1, 1, 1, 1, 0, 0, 0,
    0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1 ]
7: Order: 5040, Degrees: [ 1, 1, 1, 1, 1, 1, 1 ]
Time: 1.610
```

Instead of computing over the rational field, for each group G we can instead compute over $\mathbf{F}_p$, where p is the smallest prime which does not divide the order of G. This is faster, and it

is conjectured that the resulting degrees are always the same as for the computation over the rationals.

```
> d := 7;
> time for i := 1 to NumberOfTransitiveGroups(d) do
>     G := TransitiveGroup(d, i);
>     p := rep{p: p in [2 .. #G] | IsPrime(p) and #G mod p ne 0};
>     R := InvariantRing(G, GF(p));
>     F := FundamentalInvariants(R);
>     printf "%o: Order: %o, Degrees: %o\n", i, #G, deg_summary(F);
> end for;
1: Order: 7, Degrees: [ 1, 3, 8, 12, 12, 6, 6 ]
2: Order: 14, Degrees: [ 1, 3, 4, 6, 6, 3, 3 ]
3: Order: 21, Degrees: [ 1, 1, 4, 5, 8, 8, 6 ]
4: Order: 42, Degrees: [ 1, 1, 2, 3, 4, 7, 7, 5, 1 ]
5: Order: 168, Degrees: [ 1, 1, 2, 2, 2, 2, 2 ]
6: Order: 2520, Degrees: [ 1, 1, 1, 1, 1, 1, 1, 0, 0, 0,
    0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1 ]
7: Order: 5040, Degrees: [ 1, 1, 1, 1, 1, 1, 1 ]
Time: 0.790
```

Finally, we can do the same for all transitive groups of degree 8 in about 2 minutes.

```
> d := 8;
> time for i := 1 to NumberOfTransitiveGroups(d) do
>     G := TransitiveGroup(d, i);
>     p := rep{p: p in [2 .. #G] | IsPrime(p) and #G mod p ne 0};
>     R := InvariantRing(G, GF(p));
>     F := FundamentalInvariants(R);
>     printf "%o: Order: %o, Degrees: %o\n", i, #G, deg_summary(F);
> end for;
1: Order: 8, Degrees: [ 1, 4, 10, 18, 16, 8, 4, 4 ]
2: Order: 8, Degrees: [ 1, 5, 9, 16, 8 ]
3: Order: 8, Degrees: [ 1, 7, 7, 7 ]
4: Order: 8, Degrees: [ 1, 6, 8, 12, 5 ]
5: Order: 8, Degrees: [ 1, 4, 10, 19, 15, 7 ]
6: Order: 16, Degrees: [ 1, 4, 5, 9, 8, 4, 2, 2 ]
7: Order: 16, Degrees: [ 1, 3, 7, 12, 13, 9, 4, 4 ]
8: Order: 16, Degrees: [ 1, 3, 6, 11, 12, 7, 2, 2 ]

Time: 128.030
```

Example H110E10

We compute fundamental invariants of a degree-10 representation of S_5 acting on pairs. See [Kin07, p.11–12]. First we compute the fundamental invariants mod 7 of the permutation representation (very difficult in practice hitherto).

```
> G := PermutationGroup<10 | (2,5)(3,6)(4,7),(1,5,8,10,4)(2,6,9,3,7)>;
> #G;
120
> R := InvariantRing(G, GF(7));
> time F := FundamentalInvariants(R);
Time: 29.310
> {* Degree(f): f in F *};
```

```
{* 1, 2^^2, 3^^4, 4^^7, 5^^10, 6^^13, 7^^13, 8^^4, 9^^2 *}
```

Finally, we can compute a matrix representation of G as a direct sum of irreducible representations of degrees 1, 4 and 5. We then compute the fundamental invariants of the invariant ring of this representation mod 7.

```
> Q := RationalField();
> R0 := InvariantRing(G, Q);
> P0 := PolynomialRing(R0);
> M := GModule(G, Q);
> Gl := MatrixGroup(M);
> C := CharacterTable(Gl);
> Pi := [&+[Q!Integers()!c(g)*MatrixAlgebra(Q, 10)!g: g in Gl]/#G: c in C];
> Pi := [p: p in Pi | p ne 0];
> L := [sub<M | Image(p)>: p in Pi];
> G := MatrixGroup(DirectSum(DirectSum(L[1],L[2]),L[3]));
> G;
MatrixGroup(10, Rational Field)

110.14 The Module of an Invariant Ring

Let $R = K[V]^G$ be the invariant ring of a finite group G over the field K and suppose the degree of G is n. Suppose also that primary invariants $\{f_1, \ldots, f_n\}$ for R have been constructed, together with minimal secondary invariants $S = \{g_1, \ldots, g_m\}$ for R with respect to these primary invariants. (These secondary invariants may possess non-trivial module syzygies.) Then R can be considered as a module over the algebra $A = K[f_1, \ldots, f_n]$ with the minimal (module) generating set S.

To compute with this module structure of R easily, MAGMA automatically constructs the graded multivariate polynomial algebra $A' = K[t_1, \ldots, t_n]$ (with the weighted degree of the variable t_i defined to be the degree of f_i) which is isomorphic to A, and then constructs the graded module $M = A'^m/Q$ over A' with the quotient relations Q given by the syzygies of the g_i (and with the weighted degree of column i equal to the degree of g_i). The algebra A' is isomorphic to A under the map $t_i \mapsto f_i$, and the module M is isomorphic to R (considered as a module) under the map $M.i \mapsto g_i$ (extended by the isomorphism from A' onto A). (See the chapter on modules over $K[x_1, \ldots, x_n]$ for details on how to compute with the module M and an explanation of quotient relations, the unit vectors $M.i$, etc.) Once the module M is created, together with the isomorphism $f : R \to M$, one can apply f to a general element h of R to obtain the element of M corresponding to h. This effectively yields a representation of h as a sum $\sum_{i=1} ka_i g_i$ with $a_i \in A$ in terms of the primary and secondary invariants. This representation is also unique up to the relations given by the syzygies of the g_i.

When creating the module M, the coefficient ring A' of M is assigned the print names `"t1", "t2"`, etc. – the angle bracket notation or the . operator should be used to assign the variables of A' to actual MAGMA variables.

`Module(R)`

The module M isomorphic to $R = K[V]^G$, together with the isomorphism $f : R \to M$.

Example H110E11

We create the module M corresponding to the invariant ring R of the group G generated by the 4 by 4 Jordan block over $\mathbf{F}_3$.

```
> K := GF(3);
> G := MatrixGroup<4,K | [1,0,0,0, 1,1,0,0, 0,1,1,0, 0,0,1,1]>;

110.15 The Algebra of an Invariant Ring and Algebraic Relations

Let $R = K[V]^G$ be the invariant ring of a finite group G over the field K and suppose the degree of G is n. Suppose also that primary invariants $\{f_1, \ldots, f_n\}$ for R have been constructed, together with minimal secondary invariants $S = \{g_1, \ldots, g_m\}$ for R with respect to these primary invariants. Suppose also that the irreducible secondary invariants for R are $S = \{h_1, \ldots, h_r\}$ so that the g_i are power products of the h_i. We write $g_i = p_i(h_i)$ where the p_i are monomials of the indeterminates $t_1, \ldots, t_r$. Then R is generated as an algebra over K by the primary invariants $f_1, \ldots, f_n$ and the irreducible secondary invariants $h_1, \ldots, h_r$. MAGMA allows the construction of a polynomial algebra A with indeterminate names `"f1"`, `"f2"`, etc. corresponding to the primary invariants and indeterminate names `"h1"`, `"h2"`, etc. corresponding to the irreducible secondary invariants. Thus R can be regarded as an homomorphic image of A and finding the algebraic relations between these (algebra) generators of R yields a presentation of R as a quotient of a polynomial algebra. The functions in this section construct the algebra A and the algebraic relations for R. When creating the algebra A, the algebra A is assigned the print names `"f1", "f2",`

`"h1", "h2"`, etc. – the angle bracket notation or the . operator should be used to assign the variables of A to actual MAGMA variables.

`Algebra(R)`

Given an invariant ring $R = K[V]^G$, return the polynomial algebra $A = K[f_1, \ldots, f_n, h_1, \ldots, h_r]$ of which R is an homomorphic image. This function also returns a sequence Q giving the secondary invariants in terms of the irreducible secondary invariants as monomials in A. Thus $Q[i]$ is the monomial $p_i(t_i)$ mentioned in the introduction to this section. Note that the secondary invariant 1 is *not* an irreducible secondary invariant so no h-variable corresponds to it (the polynomial 1 in A simply corresponds to it).

`Relations(R)`

Given an invariant ring $R = K[V]^G$, return a (sorted) sequence L giving the algebraic relations amongst the algebra generators of R as elements of the algebra A corresponding to R. Thus R is isomorphic as an algebra (or ring) to the quotient of A by the ideal of A generated by the relations in L.

`RelationIdeal(R)`

Given an invariant ring $R = K[V]^G$, return the ideal of algebraic relations corresponding to R. This is simply the same as taking the ideal generated by the algebra A by the sequence L returned by the function `Relations(R)`.

`PrimaryAlgebra(R)`

Given an invariant ring $R = K[V]^G$, return the algebra corresponding to the primary invariants of R as a graded polynomial ring (with the weights corresponding to the degrees of the primary invariants).

`PrimaryIdeal(R)`

Given an invariant ring $R = K[V]^G$, return the ideal generated by the primary invariants of R (this is stored in R).

Example H110E12

We create the invariant ring $R = K[V]^G$ where G is a degree-6 permutation representation of the direct product $C_3 \times C_3$ of two cyclic groups both of order 3 and K is the rational field. We construct the algebra A and the sequence Q giving the secondary invariants in terms of the irreducible secondary invariants. We then note that the degree-6 secondary invariant is obtained as the product of two degree-3 irreducible secondary invariants. We then construct the list L of algebraic relations in A for R. Thus R is isomorphic to the quotient ring $A/ < L >$. We then construct an homomorphism h from A onto R and check that the relations in L are correct. Finally, we check that the Hilbert series of the (quotient by the) ideal of A generated by L is the same as the Hilbert series of R as expected.

```
> G := PermutationGroup<6 | (1, 2, 3), (4, 5, 6)>;
> R := InvariantRing(G, RationalField());

110.16 Properties of Invariant Rings

The following functions return non-trivial structural properties of invariant rings of finite groups.

`HilbertSeries(R)`

The Hilbert series of the invariant ring $R = K[V]^G$, returned as an element of the rational function field $\mathbf{Z}(t)$. The Molien series of G will be used if possible; otherwise (the modular matrix group case) secondary invariants for R will be constructed to determine the result.

`HilbertSeriesApproximation(R, n)`

The Hilbert series of the invariant ring $R = K[V]^G$, returned as a Laurent series with n known terms. The conjugacy classes of G will be used to compute the approximation.

`IsCohenMacaulay(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return `true` iff R is Cohen-Macaulay. This is always true in the non-modular case. Otherwise, secondary invariants for R will be constructed to determine the result.

`FreeResolution(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return a free resolution of (the module of) R. This is just the same as the invocation `FreeResolution(Module(R))`. The free resolution is returned as a sequence F such that $F[1]$ is M, $F[i+1]$ is the syzygy module of $F[i]$ for $i < \#F$, and the last element of F is free (its basis has no syzygies).

`MinimalFreeResolution(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return a minimal free resolution of (the module of) R. This is just the same as the invocation `MinimalFreeResolution(Module(R))`.

`HomologicalDimension(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return the homological dimension of R. This is just the length of a minimal free resolution of R minus 1 (taking account of the fact that the module M of R is always included in the free resolution).

`Depth(R)`

Given the invariant ring $R = K[V]^G$ of the group G over the field K, return the depth of R. This is $n-d$ by the Auslander-Buchsbaum formula, where n is the rank of R and d is the homological dimension of R.

Example H110E13

We construct a minimal free resolution of the invariant ring of the group generated by the degree-5 Jordan block over $\mathbf{F}_2$ and verify that the depth is 3.

```
> K:=GF(2);
> G := MatrixGroup<5,K | [1,0,0,0,0, 1,1,0,0,0, 0,1,1,0,0,
>                         0,0,1,1,0, 0,0,0,1,1]>;
> R := InvariantRing(G);
> time F := MinimalFreeResolution(R);
Time: 0.690
> F;
Chain complex with terms of degree 3 down to -1
Dimensions of terms: 0 1 7 22 0
> Depth(R);
3
> HomologicalDimension(R);
2
```

Sections 110.17 and 110.18 present functions whose scope is not limited to the context of invariant theory.

110.17 Steenrod Operations

`SteenrodOperation(f, i)`

The i-th Steenrod operation $P^i(f)$ of f, which must be a multivariate polynomial with coefficients in a finite field, and i must be a non-negative integer.

Example H110E14

We demonstrate an elementary use of Steenrod operations.

```
> K:=GF(3);
> F4:=MatrixGroup<4,K |
>   [-1,0,0,0, 1,1,0,0, 0,0,1,0, 0,0,0,1],

true
> f10 in R;
true
```

110.18 Minimalization and Homogeneous Module Testing

The following functions work with collections of polynomials which are considered as generators for subalgebras or submodules of a polynomial ring. They are repeated from the chapter on multivariate polynomials since they are used extremely often in invariant theory to express an invariant in terms of the primary and secondary invariants of an invariant ring. Full descriptions of the functions are not given here. See the descriptions in the chapter on multivariate polynomials.

`MinimalAlgebraGenerators(L)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose L is a set or sequence of k polynomials $p_1, \ldots, p_k$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by L. This function returns a minimal generating set of the algebra A as a (sorted) sequence of elements taken from L.

`HomogeneousModuleTest(P, S, F)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose P is a sequence of k homogeneous polynomials $p_1, \ldots, p_k$ in R and suppose S is a sequence of r homogeneous polynomials $s_1, \ldots, s_r$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by P and let $M = A[s_1, \ldots, s_r]$ be the A-module generated by S over A. Finally, suppose F is an element of R. This function returns whether F is in the module M (considered as a submodule of R). If the result is `true`, the function also returns a sequence $C = [c_1, \ldots, c_r]$ of length r with $c_i \in K[t_1, \ldots, t_r]$ such that $F = \sum_{i=1}^{r} c_i(p_1, \ldots, p_k) \cdot s_i$.

`HomogeneousModuleTest(P, S, L)`

Let $R = K[x_1, \ldots, x_n]$ be a polynomial ring of rank n over the field K. Suppose P is a sequence of k homogeneous polynomials $p_1, \ldots, p_k$ in R and suppose S is a sequence of r homogeneous polynomials $s_1, \ldots, s_r$ in R. Let $A = K[p_1, \ldots, p_k]$ be the subalgebra (*not* ideal) of R generated by P and let $M = A[s_1, \ldots, s_r]$ be the A-module generated by S over A. Finally, suppose L is a sequence of length l of elements of R which are all homogeneous of (weighted) degree d. This function returns parallel sequences B and V with the following properties:

(a) B is sequence of length l of booleans such that for $1 \leq i \leq l$, $B[i]$ is `true` iff $L[i]$ is in the module M.

(b) V is a sequence of length l consisting of sequences of length r and consisting of polynomials in the polynomial ring $T = K[t_1, \ldots, t_r]$. (The polynomial ring $T = K[t_1, \ldots, t_r]$ is constructed separately but automatically with the print names `t1`, `t2`, etc.) If $B[i]$ is `false` (so $L[i]$ is not in M), $V[i]$ is a sequence of r zero polynomials. Otherwise $V[i]$ is a sequence of r polynomials $c_{i,1}, \ldots, c_{i,r}$ in T such that that $L[i] = \sum_{j=1}^{r} c_{i,j}(p_1, \ldots, p_k) \cdot s_j$.

Example H110E15

We demonstrate how the function `MinimalAlgebraGenerators` can be used to compute fundamental invariants (in fact, the MAGMA function `FundamentalInvariants` does just this).

```
> K := RationalField();
> G := PermutationGroup<6 | (1,2,3)(4,5,6), (1,2)(4,5)>;
> R := InvariantRing(G, K);
> P := PrimaryInvariants(R);
> P;

110.19 Attributes of Invariant Rings and Fields

In this section we list various attributes of invariant rings which can be examined and set by the user. This allows low-level control of information stored in invariant rings or fields. Note that when the user sets an attribute, only minimal testing can be done on the value so if an incorrect value is set, unpredictable results may occur. Note also that if an attribute is not set, referring to it in an expression (using the ‘ operator) will *not* trigger the calculation of it (while intrinsic functions do); rather an error will ensue. Use the `assigned` operator to test whether an attribute is set.

`R‘PrimaryInvariants`

The attribute for the primary invariants of invariant ring $R = K[V]^G$. If the attribute `R‘PrimaryInvariants` is examined, either the current primary invariants of R are set so they are returned or an error results. If the attribute `R‘PrimaryInvariants` is set by assignment, it must be sequence of n algebraically-independent invariants of G, where n is the rank of R. MAGMA will not necessarily check that this condition is met since that may be very time-consuming. If the attribute is already set, the new value must be the same as the old value. Note that this attribute is useful when it is desired to compute secondary invariants of R with respect to some specially constructed primary invariants which would not be constructed by the automatic algorithm in MAGMA.

R‘SecondaryInvariants

The attribute for the secondary invariants of invariant ring $R = K[V]^G$. If the attribute R‘SecondaryInvariants is examined, either the current primary invariants of R are set so they are returned or an error results. If the attribute R‘SecondaryInvariants is set by assignment to Q, primary invariants for R must already be defined, and Q must be sequence of secondary invariants with respect to the primary invariants of R. MAGMA will not necessarily check that this condition is met since that may be very time-consuming. If the attribute is already set, the new value must be the same as the old value.

R‘HilbertSeries

The attribute for the Hilbert series of invariant ring $R = K[V]^G$. If the attribute R‘HilbertSeries is examined, either the Hilbert series of R is computed so it is returned or an error results. If the attribute R‘HilbertSeries is set by assignment to H, H must be rational function in the function field $Z(t)$ and equal to the Hilbert series of R. MAGMA will not necessarily check that this condition is met since that may be very time-consuming. If the attribute is already set, the new value must be the same as the old value.

Example H110E17

We demonstrate elementary uses of attributes.

```
> // Create group G and subgroup H of G and invariant rings
> // RG and RH of G and H respectively.

110.20 Invariant Rings of Linear Algebraic Groups

By definition, a linear algebraic group is an affine variety G together with morphisms giving G the structure of a group. In the invariant theory algorithms of MAGMA, the group structure of G is nowhere required. Therefore an algebraic group will be defined by simply giving polynomials defining G as an affine variety. A G-module of an algebraic group is a finite dimensional vector space K^n together with a morphism $G \to \mathrm{GL}_n$ of algebraic groups. In MAGMA, such a morphism is given by specifying an n by n matrix whose entries are polynomials in the same variables as the polynomials specifying G (for more details, see section 110.6). An invariant ring of a linear algebraic group is constructed by giving a linear algebraic group together with a G-module. MAGMA makes no checks that the variety defined by the user has a multiplication making it into an algebraic group, or that the morphism $G \to \mathrm{GL}_n(K)$ really provides an action of G. If they do not, the computations will have unpredictable results. Likewise, MAGMA is unable to decide whether an algebraic group is reductive or linearly reductive. Therefore the user should indicate whether a group has these properties at creation by the options described below. This is important because Derksen's algorithm only works for linearly reductive groups.

110.20.1 Creation

`InvariantRing(I, A)`

`Reductive`	BoolElt	*Default :* `false`
`LinearlyReductive`	BoolElt	*Default :* `false`
`PolynomialRing`	RngMPol	*Default :*

Construct the invariant ring R for the algebraic group G defined by the ideal I and representation matrix A.

If the parameter `Reductive` is set to `true`, then G is assumed to be reductive, while if the parameter `LinearlyReductive` is set to `true`, then G is assumed to be linearly reductive.

If the parameter `PolynomialRing` is set to a value P, then P is used as the polynomial ring in which the invariants of R will lie.

`BinaryForms(N, p)`

`BinaryForms(n, p)`

Let $N = [n_1, \ldots, n_k]$ be a sequence of positive integers and let p be a positive prime or zero. Let $G = \mathrm{SL}_2(K)$ with K an algebraically closed field of characteristic p. This function defines the action on a direct sum of spaces of binary forms with degrees given by the n_i. The function returns three items: the ideal I_G defining G as an algebraic group, the representation matrix A (as a sequence of sequences of polynomials), and a polynomial ring on which G acts with appropriate naming of variables.

The second version of the function is given an integer n, and takes N to be $[n]$.

110.20.2 Access

`GroupIdeal(R)`

Given an invariant ring R defined over an algebraic group G, return the ideal I defining G.

`Representation(R)`

Given an invariant ring R defined over an algebraic group G, return the representation matrix A for G.

110.20.3 Functions

`InvariantsOfDegree(R, d)`

Return a K-basis of the space R_d of the homogeneous invariants of degree d in the invariant ring $R = K[V]^G$ of the algebraic group G over the field K as a sequence of polynomials.

`FundamentalInvariants(R)`

`Optimize`	BoolElt	*Default :* `true`
`Minimize`	BoolElt	*Default :* `true`
`MinimizeHilbert`	BoolElt	*Default :* `true`
`Force`	BoolElt	*Default :* `false`

Given an invariant ring R defined over an algebraic group, return a sequence of fundamental invariants of R, using Derksen's algorithm.

By default, the computation of homogeneous invariants is optimized by extending at each the degree the basis obtained from multiplying lower-degree invariants by appropriate monomials. This method can be suppressed by setting `Optimize` to `false`. By default the generators will be minimal. By setting the parameter `Minimize` to `false`, no minimization will be attempted. By setting the parameter `MinimizeHilbert` to `false`, the basis of the Hilbert ideal will not be minimized.

By default the group must be linearly reductive. Setting the parameter `Force` to `true` will force the application of Derksen's algorithm even though the group may not be linearly reductive.

`DerksenIdeal(R)`

Given an invariant ring R defined over an algebraic group, return a sequence of generators of the Derksen ideal of R. The Derksen ideal is an ideal D of $P[y_1, \ldots, y_n]$, where $P = K[x_1, \ldots, x_n]$ is the ambient polynomial ring of R, and the y_i are new indeterminates. By definition, D is the intersection of all the ideals

$$\langle y_1 - g(x_1), \ldots, y_n - g(x_n) \rangle$$

for all $g \in G$, the group of R. Geometrically, D is the vanishing ideal of the subset

$$\{(x, g(x)) | x \in K^n, g \in G\}$$

of the cartesian product $K^n \times K^n$.

`HilbertIdeal(R)`

`Minimize`	BoolElt	*Default :* `true`
`Force`	BoolElt	*Default :* `false`

Given an invariant ring R defined over a linear algebraic group, return the Hilbert ideal of R. This is the ideal in the polynomial ring generated by all non-constant, homogeneous invariants. The result is a sequence of homogeneous generators (not necessarily invariant).

By default the generators will be minimal. By setting the parameter `Minimize` to `false`, no minimization will be attempted. Also, setting the parameter `Force` to `true` will force the application of Derksen's algorithm even though the group may not be linearly reductive.

Example H110E18

We consider invariant ring of the group $G = SL_2(\mathbf{Q})$, which is is characterised by the equation $\det(A) = 1$.

```
> Q := RationalField();
> P<[a]>:=PolynomialRing(Q, 4);
> A := MatrixRing(P,2)!a;
> IG := ideal<P | Determinant(A) - 1>;
> IG;
Ideal of Polynomial ring of rank 4 over Rational Field
Lexicographical Order
Variables: a[1], a[2], a[3], a[4]
Basis:
[
    a[1]*a[4] - a[2]*a[3] - 1
]
```

The simultaneous action of G on three vectors is given by the matrix $I_3 \otimes A$:

```
> T := TensorProduct(MatrixRing(P, 3) ! 1, A);
> T;
[a[1] a[2]    0    0    0    0]
[a[3] a[4]    0    0    0    0]
[   0    0 a[1] a[2]    0    0]
[   0    0 a[3] a[4]    0    0]
[   0    0    0    0 a[1] a[2]]
[   0    0    0    0 a[3] a[4]]
```

We create the invariant ring R of G (which is reductive) with this action and compute fundamental invariants.

```
> IR := InvariantRing(IG, T: Reductive);
> FundamentalInvariants(IR);
[
    x3*x6 - x4*x5,
    x1*x6 - x2*x5,
    x1*x4 - x2*x3
]
```

We see that there are three fundamental invariants. It is well known that the invariant ring of the simultaneous action of SL_n on m vectors is generated by the minors of the $n \times m$ matrix formed by the vectors. We can see this in the present case.

```
> R<x1,x2,x3,x4,x5,x6> := PolynomialRing(Q, 6);
> M := Matrix([[x1,x3,x5], [x2,x4,x6]]);
> M;
[x1 x3 x5]
[x2 x4 x6]
> Minors(M, 2);
[
```

```
    x1*x4 - x2*x3,
    -x1*x6 + x2*x5,
    x3*x6 - x4*x5
]
```

Example H110E19

As a second example, we consider the representation of the group $SL_2(\mathbf{Q}) \times SL_2(\mathbf{Q}) \times SL_2(\mathbf{Q})$ given by the tensor product of the canonical representation:

```
> n:=3;
> P<[x]>:=PolynomialRing(RationalField(), n*4, "grevlex");
> L_A := [MatrixRing(P,2)!x[i..i+3]:i in [1..n*4 by 4]];
> IG := ideal<P|[Determinant(A)-1:A in L_A]>;
> IG;
Ideal of Polynomial ring of rank 12 over Rational Field
Graded Reverse Lexicographical Order
Variables: x[1], x[2], x[3], x[4], x[5], x[6], x[7], x[8],
x[9], x[10], x[11], x[12]
Basis:
[
    -x[2]*x[3] + x[1]*x[4] - 1,
    -x[6]*x[7] + x[5]*x[8] - 1,
    -x[10]*x[11] + x[9]*x[12] - 1
]
>
> M:=L_A[1];
> for i:=2 to n do
>     M:=TensorProduct(M,L_A[i]);
> end for;
> M;
[x[1]*x[5]*x[9]   x[1]*x[5]*x[10]   x[1]*x[6]*x[9]   x[1]*x[6]*x[10]
    x[2]*x[5]*x[9]   x[2]*x[5]*x[10]   x[2]*x[6]*x[9]   x[2]*x[6]*x[10]]
[x[1]*x[5]*x[11]   x[1]*x[5]*x[12]   x[1]*x[6]*x[11]   x[1]*x[6]*x[12]
    x[2]*x[5]*x[11]   x[2]*x[5]*x[12]   x[2]*x[6]*x[11]   x[2]*x[6]*x[12]]
[x[1]*x[7]*x[9]   x[1]*x[7]*x[10]   x[1]*x[8]*x[9]   x[1]*x[8]*x[10]
    x[2]*x[7]*x[9]   x[2]*x[7]*x[10]   x[2]*x[8]*x[9]   x[2]*x[8]*x[10]]
[x[1]*x[7]*x[11]   x[1]*x[7]*x[12]   x[1]*x[8]*x[11]   x[1]*x[8]*x[12]
    x[2]*x[7]*x[11]   x[2]*x[7]*x[12]   x[2]*x[8]*x[11]   x[2]*x[8]*x[12]]
[x[3]*x[5]*x[9]   x[3]*x[5]*x[10]   x[3]*x[6]*x[9]   x[3]*x[6]*x[10]
    x[4]*x[5]*x[9]   x[4]*x[5]*x[10]   x[4]*x[6]*x[9]   x[4]*x[6]*x[10]]
[x[3]*x[5]*x[11]   x[3]*x[5]*x[12]   x[3]*x[6]*x[11]   x[3]*x[6]*x[12]
    x[4]*x[5]*x[11]   x[4]*x[5]*x[12]   x[4]*x[6]*x[11]   x[4]*x[6]*x[12]]
[x[3]*x[7]*x[9]   x[3]*x[7]*x[10]   x[3]*x[8]*x[9]   x[3]*x[8]*x[10]
    x[4]*x[7]*x[9]   x[4]*x[7]*x[10]   x[4]*x[8]*x[9]   x[4]*x[8]*x[10]]
[x[3]*x[7]*x[11]   x[3]*x[7]*x[12]   x[3]*x[8]*x[11]   x[3]*x[8]*x[12]
    x[4]*x[7]*x[11]   x[4]*x[7]*x[12]   x[4]*x[8]*x[11]   x[4]*x[8]*x[12]]
> IR:=InvariantRing(IG, M: Reductive);
```

```
> time FundamentalInvariants(IR);
[
    x1^2*x8^2 - 2*x1*x2*x7*x8 - 2*x1*x3*x6*x8 - 2*x1*x4*x5*x8 +
        4*x1*x4*x6*x7 + x2^2*x7^2 + 4*x2*x3*x5*x8 - 2*x2*x3*x6*x7 -
        2*x2*x4*x5*x7 + x3^2*x6^2 - 2*x3*x4*x5*x6 + x4^2*x5^2
]
Time: 0.610
> time DerksenIdeal(IR);
[
    y1^2*y8^2 - 2*y1*y2*y7*y8 - 2*y1*y3*y6*y8 - 2*y1*y4*y5*y8 + 4*y1*y4*y6*y7 +
        y2^2*y7^2 + 4*y2*y3*y5*y8 - 2*y2*y3*y6*y7 - 2*y2*y4*y5*y7 + y3^2*y6^2 -
        2*y3*y4*y5*y6 + y4^2*y5^2 - x1^2*x8^2 + 2*x1*x2*x7*x8 + 2*x1*x3*x6*x8 +
        2*x1*x4*x5*x8 - 4*x1*x4*x6*x7 - x2^2*x7^2 - 4*x2*x3*x5*x8 +
        2*x2*x3*x6*x7 + 2*x2*x4*x5*x7 - x3^2*x6^2 + 2*x3*x4*x5*x6 - x4^2*x5^2
]
Time: 0.010
> time HilbertIdeal(IR);
[
    x1^2*x8^2 - 2*x1*x2*x7*x8 - 2*x1*x3*x6*x8 - 2*x1*x4*x5*x8 + 4*x1*x4*x6*x7 +
        x2^2*x7^2 + 4*x2*x3*x5*x8 - 2*x2*x3*x6*x7 - 2*x2*x4*x5*x7 + x3^2*x6^2 -
        2*x3*x4*x5*x6 + x4^2*x5^2
]
Time: 0.000
```

So in this case, we find that the invariant ring is generated by a single polynomial.

Example H110E20

We compute fundamental invariants for the invariant ring of $G = \mathrm{SL}_2(\mathbf{Q})$ acting on a space of binary forms.

```
> IG, A := BinaryForms([1,1,2,2], 0);
> IG;
Ideal of Polynomial ring of rank 4 over Rational Field
Lexicographical Order
Variables: t1, t2, t3, t4
Basis:
[
    t1*t4 - t2*t3 - 1
]
> A;
[t4   -t3   0   0   0   0   0   0   0   0]
[-t2   t1   0   0   0   0   0   0   0   0]
[0   0   t4   -t3   0   0   0   0   0   0]
[0   0   -t2   t1   0   0   0   0   0   0]
[0   0   0   0   t4^2   -t3*t4   t3^2   0   0   0]

Derksen's algorithm) is only possible for linearly reductive groups
```

110.21 Invariant Fields

If G is a group acting on a polynomial ring $K[x_1, \ldots, x_n]$, it also acts on the rational function field $K(x_1, \ldots, x_n)$ by homomorphic extension. The invariants field $K(x_1, \ldots, x_n)^G$ is the field consisting of all functions which are fixed by G. MAGMA allows the construction of the invariant field by the function `InvariantField`. All that was said above about possible arguments of `InvariantRing` and access functions for invariant rings carries over to invariant fields. The category of invariant fields is `FldInvar`.

110.21.1 Creation

`InvariantField(G, K)`

`InvariantField(G)`

`InvariantField(I, A)`

`Reductive`	BOOLELT	*Default :* `false`
`LinearlyReductive`	BOOLELT	*Default :* `false`
`FunctionField`	FLDFUNRAT	*Default :*

Create the invariant field for the group G over the field K. The arguments and parameters are the same as for the function `InvariantRing`, in the three cases of permutation groups, matrix groups, and algebraic groups.

110.21.2 Access

`FunctionField(F)`

Given an invariant field F, return the underlying function field of F.

`Group(F)`

Given an invariant field F, return the underlying group of F.

`GroupIdeal(F)`

Given an invariant field F defined over an algebraic group G, return the ideal I defining G.

`Representation(F)`

Given an invariant field F defined over an algebraic group G, return the representation matrix A for G.

110.21.3 Functions for Invariant Fields

This section describes functions that apply to invariant fields.

`FundamentalInvariants(F)`

`Al`	MonStgElt	*Default :* "*BethMuellerQuade*"
`Minimize`	BoolElt	*Default :* `true`
`Min`	RngIntElt	*Default :* 0
`BottomUpTo`	RngIntElt	*Default :* 0

Given an invariant field F, return a sequence of fundamental invariants of F which generate F as an algebra over the base field of the ambient rational function field of F.

By default this function uses the algorithm of Beth and Müller-Quade [MQB99]. By setting the parameter `Al` to `"FleischmannKemperWoodcock"`, an alternative algorithm of Fleischmann, Kemper and Woodcock will be used.

By default the returned invariants will be minimal (in the sense of 'non-redundant'). By setting the parameter `Minimize` to `false`, no minimization will be attempted. The other parameters apply to the minimization and are as in the function `MinimizeGenerators` below.

`DerksenIdeal(F)`

Given an invariant field F, return the Derksen ideal of F. This is an ideal D in $K[y_1 \dots y_n]$, where $K = k(x_1 \dots x_n)$ is the ambient rational function field of F, and the y_i are new indeterminates. By definition, D is the intersection of all the ideals

$$< y_1 - g(x_1), \dots, y_n - g(x_n) >$$

for $g \in G$, the group of R. The function returns D as an ideal with a Groebner basis.

`MinimizeGenerators(L)`

`Min`	RngIntElt	*Default :* 0
`BottomUpTo`	RngIntElt	*Default :* 0

Suppose L is a set or sequence of non-constant elements of a rational function field. This function selects a minimal (in the sense of 'irredundant') subset of L which generates the same subfield as L. The function returns a sequence of such minimal generators.

If the parameter `Min` is set to $m > 0$, then the function stops when a generating set with m elements is reached ($m = 0$ is the default and implies no limit).

If the parameter `BottomUpTo` is set to $b > 0$, then the function first tries to eliminate generators by testing if they lie in the subfield generated by a small number of elements from L. This small number is limited by b.

`QuadeIdeal(L)`

`Fy`	BoolElt	*Default :*
`LargeIdeal`	BoolElt	*Default :* `false`

Suppose L is a non-empty set or sequence of non-constant elements from a rational function field $F = k(x_1, \ldots, x_n)$, generating a subfield $K = k(L)$. The Quade ideal, introduced in [MQS99], is the ideal in $F[y_1, \ldots, y_n]$ generated by the kernel of the map $K[y_1, \ldots, y_n] \to F$ given by $y_i \mapsto x_i$. This function returns the Quade ideal (with its basis being a Groebner basis).

The parameter `Fy` may be set to a polynomial ring P of rank n over F, so that the result is an ideal of P. If the parameter `LargeIdeal` is set to `true`, then an ideal in a larger polynomial ring is returned, whose intersection with $F[y_1, \ldots, y_n]$ is the Quade ideal.

Example H110E22

This example works with the invariant field of the finite group C_3 over the rational field.

```
> IF := InvariantField(CyclicGroup(3), RationalField());
> time L := FundamentalInvariants(IF);
Time: 1.780
> L;
[
    x1 + x2 + x3,
    (x1^2*x2 - 3*x1*x2*x3 + x1*x3^2 + x2^2*x3)/(x1^2 - x1*x2 - x1*x3 + x2^2 -
        x2*x3 + x3^2),
    (x1^3 - x1^2*x3 - x1*x2^2 + x2^3 - x2*x3^2 + x3^3)/(x1^2 - x1*x2 - x1*x3 +
        x2^2 - x2*x3 + x3^2)
]
> time DerksenIdeal(IF);

        x1^2*x2*x3 + x1^2*x3^2 - x1*x2^2*x3 - x1*x2*x3^2 + x2^2*x3^2)/(x1^2 -
        x1*x2 - x1*x3 + x2^2 - x2*x3 + x3^2),
    y3^2 + (x1^2*x2 - x1^2*x3 - x1*x2^2 + x1*x3^2 + x2^2*x3 - x2*x3^2)/(x1^2 -
        x1*x2 - x1*x3 + x2^2 - x2*x3 + x3^2)*y2 + (-x1^3 + x1^2*x2 + x1*x3^2 -
        x2^3 + x2^2*x3 - x3^3)/(x1^2 - x1*x2 - x1*x3 + x2^2 - x2*x3 + x3^2)*y3 +
        (x1^3*x3 - x1^2*x2^2 - x1^2*x3^2 + x1*x2^3 - x2^2*x3^2 + x2*x3^3)/(x1^2
        - x1*x2 - x1*x3 + x2^2 - x2*x3 + x3^2),
    y1 + y2 + y3 - x1 - x2 - x3
]
```

Example H110E23

We can compute with the invariant field of the non-reductive group presented above.

```
> K := RationalField();
> Pa<a,b> := PolynomialRing(K, 2);
> IG := ideal<Pa|>;
> A := Matrix(7,
> [1, 0, 0, 0, 0, 0, 0, a, 1, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0,

110.22 Invariants of the Symmetric Group

MAGMA includes basic functions for working with symmetric polynomials, which are invariants of the symmetric group.

`ElementarySymmetricPolynomial(P, k)`

Given a polynomial ring P of rank n, and an integer k with $1 \leq k \leq n$, return the k-th elementary symmetric polynomial of P.

`IsSymmetric(f)`

`IsSymmetric(f, S)`

Given a polynomial f from a polynomial ring P of rank n, return whether f is a symmetric polynomial of P (i.e., is symmetric in all the n variables of P). If the answer is true, a polynomial g from a new polynomial ring of rank n is returned such that $f = g(e_1, \ldots, e_n)$, where e_i is the i-th elementary symmetric polynomial of P. If g is desired to be a member of a particular polynomial ring S of rank n (to obtain predetermined names of variables, for example), then S may also be passed.

Example H110E24

We create a symmetric polynomial from $\mathbf{Q}[a, b, c, d]$ and express it in terms of the elementary symmetric polynomials.

```
> P<a, b, c, d> := PolynomialRing(RationalField(), 4, "grevlex");
> f :=
> a^2*b^2*c*d + a^2*b*c^2*d + a*b^2*c^2*d + a^2*b*c*d^2 + a*b^2*c*d^2 +
>     a*b*c^2*d^2 - a^2*b^2*c - a^2*b*c^2 - a*b^2*c^2 - a^2*b^2*d -
>     3*a^2*b*c*d - 3*a*b^2*c*d - a^2*c^2*d - 3*a*b*c^2*d - b^2*c^2*d -
>     a^2*b*d^2 - a*b^2*d^2 - a^2*c*d^2 - 3*a*b*c*d^2 - b^2*c*d^2 -
>     a*c^2*d^2 - b*c^2*d^2 + a + b + c + d;
> // Check orbit under Sym(4) has size one:
> #(f^Sym(4));
1
> Q<e1, e2, e3, e4> := PolynomialRing(RationalField(), 4);
> l, E := IsSymmetric(f, Q);
> l;
true
> E;
e1 - e2*e3 + e2*e4
```

In the following example, we use a rational function field to define parameters a and b which occur as coefficients of the symmetric polynomial f.

```
> F<a,b> := FunctionField(RationalField(), 2);
> P<x1,x2,x3,x4,x5> := PolynomialRing(F, 5, "grevlex");
> y1 := x1^4 + x1^2*a + x1*b;
> y2 := x2^4 + x2^2*a + x2*b;
> y3 := x3^4 + x3^2*a + x3*b;
> y4 := x4^4 + x4^2*a + x4*b;
> y5 := x5^4 + x5^2*a + x5*b;
> f := y1*y2 + y1*y3 + y1*y4 + y1*y5 + y2*y3 + y2*y4 +
>      y2*y5 + y3*y4 + y3*y5 + y4*y5;
> Q<e1,e2,e3,e4,e5> := PolynomialRing(F,  5);
> l,E := IsSymmetric(f, Q);
> l, E;
true b*e1^3*e2 - 2*a*e1^3*e3 - 4*e1^3*e5 + a*e1^2*e2^2 +
    4*e1^2*e2*e4 + 2*e1^2*e3^2 - b*e1^2*e3 + 2*a*e1^2*e4 -
    4*e1*e2^2*e3 - 3*b*e1*e2^2 + 4*a*e1*e2*e3 + 8*e1*e2*e5 +
    a*b*e1*e2 - 8*e1*e3*e4 - 2*a^2*e1*e3 + b*e1*e4 - 6*a*e1*e5 +
    e2^4 - 2*a*e2^3 - 4*e2^2*e4 + a^2*e2^2 + 4*e2*e3^2 +
    5*b*e2*e3 + 2*a*e2*e4 + b^2*e2 - 3*a*e3^2 - 4*e3*e5 -
    3*a*b*e3 + 6*e4^2 + 2*a^2*e4 - 5*b*e5
```

111 DIFFERENTIAL RINGS

Chapter 111
DIFFERENTIAL RINGS

111.1 Introduction

The Galois theory of linear differential equations, or differential Galois theory, is the analogue of the classical Galois theory of polynomials for linear differential equations. Generally speaking one studies linear differential equations, that is differential equations of the form

$$L(y) = a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 y^{(1)} + a_0 y = 0,$$

in which the coefficients a_i are contained in some ring. The natural analogue of a field in the classical case is the notion of a differential field, that is a specific case of a differential ring. A *differential ring* F is equipped with an additive map $\delta_F : F \to F$ called a *derivation*, satisfying the multiplicative rule

$$\delta_F(a \cdot b) = \delta_F(a) \cdot b + a \cdot \delta_F(b), \quad a, b \in F.$$

A classical derivation is the usual derivative. All differential rings have a ring structure and have a map defined on them. A differential ring that is also a field is called a *differential field*.

The differential rings have type `RngDiff` and their elements have type `RngDiffElt`. All differential rings contain a *differential ring of constants* on which the derivation acts as the zero map. The differential rings and their elements inherit all functionality of the rings from which the differential ring is created. We call the ring from which a differential ring F is created the *underlying ring* of F.

A solution of a differential equation is an element of some differential field. It can happen that a solution is not an element of a given differential field F, but is an element of a differential extension of F. By this we mean a differential field (ring) M with $F \subset M$ such that the derivations satisfy $\delta_M|_F = \delta_F$. This is completely analogous to field extensions induced by solutions of a polynomial.

To clearly describe linear differential equations in Magma we formalize the concept of taking the derivative. To a differential field F with derivation δ_F, one associates a non–commutative ring $F[D]$, *the ring of linear differential operators*. An element of $F[D]$ is called a *differential operator*. A differential operator of *degree* $n \in \mathbf{Z}_{\geq 0}$ in $F[D]$ is of the form

$$L = a_n D^n + a_{n-1} D^{n-1} + \cdots + a_1 D + a_0,$$

with $a_n \neq 0$ and all $a_i \in F$. Addition in $F[D]$ is term–wise and the multiplication of elements in $F[D]$ is determined by the rule

$$D * a = aD + \delta_F(a), \quad a \in F.$$

With these concepts $L(y) = 0$ is the linear differential equation

$$a_n\delta_F^n(y) + a_{n-1}\delta_F^{n-1}(y) + \cdots + a_1\delta_F(y) + a_0 y = 0.$$

For an introduction to the basic concepts in differential Galois theory, one is encouraged to consult [vdPS03]. This book is used as the basis for the implementation of differential rings, fields and operator rings in MAGMA.

111.2 Differential Rings and Fields

111.2.1 Creation

There are two ways to create a differential ring. The first creation is a general creation of a differential ring, for which the user specifies the ring and its derivation. The second creates a differential field which has the structure of a rational function field of transcendence degree 1 over its base field. Its derivation is specified by a differential.

Once a differential ring is created one can ask for its ring or field of fractions.

`DifferentialRing(P, f, C)`

Given a ring P and derivation f acting on P, return the differential ring isomorphic to P, with induced derivation f acting on it, and ring of constants C. The ring C should be a subring of P on which f is zero.

Example H111E1

Here we illustrate the creation and printing of a general differential ring.

```
> P := PolynomialRing(Rationals());
> f := map<P->P | a:->5*Derivative(a)>;
> R := DifferentialRing(P, f, Rationals());
> R;
Differential Ring of Univariate Polynomial Ring over
Rational Field with derivation given by Mapping
from: RngUPol: P to RngUPol: P given by a rule [no inverse]
```

`RationalDifferentialField(C)`

The differential field in one variable over the constant field C. If this field is called F, say, then the derivation on F is given by $d/(1)d(F.1)$, where $F.1$ is the variable of F, and $(1)d(F.1)$ is its differential in the differential space of F. Any exact field with polynomial GCD is valid input for C.

Example H111E2

Here we illustrate the creation and printing of the differential field obtained from the command `RationalDifferentialField`.

```
> F<z> := RationalDifferentialField(Rationals());
> F;
Differential Ring of Algebraic function field defined over
Rational Field by $.2 - 4711 with
derivation given by (1) d(z)
```

`DifferentialLaurentSeriesRing(C)`

The differential Laurent series ring (in one variable) over the constant field C. If this field is called F, say, then the derivation on F is given by $F.1 \cdot d/d(F.1)$, where $F.1$ is the variable of F.

Example H111E3

This example illustrates the creation and printing of the differential Laurent series ring obtained from the command `DifferentialLaurentSeriesRing`.

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> S;
Differential Ring of Laurent series field in t over Rational Field
with derivation given by Mapping from: Laurent series field in t over Rational
Field to Laurent series field in t over Rational Field given by a rule [no
inverse]
```

`RingOfFractions(R)`

Returns the differential ring $R[r^{-1} : r \in R$ not a zero divisor$]$ of fractions of the differential ring R, together with the inclusion map from R to the newly created ring.

`FieldOfFractions(R)`

Returns the differential field of fractions of the differential ring R, together with the inclusion map from R to the newly created field.

`AssignNames(~R, S)`

Given a differential ring R with n indeterminates and a sequence S of n strings, assign the elements of S to the names of the variables of R.

This procedure only changes the names used in the printing of the elements of R.

111.2.2 Creation of Differential Ring Elements

The easiest way to create an element in a given ring is to use the angle bracket construction to attach names to the indeterminates of the ring. Others are given below.

`Name(R, i)`

`R . i`

The i-th indeterminate of the differential ring R, where i is between 1 and the number of generators of R.

`R ! s`

Coerce the element s in the differential ring R. Elements that are coercible are elements that are coercible in the underlying ring of the differential ring R.

`Zero(R)`

The zero element of the differential ring R.

`One(R)`

`Identity(R)`

The identity element of the differential ring R.

`SeparatingElement(F)`

Returns the separating element of the algebraic differential field F.

Example H111E4

We construct the differential field $F = \mathbf{Q}(z)$ with derivation d/dz and show some of the elements that can be created.

```
> F<z> := RationalDifferentialField(Rationals());
> F.1;
z
> two := F!2;
> two;
2
> Parent(two) eq F;
true
> Zero(F); One(F);
0
1
> Parent(Zero(F)) eq F and Parent(Identity(F)) eq F;
true
> elt := SeparatingElement(F);
> elt;
z
> ISA(Type(elt),RngDiffElt);
true
> Parent(elt) eq F;
```

```
true
> elt eq F!SeparatingElement(UnderlyingRing(F));
true
```

111.3 Structure Operations on Differential Rings

111.3.1 Category and Parent

Differential Rings form the MAGMA category `RngDiff`. The notional power structures exist as parents of differential rings.

`Category(R)`

`Type(R)`

The category, or type, of the differential ring R.

`Parent(R)`

The power structure of the differential ring R.

111.3.2 Related Structures

The underlying ring and constant ring from which the differential ring was created can each be retrieved as described below. There is also the concept of a base ring. If one has created a differential extension M/F in MAGMA, then F is the *base ring* of M.

`UnderlyingRing(R)`

The underlying ring of the differential ring R. The type of the underlying ring indicates what ring R inherits from.

`UnderlyingField(R)`

The underlying ring of the differential ring R, provided it is a field.

`BaseRing(R)`

The base ring of the differential ring R.

`BaseField(R)`

The base ring of the differential ring R, provided it is a field.

`ConstantRing(R)`

The constant ring of the differential ring R. The derivation of R acts trivially on the constant ring. It is therefore contained in the differential ring of constants of R.

`ConstantField(R)`

The constant ring of the differential ring R, provided it is a field.

`ExactConstantField(F)`

The exact constant field of F, i.e. the algebraic closure in F of the constant field of F, together with the inclusion map to F. The field F must be a function field. The differential field F must have been created with respect to a differential. If the derivation of F has been constructed with respect to a differential, then the exact constant field coincides with the differential field of constants of F.

`Generators(R)`

The list of generators of the differential ring R. If there is no list assigned to R, one is constructed by default from the underlying ring of R.

Example H111E5

First we construct the differential field $F = \mathbf{Q}(z)$ with derivation d/dz and show what some of the related structures are. Then we construct the field extension $M = \mathbf{Q}(z, \alpha)$, where α is a root of the polynomial $X^2 - 2$. We do this with the usual `ext< >` constructor. For M we again derive some related structures.

```
> F<z> := RationalDifferentialField(Rationals());
> ConstantRing(F);
Rational Field
> UnderlyingRing(F);
Algebraic function field defined over Rational Field by
$.2 - 4711
>
> _<X> := PolynomialRing(F);
> M<alpha> := ext< F | X^2-2 >;
> BaseRing(M);
Differential Ring of Algebraic function field defined over Rational Field by
$.2 - 4711
with derivation given by (1) d(z)
> BaseRing(M) eq F;
true
> ConstantRing(M);
Rational Field
> E := ExactConstantField(M);
> E;
Number Field with defining polynomial $.1^2 - 2 over the Rational Field
> Generators(M);
[ alpha ]
```

Example H111E6

Related structures also exist for differential Laurent series rings.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> UnderlyingRing(S);
Laurent series field in t over Rational Field
```

```
> ConstantRing(S);
Rational Field
> Generators(S);
[ t ]
```

111.3.3 Derivation and Differential

The derivation of a differential ring and its differential, whenever applicable, can be retrieved as indicated below.

`Derivation(R)`

The derivation of the differential ring R.

`Differential(F)`

The differential belonging to the derivation of the differential field F. The field F must have been constructed in such a way that its derivation is defined by a differential.

Example H111E7

```
> F<z> := RationalDifferentialField(Rationals());
> Derivation(F);
Mapping from: RngDiff: F to RngDiff: F given by a rule [no inverse]
> Differential(F);
(1) d(z)
```

111.3.4 Numerical Invariants

`Ngens(R)`

The number of indeterminates associated with the differential ring R.

111.3.5 Predicates and Booleans

`R eq F`

Returns `true` if and only if the differential rings R and F are the same.

`IsIdentical(R, F)`

Returns `true` if and only if the differential rings R and F are identical.

`IsDomain(R)`

Returns `true` if and only if the differential ring R is a domain.

`IsField(R)`

Returns `true` if and only if the differential ring R is field.

`IsDifferentialField(R)`

Returns `true` if and only if the ring R is a differential field.

`IsAlgebraicDifferentialField(R)`

Returns `true` if and only if the field structure of the differential ring R is an algebraic function field.

`IsDifferentialSeriesRing(R)`

Returns `true` if and only if the underlying ring of the differential ring R is a series ring.

`IsDifferentialLaurentSeriesRing(R)`

Returns `true` if and only if the underlying ring of the differential ring R is a Laurent series ring and R has been created with a known constant ring.

Example H111E8

This example shows some booleans for various differential rings.

```
> F<z>:=RationalDifferentialField(Rationals());
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> IsAlgebraicDifferentialField(F);
true
> IsDifferentialSeriesRing(F);
false
> IsAlgebraicDifferentialField(S);
false
> IsDifferentialSeriesRing(S);
true
> IsDifferentialLaurentSeriesRing(S);
true
```

`HasProjectiveDerivation(F)`

Returns `true` if and only if F is a differential ring with derivation weakly of the form $(F.1) \cdot d/d(F.1)$.

`HasZeroDerivation(F)`

Returns `true` if and only if the algebraic differential field or differential series ring F has zero derivation. When F is a series ring we relax being zero to being weakly zero.

Example H111E9

```
> F<z>:=RationalDifferentialField(Rationals());
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> HasProjectiveDerivation(F);
false
> HasProjectiveDerivation(ChangeDerivation(F,z));
true
> HasZeroDerivation(F);
false
> HasProjectiveDerivation(S);
true
> HasProjectiveDerivation(ChangeDerivation(S,S!3));
false
> HasZeroDerivation(S);
false
```

111.3.6 Precision

`RelativePrecision(F)`

Returns the relative precision of the underlying series ring of F.

`RelativePrecisionOfDerivation(F)`

Given a differential Laurent series ring F, returns the relative precision of the ring derivative of $F.1$.

Example H111E10

This example illustrate the relative precision of differential rings.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> Derivative(t);
t
> IsDifferentialLaurentSeriesRing(S);
true
> RelativePrecision(S);
20
> RelativePrecision(UnderlyingRing(S));
20;
> V<w>:=DifferentialLaurentSeriesRing(Rationals():Precision:=30);
> RelativePrecision(V);
30
> RelativePrecision(V) eq RelativePrecision(UnderlyingRing(V));
true
```

Example H111E11

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> RelativePrecisionOfDerivation(S);
Infinity
> V<w> := ChangeDerivation(S,t+O(t^6));
> Derivation(V)(w);
w^2 + O(w^7)
> RelativePrecisionOfDerivation(V);
5
```

`ChangePrecision(F, p)`

Returns the differential series ring isomorphic to F with relative precision p. The map returned is the induced map of F to the new field.

Example H111E12

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RelativePrecision(S);
20
> V<w>,mp :=  ChangePrecision(S,10);
> Type(V);
RngDiff
> IsDifferentialLaurentSeriesRing(V);
true
> RelativePrecision(V);
10
```

```
> RelativePrecision(1/(w-1)) eq 10;
true
> mp(t) eq w;
true
> w@@mp eq t;
true
> derivt := Derivation(S)(t);
> derivt;
t
> derivw := Derivation(V)(w);
> derivw;
w
> mp(derivt) eq Derivation(V)(w);
true
```

111.4 Element Operations on Differential Ring Elements

111.4.1 Category and Parent

`Category(s)`

`Type(s)`

The category, or type, of the differential ring element s.

`Parent(s)`

The parent of the differential ring element s.

111.4.2 Arithmetic

All the usual arithmetic operations are possible for differential ring elements.

`s + t`

The sum of the two differential ring elements s and t.

`-s`

The negation of the differential ring element s.

`s - t`

The difference between the differential ring elements s and t.

`s * t`

The product of the differential ring elements s and t.

`s ^ n`

Given a differential ring element s and an integer n, return the n-th power of s. If s is invertible, n may be negative.

`s div t`

Given the differential ring elements s and t, return the exact division of s by t, if s is divisible by t.

`s / t`

Given the differential field elements s and t, return s divided by t.

111.4.3 Predicates and Booleans

`s eq t`

Return `true` iff the differential ring elements s and t are exactly the same.

`IsZero(s)`

Return `true` iff the differential ring element s is the zero element of its parent.

`IsOne(s)`

Return `true` iff the differential ring element s is the unity element of its parent.

`IsWeaklyEqual(s, t)`

Return `true` if and only if the differential ring element s is weakly equal to the differential ring element t.

`IsWeaklyZero(s)`

Return `true` if and only if the differential ring element s is weakly equal to the zero element of its parent.

`IsOrderTerm(s)`

Return `true` if and only if the differential ring element s is purely an order term of a differential series ring.

Example H111E13

This examples shows the booleans for various differential rings.

```
> F<z> := RationalDifferentialField(Rationals());
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> IsOne(F!1);
true
> t eq t+O(t^2);
false
> IsWeaklyEqual(t, t+O(t^2));
true
> IsWeaklyZero(t^(-1));
false
> IsWeaklyZero(O(t));
true
> IsOrderTerm(t+O(t^2));
false
> IsOrderTerm(O(t));
true
```

111.4.4 Coefficients and Terms

`O(s)`

Creates the order term of the differential series s.

`Truncate(s)`

The known part of the differential series s.

`Eltseq(s)`

Returns the coefficients of the differential ring element s.

`Exponents(s)`

Returns the interval from the valuation of s to (including) the degree of s.

Example H111E14

```
> F<z> := RationalDifferentialField(Rationals());
> _<X> := PolynomialRing(F);
> K<x>, mp := ext<F|X^2+X+1>;
> seq := Eltseq(x^2);
> seq;
[ -1, -1 ]
> Universe(seq) eq F;
true
```

Example H111E15

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> O(t+t^2);
O(t)
> Parent(O(t)) eq S;
true
> trunc := Truncate(t^(-1)+5*t^2 +O(t^4));
> trunc;
t^-1 + 5*t^2
> Parent(trunc) eq S;
true
> seq := Eltseq(trunc);
> seq;
[ 1, 0, 0, 5 ]
> Universe(seq) eq Rationals();
true
> Exponents(trunc);
[ -1 .. 2 ]
```

111.4.5 Conjugates, Norm and Trace

`MinimalPolynomial(s)`

The minimal polynomial of the differential field element s over the base field.

Example H111E16

```
> F<z> := RationalDifferentialField(Rationals());
> P<X> := PolynomialRing(F);
> K<x>, mp := ext<F|X^2+X+1>;
> f := MinimalPolynomial(x^2);
> f;
X^2 + X + 1
> Parent(f) eq P;
true
> g := MinimalPolynomial(x+3/2);
> g;
X^2 + -2*X + 7/4
```

111.4.6 Derivatives and Differentials

`Derivative(s)`

The image of s under the derivation of the parent of s. Notice that it can be different to the "usual" derivative, as it relies on the defined derivation.

`Differential(s)`

Returns the differential of s in the algebraic differential field F, as a differential in the differential space of the underlying ring of F.

Example H111E17

```
> F<z> := RationalDifferentialField(Rationals());
> Derivative(z^2 + 7/z);
(2*z^3 - 7)/z^2
> Differential(z);
(1) d(z)
> Differential(1/z+6+5*z);
((5*z^2 - 1)/z^2) d(z)
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> Derivative(5 + 2*t + 3*t^2);
2*t + 6*t^2
```

111.5 Changing Related Structures

Sometimes whilst working with a differential ring R, one might wish to consider the same ring, but with a different derivation or with a larger constant ring. It is a consequence of the creation of a differential ring, that its constant ring may actually be smaller than its differential ring of constants.

To alter the settings defined by the creation of a differential ring or field the following functions are available.

`ChangeDerivation(R, f)`

Returns a differential ring isomorphic to R, but whose derivation is the map $f\cdot$ `Derivation(`R`)` induced by the isomorphism. The ring element f must be non–zero. The isomorphism of R to the new differential ring is also returned. The new differential ring has the same underlying ring as R.

Example H111E18

```
> F<z> := RationalDifferentialField(Rationals());
> Derivative(z^2);
2*z
> K, toK := ChangeDerivation(F, z);
> K;
Differential Ring of Algebraic function field defined over Rational Field by
$.2 - 4711
with derivation given by (1/z) d(z)
> toK;
Mapping from: RngDiff: F to RngDiff: K given by a rule
> Derivative(toK(z^2));
2*z^2
> UnderlyingRing(F) eq UnderlyingRing(K);
true
```

Notice that the differential of K is $(1/z)d(z)$, so that the derivation of K is $z \cdot d/dz$, as requested.

`ChangeDifferential(F, df)`

Returns the algebraic differential field, whose underlying ring is the one of F, but with derivation with respect to the differential df. The map returned is the bijective map from F into the new algebraic differential field.

Example H111E19

```
> F<z> := RationalDifferentialField(Rationals());
> df := Differential(1/z);
> df in DifferentialSpace(UnderlyingRing(F));
true
> M<u>, mp := ChangeDifferential(F,df);
> IsAlgebraicDifferentialField(M);
true
> Domain(mp) eq F and Codomain(mp) eq M;
true
> Differential(M);
(-1/u^2) d(u)
> mp(z);
u
> Derivation(M)(u);
u^2
> Derivation(F)(z);
1
> dg := Differential(z^3+5);
> N<v>, mp := ChangeDifferential(F,dg);
> Differential(M);
```

```
(3*v^2) d(v)
> mp(z);
v
> Derivation(N)(mp(z));
1/3/v^2
```

`ConstantFieldExtension(F, C)`

Returns the differential field isomorphic to the differential field F, but whose constant field is the extension C, and the isomorphism from F to the new field. The differential field F must be an algebraic function field.

Example H111E20

```
> F<z> := RationalDifferentialField(Rationals());
> _<X> := PolynomialRing(F);
> M := ext< F | X^2-2 >;
> ConstantField(M);
Rational Field
> _<x>:=PolynomialRing(Rationals());
> C := NumberField(x^2-2);
> Mext, toMext := ConstantFieldExtension(M, C);
> ConstantField(Mext);
Number Field with defining polynomial x^2 - 2 over the Rational Field
> toMext;
Mapping from: RngDiff: M to RngDiff: Mext given by a rule
```

Example H111E21

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> P<T> := PolynomialRing(Rationals());
> Cext := ext<Rationals()|T^2+1>;
> Sext<text>, mp := ConstantFieldExtension(S,Cext);
> IsDifferentialLaurentSeriesRing(Sext);
true
> ConstantRing(Sext) eq Cext;
true
> Derivative(text^(-2)+7+2*text^3+O(text^6));
-2*text^-2 + 6*text^3 + O(text^6);
> mp;
Mapping from: RngDiff: S to RngDiff: Sext given by a rule
> mp(t);
text
```

`Completion(F, p)`

`Precision` RngIntElt *Default :* ∞

The completion of the differential field F with respect to the place p. The place p should be an element of the set of places of F. The derivation of the completion is the one naturally induced by the derivation of F. The map returned is the embedding of F into the completion. Upon creation one can set the precision by using `Precision`. If no precision is given, then a default value is taken.

Example H111E22

This example illustrates the creation of the differential Laurent series ring by using the command `Completion`.

```
> F<z> := RationalDifferentialField(Rationals());
> pl := Zeros(z)[1];
> S<t>, mp := Completion(F,pl: Precision := 5);
> IsDifferentialLaurentSeriesRing(S);
true
> mp;
Mapping from: RngDiff: F to RngDiff: S given by a rule
> Domain(mp) eq F, Codomain(mp) eq S;
true true
> Derivation(S)(t);
1
> 1/(1-t);
1 + t + t^2 + t^3 + t^4 + O(t^5)
```

Example H111E23

This example shows that one does not have to restrict to differential fields of genus 0 to use `Completion`.

```
> F<z> := RationalDifferentialField(Rationals());
> P<Y> := PolynomialRing(F);
> K<y> := ext<F|Y^2-z^3+z+1>;
> Genus(UnderlyingRing(K));
1
> pl:=Zeros(K!z)[1];
> Degree(pl);
2
> S<t>, mp := Completion(K,pl);
> IsDifferentialLaurentSeriesRing(S);
true
> C<c> := ConstantRing(S);
> C;
Number Field with defining polynomial $.1^2 + 1 over the Rational Field
> mp(y) + O(t^4);
```

```
c - t - 4*t^3 + O(t^4)
```

111.6 Ring and Field Extensions

The first differential ring and field extensions we consider are the ones induced by a differential operator. Given a differential operator

$$L = a_n D^n + a_{n-1} D^{n-1} + \cdots + a_1 D + a_0, \quad a_n \neq 0$$

in a differential operator ring $F[D]$ with coefficients in a differential field F, we construct a ring or field extension of degree n over F, whose indeterminates play the role of a formal solution of $L(y) = 0$ and its derivatives.

Given a differential field F, it is also possible to construct differential extensions of the form $F[X]/f(X)$, where $f(X)$ is an irreducible polynomial over F.

`DifferentialRingExtension(L)`

Constructs a differential ring extension of the base ring of the differential operator L, by adding a formal solution of L and its formal derivatives as indeterminates.

Let P denote the new differential ring, and F the coefficient ring of L. The ring F is a differential field. If n is the degree of L, the underlying ring of P is a multivariate polynomial ring of degree n over F. We thus have $P = F[Y_1, Y_2, \ldots, Y_n]$, with indeterminates $Y_1, Y_2, \ldots, Y_n$. If L is written as $a_n D^n + a_{n-1} D^{n-1} + \cdots + a_1 D + a_0 \in F[D]$, then the derivation of P is induced by the differential operator L as follows: $\delta_P(Y_i) = Y_{i+1}$, for $i < n$ and $a_n \delta_P(Y_n) = -a_{n-1} Y_{n-1} - \cdots - a_2 Y_2 - a_1 Y_1$. With this construction Y_1 mimics a solution of $L(y) = 0$, and all the others are its derivatives.

`DifferentialFieldExtension(L)`

Constructs a differential field extension of the base ring of the differential operator L, by adding a formal solution of L and its formal derivatives as indeterminates.

The construction of the new differential field is completely analogous to the differential ring created by `DifferentialRingExtension(L)`. The only difference is that now a differential field $M = F(Y_1, Y_2, \ldots, Y_n)$, with n indeterminates $Y_1, Y_2, \ldots, Y_n$ is created. The action of the derivation of M on $Y_1, Y_2, \ldots, Y_n$ is as described in `DifferentialRingExtension(L)`.

Example H111E24

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := z^2*D^2-z*D+1;
> P<Y1,Y2> := DifferentialRingExtension(L);
> P;
Differential Ring Extension over F
with derivation given by Mapping from: Polynomial ring of rank 2 over F to
Polynomial ring of rank 2 over F given by a rule [no inverse]
> Derivative(Y1);
Y2
> Derivative(Y2);
-1/z^2*Y1 + 1/z*Y2
```

Example H111E25

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := z^2*D^2-1;
> M<Y,DY> := DifferentialFieldExtension(L);
> IsDifferentialField(M);
true
> Derivative(Y);
DY
> Derivative(DY);
-1/z^2*Y
```

`ext< F | f >`

The differential field extension $F(\alpha)$ of the differential field F, where α is a root of the irreducible polynomial f over F. The angle bracket notation may be used to assign the root α to an identifier.

Example H111E26

```
> F<z> := RationalDifferentialField(Rationals());
> _<X> := PolynomialRing(F);
> M<alpha> := ext< F | X^2-z >;
> M;
Differential Ring Extension over F by $.1^2 - z
with derivation given by (1) d(z)
> alpha^2;
z
```

The differential of M is the differential dz of the differential space of F lifted to the space of differentials of M.

`ExponentialFieldExtension(F, f)`

Returns the differential field $F(E)$ as an extension of F, such that the derivation of E is $f \cdot E$. The parent of f must be F.

`LogarithmicFieldExtension(F, f)`

Returns the differential field $F(L)$ as an extension of F, such that the derivation of L is $F(L)!f$. The parent of f must be F.

Example H111E27

```
> F<z> := RationalDifferentialField(Rationals());
> K<E> := ExponentialFieldExtension(F, z);
> K;
Differential Ring Extension over F
with derivation given by Mapping from: Multivariate Rational function field of
rank 1 over F to Multivariate Rational function field of rank 1 over F given by
a rule [no inverse]
> Derivative(E);
z*E
> _<L> := LogarithmicFieldExtension(F, 1/z);
> Derivative(L);
1/z
> Parent($1) eq Parent(L);
true
```

`PurelyRamifiedExtension(f)`

Creates a purely ramified field extension M of the differential field F with respect to the purely ramified polynomial $f \in F[X]$. By definition, such a polynomial f is of the form $X^n - a \cdot (F.1)$ for some constant element a in F and positive integer n. The returned extension field M is of the same type as F. The allowed differential fields are algebraic differential fields and differential Laurent series rings. When F is a differential Laurent series ring, its derivation is required to be weakly of the form $c * (F.1) * d/d(F.1)$ for some constant c. The relative precision of M is then n times the relative precision of F. The second argument returned is the embedding map of F into M. The inverse map acts on elements for which it is defined. Otherwise it returns 0.

Example H111E28

A purely ramified extension of an algebraic differential field is constructed in this example.

```
> F<z> := RationalDifferentialField(Rationals());
> _<X> := PolynomialRing(F);
> Fext<v>, mp := PurelyRamifiedExtension(X^2-5*z);
> IsAlgebraicDifferentialField(Fext);
true
> mp(z) eq 1/5*v^2;
true
> Parent(mp(z)) eq Fext;
true
> Derivation(Fext)(mp(z));
1
> Derivation(Fext)(v);
1/2/z*v
> Derivation(Fext)(v^2) eq Fext!5;
true
> Inverse(mp)(v^2);
5*z;
```

Example H111E29

A differential Laurent series ring with a derivation without an order term is considered in this example.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> _<T>:=PolynomialRing(S);
> pol := T^4-5*t;
> Sext<r>,mp := PurelyRamifiedExtension(pol);
> IsDifferentialLaurentSeriesRing(Sext);
true
> BaseRing(Sext) eq S and ConstantField(Sext) eq ConstantField(S);
true
> RelativePrecision(Sext);
80
> RelativePrecisionOfDerivation(Sext);
Infinity
> Derivation(S)(t);
t
> mp(t);
1/5*r^4
> Derivation(Sext)(mp(t));
1/5*r^4
> mp(Derivation(S)(t));
1/5*r^4
> x := 4+6*t+O(t^6);
> mp(x);
```

```
4 + 6/5*r^4 + O(r^24)
> Derivation(Sext)(mp(x));
6/5*r^4 + O(r^24)
> mp(Derivation(S)(x));
6/5*r^4 + O(r^24)
> Inverse(mp)(r^4-r^8);
5*t - 25*t^2
> Inverse(mp)(r^4+O(r^5));
5*t + O(t^2)
> Derivation(Sext)(r);
1/4*r
```

Example H111E30

The ring in this example has an order term in its derivation. Therefore, taking a derivative of an element x is of influence on the relative precision of the image of x.

```
> F<z> := RationalDifferentialField(Rationals());
> FF<z>:=ChangeDerivation(RationalDifferentialField(Rationals()),z);
> RR<DD>:=DifferentialOperatorRing(FF);
> RS<DS>, mpRRtoRS :=Completion(RR,Zeros(z)[1]);
> S<t>:=BaseRing(RS);
> IsDifferentialLaurentSeriesRing(S);
true
> _<T> := PolynomialRing(S);
> E<r>, mp := PurelyRamifiedExtension(T^3-5*t);
> IsDifferentialLaurentSeriesRing(E);
true
> RelativePrecision(E);
60
> RelativePrecisionOfDerivation(E);
60
> Derivation(E)(r);
1/3*r + O(r^61);
> mp(t);
1/5*r^3
> Derivation(S)(t);
t + O(t^21)
> Derivation(E)(mp(t));
1/5*r^3 + O(r^63)
> mp(Derivation(S)(t));
1/5*r^3 + O(r^63)
> x:=t^(-2) +7+t^3 +O(t^15);
> Derivation(S)(x);
-2*t^-2 + 3*t^3 + O(t^15)
> Derivation(E)(mp(x));
-50*r^-6 + 3/125*r^9 + O(r^45)
> mp(Derivation(S)(x));
```

```
-50*r^-6 + 3/125*r^9 + O(r^45)
> y := 2*t+O(t^25);
> Derivation(S)(y);
2*t + O(t^21)
> Derivation(E)(mp(y)) eq mp(Derivation(S)(y));
true
> Derivation(E)(mp(y));
2/5*r^3 + O(r^63)
```

111.7 Ideals and Quotient Rings

A differential ideal $I \subset R$ of a differential ring R is an ideal of R that is closed under the derivation of R. However, we consider a differential ideal as an ideal of the underlying ring of R. More specifically, ideals of differential rings are restricted to those rings whose underlying rings are multivariate polynomial rings.

111.7.1 Defining Ideals and Quotient Rings

`DifferentialIdeal(L)`

Given a sequence L with entries in a differential ring R, return the differential ideal generated by the entries of L as an ideal of the underlying ring of R. The underlying ring of R must be of type `RngMPol`. At first the elements of L may generate an ideal which is not closed under the derivation of R. By adding as many derivatives of the elements to the set of generators of the ideal as needed, one obtains a full set of generators for the calculated differential ideal.

`QuotientRing(R, I)`

Given a differential ring R and a differential ideal I, return the differential quotient ring $Q = R/I$. The derivation of Q is induced by the derivation of R. It maps $Q.i$ to $Q!\delta_R(R.i)$, for $i = 1, 2, \ldots, m$ where m is the number of generators of Q (or R). The induced quotient map from R to Q is also returned.

Example H111E31

```
> P := PolynomialRing(Rationals(),1);
> f := map<P->P | a:->a*Derivative(a,1)>;
> R<T> := DifferentialRing(P, f, Rationals());
> L := [T^2+T-1];
> I := DifferentialIdeal(L);
> I;
Ideal of Polynomial ring of rank 1 over Rational Field
Lexicographical Order
Variables: T
Basis:
```

```
[
    T^2 + T - 1,
]
> Q<X>, toQ := QuotientRing(R,I);
> Q;
Differential Ring of Affine Algebra of rank 1 over Rational Field
Lexicographical Order
Variables: X
Quotient relations:
[
    X^2 + X - 1
]
with derivation given by Mapping from: Affine Algebra of rank 1 over Rational
    Field to Affine Algebra of rank 1 over Rational Field given by a rule [no
inverse]
> toQ(T);
X
> Derivative(T^2);
2*T^3
> Derivative(X^2);
X
```

111.7.2 Boolean Operations on Ideals

`IsDifferentialIdeal(R, I)`

Returns `true` if and only if I is a differential ideal of the differential ring R.

111.8 Wronskian Matrix

Let R be a differential ring and let $y_1, y_2, \ldots, y_n$ be elements of R. The *wronskian matrix* of $y_1, y_2, \ldots, y_n$ is defined as the $n \times n$ matrix

$$W(y_1, y_2, \ldots, y_n) = \begin{pmatrix} y_1 & y_2 & \cdots & y_n \\ \delta_R(y_1) & \delta_R(y_2) & \cdots & \delta_R(y_n) \\ \vdots & \vdots & \ddots & \vdots \\ \delta_R^{n-1}(y_1) & \delta_R^{n-1}(y_2) & \cdots & \delta_R^{n-1}(y_n) \end{pmatrix}$$

The *wronskian determinant*, or simply the *wronskian*, of $y_1, y_2, \ldots, y_n$ is the determinant of the wronskian matrix $W(y_1, y_2, \ldots, y_n)$.

`WronskianMatrix(L)`

Given a sequence of differential ring elements L, return the Wronskian matrix of L whose entries are elements of the universe of L.

`WronskianDeterminant(L)`

Given a sequence of differential ring elements L, return the determinant of the Wronskian matrix of L as well as the matrix itself.

Example H111E32

```
> F<z> := RationalDifferentialField(Rationals());
> WronskianMatrix([1,z,z^2]);
[1 z z^2]
[0 1 2*z]
[0 0 2]
> WronskianDeterminant([1,z^2,1/z]);
6/z
[z z^2 1/z]
[1 2*z -1/z^2]
[0 2 2/z^3]
```

111.9 Differential Operator Rings

111.9.1 Creation

`DifferentialOperatorRing(F)`

Returns the differential operator ring over the differential field F.

Example H111E33

```
> F<z> := RationalDifferentialField(Rationals());
> R := DifferentialOperatorRing(F);
> R;
Differential operator ring over Differential Ring of Algebraic function field
defined over Rational Field by
$.2 - 4711
with derivation given by (1) d(z)
```

`AssignNames(~R, S)`

Given a differential operator ring R with n indeterminates and a sequence S of n strings, assign the elements of S to the names of the variables of R.

This procedure only changes the names used in the printing of the elements of R.

111.9.2 Creation of Differential Operators

The easiest way to create an element in a given ring is to use the angle bracket construction to attach a name to the indeterminate of the differential operator ring. Other constructions are given below.

`Name(R, i)`

`R . i`

The i-th indeterminate of the differential ring R, where i must be 1.

`R ! s`

Coerce the element s into the differential operator ring R. Elements that are coercible into R are elements coercible into its underlying ring, sequences, and differential operators defined over the base ring of the coefficient ring of R.

When the base ring of R is an algebraic differential field, elements of other differential operator rings over algebraic differential fields can be coerced into R so long as the underlying rings of the differential fields are the same.

`Zero(R)`

The zero element of the differential operator ring R.

`One(R)`

The identity element of the differential operator ring R.

Example H111E34

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> R.1;
D
> R!(1/z);
1/z;
>R![1/2,0,5,z];
z*D^3 + 5*D^2 + 1/2
> S<T> := DifferentialOperatorRing(ChangeDerivation(F,z));
> R!T;
z*D
> S!D;
1/z*T
```

111.10 Structure Operations on Differential Operator Rings

111.10.1 Category and Parent

Differential Operator Rings form the MAGMA category `RngDiffOp`. The notional power structures exist as parents of differential operator rings.

`Category(R)`

`Type(R)`

The category, or type, of the differential operator ring R.

`Parent(R)`

The power structure of the differential operator ring R.

111.10.2 Related Structures

As outlined in the introduction, a differential operator ring R is of the form $F[D]$, for a differential ring F. The ring F is called the *base ring* or *coefficient ring* of R.

`BaseRing(R)`

`CoefficientRing(R)`

The base ring, or coefficient ring, of the differential operator ring R.

`ConstantRing(R)`

The constant ring of the differential ring operator R.

111.10.3 Derivation and Differential

By construction the variable D of a differential operator ring $F[D]$ is related to the derivation δ_F. That is why δ_F is also considered to be the derivation of R.

`Derivation(R)`

The derivation of the differential operator ring R.

`Differential(R)`

The differential belonging to the derivation of the differential operator ring R. The derivation must have been constructed in such a way that it is defined by a differential.

Example H111E35

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> BaseRing(R) eq F;
true
> Derivation(R);
Mapping from: RngDiff: F to RngDiff: F given by a rule [no inverse]
> Differential(R);
(1) d(z)
```

111.10.4 Predicates and Booleans

`R eq F`

Returns `true` if and only if the differential operator rings R and F are the same.

`IsIdentical(R, F)`

Returns `true` if and only if the differential operator rings R and F are identical.

`IsDifferentialOperatorRing(R)`

Returns `true` if and only if the given argument is a differential operator ring.

`HasProjectiveDerivation(R)`

Returns `true` iff R is defined over a ring F with derivation weakly of the form $(F.1) \cdot d/d(F.1)$.

`HasZeroDerivation(R)`

Returns `true` iff the base ring of R is an algebraic differential field or a differential series ring F such that the derivation of R acts as a (weak) zero derivation on $F.1$.

Example H111E36

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> IsDifferentialOperatorRing(F);
false
> IsDifferentialOperatorRing(R);
true
> Derivation(R)(z);
1
> HasProjectiveDerivation(R);
false
> HasProjectiveDerivation(ChangeDerivation(R,z));
true
> HasZeroDerivation(R);
false
```

Example H111E37

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> V<W> := DifferentialOperatorRing(S);
> IsDifferentialOperatorRing(V);
true
> Derivation(V)(t);
t
> HasProjectiveDerivation(V);
true
> HasZeroDerivation(V);
false
> P<Q>, mp := ChangeDerivation(V,3/t);
> IsDifferentialOperatorRing(P);
true
> HasProjectiveDerivation(P);
false
> X<y> := BaseRing(P);
> Q*y;
y*Q + 3
```

111.10.5 Precision

`RelativePrecisionOfDerivation(R)`

The relative precision of the derivation of an operator ring over a Laurent series ring.

Example H111E38

This example illustrates the relative precision of derivations of differential operatorrings.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> RelativePrecisionOfDerivation(RS);
Infinity
> RV<DV> := ChangeDerivation(RS, t^2+O(t^8));
> relprec := RelativePrecisionOfDerivation(RV);
> relprec;
6
> RelativePrecisionOfDerivation(BaseRing(RV)) eq relprec;
true
```

111.11 Element Operations on Differential Operators

111.11.1 Category and Parent

`Category(L)`

`Type(L)`

The category, or type, of the differential operator L.

`Parent(L)`

The parent of the differential operator L.

111.11.2 Arithmetic

All the usual arithmetic operations are possible for differential operators. It follows from the multiplication rule for differential operators that the multiplication of differential operators is non–commutative.

`s + t`

The sum of the two differential operators s and t.

`-s`

The negation of the differential operator s.

`s - t`

The difference between the differential operators s and t.

`s * t`

The product of the differential operators s and t.

`s ^ n`

Given a differential operator s and an integer $n \geq 0$, return the n-th power of s.

Example H111E39

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> (z*D-1)*(D+1);
z*D^2 + (z - 1)*D + -1
> (D+1)*(z*D-1);
z*D^2 + z*D + -1
> (D-1/z)^2;
D^2 + -2/z*D + 2/z^2
```

111.11.3 Predicates and Booleans

`s eq t`

Return `true` iff the differential operators s and t are exactly the same.

`IsZero(L)`

Return `true` iff the differential operator L is the zero element of its parent.

`IsOne(L)`

Return `true` iff the differential operator L is the unity element of its parent.

`IsMonic(L)`

Return `true` iff the differential operator L is monic.

`IsWeaklyEqual(L, P)`

Returns `true` if and only if the differential operator L is weakly equal to the operator P. This means that the i-th coefficients of L and P should be weakly equal to each other for every $i \in [0..\max(\deg(L), \deg(P))]$.

`IsWeaklyZero(L)`

Returns `true` if and only if the differential operator $L \in R$ is weakly equal to $R!0$.

`IsWeaklyMonic(L)`

Returns `true` if and only if the leading coefficient of the differential operator L is weakly equal to 1.

111.11.4 Coefficients and Terms

Differential operators look like univariate polynomials with coefficients in a differential ring. Some of the terminology used for polynomial rings is mimicked for differential operators.

`Eltseq(L)`

`Coefficients(L)`

Given an operator L with coefficients in R, this function returns the sequence of elements in R, that are the coefficients of L. The sequence is ordered from the constant coefficient to the coefficient of the highest order term of L.

`Coefficient(L, i)`

Given an operator L with coefficients in R, this function returns the coefficient of the monomial of degree i in L, as an element of R.

`LeadingCoefficient(L)`

Given an operator L with coefficients in R, this function returns the coefficient of the highest order term of L.

`LeadingTerm(L)`

The leading term of the differential operator L.

`Terms(L)`

Given an operator L with coefficients in R, this function returns the sequence of non–zero coefficients of L as elements of R. The sequence is ordered from the lowest order term to the highest order term in L.

Example H111E40

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := D^3  + (-4*z + 5)*D + (3*z - 4);
> L;
D^3 + (-4*z + 5)*D + 3*z - 4
> Eltseq(L);
[ 3*z - 4, -4*z + 5, 0, 1 ]
> LeadingTerm(L);
D^3
> Terms(L);
[
    3*z - 4,
    (-4*z + 5)*D,
    D^3
]
```

111.11.5 Order and Degree

`Order(L)`
`Degree(L)`

Returns the order of the differential operator L. In the case that L is identically 0, the order is defined to be -1.

`WeakOrder(L)`
`WeakDegree(L)`

If the differential operator L is defined over a differential series ring, then the exponent of the highest coefficient of L that is not weakly 0 is returned.

Example H111E41

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> R<D> := DifferentialOperatorRing(S);
> L := D^2 + 2*t;
> P := O(t)*D^3 + (1+O(t))*D^2  + 2*t;
> Order(L);
2
> Degree(P);
3
> L eq P;
false
> IsWeaklyEqual(L,P);
true
> WeakOrder(P);
2
```

111.11.6 Related Differential Operators

`MonicDifferentialOperator(L)`

Given the differential operator L, this function returns the monic differential operator $1/c \cdot L$, where c is the leading coefficient of L.

`Adjoint(L)`

Returns the formal adjoint of the differential operator L. The *formal adjoint* of $L = \sum_{i=0}^{n} a_i D^i$ in the differential operator ring $R = F[D]$ over F, is the differential operator $L^* := \sum_{i=0}^{n} (-1)^i D^i * a_i \in R$. It follows from the definition that the orders of L and L^* are the same and that the leading coefficient of L^* is $(-1)^n a_n$.

`Translation(L, e)`

If R is the parent of the differential operator L and e is a suitable ring element, then the operator in R obtained by replacing $R.1$ by $R.1 + e$ in L is returned. The second argument returned is the translation map on R by e.

`TruncateCoefficients(L)`

If L is defined over a differential series ring, then returned is the operator whose coefficients are the truncations of the coefficients of L.

Example H111E42

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := z*D^3  + (-4*z + 5)*D + (3*z - 4);
> Order(L);
3
> MonicDifferentialOperator(L);
D^3 + (-4*z + 5)/z*D + (3*z - 4)/z
> Adjoint(L);
-z*D^3 + -3*D^2 + (4*z - 5)*D + 3*z
> trans, mp := Translation(L, 2);
> trans;
z*D^3 + 6*z*D^2 + (8*z + 5)*D + 3*z + 6
```

Example H111E43

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L := (5-O(t))*DS^3+(2*t^-1+t^2+O(t^4))*DS - t^-2+t+O(t^3);
> L;
(5 + O(t))*DS^3 + (2*t^-1 + t^2 + O(t^4))*DS + -t^-2 + t + O(t^3)
> TruncateCoefficients(L);
5*DS^3 + (2*t^-1 + t^2)*DS + -t^-2 + t
> L -TruncateCoefficients(L);
O(t)*DS^3 + O(t^4)*DS + O(t^3)
```

111.11.7 Application of Operators

As pointed out in the introduction a differential operator $L = a_n D^n + a_{n-1} D^{n-1} + \cdots + a_1 D + a_0$ in $F[D]$ leads to the differential equation $L(y) = 0$ given by

$$L(y) = a_n \delta_F^n(y) + a_{n-1} \delta_F^{n-1}(y) + \cdots + a_1 \delta_F(y) + a_0 y$$

This notation is formal, but also defines an action of L on any element $y \in F$. The function `Apply` returns the ring element obtained by this action.

`Apply(L, f)`
`L(f)`
`f @ L`

Given a differential operator L and a ring element f, return the ring element obtained after applying L to f, as an element of the base ring of L. The element f must be coercible into the base ring of L.

Example H111E44

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := D^2-2/z^2;
> Apply(L, z);
-2/z
> L(z);
-2/z
> Apply(L, z^2);
0
```

111.12 Related Maps

This section is devoted to maps between differential operator rings.

`TranslationMap(R, e)`

Returns a map on the differential operator ring R that replaces $R.1$ by $R.1 + e$ when applied to a differential operator for some suitable ring element e.

`LiftMap(m, R)`

Let $m : F \to M$ be a differential map on differential fields and R a differential operator ring over F. Then this routine lifts the given map to a map on the differential operator rings $R \to S$, where the basefield of S is M.

Example H111E45

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> transmap := TranslationMap(R, 2 + z);
> Codomain(transmap) eq R;
> transmap(D);
D + z + 2
> transmap(D^2);
D^2 + (2*z + 4)*D + z^2 + 4*z + 5
> P<T> := PolynomialRing(F);
> M<u>, mp := ext<F|T^2+z>;
> liftmap := LiftMap(mp, R);
> Rprime<Dprime> := Codomain(liftmap);
> IsDifferentialOperatorRing(Rprime);
true
> BaseRing(Rprime) eq M;
true
> liftmap(D);
Dprime
```

```
> liftmap(R!z);
z
> Derivation(Rprime)(liftmap(z));
1
> Derivation(Rprime)(u);
1/2/z*u
```

111.13 Changing Related Structures

It may happen that certain intrinsics only work for differential operator rings whose derivations are of a specific form, or whose constant fields have to be large enough. Some of the functions available for changing settings of the differential rings or fields can be used to change the desired related structure on the operator ring directly. To alter some of the settings of a differential operator ring, the following functions are available.

`ChangeDerivation(R, f)`

Returns a differential operator ring isomorphic to R, but whose derivation is given by $f*$ `Derivation(`R`)`. The ring element f must be non–zero. The isomorphism of R to the new differential ring is also returned. The base ring of the new differential operator ring is isomorphic to the one of R, but it has derivation `ChangeDerivation(BaseRing(`R`))`.

`ChangeDifferential(R, df)`

Returns the differential operator ring with differential df, and whose underlying ring of its basefield coincides with the one of R. The map returned is the bijective map of R into the new operator ring. The base ring of the new differential operator ring is isomorphic to the one of R. However, the returned inclusion map and taking derivatives may not be commutative.

Example H111E46

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> df := Differential(z^3+5);
> RM<DM>, mp := ChangeDifferential(R,df);
> Domain(mp) eq R and Codomain(mp) eq RM;
true
> M<u> := BaseRing(RM);
> IsDifferentialOperatorRing(RM) and IsAlgebraicDifferentialField(M);
true
> mp(RM!z);
u
> mp(D);
3*u^2*DM
```

```
> D*z, mp(D*z);
u*D + 1
3*u^3*DM + 1
> DM*u;
u*DM + 1/3/u^2
> Differential(RM);
(3*u^2) d(u)
```

`ConstantFieldExtension(R, C)`

Returns the ring of differential operators with base ring isomorphic to that of the differential operator ring R, but whose constant field is C. The derivation is extended over the new constant field. The second argument returned is the map from R to the new operator ring.

`PurelyRamifiedExtension(R,f)`

When R is a differential operator ring over a differential ring F, this function returns an operator ring over the purely ramified extension of F, as induced by the polynomial f. The polynomial f is of the form $X^n - a \cdot (F.1)$ for some constant element a in F and positive integer n.

Example H111E47

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> R<D> := DifferentialOperatorRing(S);
> _<T> := PolynomialRing(S);
> Rext<Dext>, mp := PurelyRamifiedExtension(R, T^7-3*t);
> Sext<text> := BaseRing(Rext);
> Domain(mp) eq R and Codomain(mp) eq Rext;
true
> IsDifferentialLaurentSeriesRing(Sext);
true
> BaseRing(Sext) eq S;
true
> RelativePrecision(Sext) eq 7*RelativePrecision(S);
true
> D*t;
t*D + t
> mp(D);
Dext
> mp(R!t) eq Rext!(1/3*text^7);
true
> Dext*text;
text*Dext + 1/7*text
```

`Completion(R, p)`

`Precision` RngIntElt *Default :* ∞

Returns the operator ring $\tilde{R}$, whose base ring is the completion of the base ring of the operator ring R w.r.t. the place p. The second return value is the natural embedding of R into $\tilde{R}$. The precision of the base ring of $\tilde{R}$ can be set by setting `Precision` upon creation. If no precision is set, a default value for the precision is taken.

`Localization(R, p)`

Returns the operator ring whose differential has valuation -1 at p, with derivation $t \cdot d/dt$, where t is the uniformizing element at the place p. The natural map between the operator rings, and the induced image of p are also returned.

`Localization(L, p)`

Given the differential operator L over an algebraic differential field, returns the localized operator of L at the place p. The embedding map between the parents as well as the induced image of the place are also returned.

`Localization(R)`

Given a differential operator ring R over the differential Laurent series ring $C((t))$, returns the operator ring whose derivation is of the form $t \cdot d/dt$, and the natural map between the operator rings.

`Localization(L)`

Given the differential operator L over a differential series ring, returns the localized operator of L and the embedding map between the parents.

Example H111E48

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D> := DifferentialOperatorRing(S);
> D*t;
t*D + t
> Rprime<Dprime>, mp := ChangeDerivation(R,t^2);
> Fprime<tprime> := BaseRing(Rprime);
> mp;
Mapping from: RngDiffOp: R to RngDiffOp: Rprime given by a rule
> Dprime*tprime;
tprime*Dprime + tprime^3
> P<T> := PolynomialRing(Rationals());
> Cext := ext<Rationals()|T^2+1>;
> Rext<Dext>, mp := ConstantFieldExtension(R,Cext);
> Cext eq ConstantRing(BaseRing(Rext));
true
> mp(D);
```

Dext

Example H111E49

This examples illustrates how to use Completion on operator rings.

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> pl := Zeros(z)[1];
> Rcompl<Dcompl>, mp := Completion(R,pl);
> IsDifferentialOperatorRing(Rcompl);
true
> S<t> := BaseRing(Rcompl);
> IsDifferentialLaurentSeriesRing(S);
true
> mp(D);
Dcompl
> Dcompl*t;
t*Dcompl + 1
```

Example H111E50

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> pl := Zeros(z-1)[1];
> Rloc<Dloc>, mp, place:=  Localization(R,pl);
> Domain(mp) eq R, Codomain(mp) eq Rloc;
true true
> place;
(z - 1)
> Differential(BaseRing(Rloc));
(1/(z - 1)) d(z)
> mp(D);
1/(z - 1)*Dloc
> Dloc*(z-1);
(z - 1)*Dloc + z - 1
> L := D + z;
> Lloc, mp, place := Localization(L,Zeros(z)[1]);
> Lloc;
1/z*$.1 + z
```

111.14 Euclidean Algorithms, GCDs and LCMs

A ring of differential operators shares many properties with a univariate polynomial ring. Two of them are GCD and LCM algorithms. However, a consequence of the non–commutative multiplication of a differential operator ring is that the GCD and LCM algorithms cannot be used directly. For instance, in the euclidean algorithm multiplication of the quotient can be done on the left or the right. Therefore one needs to specify the direction of the multiplication in the GCD and LCM algorithms for differential operator rings.

111.14.1 Euclidean Right and Left Division

`EuclideanRightDivision(N, D)`

Given differential operators N and D, return two differential operators Q and R, such that $N = Q \cdot D + R$, with `Degree(`R`)` $<$ `Degree(`D`)`. An error occurs if D is 0.

`EuclideanLeftDivision(D, N)`

Given differential operators D and N, return two differential operators Q and R, such that $N = D \cdot Q + R$, with `Degree(`R`)` $<$ `Degree(`D`)`. An error occurs if D is 0.

Example H111E51

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L1 := D;
> L2 := (D-3)*(D+z);
> EuclideanRightDivision(L1, L2);
0
D
> Q, R := EuclideanRightDivision(L2, L1);
> Q, R;
D + z - 3
-3*z + 1
> L2 eq Q*L1+R;
true
> EuclideanLeftDivision(L2, L1);
0
D
> S, T := EuclideanLeftDivision(L1, L2);
> S, T;
D + z - 3
-3*z
> L2 eq L1*S+T;
true
```

111.14.2 Greatest Common Right and Left Divisors

`GreatestCommonRightDivisor(A, B)`

`GCRD(A, B)`

Given two differential operators $A, B \in R$, return the unique monic differential operator $G \in R$ that generates the left ideal $RA + RB$.

`ExtendedGreatestCommonRightDivisor(A, B)`

Given two differential operators $A, B \in R$, this function returns three operators $G, U, V \in R$, that satisfy $U \cdot A + V \cdot B = G$. The differential operator G is the unique monic right GCD of A and B.

`GreatestCommonLeftDivisor(A, B)`

`GCLD(A, B)`

Given two differential operators $A, B \in R$, return the unique monic differential operator $G \in R$ that generates the right ideal $AR + BR$.

`ExtendedGreatestCommonLeftDivisor(A, B)`

Given two differential operators $A, B \in R$, this function returns three operators $G, U, V \in R$, that satisfy $A \cdot U + B \cdot V = G$. The differential operator G is the unique monic left GCD of A and B.

Example H111E52

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L1 := D^3+z*D^2+D-z;
> L2 := D^2+(z-3)*D-3*z+1;
> GreatestCommonRightDivisor(L1, L2);
D + z
> GreatestCommonRightDivisor(L1, L2) eq GCRD(L1, L2);
true
> G, U, V :=ExtendedGreatestCommonRightDivisor(L1, L2);
> G, U, V;
D + z
1/8
-1/8*D + -3/8
> G eq U*L1+V*L2;
true
> GreatestCommonLeftDivisor(L1, L2);
1
> GCLD(L2,L2*L1) eq L2;
true
```

111.14.3 Least Common Left Multiples

`LeastCommonLeftMultiple(L)`

Let $L = D - r$ be a monic operator of degree 1 in $R = F[D]$. Return the least common left multiple of L and all its conjugates over the base ring of F, with respect to the coercion of this base ring into F.

`LeastCommonLeftMultiple(A, B)`

`LCLM(A, B)`

Given two differential operators $A, B \in R$, return the unique monic differential operator $L \in R$, that generates the left ideal $RA \cap RB$. The order of the least common multiple of A and B is at most `Order(`A`)+ Order(`B`)`.

`ExtendedLeastCommonLeftMultiple(A, B)`

Given two differential operators $A, B \in R$, return three operators $L, U, V \in R$, that satisfy $L = U \cdot A = V \cdot B$. The differential operator L is the unique monic left LCM of A and B.

`ExtendedLeastCommonLeftMultiple(S)`

Given the non–empty sequence of differential operators S, this function returns the unique monic left LCM L of the entries of S, as well as a sequence Q of length $\#S$, satisfying $L = Q[i] \cdot S[i]$ for $i = 1, 2, \ldots, \#S$.

Example H111E53

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> LCLM(D, D-z);
D^2 + (-z^2 - 1)/z*D
> L1 := D^3+z*D^2+D-z;
> L2 := D^2+(z-3)*D-3*z+1;
> LeastCommonLeftMultiple(L1, L2);
D^4 + (z - 3)*D^3 + (-3*z + 2)*D^2 + (-z - 3)*D + 3*z - 1
> L, U, V := ExtendedLeastCommonLeftMultiple(L1, L2);
> L, U, V;
D^4 + (z - 3)*D^3 + (-3*z + 2)*D^2 + (-z - 3)*D + 3*z - 1
D + -3
D^2 + -1
> L eq U*L1;
true
> L eq V*L2;
true
> L, Q := ExtendedLeastCommonLeftMultiple([D,D+1,z*D+1]);
> L;
D^3 + (z^2 - 6)/(z^2 - 2*z)*D^2 + (2*z - 6)/(z^2 - 2*z)*D
> Q[3]*(z*D+1) eq L;
true
```

Example H111E54

```
> F<z> := RationalDifferentialField(Rationals());
> P<T> := PolynomialRing(F);
> M<u> := ext<F|T^2+T+1>;
> RM<DM> := DifferentialOperatorRing(M);
> LeastCommonLeftMultiple(DM-u^2);
DM^2 + DM + 1
> lclm := LeastCommonLeftMultiple(DM-u+1);
DM^2 + 3*DM + 3
> EuclideanRightDivision(lclm, DM-u+1);
DM + u + 2
0
> N<v>, mp := ext<F|T^2-z>;
> RN<DN> := DifferentialOperatorRing(N);
> lclm := LeastCommonLeftMultiple(DN-v);
> lclm;
DN^2 + -1/2/z*DN + -z
> LeastCommonLeftMultiple(DN-v, DN+v) eq lclm;
true
> EuclideanRightDivision(lclm,DN-v);
DN + v - 1/2/z
0
> EuclideanRightDivision(lclm,DN+v);
DN + -v - 1/2/z
0
```

111.15 Related Matrices

The *companion matrix* of a monic linear differential operator

$$D^n + a_{n-1}D^{n-1} + \cdots + a_0 \in F[D]$$

is defined as the $n \times n$ matrix

$$\begin{pmatrix} 0 & 1 & 0 & 0 & \dots & 0 \\ 0 & 0 & 1 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & 0 & \dots & 1 \\ -a_0 & -a_1 & -a_2 & -a_3 & \dots & -a_{n-1} \end{pmatrix}$$

`CompanionMatrix(L)`

Returns the companion matrix of the monic differential operator L.

Example H111E55

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := D^3-z*D^2+2*D+5;
> CompanionMatrix(L);
[0 1 0]
[0 0 1]
[-5 -2 z]
```

111.16 Singular Places and Indicial Polynomials

All functions treated in this section concern differential operator rings defined over a function field of transcendence degree one. They all require that the derivation of such an operator ring $F[D]$ over F is defined with respect to a differential.

Any solution of a differential operator $L \in F[D]$ is also a solution of the operator $c \cdot L$, for any non–zero $c \in F$. For considering solutions we may therefore consider L to be monic of the form

$$L = D^n + a_{n-1}D^{n-1} + \cdots + a_0,$$

with coefficients $a_i \in F$ for $i = 1, 2, \ldots n-1$. Each of the coefficients is a rational function in F. They play an important role in the rational solutions of $L(y) = 0$ in F that come to expression in so-called regular and singular places.

111.16.1 Singular Places

Given a place (q) in the set of places of F, a putative rational solution $y \in F$ of $L(y) = 0$ has a q-adic expansion

$$y = y_\alpha \, q^\alpha + y_{\alpha+1} \, q^{\alpha+1} + \ldots$$

It has a pole at the place (q) if the valuation α is negative. After substituting this solution in $L(y)$ it becomes clear that there is only a finite number of places which can occur as poles of an arbitrary solution of $Ly = 0$. Such a place is either a pole of one of the coefficients a_i or a zero or a pole of the differential ω of $F[D]$. There exists a classification for the poles of solutions of $L(y) = 0$.

Given a place (q) and local parameter t at (q), the differential operator can be rewritten as a differential operator $\tilde{L} \in \tilde{F}[\tilde{D}]$, with $\tilde{F} \cong F$, the valuation of whose differential at (q) is 0. The place (q) is defined to be a *singular place* of L, if one of the coefficients of $\tilde{L}$ has negative valuation at (q). Places that are not singular are called *regular*.

There are two kinds of singular places of a differential operator; the *regular singular* places and the *irregular singular* places. With the notation as above, a singular place (q) of L is regular singular if the valuation of the coefficient of $(\tilde{D})^i$ in $\tilde{L}$ is at most $i - n$ for every $i \in \{0, 1, \ldots, n-1\}$. Otherwise it is irregular singular.

`IsRegularPlace(L, p)`

Returns `true` iff the place p is a regular place of the differential operator L. If p is not a regular place of L `false` is returned. This function only works for operators whose derivation is defined by a differential.

`IsRegularSingularPlace(L, p)`

Returns `true` iff the place p is a regular singular place of the differential operator L. If p is not a regular singular place of L `false` is returned. This function only works for operators whose derivation is defined by a differential.

`IsIrregularSingularPlace(L, p)`

Returns `true` iff the place p is an irregular singular place of the differential operator L. If p is not an irregular singular place of L `false` is returned. This function only works for operators whose derivation is defined by a differential.

`SetsOfSingularPlaces(L)`

Two sets are returned. The first set contains precisely all regular singular places of the differential operator L. The second set consists of all irregular singular places of L. This function only works for operators whose derivation is defined by a differential.

`IsFuchsianOperator(L)`

Returns `true` iff the differential operator L is Fuchsian (i.e. if all singular places of L are regular singular). If L is not Fuchsian, `false` is returned. Secondly, the set of all singular places of L, is returned only if L is a Fuchsian differential operator. This function only works for operators whose derivation is defined by a differential.

`IsRegularSingularOperator(L)`

Returns `true` if and only if the differential operator L is regular singular. The operator may be defined over a differential Laurent series ring, F say. In this case being regular singular means that the operator must be regular singular at $F.1$. Then also there is no second argument returned. In the case that the derivation is defined with respect to a differential, then the values from `IsFuchsianOperator(`L`)` are returned.

Example H111E56

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> H := (z^2-z)*D^2+(3*z-6)*D+1;
> IsRegularPlace(H, Zeros(z)[1]);
false
> IsRegularSingularPlace(H, Zeros(z)[1]);
true
> SetsOfSingularPlaces(H);
```

```
{ (1/z), (z - 1), (z) }
{}
> IsFuchsianOperator(H);
true { (z), (1/z), (z - 1) }
> IsFuchsianOperator(D^2-1/z^3);
false
```

Example H111E57

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> R<D> := DifferentialOperatorRing(S);
> IsRegularSingularOperator(D^2 -t*D+2);
true
> IsRegularSingularOperator(D^2 +3);
true
> IsRegularSingularOperator(D^2 +3 +O(t));
true
> IsRegularSingularOperator(D^2 +3*t^(-1));
false
```

111.16.2 Indicial Polynomials

For the definition of a indicial polynomial at a place, we refer to Section 4.1 in [vdPS03].

`IndicialPolynomial(L, p)`

Returns the monic indicial polynomial of the differential operator L at the place p. This function only works for operators whose derivation is defined by a differential and whose base ring has one generator.

Example H111E58

```
> F<z> := RationalDifferentialField(Rationals());
> _<T> := PolynomialRing(Rationals());
> R<D> := DifferentialOperatorRing(F);
> H := (z^2-z)*D^2+(3*z-6)*D+1;
> IndicialPolynomial(H, Zeros(z)[1]);
T^2 + 5*T
> IndicialPolynomial(H, Zeros(z-1)[1]);
T^2 - 4*T
> IndicialPolynomial(H, Zeros(1/z)[1]);
T^2 - 2*T + 1
> Apply(H, (z-1)^4/z^5);
0
```

111.17 Rational Solutions

`RationalSolutions(L)`

Given a differential operator L, a basis of the nullspace of rational solutions of $L(y) = 0$ in F is returned as a sequence of basis elements. This function only works for operators whose derivation is defined by a differential. The algorithm that is used is described in Section 4.1 of [vdPS03].

`HasRationalSolutions(L, g)`

Given a differential operator L with coefficients in F and an element g of F, return `true` if there is an element $y \in F$ satisfying $L(y) = g$. If such a solution exists a particular solution in F and the basis of the nullspace of rational solutions in F are also returned. If there is no solution, only `false` is returned. This function only works for operators whose derivation is defined by a differential.

Example H111E59

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> H := (z^2-z)*D^2+(3*z-6)*D+1;
> RationalSolutions(H);
[ (z^4 - 4*z^3 + 6*z^2 - 4*z + 1)/z^5 ]
> L := D^2-6/z^2;
> RationalSolutions(L);
[ z^3, 1/z^2 ]
> Apply(L, z^3+1/z^2);
0
> HasRationalSolutions(L, 6/z);
true -z [ z^3, 1/z^2 ]
> L(-z);
6/z
```

111.18 Newton Polygons

The Newton polygon of a differential operator L and its Newton polynomials can be used to factorize L. A classical example of the Newton polygon uses the derivation $z \cdot d/dz$, where z is a generator of the basefield of L. This Newton polygon is known as *the* Newton polygon of L. Its definition, as used in MAGMA, is given in §3 of [vH97b] and is applicable to operators over a Laurent series ring with generator z, as well as to operators over fields for which a set of places exist. For fields in the latter category it is however not necessary to restrict to the derivation $z \cdot d/dz$ based at $z = 0$ (in other words: at the place (z)). More generally, the Newton polygon of L at the place (p) is the Newton polygon at $t = 0$ after rewriting L as a differential operator $\tilde{L}$ in a local parameter t of (p), such that derivation of $\tilde{L}$ is of the form $t \cdot d/dt$.

`NewtonPolygon(L)`

Returns the Newton Polygon of the differential operator L over a differential Laurent series ring. This means that for the computation of the Newton polygon L may have had to be rewritten as a differential operator $\tilde{L}$ over a differential Laurent series ring $C((t))$, say, such that $\tilde{L}$ has derivation $t \cdot d/dt$. The second argument returned is the operator $\tilde{L}$.

`NewtonPolygon(L, p)`

Returns the Newton polygon of the differential operator L at the place p. The derivation of L must be defined with respect to a differential and the base ring of L should have one generator. For the computation of the Newton polygon another differential operator $\tilde{L}$, say, may have had to be calculated. The differential of the derivation of $\tilde{L}$ has valuation -1 at the place p. The differential operator $\tilde{L}$ is also returned.

`NewtonPolynomial(F)`

Returns the Newton polynomial of the face F of a Newton polygon. The Newton polygon must have been created with respect to a differential operator. The Newton polynomial depends on a uniformizing element, therefore, its variable is well–defined up to scalar multiplication by a non–zero element. The definition of the Newton polynomial of a face that is used by MAGMA, is given in Section 3 of [vH97b].

`NewtonPolynomials(L)`

Returns all Newton polynomials of L with respect to the faces of its Newton polygon. The second argument returned is the corresponding slopes.

Example H111E60

```
> K := RationalDifferentialField(Rationals());
> F<z> := ChangeDerivation(K, K.1);
> Differential(F);
(1/z) d(z)
```

```
> R<D> := DifferentialOperatorRing(F);
> L := 10*z*D^2+3*D-1;
> npgon, op := NewtonPolygon(L, Zeros(z)[1]);
> npgon;
Newton Polygon of 10*z*$.1^2 + 3*$.1 - 1 over Algebraic function field
defined over Rational Field by
$.2 - 4711 at (z)
> op;
10*z*D^2 + 3*D + -1
> faces:= Faces(npgon);
> faces;
[ <0, 1, 0>, <-1, 1, -1> ]
> _<T> := PolynomialRing(Rationals());
> NewtonPolynomial(faces[1]);
3*T - 1
> NewtonPolynomial(faces[2]);
10*T + 3
```

Example H111E61

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> L := D^2+z*D-3*z^2;
> npgon, op := NewtonPolygon(L, Zeros(1/z)[1]);
> op;
1/z^2*$.1^2 + (-z^2 + 1)/z^2*$.1 + -3*z^2
> Differential(Parent(op));
(-1/z) d(z)
> Valuation($1,Zeros(1/z)[1]);
-1
> faces:= Faces(npgon);
> faces;
[ <-2, 1, -2> ]
> _<T> := PolynomialRing(Rationals());
> NewtonPolynomial(faces[1]);
T^2 - T - 3
```

Example H111E62

This example corresponds to Examples 3.46 and 3.49.2 from [vdPS03].

```
> S<t> := DifferentialLaurentSeriesRing(Rationals());
> R<D> := DifferentialOperatorRing(S);
> L := t*D^2+D-1;
> npgon, op := NewtonPolygon(L);
> L eq op;
true
```

```
> Faces(npgon);
[ <0, 1, 0>, <-1, 1, -1> ]
> _<T> := PolynomialRing(Rationals());
> NewtonPolynomials(L);
[
    T - 1,
    T + 1
]
[ 0, 1 ]
> L := D^2+(1/t^2+1/t)*D+(1/t^3-2/t^2);
> npgon, op := NewtonPolygon(L);
> L eq op;
true
> NewtonPolynomials(L);
[
    T + 1,
    T + 1
]
[ 1, 2 ]
```

111.19 Symmetric Powers

`SymmetricPower(L, m)`

Returns the m-th symmetric power of the differential operator L as an element of the parent of L. The symmetric power is monic where possible. If n denotes the order of L, then the degree of the m-th symmetric power of L is at most $\binom{n+m-1}{n-1}$. The algorithm that is used is based on algorithms given in [BMW97].

Example H111E63

```
> F<z> := RationalDifferentialField(Rationals());
> R<D> := DifferentialOperatorRing(F);
> SymmetricPower(D^2, 3);
D^4
> SymmetricPower(D^3-1, 2);
D^6 + -7*D^3 + -8
```

111.20 Differential Operators of Algebraic Functions

An algebraic function g in a differential field extension M/F satisfies a linear differential equation $L(y) = 0$ with coefficients in $F \subset M$. If the minimal polynomial of g over F is of degree n, then the order of L is at most n.

`DifferentialOperator(f)`

Given the irreducible polynomial $f(X) \in F[X]$, return the monic differential operator over F of minimal degree to which a formal root of f is a solution. The field F must be a differential field. The base ring of the created differential operator is F.

The algorithm used in this function is straightforward. If g is a root of an irreducible polynomial $f(X) \in F[X]$, where F is a differential field, then $f(g) = 0$ induces a unique derivation on g. The field $M = F(g)$ is an algebraic differential field extension of F containing all derivatives of g. If n is the degree of the polynomial f, then M/F is a field extension of degree n. This implies that there must be at least one non–trivial linear relation between $g, \delta_M(g), \ldots, \delta_M^n(g)$. The linear relation between these elements involving the lowest powers of δ_M^i gives exactly the desired monic differential operator after a suitable normalization.

Example H111E64

```
> F<z> := RationalDifferentialField(Rationals());
> _<X> := PolynomialRing(F);
> f := X^3-z;
> L := DifferentialOperator(f);
> L;
$.1 + -1/3/z
> M<alpha> := ext<F|f>;
> R<D> := DifferentialOperatorRing(M);
> Apply(R!L,alpha);
0
```

111.21 Factorisation of Operators over Differential Laurent Series Rings

When factoring a non-trivial linear differential operator in

$$P[\delta] := k((t))[\delta],$$

with constant field k, differential Laurent Series ring $k((t))$ in t, and derivation δ, one at least wants to compute two operators L and R in P such that $f = L \cdot R$. It is important to distinguish the left and right hand operators (L and R) as such as multiplication generally is non-commutative. When considering differential operators in the operator ring P, it is common to consider δ to be $t \cdot d/dt$. This specific form has the advantage that the degree

of $\delta \cdot t$ in t remains one, since $\delta \cdot t = t \cdot \delta + t$. This specific derivation is called the *projective derivation* and we consider this derivation in the rest of this section. In this sense powers of t are eigenvectors under the application of the derivation.

A possible approach for factoring a linear operator would be to compute all non-constant irreducible right hand factors and then use recursion on the appropriate left hand factors. However, this causes a problem as there may be infinitely many factorisations. For instance $\delta^2-\delta$ has infinitely many factorisations (parametrisations) $(\delta-c/(t+c))(\delta-t/(t+c))$ for any $c \in P^1(k)$. The approach we take to find right hand factors follows [vH97b], and chooses a canonical representative from a class of right hand factors. The obtained representatives can be used in the factorisation of linear differential operators over a rational function field, see [vH97a].

A non-trivial linear differential operator f in P acts on the solution space V of all differential operators in the differential closure of $k((t))$. This action is $\bar{k}$-linear and surjective on V. The kernel $V(f)$ of this map has dimension equal to the order of the operator. The general solution space V can be split into a direct sum of smaller $\bar{k}$-vector spaces V_e. These are minimal such that $f(V_e) \subset V_e$ for every operator in P. Its kernel $V_e(f)$ consists of all solutions of $f(y) = 0$ in V_e. As a consequence the solution space of the operator then is $V(f) = \oplus_e V_e(f)$. For each of the e with non-trivial solution space of f, the idea now is to find an irreducible right hand factor of f in $k((t))[\delta]$ that annihilates $V_e(f)$.

111.21.1 Slope Valuation of an Operator

The Newton Polynomial of an operator f and its slopes contain useful information regarding its factorisation possibilities. It was proved by Malgrange that an operator over a Laurent series ring is reducible if its Newton polygon has at least two slopes. When on the other hand the Newton polygon has one positive slope, and the accompanying Newton polynomial has two relatively prime factors, then the operator is irreducible as well. It can be shown that an irreducible right hand factor has an irreducible Newton polynomial that divides the Newton polynomial of f. When an appropriate irreducible factor of the polynomial of f is taken, One can start building a right hand factor operator with coefficients of a certain precision that has exactly the irreducible factor as its Newton polynomial. Subsequently one can try to lift the coefficients to a better, possibly predescribed precision.

Various measures for the precision are possible, for instance the absolute precision of the coefficients is common. Another valuation metric is or one related to the slope of the Newton polynomial. It is defined as follows. Assume that $P := k((t))[\delta]$ has projective derivation $t \cdot d/dt$, Let s be a rational with numerator n and denominator d such that $\gcd(n, d) = 1$ and $d > 0$ hold. Then the *slope valuation* of a monomial $ct^i\delta^j$, $c \in k\backslash\{0\}$, with respect to s is defined as $V_s(ct^i\delta^j) := id - jn$. The *slope valuation* of the operator $L \in P$ with respect to s subsequently is defined as the minimum of the slope valuation of each non-zero monomial in L w.r.t s. Commonly s is a slope of the Newton polynomial of L. If the operator is the zero operator, the slope valuation is defined to be infinite.

```
SlopeValuation(L,s)
```

Returns the valuation of L, with respect to the rational slope s, when the derivation of L is projective.

Example H111E65

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> P<D>:=DifferentialOperatorRing(S);
> L:=t^(-2)*D^3+t^7;
> SlopeValuation(L,0);
-2
> SlopeValuation(L,1/2);
-7
> SlopeValuation(L,5);
-17
> L:=(0+O(t^6))*D;
> SlopeValuation(L,0);
Infinity
> Valuation(0+O(t^6));
6
> SlopeValuation(P!0,3);
Infinity
```

111.21.2 Coprime Index 1 and LCLM Factorisation

Coprime index 1 factorisation and LCLM factorisation are two factorisation methods that use similar factorisation machinery, but may result in different factorisations, see [vH97b]. Given an operator $f \in k((t))[\delta]$, both compute a right hand factor with respect to each distinct irreducible factor of the Newton polynomial of f. A local lifting procedure with respect to the slope valuation metric is performed to obtain the coefficients of the right hand factors up to a certain accuracy. In addition, no intermediate differential field extensions of $k((t))$ are used.

The coprime index 1 algorithm does not factor an operator f that has Newton polynomial of the form p^n, $n \geq 2$, with slope $s > 0$. The sum of the degrees of the obtained right hand factors of f may be less than the degree of f itself. Their least common left divisor M divides f on the right (i.e. $f = N * M$) with a kernel of dimension less or equal to $\deg(f)$. The LCLM algorithm, on the other hand, produces a set of right hand factors of a monic operator f whose LCLM is exactly f up to some precision.

`Factorisation(L)`

`Factorization(L)`

`Precision`	RngIntElt	*Default :* -1
`Algorithm`	MonStgElt	*Default :* "*Default*"

Returns a sequence M of operator sequences $[A, B]$ such that $L = A \cdot B$ holds, and B does not have a non-trivial coprime index 1 or LCLM factorisation. As the algorithm

sometimes cannot conclude if a right hand factor is irreducible, a second sequence entry $N[i]$ states `True` if the right hand factor $M[i][2]$ is undisputedly irreducible. The optional argument for the precision is the accuracy up to which the lifting procedure would be performed. The default accuracy is the relative precision of the basering of L. The algorithms used can be eiher "LCLM" or "CoprimeIndexOne". The algorithms used are based on various algorithms in [vH97b].

Example H111E66

The operator $t^2 \cdot d/dt^2 - t \cdot d/dt$ with coefficients in Q has infinitely many factorisations, since it can be written as $(t \cdot d/dt - c/(t+c)) \cdot (t \cdot d/dt - t/(t+c))$ for any rational number c. The factorisation code chooses a canonical right hand factor.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D>:=DifferentialOperatorRing(S);
> L := D^2 -D;
> factsL,blsL:=Factorisation(L:Algorithm:="LCLM");
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
The number of slopes of the Newton polynomial: 1
> (#factsL eq #blsL) and (#factsL eq 1);
true
> blsL;
[ false ]
> factsL[1];
[
    1,
    D^2 + -1*D
]
> factsL,blsL:=Factorization(L:Algorithm:="CoprimeIndexOne");
Ring precision as default precision taken.
Performing coprime index 1 factorisation.
> (#factsL eq #blsL) and (#factsL eq 1);
true
> blsL;
[ true ]
> factsL[1];
[
    D,
    D + -1
]
```

Example H111E67

This example corresponds to Example 3.46 in [vdPS03].

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D>:=DifferentialOperatorRing(S);
```

```
> L:=D*(D+1/t);
> L;
D^2 + t^-1*D + -t^-1
> factsL,blsL:=Factorisation(L:Precision:=4);
Performing coprime index 1 LCLM factorisation.
> blsL;
[ true, true ]
> #factsL eq 2;
true
> factsL[1];
[
    D + t^-1 + 1 - t + 3*t^2 + O(t^3),
    D + -1 + t - 3*t^2 + 13*t^3 + O(t^4)
]
> factsL[2];
[
    D,
    D + t^-1
]
> factsL:=Factorisation(L:Algorithm:="CoprimeIndexOne");
Ring precision as default precision taken.
Performing coprime index 1 factorisation.
> #factsL eq 2;
true
> blsL;
[ true, true ]
> [v[1]*v[2]:v in factsL];
[
    D^2 + (t^-1 + O(t^19))*D + -t^-1 + O(t^19),
    D^2 + t^-1*D + -t^-1
]
```

Example H111E68

This example corresponds to Example 3.49 in [vdPS03].

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D>:=DifferentialOperatorRing(S);
> L:=(D+1/t)*(D+1/t^2);
> L;
D^2 + (t^-2 + t^-1)*D + t^-3 - 2*t^-2
> factsL, blsL:=Factorisation(L:Algorithm:="CoprimeIndexOne",Precision:=6);
Performing coprime index 1 factorisation.
> blsL;
[ true, true ]
> #factsL;
2
> factsL[1];
```

```
[
    D + t^-2 + 2 + t - 3*t^2 - 8*t^3 + O(t^4),
    D + t^-1 - 2 - t + 3*t^2 + 8*t^3 - 9*t^4 + O(t^5)
]
> factsL[2];
[
    D + t^-1,
    D + t^-2
]
> [v[1]*v[2] :v in factsL];
[
    D^2 + (t^-2 + t^-1 + O(t^4))*D + t^-3 - 2*t^-2 + O(t^3),
    D^2 + (t^-2 + t^-1)*D + t^-3 - 2*t^-2
]
```

Example H111E69

This example shows that not all operators may be factored by the factorisation routine. Notice that the Newton polynomial of the operator is a square of a polynomial.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D>:=DifferentialOperatorRing(S);
> L:=(D+2/t)^2;
> np:=NewtonPolygon(L);
> faces:=Faces(np);
> #faces eq 1;
true
> NewtonPolynomial(faces[1]);
$.1^2 + 4*$.1 + 4
> factsL_lclm,blsL_lclm:=Factorisation(L);
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
> factsL_lclm;
[
    [
        1,
        D^2 + 4*t^-1*D + 4*t^-2 - 2*t^-1
    ]
]
> blsL_lclm;
[ false ]
> factsL_c1,blsL_c1:=Factorisation(L:Algorithm:="CoprimeIndexOne");
Ring precision as default precision taken.
Performing coprime index 1 factorisation.
> factsL_c1 eq factsL_lclm;
true
> blsL_c1 eq blsL_lclm;
```

```
true
```

Example H111E70

This example shows that one may not retrieve the factorisation as expected.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> R<D>:=DifferentialOperatorRing(S);
> L := (D+1/(t+1))*D;
> factsL_c1,blsL_c1:=Factorisation(L:Algorithm:="CoprimeIndexOne");
Ring precision as default precision taken.
Performing coprime index 1 factorisation.
> (#factsL_c1 eq 1) and (#blsL_c1 eq 1);
true
> factsL_c1[1][2];
D + O(t^20)
> factsL_lclm, blsL_lclm:=Factorisation(L:Algorithm:="LCLM");
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
The number of slopes of the Newton polynomial: 1
> (#factsL_lclm eq 1) and (#blsL_lclm eq 1);
true
> factsL_c1[1][2], blsL_lclm[1];
D + O(t^20)
false
> M:=(D+1/(t-1))*D;
> factsM:=Factorisation(M:Algorithm:="CoprimeIndexOne");
Ring precision as default precision taken.
Performing coprime index 1 factorisation.
> # factsM eq 1;
> factsM[1][2]+O(t^4);
D + -1 - 1/2*t - 5/12*t^2 - 3/8*t^3 + O(t^4)
```

Example H111E71

One may wish to adjust the default precision to retrieve enough terms in the coefficients in the factors. This example shows the effect on a rational slope 1/5 on the number of terms in the series coefficients of the factors obtained.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals():Precision:=15);
> R<D>:=DifferentialOperatorRing(S);
> L:=(D^5+t^(-1))*D;
> np:=NewtonPolygon(L);
> Slopes(np);
[ 0 , 1/5 ]
> factsL,blsL:=Factorisation(L:Algorithm:="LCLM");
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
```

```
> blsL;
[ true, true ]
> [v[2]:v in factsL];
[
    D,
    D^5 + (-1 - t - 63*t^2 + O(t^3))*D^4 + (1 + 3*t + 253*t^2 +
    O(t^3))*D^3 + (-1 - 7*t - 825*t^2 + O(t^3))*D^2 + (1 + 15*t + 2545*t^2
    + O(t^3))*D + t^-1 - 1 - 31*t - 7713*t^2 + O(t^3)
]
> [v[1]*v[2]:v in factsL];
[
    D^6 + t^-1*D,
    D^6 + O(t^3)*D^5 + O(t^3)*D^4 + O(t^3)*D^3 + O(t^3)*D^2 + (t^-1 +
    O(t^3))*D + O(t^2)
]
> factsL:=Factorisation(L:Algorithm:="LCLM",Precision:=75);
Performing coprime index 1 LCLM factorisation.
> [v[1]*v[2]:v in factsL];
[
    D^6 + t^-1*D,
    D^6 + O(t^15)*D^5 + O(t^15)*D^4 + O(t^15)*D^3 + O(t^15)*D^2 + (t^-1 +
    O(t^15))*D + O(t^14)
]
```

111.21.3 Right Hand Factors of Operators

While resorting to field extensions can result in more complex and time consuming computations, they can be used for obtaining irreducible right hand factors over the original base field.

An effective algorithm to obtain a monic irreducible right hand factor of degree one $\tilde{L}$ of $L \in k((t))[\delta]$ in some field extension $\tilde{k}((\tilde{t}))[\tilde{\delta}]$ is presented in [vH97b, §5.1]. Such a factor $\tilde{L} = \tilde{\delta} - r(\tilde{t})$ of L is called a *Ricatti factor* of L. The operator $\mathrm{LCLM}(\tilde{\delta} - \sigma_1(r), \tilde{\delta} - \sigma_2(r), \ldots, \tilde{\delta} - \sigma_m(r))$ where the σ_i are the Galois group elements of $\tilde{k}((\tilde{t}))/k((t))$, then is a monic and irreducible operator invariant under the Galois action. Hence, it naturally reduces to a monic irreducible right hand factor of L.

Other right hand factors of L, that may be defined over a finite field extensions of $k((t))$ are the so-called *semi-regular* parts of L. Such an operator $R_e(L)$ is the monic right hand semi-regular factor of the translation $S_e(L)$ of L by e. Its degree is equal to the dimension of a non-trivial $\bar{k}$-linear vector space $V_e(L)$, and acts as zero on it. In other words $S_{-e}(R_e)$ is a monic right hand factor of L, possibly defined over a field extension of $k((t))$. It can be shown that L is the least common left multiple of all such right hand factors.

The routine `RightHandFactors` returns right hand factors of a given operator possibly by using temporary field extensions. Each of these are canonical representatives of all right hand factors belonging the slopes of the Newton polynomial of the operator. Currently

one of the internal routines may fail when performing calculations for some specific right hand factor. In this case we cannot conclude it to be irreducible.

`RightHandFactors(L)`

`Precision` RngIntElt *Default :* -1

The canonical list of monic right hand factors of L, one per slope of the Newton polynomial of L. The i^{th} entry in the second sequence returned is true if the i^{th} right hand factor is undisputedly irreducible. The precision attribute relates to the absolute precision a coefficient in a right hand factor should minimally have.

Example H111E72

This example is Example 3.49 from [vdPS03]. The same right hand factors as in Example H111E68 are obtained.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L:=DS^2+(1/t^2+1/t)*DS +(1/t^3-2/t^2);
> rhf, bl := RightHandFactors(L);
Performing coprime index 1 LCLM factorisation.
> #rhf eq 2;
true
> bl;
[ true, true ]
> (Parent(rhf[1]) eq RS) and (Parent(rhf[2]) eq RS);
true
> lhf,rem := EuclideanRightDivision(L, rhf[1]);
> rem;
O(t^20)
> lhf*rhf[1];
DS^2 + (t^-2 + t^-1 + O(t^22))*DS + t^-3 - 2*t^-2 + O(t^20)
> EuclideanRightDivision(L, rhf[2]);
DS + t^-1
0
```

Example H111E73

This example corresponds to Example 3.52 in [vdPS03]. The answer in the book is erroneous.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L:=DS^2-3/2*DS+(2*t-1)/(4*t);
> rhf, bl := RightHandFactors(L);
Performing coprime index 1 LCLM factorisation.
> bl;
[ true ]
> #rhf eq 1;
true
```

```
> rhf[1] eq L;
true
```

Example H111E74

The operator in this example is the same as in Example H111E69 where the routine `Factorisation` was used. The operator did not factor there, but does when using `RightHandFactors`.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L:=(DS+2/t)^2;
> rhf, bl := RightHandFactors(L);
Performing coprime index 1 LCLM factorisation.
Calculating semi-regular parts.
Performing coprime index 1 LCLM factorisation.
Performing coprime index 1 LCLM factorisation.
Computing a first order Ricatti factor.
Performing LCLM calculation on the Ricatti factor.
> rhf;
[
    DS + 2*t^-1
]
> bl;
[ true ]
```

Example H111E75

This example corresponds to Example 3.53 in [vdPS03].

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L:=DS^2 +(4+2*t-t^2-3*t^3)/(t^2)*DS+ (4+4*t-5*t^2-8*t^3-3*t^4+2*t^6)/(t^4);
> np:=NewtonPolygon(L);
> faces:=Faces(np);
> #faces eq 1;
true
> _<T> := PolynomialRing(Rationals());
> NewtonPolynomial(faces[1]);
T^2 + 4*T + 4
> factsL, blsL := Factorisation(L);
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
> blsL;
[ false ]
> (#factsL eq 1) and (factsL[1][2] eq L);
true
> rhf, bl := RightHandFactors(L);
Performing coprime index 1 LCLM factorisation.
```

```
Calculating semi-regular parts.
Performing coprime index 1 LCLM factorisation.
Performing coprime index 1 LCLM factorisation.
Performing coprime index 1 LCLM factorisation.
Computing a first order Ricatti factor.
Performing LCLM calculation on the Ricatti factor.
> bl;
true
> Degree(rhf[1]);
1
> bl;
true
> Parent (rhf[1]) eq RS;
true
> L - EuclideanRightDivision(L, rhf[1])*rhf[1];
O(t^22)*DS + O(t^20)
```

Example H111E76

A collection of operators having the same Newton polynomial $(T^2+1)(T-1)(T+1)$.

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L := DS^4-1/t^4;
> faces:=Faces(NewtonPolygon(L));
> faces;
[ <-1, 1, -4> ]
> _<T> := PolynomialRing(Rationals());
> NewtonPolynomial(faces[1]);
T^4 - 1
> rhf, bl := RightHandFactors(L);
Performing coprime index 1 LCLM factorisation.
> bl;
[ true, true, true ]
> [Degree(v) : v in rhf];
[ 1, 1, 2 ]
>  L - EuclideanRightDivision(L, rhf[1])*rhf[1];
O(t^23)*DS^3 + O(t^22)*DS^2 + O(t^21)*DS + O(t^20)
>  L - EuclideanRightDivision(L, rhf[2])*rhf[2];
O(t^23)*DS^3 + O(t^22)*DS^2 + O(t^21)*DS + O(t^20)
>  L - EuclideanRightDivision(L, rhf[3])*rhf[3];
O(t^23)*DS^3 + O(t^22)*DS^2 + O(t^21)*DS + O(t^20)
> M := DS^4-1;
> faces:=Faces(NewtonPolygon(M));
> faces;
[ <0, 1, 0> ]
> NewtonPolynomial(faces[1]);
T^4 - 1
```

```
> rhf, bl := RightHandFactors(M);
Performing coprime index 1 LCLM factorisation.
Calculating semi-regular parts.
Performing coprime index 1 LCLM factorisation.
Performing LCLM calculation on a semi-regular part.
Calculating semi-regular parts.
Performing coprime index 1 LCLM factorisation.
Computing a first order Ricatti factor.
Performing LCLM calculation on the Ricatti factor.
> rhf;
[
    DS^2 + 1,
    DS + -1
]
> bl;
[ true, true ]
```

Example H111E77

This is the main example of [vH97b]

```
> S<t>:=DifferentialLaurentSeriesRing(Rationals());
> RS<DS> := DifferentialOperatorRing(S);
> L:=DS^9 + 2*t^-1*DS^8 + 3*t^-2*DS^7 + 2*t^-3*DS^6 + (t^-4 + 2*t^-2)*DS^5 +
> (-3*t^-5 + 5*t^-4)*DS^3 + 3*t^-5*DS^2 + (2*t^-6 + 2*t^-5)*DS + 7*t^-5;
> facts := Factorisation(L);
Ring precision as default precision taken.
Performing coprime index 1 LCLM factorisation.
> [Degree(v[2]): v in facts];
[ 1 2 2 4 ]
> isweaklyzero := [];
> vals :=[];
> for i in [1..4] do
>   _,rem := EuclideanRightDivision(L, facts[i][2]);
>   isweaklyzero[i] := IsWeaklyZero(rem);
>   vals[i] := [Valuation(v) : v in Eltseq(rem)];
> end for;
> isweaklyzero;
[ true, true, true, true ]
> [Minimum(v) : v in vals];
[ 14 , 4 , 4 , 11]
> rhf, bl := RightHandFactors(L:Precision:=30);
Performing coprime index 1 LCLM factorisation.
Calculating semi-regular parts.
Performing coprime index 1 LCLM factorisation.
Performing coprime index 1 LCLM factorisation.
Performing coprime index 1 LCLM factorisation.
Performing LCLM calculation on a semi-regular part.
```

```
Computation of the LCLM failed.
> bl;
[ true, true, true, false ]
> [Degree(v): v in rhf];
[ 1 2 2 4 ]
> isweaklyzero := [];
> vals := [];
> for i in [1..4] do
>   [Degree(v): v in Eltseq(rhf[i])];
>   _,rem := EuclideanRightDivision(L, rhf[i]);
>   isweaklyzero[i] := IsWeaklyZero(rem);
>   vals[i] := [Valuation(v) : v in Eltseq(rem)];
> end for;
[ 35, 0 ]
[ 35, 35, 0 ]
[ 35, 35, 0 ]
[ 31, 32, 33, 34, 0 ]
> isweaklyzero;
[ true, true, true, true ]
> [ Minimum(v) : v in vals];
[ 30, 30, 30, 27 ]
```

ALGEBRAIC GEOMETRY

112 SCHEMES

Chapter 112
SCHEMES

112.1 Introduction and First Examples

Schemes are rather general objects of algebraic geometry. A standard reference is Hartshorne's introductory text [Har77]. Included among all schemes are many familiar geometric objects such as plane curves. In Magma, one can work with many of these familiar objects but not with entirely general schemes. Roughly speaking, a scheme in MAGMA is any geometric object defined by the vanishing of polynomial equations in affine or projective space. In particular, there is no facility for defining a scheme *a priori* in terms of a collection of affine patches. Schemes are not automatically normalized. Maps between schemes can be defined by polynomials or quotients of polynomials.

The sections in this introduction contain examples covering the basic idioms understood by MAGMA, especially those for creation of geometric objects, and are intended to be the first place of reference for newcomers to this module.

The design of the general scheme module is not particularly subtle or difficult but the philosophy behind it does require a small amount of understanding. There are two things in particular. Firstly, while constructing geometric objects is easy, many of the constructors take an ambient scheme as an argument as well as some polynomials. Thus one's initial step is often to create some large ambient space which is not of primary interest but in which many schemes will lie. In doing so, one usually assigns names to the coordinate functions of this space, and it is these names which are used when writing the polynomials which define some scheme. Secondly, points are not considered to be elements of schemes, but rather elements of one of a series of *point sets* of schemes indexed by the rings containing the coefficients. (Mathematically speaking, these rings are really algebras over the base ring of the scheme, but in MAGMA the algebra structure is usually implicitly determined by coercion.)

The objects that can be created include

- ambient spaces: affine space, projective space, rational scrolls or weighted projective space over a ring
- schemes as subschemes: the zero locus of polynomials defined on a particular ambient space or on any other scheme
- points of schemes: sequences of ring elements, possibly defined over some extension of the base ring
- maps: sequences of polynomials or rational functions defined on the domain
- linear systems: linear spaces of polynomials defined on ambient spaces

Schemes may be defined quite generally over any ring k, although of course many functions require k to lie in some restricted class. The following restrictions hold: Gröbner basis

calculations may only be performed over an exact field or Euclidean domain; resultant calculations may only be carried out over a unique factorization domain; GCD calculations work over any exact field and the integers and over polynomial rings over either of these; the factorisation of polynomials is possible only over the integers, rationals, finite fields, algebraically closed fields, number fields and function fields. Linear systems are based on the linear algebra module in MAGMA and so are restricted to ambient spaces defined over fields.

The functions described in this chapter are general ones that apply to all schemes. In particular situations additional functions are provided. For example, see Chapter 114 for many specialised functions that apply in the case of curves. In the final subsection of this introduction we say a few words about the various different types of schemes that MAGMA admits.

To some extent we try to emulate Hartshorne's text [Har77] although we remain only a fraction of the way through the material of that book and, of course, we have made innumerable compromises.

In the examples below, > at the start of a line is the MAGMA prompt. It is followed by input which may be typed into a MAGMA session. The remaining lines are output which has been edited slightly in some circumstances, but should nonetheless match closely what appears on screen.

112.1.1 Ambient Spaces

Most schemes are considered to live in an *ambient space*. These include affine and projective spaces, rational scrolls and products. They may be defined over any base ring. The main technical point is that they have an associated coordinate ring (or a homogeneous coordinate ring) that is a polynomial ring, possibly with one or more gradings associated to it.

The syntax for defining an affine space over a ring is similar to that employed when defining a polynomial ring over another ring. The angled bracket notation is used for assigning names to the coordinate functions. It is optional as in the case of polynomial rings. We illustrate by creating an affine 3-space over the finite field of 23 elements with coordinates x, y, z.

Example H112E1

```
> k := FiniteField(23);
> A<x,y,z> := AffineSpace(k,3);
> A;
Affine Space of dimension 3
Variables : x, y, z
```

Various attributes of A are cached and may be subsequently retrieved.

```
> BaseRing(A);
Finite field of size 23
> Dimension(A);
3
```

```
> A.1;
x
> CoordinateRing(A);
Polynomial ring of rank 3 over GF(23)
Lexicographical Order
Variables: x, y, z
```

Projective spaces are normally defined in the same way, but they can also be defined with weights.

```
> P<u,v,w> := ProjectiveSpace(k,[1,2,3]);
> P;
Projective Space of dimension 2
Variables : u, v, w
Gradings :
1       2       3
```

Having defined an ambient space A, polynomials in its coordinate functions can be created. These polynomials are elements of the coordinate ring of A. These polynomials (and sometimes also quotients of them) can be used to define geometric objects related to A. Elements of other polynomial rings have no meaning on A and their use will result in an error.

112.1.2 Schemes

Subschemes of ambient spaces prescribed by the vanishing of finitely many polynomials may be defined. Just as a polynomial ideal in MAGMA belongs to some polynomial ring, so any scheme defined by polynomials is contained in some ambient space. In the case of ideals of polynomial rings the function `Generic()` recovers the polynomial overring. For schemes the analogous function is `AmbientSpace()` (or `Ambient`) which recovers the ambient space.

At the time a scheme is created the system only checks that the defining equations make sense — that they are defined on the nominated ambient space, and are homogeneous if necessary — and does not check other properties such as whether or not the scheme is empty.

In this example, the twisted cubic curve in projective 3-space is defined in terms of equations. The constructor takes these equations in a sequence as one of its arguments.

Example H112E2

```
> k := Rationals();
> P<u,v,w,t> := ProjectiveSpace(k,3);
> M := Matrix(CoordinateRing(P),2,3,[u,v,w,v,w,t]);
> eqns := Minors(M,2);
> C := Scheme(P,eqns);
> C;
Scheme over Rational Field defined by
u*w - v^2
```

```
-u*t + v*w
v*t - w^2
> AmbientSpace(C);
Projective Space of dimension 3
Variables : u, v, w, t
> Dimension(C);
1
> IsNonsingular(C);
true
```

In fact, it is possible to create schemes without reference to an ambient space. For instance, the intrinsic `Spec` may be applied to an affine algebra. But even so, the ambient space defined by the polynomial overring of that algebra is created in the background and may be recovered using the intrinsic `Ambient`. Many constructors require a reference to some overscheme to be clear about *which* scheme the new object is meant to live in.

We note here that there is an important difference between affine schemes and projective ones.

For affine schemes, the defining ideal (generated by the defining equations) is *unique*. That is, there is a $1-1$ correspondence between subschemes of an affine ambient space and the ideals of the coordinate ring of that ambient.

On the other hand, for projective ambients, a given subscheme is defined by multiple homogeneous ideals of the ambient coordinate ring. In this case however, there is a *largest* defining ideal for each subscheme, which we refer to as the *saturated* one.

The practical effect of this is that MAGMA may have to replace the original defining ideal of a projective scheme with the saturated ideal to guarantee the correct result of certain functions (see section 112.3 on page 3494 for more details).

112.1.3 Rational Points

Although closed points of schemes may be defined as schemes in terms of polynomials, there is a far more convenient way to define them: simply coerce the coordinates of the point into the scheme. This is to allow points to be used in a mathematically colloquial way: one understands the statement "the point p lies on the curve C" to mean that the coordinates of p satisfy the equation of C, rather than to mean an inclusion between the two defining ideals. (It also avoids the ideal inclusion test which would be a much more expensive calculation.)

The points $p = (-1, 1)$, $q = (1, 2)$ are created in the affine plane over the finite field of 31 elements. MAGMA's coercion operator, the `!` symbol, provides a concise notation for specifying natural reinterpretations of objects. In this case a sequence of integers is reinterpreted as a point of the finite plane. One of the points created below lies on the standard parabola C.

Example H112E3

```
> k := GF(31);
> A<x,y> := AffineSpace(k,2);
> p := A ! [-1,1];
> q := A ! [1,2];
> p,q;
(30, 1) (1, 2)
> C := Scheme(A,y-x^2);
> p in C;
true (30,1)
> q in C;
false
> [-1,1] in C;
true (30, 1)
```

But this is only the beginning of the story. Objects in MAGMA are always considered to lie in some set or structure called their *parent*. Although it would be natural to take the scheme as the parent of points, instead points have a *point set* as their parent. Point sets are the MAGMA equivalent of "L-valued points" of schemes. If k is the base ring of a scheme X and L is some k-algebra, then the point set of X over L, denoted $X(L)$, comprises points with coordinates in L. In the previous example, the sequences of coordinates were defined over the base ring k and the coercion created elements in the point set $A(k)$. Predicates such as `p in C` were evaluated by testing whether the coordinates of p satisfied the equations of the scheme rather than by consulting their parents. If the point does happen to lie on C, then p is returned as a point of C as second return value. Note the difference between the apparently identical points $(30, 1)$: the first, (p), lies in a point set of A while the second lies in a point set of C. The same effect was achieved using the sequence alone in the last line.
Point sets thus allow one to define points over extensions of k without having to define a new scheme over that extension. In the next fragment, we show how to make a point of C over an extension.

```
> k1<w> := ext< k | 2 >;
> C(k1) ! [w^16,3];
(w^16, 3)
```

An error is signalled if a point set is not nominated.

```
>  C ! [w^16,3];
>>   C ! [w^16,3];
       ^
Runtime error in '!': Illegal coercion
LHS: Sch
RHS: [FldFinElt]
```

The moral is:

A point of a scheme is created by coercing a sequence of coordinates into a point set of the scheme.

While it is true that the "scheme ! coordinates" operation applies when the sequence is defined over the base ring, it might best be thought of as a convenient shorthand in predictable and simple situations. This is analogous to the situation when constructing sets or sequences.

```
> C(k1) ! [w,w^2];
(w, w^2)
>  C(k) ! [w,w^2];
>> C ! [w,w^2];
     ^
Runtime error in '!': Illegal coercion
```

This coercion fails since the coordinates do not belong to a field that embeds into k.

112.1.4 Projective Closure

Affine schemes have projective closures and projective schemes have standard affine patches. For example, the projective plane has three standard affine patches, each of which may be recovered as illustrated in the following example. Here we compute the third affine patch, that is the patch whose points have nonzero first coefficient (in the projective space).

Example H112E4

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> A := AffinePatch(P,3);
> A;
Affine Space of dimension 2
Variables : $.1, $.2
> A<u,v> := A;
> A;
Affine Space of dimension 2
Variables : u, v
> P eq Codomain(ProjectiveClosureMap(A));
true
```

Note that variable names on the patch, and also on closures, are not created automatically. Also, the relationship between patch and closure is cemented by a map.
The projective closures of all schemes contained in a single affine space will lie in a common projective space. Moreover, the closures of schemes lying in distinct affine patches of a single projective space will lie in that same space. In particular, the projective closures of different patches of a projective scheme will be identical.

```
> X := Scheme(A,[u^2-v^3,u^2+v^3]);
> PX := ProjectiveClosure(X);
> PX;
Scheme over Rational Field defined by
z^3
y^2
```

```
> AffinePatch(PX,3) eq X;                    // (1)
true
> aX1:=AffinePatch(PX,1);
> IsEmpty(aX1);                              // (2)
true
> ProjectiveClosure(aX1) eq PX;              // (2)
true
> Y := Scheme(P,[x*y^2-z^3,x*y^2+z^3]);
> AffinePatch(Y,3);
Scheme over Rational Field defined by
u^2 - v^3
u^2 + v^3
> AffinePatch(Y,3) eq X;                     // (3)
true
> Y eq PX;
false
```

This example shows several things. First it shows that taking the appropriate affine patch of a projective closure returns the same scheme again (1). Second, it shows that the projective closure of an affine patch always returns the exactly the same scheme and not a newly created version. This is not always mathematically correct and means that projective closure is dependent on how a scheme was created. Finally, it shows that projective schemes are "saturated at infinity", thereby removing the unnecessary x factor (3).
Points are handled cleanly with respect to projective closure.

```
> p := A ! [0,0];
> PX ! p;
(1 : 0 : 0)
```

Although the coercion of points is very flexible — the affine point p can usually be used in place of the projective point `PX ! p` even when working in PX — code which is explicit about this kind of coercion is probably more clear.

112.1.5 Maps

Maps between schemes are defined in terms of either polynomials or rational polynomials. When a function field exists for the domain, function field elements may also be used. When the domain or codomain is projective, that is, has at least one grading, then compatibility of the defining functions with the gradings will be checked.

Maps to projective spaces are normalised by clearing polynomial denominators.

Example H112E5

```
> k := Rationals();
> P1<s,t> := ProjectiveSpace(k,1);
> P2<x,y,z> := ProjectiveSpace(k,2);
> f := map< P1 -> P2 | [s/t,s^2/(s^2 - t^2),t/s] >;
> f;
```

```
Mapping from: Prj: P1 to Prj: P2
with equations :
s^4 - s^2*t^2
s^3*t
s^2*t^2 - t^4
> IsRegular(f);
true
> Image(f);
Scheme over Rational Field defined by
-x^3*z + x^2*y^2 - 2*x*y^2*z + y^2*z^2
```

The images of points may be computed in the natural way:

```
> p := P1 ! [3,2];
> f(p);
(9/4 : 27/10 : 1)
> f(p) in Image(f);
true (9/4 : 27/10 : 1)
```

And schemes may be pulled back by maps.

```
> S := Scheme(P2,x^2 - y*z);
> Z := Pullback(f,S);
> Z;
Scheme over Rational Field defined by
s^8 - 2*s^6*t^2 - s^5*t^3 + s^4*t^4 + s^3*t^5
> RationalPoints(Z);
{@ (1 : 1), (-1 : 1), (0 : 1) @}
> P := PointsOverSplittingField(Z); P;
{@ (0 : 1), (-1 : 1), (1 : 1), (r1 : 1), (r2 : 1), (r3 : 1) @}
> Ring(Universe($1));
Algebraically closed field with 3 variables
Defining relations:
[
    r3^3 - r3 - 1,
    r2^3 - r2 - 1,
    r1^3 - r1 - 1
]
```

This code computes the intersection of the scheme which is image of f with the conic S (although note that S is defined only as a scheme here and not as a conic). Moving to an algebraic closure one sees a Galois 3-cycle of points among the rational points. Additional functions for analysis of the multiplicities of these intersections are described in Chapter 114.

112.1.6 Linear Systems

Linear systems in projective space are simply collections of hypersurfaces having a common degree which are parametrised linearly by a vector space. The set of all conics in the plane is an example, being parametrised by the 6-dimensional vector space of possible coefficients of a general conic:

$$(a, b, c, d, e, f) \longleftrightarrow (ax^2 + bxy + cy^2 + dxz + eyz + fz^2 = 0).$$

A linear system in MAGMA has associated with it a fixed basis of forms, called its *sections*, of the given degree which allows vectors of coefficients to be interpreted as hypersurfaces. In the example above, the basis is the set of monomials of degree 2 and the bijection between vectors of coefficients and hypersurfaces is explicit. Linear systems are closely related to maps since their sections may be used to define a map from the space on which they are defined to some other projective space.

Let P be a projective plane over some field k with coordinates x, y, z. The linear system of conics on P is created.

Example H112E6

```
> Q := RationalField();
> P<x,y,z> := ProjectiveSpace(Q,2);
> L := LinearSystem(P,2);
> L;
Linear system on Projective Space of dimension 2
Variables : x, y, z
with 6 sections: x^2 x*y x*z y^2 y*z z^2
> Sections(L);
[ x^2, x*y, x*z, y^2, y*z, z^2 ]
```

These sections are now used to make a map from the plane P to 5-space. Its image is the *Veronese surface*.

```
> P5<u0,u1,u2,u3,u4,u5> := ProjectiveSpace(Q,5);
> phi := map< P -> P5 | Sections(L) >;
> Image(phi);
Scheme over Rational Field defined by
-u0*u3 + u1^2
-u0*u4 + u1*u2
-u0*u5 + u2^2
-u1*u4 + u2*u3
-u1*u5 + u2*u4
-u3*u5 + u4^2
```

Geometrical conditions may also be imposed on a linear system. For example, given a linear system L and a point p lying in the projective space on which L is defined, a subsystem of L consisting of those hypersurfaces of L which contain p may be defined implicitly. It may be checked (choosing more convenient coordinates) that the image of this new system is a projection

of the Veronese surface from the point $f(3,2,1) = (9,6,4,3,2,1)$ lying on it. This is an embedding of the blowup of the plane P at the point $(3,2,1)$ also known as the *cubic scroll*.

```
> p := P ! [3,2,1];
> L1 := LinearSystem(L,p);
> L1;
Linear system on Projective Space of dimension 2
Variables : x, y, z
with 5 sections:
x^2 - 9*z^2
x*y - 6*z^2
x*z - 3*z^2
y^2 - 4*z^2
y*z - 2*z^2
> P4<v0,v1,v2,v3,v4> := ProjectiveSpace(Q,4);
> phi := map< P -> P4 | Sections(L1) >;
> Image(phi);
Scheme over Rational Field defined by
-v0*v3 + v1^2 - 4*v2^2 + 12*v2*v4 - 9*v4^2
-v0*v4 + v1*v2 - 2*v2^2 + 3*v2*v4
-v1*v4 + v2*v3 - 2*v2*v4 + 3*v4^2
```

It may also be checked that this image can be described as the vanishing of the two by two minors of a certain matrix.

```
> M := Matrix(3,[v0, v1 + (2*v2 - 3*v4), v2, v1 - (2*v2 - 3*v4), v3, v4]);
> Minors(M,2);
[
    v0*v4 - v1*v2 + 2*v2^2 - 3*v2*v4,
    v1*v4 - v2*v3 + 2*v2*v4 - 3*v4^2,
    v0*v3 - v1^2 + 4*v2^2 - 12*v2*v4 + 9*v4^2
]
> ideal< CoordinateRing(P4) | $1 > eq Ideal(Image(phi));
true
```

112.1.7 Aside: Types of Schemes

This section gives a general overview of the types of scheme that MAGMA admits. While it is not necessary to know this for most applications, it is a useful guide to our point of view and gives some indication of the different data structures used.

The main type is `Sch`. Very general functions such as `BaseRing()` apply at this level. Gröbner basis calculations also apply. One level below this there are

`Aff` — a type for affine spaces

`Prj` — a type for projective spaces

`Crv` — a type for curves

`Clstr` — a type for zero-dimensional schemes, or clusters

These inherit all the operations which apply at the level of `Sch`. The affine type is straightforward. The projective type contains spaces with graded polynomial coordinate rings. There are a number of subtypes of this which identify spaces with more than one grading.

Objects of the curve type `Crv` currently only include schemes defined by a single non-trivial equation in a two-dimensional ambient space. Functions which apply to the curve type are detailed in Chapter 114. The most powerful of those require certain irreducibility and separability conditions to be satisfied by the equation.

More specialised curve types are derived from `Crv`. They include `CrvCon` for plane conics especially those defined over the rationals where fast point-finding algorithms exist; `CrvRat` for rational curves for which a parametrisation algorithm exists; `CrvEll` for elliptic curves, probably the most sophisticated part of the entire geometry module; and `CrvHyp` for hyperelliptic curves where there are fast algorithms for computing on the jacobian. Each of these has a handbook chapter which presents their specialised functions.

112.2 Ambients

For the purposes of this chapter, any scheme is contained in some ambient space, either an affine space or one of a small number of standard projective spaces: these are projective space itself, possibly weighted, and rational scrolls. The basic property of these spaces is that they have some kind of coordinate ring that is a polynomial ring. It happens again and again that we lift polynomials to these polynomial rings before working with them. It is possible to define schemes without reference to such an ambient space, but one will be created in the background in any case.

Listed in this section are the basic creation methods for ambient spaces. Names for the coordinates will usually be required for creating polynomials later on. Names of coordinate functions may be defined using the diamond bracket notation in the same way as for polynomial rings. Coordinate names defined using this will be *globally* defined and retained even outside the context in which they were set. Alternatively, explicit naming functions may be used after creation.

112.2.1 Affine and Projective Spaces

These are the basic ambient spaces. They are used in many situations and are usually sufficient, although there are more in the next section.

`AffineSpace(k,n)`

Create an n-dimensional affine space over the ring k. The integer n must be positive. Names can be assigned using the angle bracket notation, e.g. `A<x, y, z> := AffineSpace(Rationals(), 3)`, which will assign the names to the coordinate ring, usually a multivariate polynomial ring, in the same way as the angle bracket notation works for the multivariate polynomial rings.

`ProjectiveSpace(k,n)`

`ProjectiveSpace(k,W)`

Create an n-dimensional projective space over the ring k. The integer n must be positive. The second argument to this intrinsic can be a sequence of positive integer weights. These weights will be assigned to the coordinate functions of the space. The dimension of the space is one less than the length of this sequence. (At present there are very few functions to perform analysis on weighted projective spaces, but maps between them are treated correctly.) Names can be assigned using the angle bracket notation, e.g. `P<x, y, z> := ProjectiveSpace(Rationals(), 2)`, which will assign the names to the coordinate ring, usually a multivariate polynomial ring, in the same way as the angle bracket notation works for multivariate polynomial rings.

`AffineSpace(R)`

`Spec(R)`

Create the affine space whose coordinate ring is the multivariate polynomial ring R. The coordinate names for the affine space will be inherited from R.

`ProjectiveSpace(R)`

`Proj(R)`

Create the projective plane whose homogeneous coordinate ring is the multivariate polynomial ring R. If R has been assigned a grading then that grading will be used otherwise it will be considered to have the standard grading by degree.

`AssignNames(~A,N)`

A procedure to change the print names of the coordinate functions of the ambient space A. It leaves A unchanged except that the visible names of the first $\#N$ coordinate functions are replaced by the strings of N and the rest return to their default. It does *not* assign the coordinate functions themselves to any identifiers. That must be done by hand, for instance by the command `x := A.1;`. Note that this will change the variable names of the coordinate (polynomial) ring.

`A . i`

`Name(A,i)`

The ith coordinate function of A as an element of the coordinate ring of A.

Example H112E7

An affine 3-space over the finite field of 11^2 elements is created. Initially only the first two coordinate functions are named. The third adopts the default name `$.3`. The identifier which refers to it is `A.3`. Then new names are assigned to all coordinate functions and new identifiers set to refer to them. (Check what happens if the identifiers are not assigned.) Notice that the previous identifiers, x, y, are not erased, although their print values have been updated.

```
> A<x,y> := AffineSpace(FiniteField(11,2),3);
> A;
Affine Space of dimension 3
Variables : x, y, $.3
> AssignNames(~A,["u","v","w"]);
> u := A.1; v := A.2; w := A.3;
> A;
Affine Space of dimension 3
Variables : u, v, w
> x;
u
> u eq x;
true
```

Print values are global in MAGMA, meaning that even if they are changed in the local environment of a function or procedure the new names will persist.

`A eq B`

Returns `true` if and only if the ambient spaces A and B are identical. This will only be the case if both A and B refer to the same instance of creation of the space.

112.2.2 Scrolls and Products

These spaces are created using multiple gradings. They are not as fundamental as the affine and projective spaces of the previous section and may be passed over on first reading.

As we have said, the important thing about ambient spaces in this system is that their coordinate rings are essentially polynomial rings. For affine spaces, this is literally true. For projective spaces, one talks about the *homogeneous* coordinate ring and restricts attention to homogeneous polynomials, that is, polynomials whose terms all have the same weight with respect to a single grading, but nonetheless one is working inside a polynomial ring.

This trick can be pushed further by admitting more than one grading on a polynomial ring. The standard example of this is the family of rational ruled surfaces, or rational surface scrolls, which have a bihomogeneous coordinate ring with four variables u, v, x, y and two gradings which are often chosen to be

$$[1, 1, -n, 0] \quad \text{and} \quad [0, 0, 1, 1]$$

for some nonnegative integer n. Now we restrict attention to polynomials of some homogeneous *bidegree* (or more generally, *multidegree*) of the form $[a, b]$. As with ordinary

projective space, polynomials of a given bidegree form a vector space with a favourite basis of monomials. For example, if $n = 3$, then monomials of bidegree $[2, 1]$ have as their basis

$$u^5x, u^4vx, \ldots, v^5x, uy, vy.$$

As with ordinary projective space, one can ask which polynomials have negative degree. The difference is that this time there is just a little room for manoeuvre: with the same n the monomials of degree $[-4, 2]$ are

$$u^2x^2, uvx^2, v^2x^2.$$

We consider the geometric object having this coordinate ring to be a primitive object of the system. It is called a ruled surface and denoted $\mathbf{F}_n$. This seems to be a rather implicit approach at first, but is very similar to the way one works with projective space itself: at first one learns about homogeneous polynomials, degree 0 rational polynomials, affine patches and so on, but once used to that one gets on and uses it.

There are affine patches on $\mathbf{F}_n$ — a standard 'first' patch is the affine plane where $v \neq 0$ and $y \neq 0$ — and one can study them to get an idea of what this surface looks like. In this case it is a $\mathbf{P}^1$ bundle over $\mathbf{P}^1$, the map to $\mathbf{P}^1$ given by the bidegree $[0, 0]$ ratio u/v and the fibre coordinate being the ratio x/y, not of trivial bidegree on the whole surface, but well-defined for any fixed value of u/v.

We think of the gradings as forming a matrix and allow more general scrolls arising from matrices which are partially row reduced to have rows of the form

$$\begin{pmatrix} 1 & \ldots & 1 & * & \ldots & * & \ldots & & & & \\ 0 & \ldots & 0 & 1 & \ldots & 1 & * & \ldots & & & \\ \vdots & & & & & & & & & & \\ 0 & \ldots & 0 & 0 & \ldots & 0 & 0 & \ldots & 0 & 1 & \ldots & 1 \end{pmatrix}$$

where the $*$ entries may be any integers. To get products of projective spaces we simply set all the entries to be 0. Thinking about which multihomogeneous polynomials arise in this ring and comparing with functions on products of projective spaces is a first exercise.

A reference for the point of view we take on these scrolls is [Rei97] Chapter 2.

`DirectProduct(A,B)`

The product of the ambient spaces A and B together with a sequence containing the two projection maps.

`RuledSurface(k,a,b)`

This returns the ruled surface defined over the ring k whose negative section has selfintersection $\pm(a - b)$, where a, b are non-negative integers.

`RuledSurface(k,n)`

If n is a nonnegative integer, this returns the ruled surface defined over the ring k whose negative section has selfintersection $-n$. The integer n must be non-negative. In terms of the gradings, this means using the standard gradings as described in the introduction with the top-right-hand entries being $-n, 0$.

`AbsoluteRationalScroll(k,N)`

If N is a sequence nonnegative integers this returns the rational scroll with base ring k and gradings with entries being $-N$.

`ProductProjectiveSpace(k,N)`

If $N = [n_1, \ldots, n_r]$ is a sequence of positive integers this returns the product of ordinary projective spaces

$$\mathbf{P}^{n_1} \times \ldots \times \mathbf{P}^{n_r}$$

of dimensions of N over the ring k. This does not create independent copies of the projective factors and in particular does not return projection maps to the factors.

`SegreProduct(Xs)`

Computes the product X of a finite sequence of schemes Xs lying in ordinary projective space. X is constructed in *ordinary* projective space. It is embedded there via an iterated Segre embedding (see Ex. 2.14, Section 2, Chapter 1 of [Har77]). This intrinsic is provided because it is often easier to work in ordinary projective space. However, the user should be warned that the dimension of the ambient increases markedly with Segre embeddings. If the r schemes $Xs[i]$ lie in $\mathbf{P}^{n_i}$, then X will lie in $\mathbf{P}^N$ where N is $(n_1 + 1) * (n_2 + 1) * \ldots (n_r + 1) - 1$.

A sequence containing the r projection maps from X to the $Xs[i]$ is also returned.

`SegreEmbedding(X)`

X should be a scheme lying in a product projective ambient (or the ambient itself!). Computes and returns the image Y of X in ordinary projective space under the iterated Segre embedding (see the preceding intrinsic) along with a scheme isomorphism from X to Y. This is a specialised intrinsic that is generally much faster than using the general machinery to construct the Segre map on the ambient of X and ask for the image of X.

Example H112E8

In the following example, we Segre embed the product of an elliptic curve E with itself into ordinary projective space using the two intrinsics.

```
> Q := RationalField();
> P2<x,y,z> := ProjectiveSpace(Q,2);
> E := Curve(P2,y^2*z-x^3-x^2*z-z^3);
> ExE := SegreProduct([E,E]);
```

```
> P8<a,b,c,d,e,f,g,h,i> := Ambient(ExE);
> ExE;
Scheme over Rational Field defined by
-f*h + e*i,
-c*h + b*i,
-f*g + d*i,
-e*g + d*h,
-c*g + a*i,
-b*g + a*h,
-c*e + b*f,
-c*d + a*f,
-b*d + a*e,
-g^3 - g^2*i + h^2*i - i^3,
-d^3 - d^2*f + e^2*f - f^3,
-c^3 - c^2*i + f^2*i - i^3,
-b^3 - b^2*h + e^2*h - h^3,
-a^3 - a^2*g + d^2*g - g^3,
-a^3 - a^2*c + b^2*c - c^3
> // or we could have started with ExE in product projective space
> P22<x,y,z,s,t,u> := ProductProjectiveSpace(Q,[2,2]);
> EE := Scheme(P22,[y^2*z-x^3-x^2*z-z^3, t^2*u-s^3-s^2*u-u^3]);
> EE;
Scheme over Rational Field defined by
-x^3 - x^2*z + y^2*z - z^3,
-s^3 - s^2*u + t^2*u - u^3
> ExE_1 := SegreEmbedding(EE);
> // transfer ExE_1 to the Ambient of ExE to compare
> ExE_1 := Scheme(P8,[Evaluate(pol,[a,b,c,d,e,f,g,h,i]) : pol in
>             DefiningPolynomials(ExE_1)]);
> ExE eq ExE_1;
true
```

112.2.3 Functions and Homogeneity on Ambient Spaces

`CoordinateRing(A)`

The coordinate ring of the ambient space A. This is some polynomial ring of appropriate rank over the base ring. Gradings on this ring are usually independent of those of the scheme. Note that if the coordinate ring has zero rank then it will be the base ring.

`FunctionField(A)`

The function field of the ambient space A. This is a field isomorphic to the field of fractions of the coordinate ring of A.

`HasFunctionField(A)`

`Gradings(X)`

A sequence containing all the gradings on the projective space X. Each such grading is a sequence of integers whose length is the same as the number of coordinate functions of X. The same sequence is returned when this function is applied to any scheme contained in X.

`NumberOfGradings(X)`

`NGrad(X)`

The number of independent gradings on the projective space X. The same number is returned when this function is applied to any scheme contained in X.

`NumberOfCoordinates(X)`

`Length(X)`

The number of coordinate functions of the ambient space of the scheme X. This is equal to the number of coordinates of any point of X.

`Lengths(X)`

The lengths of the groups of ones in the gradings of a scroll X.

`IsHomogeneous(X,f)`

Returns `true` if and only if the polynomial f is homogeneous with respect to all of the gradings on the scheme X.

`Multidegree(X,f)`

The sequence of homogeneous degrees of the polynomial f with respect to the gradings on the scheme X.

112.2.4 Prelude to Points

Points of schemes are handled in an extremely flexible way: their coordinates need not be elements of the base ring, for instance. We don't discuss the details here but simply show how to create points in ambient spaces and illustrate with an example. This is already enough for non-specialised purposes: intrinsics which take point arguments for computing, say, the tangent space to a curve at a point, can take the underlying point of the ambient space or the point of the curve equally well. Having said that, the later section on points, Section 112.7, should be taken as the definitive reference.

`A ! [a,b,...]`

`A(L) ! [a,b,...]`

For elements $a, b, \ldots$ in the base ring of the scheme A this creates the set-theoretic point $(a, b, \ldots)$ in the affine case, or $(a : b : \ldots)$ in the projective case. Over a field, the projective point will be normalised so that its final nonzero coordinate entry is 1 (and further analogous normalisations when there are at least two gradings as in the case of surface scrolls). The first constructor can only be used if the sequence contains elements of the base ring of A. The second version of the constructor is the standard one. Using it rather than the first allows the user to specify the ring in which the coefficients are to be considered. See the discussion of point sets in the section below on points.

Example H112E9

We create some points with identical coordinates. They are deemed to be unequal by the equality test, but if what you really care about is their coordinates you can check that those are equal.

```
> k<w> := FiniteField(3^2);
> A := AffineSpace(k,2);
> p := A ! [1,2];
> K := ext< k | 2 >;
> q := A(K) ! [1,2];
> m := hom< k -> k | w^3 >;  // Frobenius
> r := A(m) ! [1,2];
> p eq q;
true
>  p eq r;
>>   p eq r;
     ^
Runtime error in 'eq': Arguments are not compatible
Argument types given: Pt, Pt
>  q eq r;
>> q eq r;
     ^
Runtime error in 'eq': Arguments are not compatible
Argument types given: Pt, Pt
```

In the example above, the first method used for the creation of a point is sufficient if you only want to create a point with coefficients in the base ring. The second and third point creations are more precise: they decree exactly the k-algebra in which the coefficients will lie. One should think of the expression `A ! [1,2]` as merely being a convenient shorthand, analogous to defining a sequence without being explicit about its universe.

`Origin(A)`

The origin of the affine space A.

`Simplex(A)`

The sequence of points of the ambient space A having coordinates $(1, 0, \ldots, 0)$, $\ldots (0, \ldots, 0, 1)$ and $(1, \ldots, 1)$ whether A is affine or projective space.

`Coordinates(p)`

The sequence of ring elements corresponding to the coordinates of the point p.

`p[i]`

`Coordinate(p,i)`

The ith coordinate of the point p.

`p @ f`

`f(p)`

`Evaluate(f, p)`

Evaluate the function f of the function field of the scheme X or its ambient at point p which lies on X.

Example H112E10

Although there are many rings which may appear as function fields in various contexts, their elements can all be evaluated at points. (Section 114.8 discusses the function field of a curve which is being used here only as an example.)

```
> A<x,y> := AffineSpace(Rationals(),2);
> FA<X,Y> := FunctionField(A);
> C := Curve(A,x^3 - y^2 + 3*x);
> FC<u,v> := FunctionField(C);
> p := A ! [1,2];
> q := C ! [1,2];
> f := x/y;
> g := X/Y;
> h := u/v;
> Evaluate(f,p), Evaluate(f,q);
1/2 1/2
> Evaluate(g,p), Evaluate(g,q);
1/2 1/2
> Evaluate(h,q);
1/2
> Evaluate(h,p);
1/2
> Evaluate(h,C!p);
1/2
```

112.3 Constructing Schemes

As shown in the examples in the introduction to this chapter, schemes are defined inside some ambient space, either affine or projective space, by a collection of polynomials from the coordinate ring associated with that space. Schemes may also be defined inside other schemes using polynomials from the coordinate ring of the bigger scheme or polynomials from the ambient space.

There is very little difference between creation methods for affine and projective schemes. Of course, in the projective case, the defining polynomials are checked for homogeneity or if an ideal is used, a check is made that its basis contains only homogeneous elements. Otherwise, the only check made at the time of creation is that the polynomials used to define the scheme really do lie in, or are coerced automatically into, the coordinate ring of the chosen ambient space.

Saturation:

As mentioned in the introduction, for schemes in projective spaces, there is a largest ideal which defines that scheme. Technically speaking, if I is any homogeneous defining ideal, this maximal one can be obtained from I by removing the primary components whose radical contains a certain *redundant ideal* of the ambient coordinate ring. This redundant ideal defines sets of points that are illegal projectively. For example, in ordinary projective space, there is one illegal point with all coordinates 0 and this is defined by the redundant ideal $(x_1, \ldots, x_n)$. The operation to remove these primary components is ideal saturation of I by the redundant ideal, so we refer to the maximal defining ideal as *saturated* and a scheme X as saturated if its current ideal (as returned by `DefiningIdeal(X)`) is known to be the maximal one.

There are several basic functions that rely on the defining ideal of a scheme X being saturated. The most important are `IsReduced, IsIrreducible, Prime/Primary Components, eq` for any projective schemes and `Dimension, f(X)` (map images) for multi-graded projective schemes.

As the process of saturation may be quite expensive in higher dimensional ambient spaces, the ideal of X is not saturated until the saturation property is required and once saturation has been performed, this is recorded internally. Additionally, scheme constructions like `Union` will automatically produce a result marked as saturated if that can be deduced from the construction method and the saturation state of the argument schemes. In particular, any ambient or scheme defined by a single equation in an ambient is marked as saturated on construction. The `ProjectiveClosure` of an affine scheme is also saturated by construction.

Furthermore, for all of the basic `Scheme` and `Curve` constructors where saturation of the ideal generated by the defining equations is not automatic, there is a `Saturated` parameter that the user can set to be `true` to mark the initial defining ideal as saturated without further checking.

`Scheme(X,f)`
`Scheme(X,F)`
`Scheme(X,I)`

`Scheme(X,Q)`

`Nonsingular`	BoolElt	*Default :* `false`
`Reduced`	BoolElt	*Default :* `false`
`Irreducible`	BoolElt	*Default :* `false`
`GeometricallyIrreducible`	BoolElt	*Default :* `false`
`Saturated`	BoolElt	*Default :* `false`

Create the scheme inside the scheme X defined by the vanishing of the polynomial f, or the sequence of polynomials F, or the ideal of polynomials I, or the ideal in the denominator of the quotient ring $Q = R/I$. In each case, the polynomials must be elements of the coordinate ring of A or automatically coercible into it.

If any of the optional parameters are set to `true`, MAGMA will assume without checking that the scheme has the corresponding property. This may enable subsequent calculations to be done faster; note that if the assumption is not correct, *arbitrary misbehaviour may result.* The option `Saturated` only makes sense when the ambient is projective, and refers to the defining ideal rather than the scheme.

`Cluster(X,f)`
`Cluster(X,F)`
`Cluster(X,I)`
`Cluster(X,Q)`

`Saturated`	BoolElt	*Default :* `false`

Create the 0-dimensional scheme inside the scheme X defined by the vanishing of the given polynomials. These can be given as the single polynomial f, or the sequence of polynomials F, or the ideal of polynomials I, or the ideal in the denominator of the quotient ring $Q = R/I$. In each case, the polynomials must be elements of the coordinate ring of X or automatically coercible into it.

Example H112E11

In this example we simply create three schemes. The first is an ambient space A, the affine plane, while the others are subschemes of A.

```
> A<x,y,z> := AffineSpace(Rationals(),3);
> X := Scheme(A,x-y);
> X;
Scheme over Rational Field defined by
x - y
> Y := Scheme(X,[x^2 - z^3,y^3 - z^4]);
> Y;
Scheme over Rational Field defined by
x^2 - z^3
y^3 - z^4
```

```
x - y
> Ambient(Y) eq A;
true
```

Note that since Y was created as a subscheme of X it inherits the equations of X. The ambient space of Y is still considered to be A.

`Spec(R)`

The scheme Spec(R) associated to the affine algebra R. A new affine space `Spec(Generic(R))` will be created as the ambient space of this scheme.

`Proj(R)`

The scheme Proj(R) associated to the affine algebra R which will be interpreted with its grading (which will be the standard grading by degree if no other has been assigned). A new projective space `Proj(Generic(R))` will be created as the ambient space of this scheme.

`EmptyScheme(X)`

`EmptySubscheme(X)`

The subscheme of X defined, for an affine scheme X by the trivial polynomial 1, or by maximal ideal $(x_1, \ldots, x_n)$ for a projective scheme X. The returned scheme is marked as saturated.

`X meet Y`

`Intersection(X,Y)`

The intersection of schemes X and Y in their common ambient space. This simply concatenates their defining equations without testing for emptiness.

`X join Y`

`Union(X,Y)`

The union of schemes X and Y in their common ambient space. This is formed by creating the intersection of their defining ideals which is done using a Gröbner basis computation. If both X and Y are saturated then the result is as well and is marked as such.

`&join S`

The union of the schemes in the sequence S in their common ambient space.

`Difference(X, Y)`

Returns the scheme that is obtained by taking the closure of the result of removing (`X meet Y`) from the scheme X, counting multiplicity. The ideal of the result will be the colon ideal of the ideal of X and the ideal of the scheme Y. If X is saturated then the result is as well and is marked as such.

`RemoveLinearRelations(X)`

Convenience function that takes linear relations between variables on X and uses them to eliminate variables. The intrinsic is currently only avaialable for X in ordinary projective space. The result is scheme Y that lies in a lower dimensional projective space that can be identified with the smallest linear subspace of the ambient of X that contains X. Y is returned along with the (linear) scheme isomorphism from X to Y.

`BlowUp(X,Y)`

`BlowUp(X,p)`

`Ordinary` BoolElt *Default :* `true`

The first intrinsic constructs the scheme obtained from blowing up subscheme Y of scheme X (see Section 7, Chapter II of [Har77]). The second is a user convenience special case that blows up the subscheme consisting of a point p (and all of its conjugates if it is not defined over the base field) in a pointset $X(K)$.

Currently X must lie in an ambient that is affine, ordinary projective or product projective. If parameter `Ordinary` is `true` (the default), and X is projective, then the result of the blow-up is embedded in ordinary projective space via the Segre embedding. Otherwise, the result will lie in an ambient that is the direct product of the ambient of X and an ordinary projective space.

For an example, see the first part of the chapter on algebraic surfaces.

The implementation makes use of the ReesIdeal intrinsic.

Example H112E12

The behaviour of `Difference` is shown.

```
> A2<x,y>:=AffineSpace(Rationals(),2);
> C:=Scheme(A2,(x*y)); //union of the x- and y-axis
> X2:=Scheme(A2,x^2);  //y-axis with double multiplicity
> Difference(X2,C); //y-axis with mult. 1.
Scheme over Rational Field defined by
x
> O:=Scheme(A2,[x,y]);
> Difference(C,O);
Scheme over Rational Field defined by
x*y
```

Removing "ambient" spaces is tricky: Everything is removed.

```
> Difference(C,A2);
Scheme over Rational Field defined by
1
> A3<x,y,z>:= AffineSpace(Rationals(),3);
> C:=Scheme(A3,Ideal([x,z])*Ideal([y,z])); //again, union of x- and y-axis
> Z:=Scheme(A3,[z]); //the x,y plane
> Difference(C,Z);
```

```
Scheme over Rational Field defined by
x,
y,
z
```

As one can see, the Z-plane is removed with multiplicities: all that's left is the origin, which has multiplicity 2 in C and only multiplicity 1 in Z.

`Saturate(~X)`

If the scheme X is projective and is not already saturated, saturate its defining ideal.

`AssignNames(~X,N)`

Assign the strings in the sequence N to the ambient coordinate functions of the scheme X.

`X . i`

`Name(X,i)`

The ith coordinate function of the ambient space of the scheme X. The dot notation `X.i` may also be used.

112.4 Different Types of Scheme

As discussed briefly in Section 112.1.7, there are a number of different increasingly specialised data types for schemes. It is often useful to check whether a given scheme can be thought of as belonging to one of these more specialised classes, and if so and appropriate then actually making the type change. In this section we document a number of such type-checking and type-change intrinsics, most of which are of the form `IsSpecialisedType`. These intrinsics always return a boolean value. If that value is `true` then they may also return a new scheme of the given specialised type, although in some trivial cases this does not happen. Of course, each of the different types of scheme has its own methods of construction independently of these intrinsics.

`IsAffine(X)`

Returns `true` if and only if the scheme X is an affine space.

`IsProjective(X)`

Returns `true` if and only if the scheme X is a projective space. Projective space here includes the case of scrolls.

`IsOrdinaryProjectiveSpace(X)`

Returns `true` if and only if the scheme X is a projective space in the usual sense: its coordinate ring has a single grading in which all the variables have weight one.

`IsAmbient(X)`

Return `true` if the scheme X is an ambient space.

`IsCluster(X)`

Returns `true` if and only if the scheme X is a zero-dimensional scheme (but not the empty scheme). See Section 112.8 for intrinsics which apply to clusters.

`IsCurve(X)`

Returns `true` if and only if X is a one-dimensional scheme. See Chapter 114 for intrinsics which apply to curves.

`IsPlaneCurve(X)`

Returns `true` if and only if X is a one-dimensional scheme defined by a single equation in a two-dimensional ambient space.

`IsConic(X)`

Returns `true` if and only if the scheme X is a curve (in the sense of `IsCurve(X)`) which is nonsingular and defined by an equation of degree 2. See Chapter 119 for intrinsics which apply to such conics.

`IsRationalCurve(X)`

Returns `true` if and only if the scheme X is a curve (in the sense of `IsCurve(X)`) which has genus 0. See Chapter 119 for intrinsics which apply to rational curves.

`IsHyperellipticCurve(X)`

Return `true` and a hyperelliptic curve if the scheme X is *trivially* a hyperelliptic curve. This occurs if and only if X is already of `CrvHyp` type or is defined by a non-singular Weierstrass equation in correctly weighted two-dimensional projective space. For a general scheme of type `Crv`, the intrinsic `IsHyperelliptic` in Chapter 114 will determine whether X is isomorphic to a hyperelliptic curve and return an isomorphism to a `CrvHyp` if so. This takes a lot more work in general. See Chapter 125 for more information on hyperelliptic curves.

`IsModularCurve(X)`

Return `true` if and only if the scheme X is a curve of type `CrvMod`. See Chapter 128 for more information on modular curves.

112.5 Basic Attributes of Schemes

These intrinsics report on basic features of the ambient space of a scheme or the equations defining a scheme. In many cases they simply call the corresponding function of the ambient space; the intrinsic `BaseRing()` is an example. The first set of these functions consists of those that only make reference to the ambient space, while the second set is concerned with the defining equations of the scheme.

112.5.1 Functions of the Ambient Space

`AmbientSpace(X)`

`Ambient(X)`

The ambient space containing the scheme X.

`SuperScheme(X)`

The scheme X was created as a subscheme of.

`BaseRing(X)`

`CoefficientRing(X)`

The base ring of the scheme X.

`BaseField(X)`

`CoefficientField(X)`

The base ring of the scheme X if it is a field, otherwise an error.

`IsAffine(X)`

Returns `true` if and only if the ambient space of the scheme X is affine.

`IsProjective(X)`

Returns `true` if and only if the ambient space of the scheme X is projective.

`IsOrdinaryProjective(X)`

Returns `true` if and only if the ambient space of the scheme X is an ordinary projective space, that is, its coordinate ring is generated in degree 1 with respect to the grading on the space.

`IsPlanar(X)`

Return `true` if the ambient of the scheme X is 2-dimensional.

`IsSaturated(X)`

Returns `true` if and only if the current defining ideal of the scheme X, as returned by `DefiningIdeal(X)` is saturated (see section 112.3 on page 3494).

112.5.2 Functions of the Equations

There are many ways to recover the equations which define a scheme. The standard method is to use the `DefiningPolynomials` function (or its singular versions) since it doesn't involve ideal theory overheads and certainly won't call any Gröbner basis functions.

`DefiningPolynomials(X)`

The defining polynomials for the ideal of the scheme X.

`DefiningPolynomial(X)`

The defining polynomial of the scheme X if it is a hypersurface. If X is not a hypersurface, an error is reported.

`DefiningIdeal(X)`

The ideal of a multivariate polynomial ring defining the scheme X.

`CoordinateRing(X)`

The quotient of the coordinate ring of the ambient space of the scheme X by the ideal of X.

`Curve(X)`

The smallest scheme in the inclusion chain above the scheme X which is a curve.

`GroebnerBasis(X)`

Return a sequence containing the polynomials of a Gröbner basis of the defining ideal of the scheme X. Note that the defining polynomials of X will not be changed, but that the basis of the ideal of X will be updated with the Gröbner basis as is the standard in the multivariate polynomial ring module.

`MinimalBasis(X)`

Return a minimal basis of the defining ideal of the scheme X, that is, a sequence of polynomials, no subsequence of which forms a basis of the ideal of X. Note that the defining polynomials of X will not be changed. This is the best human readable basis that MAGMA can supply.

`IsHypersurface(X)`

Returns `true` if and only if the scheme X is definable by a single polynomial. This function will perform a GCD calculation to simplify multiple defining polynomial if possible. The polynomial is returned as a second value.

`JacobianIdeal(X)`

The ideal of partial derivatives of the polynomials which define the scheme X.

`JacobianMatrix(X)`

The matrix $(\partial f_i/\partial x_j)$ of partial derivatives of the defining polynomials of the scheme X.

`HessianMatrix(X)`

The hessian matrix $(\partial^2 f/\partial x_i \partial x_j)$ of the hypersurface X where f is the polynomial which defines X.

`X eq Y`

Returns `true` if the schemes X and Y have the same types, ambients and ideals. If Gröbner basis calculations are not available this question may not be able to be decided. If X and Y are projective then they are saturated before ideal equality is tested for.

`IsSubscheme(X, Y)`

Returns `true` if and only if the scheme X is contained, scheme-theoretically, in the scheme Y. A Gröbner basis calculation checks the reverse inclusion of the corresponding ideals. If X and Y are projective, then X is saturated before the test for inclusion.

`IsLinear(X)`

Return `true` if the scheme X is defined by linear equations, possibly after taking a Gröbner basis.

Example H112E13

In this example we first create some schemes and then test them for inclusions and equality.

```
> P<u,v,w> := ProjectiveSpace(GF(11),2);
> C := Scheme(P,u^2 + u*w + 6*v^2);
> Z := Scheme(C,[u,v]);
> IsSubscheme(Z,C);
true
```

Now we will make another scheme which has the same polynomials as C but which is written in disguise. While the disguise in this case is simply to multiply the polynomial by 2 — the rather-too-obvious false nose and eyebrows among polynomials — the point is to note that the equality test in MAGMA is not fooled. The equality test identifies that the underlying defining ideals are the same and returns `true`.

```
> D := Scheme(P,2*u^2 + 2*u*w + v^2);
> D eq C;
true
> IsSubscheme(C,D) and IsSubscheme(D,C);
true
> DefiningIdeal(D) eq DefiningIdeal(C);
true
> DefiningPolynomial(D) eq DefiningPolynomial(C);
```

```
false
```

As we see in the final line above, checking the equality of ideals corresponds to the natural interpretation of equality.
There are a couple of caveats to this lesson, however. For instance, it is necessary, that the ideals to be comparable, i.e. the schemes must be embedded in the same ambient space.

```
> X<r,s,t> := ProjectiveSpace(GF(11),2);
> E := Scheme(P,r^2 + r*s + 6*t^2);
> E eq C;
false
```

112.6 Function Fields and their Elements

Since the function field of an irreducible variety is a birational invariant, function fields in MAGMA are associated with the projectively closed varieties. For an affine scheme X, the fields returned by `FunctionField(X)` and `FunctionField(ProjectiveClosure(X))` are identical. Currently, only function fields of projective spaces (and therefore of affine spaces) and curves are supported.

The following functions are provided for working with function fields and their elements. Some of these functions are concerned with converting function field elements into elements of the field of fractions of the coordinate ring of (an affine patch of) the scheme of the function field.

Additionally, function field elements may be used in the definition of scheme maps (see Section 112.14) from the projective or affine schemes on which they are defined to other schemes and may be evaluated at points as described earlier.

Function fields of schemes have type `FldFunFracSch` and their elements have type `FldFunFracSchElt`. These types inherit from `RngFunFracSch`, `RngFunFrac`, `RngMPolRes` and `RngFunFracSchElt`, `RngFunFracElt`, `RngMPolResElt` respectively.

`Scheme(F)`

Return the (projective) scheme F is the function field of.

`IntegerRing(F)`
`Integers(F)`

The integer ring of the function field F. This will be the coordinate ring of one of the patches of the scheme of F.

`AssignNames(~F, S)`

Assign the strings in S to be the names of the integer ring of F.

`F ! g`

Coerce the element g into the function field F of a scheme where g is some function on the scheme of F, for example, g may be an element of the field of fractions of the coordinate ring of a scheme having F as its function field.

`F . i`

Return the ith indeterminate of the coordinate ring of the scheme of F as an element of the function field F.

`ProjectiveFunction(f)`

Given an element f of a function field of a scheme, return f as an element of the field of fractions of the coordinate ring of the scheme f is a function on.

`ProjectiveRationalFunction(f)`

Given an element f of a function field of a (projective) scheme X, returns an element of the field of fractions of the coordinate ring of the ambient of X whose restriction to X as a rational function is f.

`RestrictionToPatch(f, Xi)`

Given an element f of a function field of a (projective) scheme X return f as an element of the field of fractions of the coordinate ring of the scheme Xi which must be a patch of X.

`Numerator(f)`
`Denominator(f)`

Given an element f of a function field of a scheme, return the numerator or denominator of f.

`f * g` `f + g` `f - g` `- f` `f / g` `f ^ n`
`f eq g` `IsZero(f)` `IsOne(f)` `IsMinusOne(f)` `IsUnit(f)`

`IntegralSplit(f, X)`

Given a function f on the (projective) scheme X return the numerator and the denominator of g, where g is some rational function on the ambient P of X restricting to f and considered as an element of the field of fractions of the coordinate ring of P.

`Numerator(f, X)`

The first return value of `IntegralSplit(f, X)`.

`Denominator(f, X)`

The second return value of `IntegralSplit(f, X)`.

Example H112E14

Some conversion of function field elements are shown.

```
> P2<X, Y, Z>:=ProjectiveSpace(Rationals(), 2);
> C := Curve(P2, X^2+Y^2-Z^2);
> K<xK, yK> := FunctionField(C);
> aC1<x1,y1> := AffinePatch(C, 1);
> aC2<x2,z2> := AffinePatch(C, 2);
> aC3<y3,z3> := AffinePatch(C, 3);
>
> f := (xK + yK)/(yK);
> K!f;
(xK + yK)/yK
> ProjectiveFunction($1);
(X + Y)/Y
> IntegralSplit(f, C);
X + Y
Y
> RestrictionToPatch(f, aC1);
($.1 + $.2)/$.2
> IntegralSplit(f, aC1);
x1 + y1
y1
> IntegralSplit(f, P2);
x2 + 1
1
```

`Restriction(f, Y)`

Given f in the function field of the scheme X and Y a subscheme of X with a function field, returns g in the function field of Y obtained by restricting f to Y. If f has a pole along Y, then `Infinity` is returned. An error occurs if f is not defined along Y. Presently, the only nontrivial application of this routine is when Y is a curve and X is the ambient of Y.

`GenericPoint(X)`

Returns a point in the pointset `X(FunctionField(X))` of the scheme X, whose coordinates generate `FunctionField(X)`.

112.7 Rational Points and Point Sets

There are two ways to think of points. If X is a scheme defined over a ring k and L is a k-algebra, then there is a set, called a *point set* and denoted $X(L)$ which is the set of points of X having coordinates in L or, in MAGMA terminology, the *parent* of such points. Note that in MAGMA a k-algebra is interpreted to mean any ring which admits coercion from k or which is the codomain of a ring homomorphism whose domain is k. When thinking of points as a sequence of coordinates on some scheme this type of point should be used. It is created by coercing the sequence of coordinates into the required point set using a statement such as

```
> X(L) ! [1,2,3];
```

Alternatively, if the universe of the sequence is equal to the base ring of the scheme, one may simply coerce the sequence into the scheme.

```
> X ! [1,2,3];
```

When the universe of the sequence is the integers, MAGMA will coerce them into the base ring of the scheme and again this shorthand will work.

The word point always refers to an object whose parent is some point set.

When a scheme is defined over a finite field, there are intrinsics which list all of its points defined over that field or over any finite extension of it.

An alternative approach is to consider points, or sets of points, as schemes in their own right. They can be defined by equations, after all. We call such zero-dimensional schemes *clusters*. They are more general than simply collections of points since their ideals could be nonradical. They are discussed in the Section 112.8 together with intrinsics which translate between points and clusters.

If p is a point, there are two ways of accessing its coordinates. The intrinsic `Coordinates` returns the sequence of all coordinates of p while `p[i]` returns the i-th coordinate alone. For example,

```
> p := X ! [1,2,3];
> Coordinates(p);
[ 1, 2, 3 ]
> p[1];
1
```

See Section 112.2.4 for descriptions of these and some other basic functions.

`X(L)`
`PointSet(X,L)`
`X(m)`
`PointSet(X,m)`

The point set of the scheme X of points whose coordinates lie in the ring L or in the codomain of the map m. The map m is a ring homomorphism from the base ring

of X to some other ring. Coercion from the base ring of X to L must be possible if m is not given.

`P eq Q`

Returns `true` if and only if the point sets P and Q where created on the same scheme and with the same map from the base ring of that scheme.

`Scheme(P)`

The scheme X associated to the point set P where P is of the form $X(L)$ for some extension L of the base ring of X.

`Curve(P)`

The smallest scheme in the inclusion chain above the scheme associated to the point set P which is a curve.

`Ring(P)`

The ring L associated to the point set P where P is of the form $X(L)$ for some scheme X.

`RingMap(P)`

The map from the base ring of the scheme of P to the ring of the pointset P.

`X ! Q`

`X(L) ! Q`

The point of the scheme X or the point set $X(L)$ (where X is a scheme and L is some extension ring of its base ring) determined by the sequence of coordinates Q. The universe of the sequence Q must be the base ring of X, or the ring L or some ring from which coercion into one of these is possible.

`p eq q`

Returns `true` if and only if the points p and q lie in some common scheme (possibly after coercion) and their coordinates are equal.

`p in X`

Returns `true` if and only if the point p lies in the scheme X or is coercible into it.

`Scheme(p)`

The scheme on which the point p lies.

`Curve(p)`

The smallest scheme in the inclusion chain above the scheme on which the point p lies which is a curve.

`Q in X`

Returns `true` if and only if all of the points of the set or sequence Q lie in the scheme X or are coercible into it.

`S subset X`

Returns `true` if and only if all points of the set S lie in the scheme X or are coercible into it.

`IsCoercible(X,Q)`

Returns `true` if and only if the sequence Q is the sequence of coordinates of some point of the scheme X. In that case, also return the point.

`RationalPoints(X)`

`RationalPoints(X,L)`

`Points(X)`

`Points(X,L)`

`Bound` RngIntElt *Default :* 1000

An indexed set containing points in the point set $X(L)$, where L is an extension of the base field of X. When not specified, L is taken to be the base field of X. This is implemented in the following situations: (i) L is a finite field, (ii) X has dimension zero, (iii) L is `Rationals()`. In cases (i) and (ii), all the points in $X(L)$ are found. In case (iii), a call to `PointSearch` is made, which searches for points with height up to the specified `Bound` (but note that it does not guarantee finding all of them).

In most cases, the first step is to determine the dimension of X by computing the Groebner basis of its defining ideal. This may be time-consuming; to avoid this one may directly call the relevant search: `Ratpoints` over finite fields, or `PointSearch` (specifying the `Dimension`) over the `Rationals()`.

`RationalPointsByFibration(X)`

`UseHypersurface` BoolElt *Default :* `false`

This is one of the methods used by `RationalPoints` when X is an affine or ordinary projective scheme over a finite field.

The basic idea is to work with a Noether Normalisation of the coordinate ring of X which, in the affine or projective case, gives an everywhere defined map with finite fibres to a linear subspace. We then run over all the points in the subspace adding in the points of X in the finite fibre. Determining the points on a zero-dimensional scheme is relatively fast and so we get a fairly efficient method for listing all points.

There is a variant to the basic algorithm. Rather than running over the linear subspace, it can take fibrations over a hypersurface of dimension one bigger the linear subspace. The points on these as fibred over the subspace may be quicker to find than for a general finite fibration and the finite fibres over the hypersurface are of smaller degree. For example, the general fibre contains only one point when the extra hypersurface equation generates X generically over the subspace.

However it is often slower to use the hypersurface because of the extra computation at the start and the two-stage processing so the default for `UseHypersurface` is `false`. The user may set this parameter to `true` for the variant to be applied.

`Random(S)`

Returns a random point in the pointset $S = X(k)$ where X is a scheme defined over a finite field, and k is a finite field. An error results if the pointset is empty. (Here 'random' simply means all points can occur, but not with uniform distribution.)

This is implemented using the Noether normalisation of X (similarly to `RationalPointsByFibration`).

`HasNonsingularPoint(X)`

`HasNonsingularPoint(X,L)`

Return `true` if and only if the scheme X defined over a finite field contains a non-singular point (defined over the finite field L if it appears as a second argument). In that case, also return such a point.

Example H112E15

In this example we define a scheme over a finite field and compute some points on it. Note that there are two point constructors used here. The first is simply `X ! Q` where Q is a sequence of integers (or base ring elements). In the second, we try to coerce a sequence Q whose elements do not lie in the base ring. The coercion into X cannot be used here. Instead one must be explicit about the intended point set. We have used the `IsCoercible(X,Q)` intrinsic which creates the point as a side-effect. One could also use the `X(L) ! Q` coercion to create the same point.

```
> A<x,y> := AffineSpace(FiniteField(7),2);
> X := Scheme(A,x^2 + y^2 + 1);
> X ! [2,3];
(2, 3)
> L<w> := ext< BaseRing(X) | 2 >;
> IsCoercible(X,[w^4,w^4]);
false
> IsCoercible(X(L),[w^4,w^4]);
true (w^4, w^4)
```

Finding those points was not simply good luck. In fact, we worked backwards and computed all points over the base field or L and chose one from each of those sets.

```
> RationalPoints(X);
{@ (3, 2), (4, 2), (2, 3), (5, 3), (2, 4), (5, 4), (3, 5), (4, 5) @}
> #RationalPoints(X,L);
48
```

We now consider an example of a curve in projective 3-space. In older versions of Magma this ran very slowly indeed. Now however, finding points over a fibration, it only takes a few seconds on a fast machine.

```
> k := GF(7823);
```

```
> R<x,y,z,w> := PolynomialRing(k, 4);
> I := ideal<R | 4*x*z + 2*x*w + y^2 + 4*y*w + 7821*z^2 + 7820*w^2,
>  4*x^2 + 4*x*y + 7821*x*w + 7822*y^2 + 7821*y*w +
>  7821*z^2 + 7819*z*w + 7820*w^2>;
> C := Curve(Proj(R), I);
> // a genus 0 curve with 1 cusp as singularities => 7823+1 points
> pts := RationalPointsByFibration(C); // could also just use RationalPoints
> #pts;
7824
```

Note that MAGMA has very fast machinery for computations like this for elliptic and hyperelliptic curves.

112.8 Zero-dimensional Schemes

This section describes intrinsics for creating zero dimensional schemes or *clusters*. It also discusses those functions which converts a finite set of points into the reduced zero dimensional having this support. Throughout this subsection, a lowercase p denotes a point of a scheme.

The word cluster refers to schemes that are known to be zero dimensional. In general, the intrinsic `Cluster` converts points to clusters while the function `RationalPoints` finds the points on a cluster which are rational over its base field.

Note that there are four constructors of the form `Cluster(X,data)` analogous to the four `Scheme(X,data)` constructors but which make an additional dimension test and type change before returning a cluster determined as a subscheme of X by the data of the second argument.

`Cluster(p)`

`Cluster(X, p)`

`Cluster(S)`

`Cluster(X, S)`

The reduced scheme supported at the point p, or supported at the set of points S, as a subscheme of the scheme X if given.

`RationalPoints(Z)`

`RationalPoints(Z,L)`

The set of rational points of the cluster Z. If an extension of the base field L is given as a second argument, the set of points of $Z(L)$, those points whose coordinates lie in L, is returned.

`PointsOverSplittingField(Z)`

If Z is a cluster this will determine some (not necessarily optimal) point set $Z(L)$ in which all points of Z having coordinates in an algebraic closure of the base field lie and will return all points of $Z(L)$.

`HasPointsOverExtension(X)`

`HasPointsOverExtension(X,L)`

Returns `false` if and only if all points in the support of the scheme X over an algebraic closure of its base field are already defined over its current base field, or all lie in the point set $X(L)$ if the second argument L is given. This intrinsic is most useful when trying to decide whether or not to make an extension of the base field of X to reveal non-rational points. The base field of X does not need to be a finite field.

`Degree(Z)`

The degree of the cluster Z. If Z is reduced, this is equal to the maximum number of points in the support over Z over some extension of its base ring.

Example H112E16

In this example we intersect a pair of plane curves. (Note that much more specialised machinery for working with curves is available in Chapter 114.) First we define two curves and find their points of intersection over the base field. The degree of the cluster Z is the usual numerical *intersection number* of the curves C and D. Here we are more interested in finding exactly those points that lie in the intersection.

```
> k := FiniteField(5);
> P<x,y,z> := ProjectiveSpace(k,2);
> C := Scheme(P,x^3 + y^3 - z^3);
> D := Scheme(P,x^2 + y^2 - z^2);
> Z := Intersection(C,D);
> IsCluster(Z);
true
> Degree(Z);
6
> RationalPoints(Z);
{ (1 : 0 : 1), (0 : 1 : 1) }
> HasPointsOverExtension(Z);
true
```

If C and D were rather general, that is, if Z was reduced, then we would expect 6 points in their intersection. We can't expect that here, but the final line above does confirm that we haven't yet seen all the points of intersection. We allow MAGMA to compute directly over a splitting field.

```
> PointsOverSplittingField(Z);
{ (0 : 1 : 1), ($.1^14 : $.1^22 : 1), ($.1^22 : $.1^14 : 1), (1 : 0 : 1) }
> L<w> := Ring(Universe($1));
> L;
```

```
Finite field of size 5^2
> PointsOverSplittingField(Z);
{ (0 : 1 : 1), (w^14 : w^22 : 1), (w^22 : w^14 : 1), (1 : 0 : 1) }
```

In this case we see that the support is not six points but only four.

112.9 Local Geometry of Schemes

We now discuss intrinsics which apply to a scheme at a single point. At the expense of increasing the number of intrinsics, we try to follow the convention that an intrinsic may simply take a point as its argument or it may take both a point and a scheme as its arguments. In the former case, the implicit scheme argument is taken to be the scheme associated to the point set of the point. In the latter case, it is first checked that the point can be coerced into some point set of the given scheme argument. There are reasons for allowing both methods. Of course, if one is confident about which scheme, X say, a point p lies on then there is no ambiguity about writing, say, `IsNonsingular(p)` rather than `IsNonsingular(X,p)`. On the other hand, the second expression is easier to read, and also guards against the possibility of accidentally referring to the wrong scheme; that is a particular risk here since the answer makes sense even if p lies on some other scheme—imagine the confusion that could arise given a point of a nonsingular curve lying on a singular surface inside a nonsingular ambient space, for instance. But also there are trivial cases when scheme arguments are necessary, `IntersectionNumber(C,D,p)` for example. In fact, that particular example exemplifies the value of points being highly coercible—it is very convenient that the point p could lie in a point set of either C or D or indeed neither of these as long as it could be coerced to them if necessary.

Sometimes a function will require that the point argument is rational, that is, has coordinates in the base ring.

112.9.1 Point Conditions

`IsSingular(X,p)`

Returns `true` if and only if the point p is a singular point of the scheme X.

`IsNonsingular(X,p)`

Returns `true` if and only if the point p is a nonsingular point of the scheme X.

`IsOrdinarySingularity(X,p)`

Returns `true` if and only if the tangent cone to the scheme X at the point p is reduced and X is singular at p. Currently, the scheme X must be a hypersurface.

112.9.2 Point Computations

`Multiplicity(p)`

`Multiplicity(X,p)`

The multiplicity of the point p as a point of the scheme X. If X is not a hypersurface, computed using local Groebner bases.

`TangentSpace(p)`

`TangentSpace(X,p)`

The tangent space to the scheme X at the point p. This linear space is embedded as a scheme in the same ambient space as X. An error will be signalled if p is a singular point of X or is not a rational point of X.

`TangentCone(p)`

`TangentCone(X,p)`

The tangent cone to X at the point p embedded as a scheme in the same ambient space. If the scheme X is not a hypersurface, the computation uses local Groebner bases.

112.9.3 Analytically Hypersurface Singularities

We will say that an isolated singular point p in a pointset $X(k)$ over a field k is a *hypersurface singularity* if the completion of its local ring is isomorphic to the quotient of a power series ring $k[[x_1, \ldots, x_d]]$ by a single power series $F(x_1, \ldots, x_d)$. That is, it is analytically equivalent to the singularity of an analytic hypersurface defined by F at the origin. Clearly d is equal to the dimension of the tangent space at p here. This type of singularity occurs quite commonly (e.g., singular points on actual hypersurfaces, A-D-E singularities on surfaces).

This section contains intrinsics to test whether such a p is a hypersurface singularity and compute the equivalent analytic equation F to given precision, to increase the precision of F at a later stage and to expand a rational function on X to the corresponding element in the field of fractions of $k[[x_1, \ldots, x_d]]$ to any required precision.

`IsHypersurfaceSingularity(p,prec)`

The point p is a singular point in $X(k)$ for a field k. It should be an isolated singularity on X and should only lie on irreducible components of X whose dimension d is maximal, i.e. the dimension of X (these conditions are not checked). The integer *prec* should be positive.

The function returns whether p is a hypersurface singularity on X as defined above. This is also equivalent to the conditions that the tangent space of p has dimension $d + 1$ and that the local ring at p is a local complete intersection ring.

If this is true, the function also returns extra values. The second return value is a multivariate polynomial F_1 in a polynomial ring $k[x_1, \ldots, x_{d+1}]$ such that the

singularity p is analytically equivalent to that of the analytic hypersurface $F \in k[[x_1, \ldots, x_{d+1}]]$ at the origin and F_1 is equal to F for terms of degree less than or equal to *prec*.

The third is a sequence of simple rational functions on X/k (i.e., quotients of polynomials in the coordinate ring of the ambient of X that, if X is projective, have the same degree for all gradings) such that x_i corresponds to the ith rational function of the sequence. If X is affine, these rational functions will all be k-linear forms in the coordinate variables and if X is ordinary projective, linear forms in the coordinate variables divided by a particular variable that is non-zero at p.

The fourth return value is a data record that is needed if the user wants to later expand F to higher precision or to expand arbitrary rational functions on X/k at p.

The implementation makes use of MAGMA's local Groebner bases, after localising p to an affine patch and translating it to the origin.

`HypersurfaceSingularityExpandFurther(dat,prec,R)`

The record *dat* should be the data record returned for a hypersurface singularity p in $X(k)$ by the intrinsic above, *prec* a positive integer and R a polynomial ring over k of rank $d+1$ (d is the dimension of X).

Returns a polynomial that expands the equation of the analytic hypersurface F to include all terms of degree less than or equal to *prec*. The result will be returned as an element of R (with the ith variable of R corresponding to the analytic variable denoted x_i in the exposition of the previous intrinsic).

This intrinsic is very useful to expand F to higher precision after the original call that determined that p was a hypersurface singularity.

`HypersurfaceSingularityExpandFunction(dat,f,prec,R)`

The record *dat* should be the data record returned for a hypersurface singularity p in $X(k)$ by the first intrinsic of this subsection, *prec* a positive integer and R a polynomial ring over k of rank $d+1$ (d is the dimension of X). f should be a rational function on X/k given as an element of the field of fractions of the coordinate ring of the ambient of X or the base change of X to k, if k isn't the base ring of X. f can in fact be given as an element of any rational function field over k whose rank is equal to the rank of the coordinate ring of X. In any case, when X is projective, the numerator and denominator of f have to be homogeneous and have the same degree with repect to all gradings of X.

Returns f pulled back to the analytic coordinate ring at p (identified with $k[[x_1, \ldots, x_{d+1}]]/(F)$ in the notation introduced above) and expanded to required precision. In fact, the return value is given as two polynomials a and b in R, whose variables are identified with the x_i, such that a/b is the finite approximation to the value of the pullback. a and b are actually just the pullbacks of the numerator and denominator of f expanded to include all terms of degree less than or equal to *prec*. The value is returned as two polynomials rather than a quotient as b may be zero if *prec* is sufficiently small even when the denominator of f doesn't vanish on X.

Example H112E17

We consider a singular degree 4 Del Pezzo surface in $\mathbf{P}^4$ over $\mathbf{Q}$ with two conjugate singular points defined over a quadratic extension.

```
> P4<x,y,z,t,u> := ProjectiveSpace(Rationals(),4);
> X := Scheme(P4,[x^2+y^2-2*z^2, x*t+t^2-y*u+2*u^2]);
> IsIrreducible(X);
true
> sngs := SingularSubscheme(X);
> Support(sngs);
> pts := PointsOverSplittingField(sngs);
> pts;
{@ (0 : 0 : 0 : r1 : 1), (0 : 0 : 0 : r2 : 1) @}
> pt := pts[1];
> k := Ring(Parent(pt));
> k;
Algebraically closed field with 2 variables over Rational Field
Defining relations:
[
    r2^2 + 2,
    r1^2 + 2
]
> p := X(k)!Eltseq(pt);
> boo,F,seq,dat := IsHypersurfaceSingularity(p,3);
> boo;
true
> R<a,b,c> := Parent(F);
> F;
2*r1*a*b^2 - 2*a^2*c - 3/2*r1*a*c^2 + 8*a^2 - 4*b^2 + 4*r1*a*c + c^2
> HypersurfaceSingularityExpandFurther(dat,4,R);
-a^4 - r1*a^3*c + 1/2*a^2*c^2 + 2*r1*a*b^2 - 2*a^2*c - 3/2*r1*a*c^2 +
Ψ8*a^2 - 4*b^2 + 4*r1*a*c + c^2
> Rk<p,q,r,s,w> := PolynomialRing(k,5);
>  //can use Rk as base-changed coordinate ring here
> HypersurfaceSingularityExpandFunction(dat,(p^2+q*s)/w^2,3,R);
2*r1*a^3 - 3*a^2*c - 1/2*r1*a*c^2 + 4*a^2 + (2*r1 + 1)*a*c - 1/2*c^2 + r1*c
1
```

112.10 Global Geometry of Schemes

Many of the names of intrinsics in this section come from the usual terminology of algebraic geometry. A reference for them is Hartshorne's book [Har77], especially Chapter II, Section 3.

`Dimension(X)`

The dimension of the scheme X. If X is irreducible then the meaning of this is clear, but in general it returns only the dimension of the highest dimensional component of X. The dimension of an empty scheme will be returned as -1. If the dimension is not already known, a Gröbner basis calculation is employed. If X is projective in a multi-graded ambient then it is saturated before this calculation takes place. The computation method involves computing the `Dimension` of the `Ideal` of the scheme, and then (for projective schemes) subtracting the number of gradings.

`Codimension(X)`

The codimension of the scheme X in its ambient space. In fact, this number is calculated as the difference of `Dimension(A)` and `Dimension(X)` where A is the ambient space, so if X is not irreducible this number is the codimension of a highest dimensional component of X.

`Degree(X)`

The degree of the scheme X.

`ArithmeticGenus(X)`

The arithmetic genus of a scheme X. The ambient space of X must be ordinary projective space.

`IsEmpty(X)`

Returns `true` if and only if the scheme X has no points over any algebraic closure of its base field. This intrinsic tests if the ideal of X is trivial (in a sense to be interpreted separately according to whether X is affine or projective) and then applies the Nullstellensatz.

`IsNonsingular(X)`

Returns `true` if and only if the scheme X is nonsingular and equidimensional over an algebraic closure of its base field. The test `IsEmpty` for the emptiness of the scheme is applied to the scheme defined by the vanishing of appropriately sized minors of the jacobian matrix of X.

`IsSingular(X)`

Returns `true` if and only if the scheme X either has a singular point or fails to be equidimensional over an algebraic closure of its base field.

`SingularSubscheme(X)`

The subscheme of the scheme X defined by the vanishing of the appropriately sized minors of the jacobian matrix of X. If X is not equidimensional, its lower dimensional components will be contained in this scheme whether they are singular or not.

`PrimeComponents(X)`

A sequence containing the irredundant prime components of the scheme X.

`PrimaryComponents(X)`

A sequence containing the irredundant primary components of the scheme X.

`ReducedSubscheme(X)`

The subscheme of X with reduced scheme structure, followed by the map of schemes to X. This function uses a Gröbner basis to compute the radical of the defining ideal of X.

`IsIrreducible(X)`

Returns `true` if and only if the scheme X has a unique prime component. If X is not a hypersurface, a Gröbner basis calculation is necessary and X is saturated before this occurs if it is projective.

`IsReduced(X)`

Returns `true` if and only if the defining ideal of the scheme X equals its radical. If X is a hypersurface the evaluation of this intrinsic uses only derivatives so works more generally than the situations where a Gröbner basis calculation is necessary. In the latter case, X is saturated before the calculation if it is projective.

`IsCohenMacaulay(X)`

`IsGorenstein(X)`

`IsArithmeticallyCohenMacaulay(X)`

`IsArithmeticallyGorenstein(X)`

`CheckEqui` BoolElt *Default :* `false`

These intrinsics currently only apply to schemes in ordinary projective space. The first two intrinsics return whether X is (locally) Cohen-Macaulay/Gorenstein, meaning that the local ring of every the scheme-theoretic point on X satisfies the property. The second two intrinsics return whether the coordinate ring of X (the polynomial coordinate ring of the projective ambient quotiented by the maximal defining ideal of X) satisfies the corresponding property. The arithmetic version implies the local version. The results are stored internally with X for future reference. Also, if X is known to be non-singular, we can immediately deduce the local version of the properties is true and this check is also performed internally.

There is a further slight restriction in that X has to be equidimensional (each irreducible component having the same dimension and there being no other scheme-theoretic "associated points" beside the generic points of the irreducible components : true if X is also reduced). This is *not* checked by default in order to save some computation time. If the user is unsure whether X is equidimensional, the `CheckEqui` parameter should be set to `true` which forces a check.

The implementations use the minimal free polynomial resolution of the maximal defining ideal of X. The arithmetic versions are actually faster than the plain versions. `IsGorenstein` may be particularly heavy computationally as it has to check whether the canonical sheaf is locally free of rank 1 after the Cohen-Macaulay property has been verified.

Example H112E18

In this example we write down a rather unpleasant scheme and analyse the basic properties of its components.

```
> A<x,y,z> := AffineSpace(Rationals(),3);
> X := Scheme(A,[x*y^3,x^3*z]);
> Dimension(X);
2
> IsReduced(X);
false
> PrimaryComponents(X);
[
    Scheme over Rational Field defined by
    x,
    Scheme over Rational Field defined by
    x^3
    y^3,
    Scheme over Rational Field defined by
    y^3
    z
]
> ReducedSubscheme(X);
Scheme over Rational Field defined by
x*y
x*z
```

The reduced scheme of X is clearly the union of a line and a plane. The scheme X itself is more complicated, having another line embedded in the plane component.

112.11 Base Change for Schemes

Let A be some ambient space in MAGMA. For example, think of A as being the affine plane. Let k be its base ring and R_A its coordinate ring. If $m : k \to L$ is a map of rings (a coercion map, for instance) then there is a new ambient space denoted A_L and called the *base change of A to L* which has coordinate ring R_{A_L} with coefficient ring L instead of k. (Mathematically, one simply tensors R_A with L over k. In MAGMA the equivalent function at the level of polynomial rings is `ChangeRing`.) There is a base change function described below which takes A and L (or the map $k \to L$) as arguments and creates this new space A_L. Note that there is a map from the coordinate ring of A to that of A_L determined by the map m.

This operation is called *base extension* since one often thinks of the map m as being an extension of fields. Of course, the map m could be many other things. One key example where the name *extension* is a little unusual would be when m is the map from the integers to some finite field.

Now let X be a scheme in MAGMA. Thus X is defined by some polynomials $f_1, \ldots, f_r$ on some ambient space A. Given a ring map $k \to L$ there is a base change operation for X which returns the *base change of X to L*, denoted X_L. This is done by first making the base change of A to L and then using the map from the coordinate ring of A to that of A_L to translate the polynomials f_i into polynomials defined on A_L. These polynomials can then be used to define a scheme in A_L. It is this resulting scheme which is the base change of X to L.

If one has a number of schemes in the same ambient space and wants to base change them all at the same time, a little care is required. The function which takes a scheme and a map of rings as argument will create a new ambient space each time so is unsuitable. Better would be to base change the ambient space and then use the base change function which takes the scheme and the desired new ambient space as argument. (This latter base change function appears to be different from the other ones. In fact it is not. We described base change above as a function of maps of rings. Of course, there is a natural extension to maps of schemes. With that extension, this final base change intrinsic really is base change with respect to map of ambient spaces.)

`BaseChange(A,K)`

`BaseExtend(A,K)`

If A is a scheme defined over a field k and K is an extension into which elements of k can be automatically coerced then this returns a new scheme A_K defined over K. No cached data about A will be transferred to A_K and coordinate names will have to be defined again on A_K if needed.

`BaseChange(A,m)`

`BaseExtend(A,m)`

If m is a map of rings whose domain is the base ring of the scheme A, this returns the base change of A to the codomain of m. The equations of A, if any, are mapped to the new ambient coordinate ring using m.

BaseChange(F,K)

BaseExtend(F,K)

BaseChange(F,m)

BaseExtend(F,m)

If F is a sequence of schemes lying in a common ambient space whose base ring admits automatic coercion to K or is the domain of a ring map m then this returns the base change of the elements of F as a new sequence.

BaseChange(X,A)

BaseExtend(X,A)

BaseChange(X,A,m)

BaseExtend(X,A,m)

If X is any scheme whose ambient space B is of the same type (affine or projective) and dimension as the ambient space A but either has a base ring which admits coercion to that of A or the map m is a ring map from the base ring of B to that of A then this returns a scheme with the equations of X as a subscheme of A. The equations are transferred to A using coercion or the map m.

BaseChange(X, n)

BaseExtend(X, n)

The base change of the scheme X, where the base ring of X is a finite field to the finite field which is a degree n extension of the base field of X.

Example H112E19

Here are two curves whose intersection points are not defined over the rationals and one of which only splits after a field extension. The basic function to calculate intersection points only searches for them over the current field of definition so misses them at first. But with an extra argument it is able to search over an extension of the base without actually changing base of the schemes. This contrasts with finding higher dimensional components of schemes which always requires the base change.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,x^2 + y^2);
> IsIrreducible(C);
true
> D := Curve(A,x - 1);
> IntersectionPoints(C,D);
{}
> Qi<i> := QuadraticField(-1);
> IntersectionPoints(C,D,Qi);
{ (0, i), (0, -i) }
```

So we have found the intersection points (although we haven't explained how we chose the right field extension). Now we do the same calculation again but by making the base change of all

schemes to the field Qi. Over this field the intersection points are immediately visible, but also the curve C splits into two components.

```
> B<u,v> := BaseChange(A,Qi);
> C1 := BaseChange(C,B);
> D1 := BaseChange(D,B);
> IsIrreducible(C1);
false
> IntersectionPoints(C1,D1);
{ (0, i), (0, -i) }
> PrimeComponents(C1);
[
    Scheme over Qi defined by u + i*v,
    Scheme over Qi defined by u - i*v
]
```

112.12 Affine Patches and Projective Closure

In MAGMA, any affine ambient space A has a unique projective closure. This may be assigned different variable names just like any projective space. The projective closure intrinsics applied to affine schemes in A will return projective schemes in the projective closure of A. Conversely, a projective space has a number of standard affine patches. These will be the ambient spaces of the standard affine patches of a projective scheme. In this way, the closures of any two schemes lying in the same space will also lie in the same space. The same goes for standard affine patches. These relationships between affine and projective objects are very tightly fixed: asking for the projective closure of an affine scheme will always return the identical object, for instance.

`ProjectiveClosure(X)`

The projective closure of the scheme X. If the projective closure has already been computed, this scheme will be returned. If X is an affine space for which no projective closure has been computed, the projective closure will be a projective space with this space as its first standard patch. Otherwise, the result will lie in the projective closure of the ambient space of X. If X has been computed as an affine patch the projective closure will be the scheme it is an affine patch of even if this is not mathematically correct (see Example H112E21).

`AffinePatch(X,i)`

The ith affine patch of the scheme X. The number of affine patches is dependent on the type of projective ambient space in which X lies, but for instance, the standard projective space of dimension n has $n+1$ affine patches. In that case, i can be any integer in the range $1, \ldots, n+1$. The order for affine patches is the natural one once you decide that the first patch is that with final coordinate entry nonzero (in the projective closure).

`AffinePatch(X,p)`

A standard affine patch of the scheme X containing the point p. The second return value is the point corresponding to p in that patch.

`IsStandardAffinePatch(A)`

Return whether the affine space A is a standard affine patch of its projective closure and if so which patch it is. For A to be a non–standard patch means that its projective closure must have been set using `MakePCMap`. Returns `false` if A does not have a projective closure to be a patch of.

`NumberOfAffinePatches(X)`

Return the number of standard affine patches of the scheme X (O if X is an affine scheme).

`HasAffinePatch(X, i)`

Return whether the ith patch of the scheme X can be created.

Example H112E20

This example shows that taking patches and closures several times really does return identical schemes.

```
> A1<u,v> := AffineSpace(GF(5),2);
> X := Scheme(A1,u^2 - v^5);
> PX<U,V,W> := ProjectiveClosure(X);
> PX;
Scheme over GF(5) defined by
U^2*W^3 + 4*V^5
> AffinePatch(PX,1) eq X;
true
> X2<u2,w2> := AffinePatch(PX,2);
> X2;
Scheme over GF(5) defined by
u2^2*w2^3 + 4
> ProjectiveClosure(X2) eq ProjectiveClosure(X);
true
```

Example H112E21

Even if those schemes are not mathematically correct.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> L := Curve(P2,Z);
> Laff := AffinePatch(L,1);
> Dimension(Laff);
-1
> Laff;
```

```
Scheme over Rational Field defined by
1
> ProjectiveClosure(Laff) eq L;
true
> ProjectiveClosure(EmptyScheme(Ambient(Laff)));
Scheme over Rational Field defined by
1
```

`HyperplaneAtInfinity(X)`

The hyperplane complement of the scheme X in its projective closure.

`ProjectiveClosureMap(A)`

`PCMap(A)`

The map from the affine space A to its projective closure.

`AffineDecomposition(P)`

Projective spaces have a standard disjoint decomposition into affine pieces—not the same thing as the affine patches—of the form

$$\mathbf{P}^n = \mathbf{A}^n \cup \mathbf{A}^{n-1} \cup \cdots \cup \mathbf{A}^1 \cup p$$

where $\mathbf{A}^n$ is the first affine patch, $\mathbf{A}^{n-1}$ is the first affine patch on the hyperplane at infinity and so on. Finally, p is the point $(1 : 0 : \cdots : 0)$. This intrinsic returns a sequence of maps from affine spaces to the projective space P whose images are these affine pieces of a decomposition. The point p is returned as a second value.

`CentredAffinePatch(S, p)`

An affine patch of S centred at the point p and the embedding into S, achieved by translation of a standard affine patch.

112.13 Arithmetic Properties of Schemes and Points

This section contains several functions of arithmetic interest, that apply to general schemes defined over the rationals, number fields, or function fields.

112.13.1 Height

`HeightOnAmbient(P)`

`Absolute`	BoolElt	*Default :* `false`
`Precision`	RngIntElt	*Default :* 30

The height of the given point, as a point in the ambient projective space (or affine space). This is the *exponential* height (for the logarithmic height, take `Log`!). By default it is the *relative* height, unless the optional parameter `Absolute` is given. The function works when the ambient space (of the scheme containing P) is any affine or projective space (possibly weighted), and the ring of definition of P is contained in the rationals, a number field or a function field.

Note that `Height` is also defined for certain special schemes, such as elliptic and hyperelliptic curves. In these cases the `Height` is a *canonical, logarithmic, absolute* height.

112.13.2 Restriction of Scalars

`RestrictionOfScalars(S, F)`

`WeilRestriction(S, F)`

`SubfieldMap`	Map	*Default :*
`ExtensionBasis`	[FldElt]	*Default :* []

Given an affine scheme S whose base ring is a field K, the function returns its restriction of scalars from K to F. The scheme S must be contained in an affine space. The field F should be either a subfield of K, or else isomorphic to a subfield of K; in this case the inclusion map may be specified as the optional argument `SubfieldMap`, or otherwise is the same as the map returned by `IsSubfield(F,K)`.

The restriction of scalars S_{res} is a scheme over F satisfying the following functorial property (for point sets): $S_{res}(R) = S(R \otimes_F K)$ for all rings $R \supseteq F$.

Four objects are returned; the first is the scheme S_{res}, and the other three are maps of various kinds:

- the natural map of schemes from the base extension $(S_{res})_{\otimes K}$ to S,
- a function which takes a point in a point set $S_{res}(R)$ and computes its image under the map $S_{res}(R) \to S(RK)$ (if there is no known relationship between R and K an error results), and
- a map of point sets $S(K) \to S_{res}(F)$.

The result is obtained by direct substitution using the standard basis of K/F, or the basis given in ExtensionBasis if this is specified.

112.13.3 Local Solubility

Let X be a scheme over a number field K. One of the fundamental problems in arithmetic geometry is to decide if $X(K)$ is empty. In general, this is a very hard question. One way to arrive at an affirmative answer is to prove that $X(L)$ is empty for some larger field L. An important class of such field is formed by *complete local fields*. These are obtained by taking the p-adic topology on K associated to a prime ideal p of the ring of integers of K and to consider the topological completion L of K (see `Completion` on page 891).

`IsEmpty(Xm)`

`Smooth`	BoolElt	*Default :* `false`
`AssumeIrreducible`	BoolElt	*Default :* `false`
`AssumeNonsingular`	BoolElt	*Default :* `false`
Verbose	`LocSol`	*Maximum :* 2

Let X be a scheme over a number field K and let L be a completion of K at a finite prime. If Xm is the point set of X taking values in L, this function returns if the point set is empty. If `false` is returned, then (a minimal approximation to) a point is returned.

Setting `AssumeIrreducible := true` tells the system to assume that X is irreducible. This leads to unpredictable results if the components of X have distinct dimensions.

Setting `AssumeNonsingular := true` tells the system to assume that X has no L-rational singular points. If there are such points and this flag is set, then an infinite loop can result.

Setting `Smooth := true` tells the system to only consider nonsingular points on X. This is only implemented for plane curves. The system will blow up any L-rational singular points when encountered and test the desingularized model for solubility. If a point is found, then an approximation may be returned that is indistinguishable from a singular point.

The following classes of schemes are recognized and treated separately :

(i) Hyperelliptic curves over fields with large residue field of odd characteristic. For these fields a generalization by Nils Bruin of an algorithm presented in [MSS96] is used. The complexity of this algorithm is independent of the size of the residue field.

(ii) Hyperelliptic curves over fields with small residue field or residue field of even characteristic. For these fields a depth-first backtracking algorithm is used to construct a solution.

(iii) Nonsingular curves represented by a possibly singular planar model. In this case, a depth-first backtracking algorithm is used to construct a solution. Whenever a tentative solution approximates a rational singularity, that singularity is blown up and the construction is continued on the desingularized model with Hensel's lemma as a stopping criterion. Use `Smooth := true` to access this option.

(iv) An intersection in $\mathbf{P}^3$ of a quadratic cone with a singularity at $(0:0:0:1)$ and another quadric. This case (often needed in computations concerning elliptic curves) is handled by testing hyperelliptic curves for local solubility.

(v) General schemes. The system decomposes X into primary components over K, which are equidimensional. For each of the components, it tests the singular subscheme for solubility. If a solution is found, this is returned. Otherwise, it tests the scheme itself for solubility using a depth-first backtracking algorithm with Hensel's lemma as stopping criterion.

Note that to construct a point set over a completion of a number field, one should use `PointSet(X,phi)` where `Kp, phi := Completion(K,p)`. This rather cryptic syntax is due to the fact that, although a completion strictly speaking is an *extension* of K, MAGMA does not recognise this fact and therefore does not allow for automatic coercion into K_p. The system has to be presented explicitly with the map ϕ from K into K_p.

For a description of the algorithms used, see [Bru04].

Example H112E22

Some usage of `IsEmpty` is illustrated below.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2,X^2+Y^2);
> IsEmpty(C(pAdicField(2,20)));
false (O(2^2) : O(2^2) : 1 + O(2^20))
> IsEmpty(C(pAdicField(2,20)):Smooth);
true
> K<i> := NumberField(PolynomialRing(Rationals())![1,0,1]);
> CK := BaseChange(C,K);
> p := (1+i)*IntegerRing(K);
> Kp,toKp := Completion(K,p);
> CKp := PointSet(CK,toKp);
> IsEmpty(CKp:Smooth);
false (O(Kp.1^3) : O(Kp.1^3) : 1 + O(Kp.1^100))
```

Example H112E23

And a simpler example.

```
> p := 32003;
> P<x> := PolynomialRing(Rationals());
> C := HyperellipticCurve(p*(x^10+p*x^3-p^2*4710));
> Qp := pAdicField(p);
> time IsEmpty(C(Qp));
true
Time: 0.090
```

`IsLocallySolvable(X, p)`

`Smooth`	BoolElt	*Default :* `false`
`AssumeIrreducible`	BoolElt	*Default :* `false`
`AssumeNonsingular`	BoolElt	*Default :* `false`

Given a projective scheme X defined over a number field or over the rationals, test if the scheme is locally solvable at the prime ideal p (for number fields) or prime number p (for rationals) indicated. If the scheme is found to have a local point, then `true` is returned together with an approximation to a point. Otherwise, `false` is returned.

The optional parameters have the same meaning as for `IsEmpty` (see above). For a description of the algorithms used, see [Bru04].

Example H112E24

A locally solvable scheme and a non–locally solvable scheme (when considering only non–singular points) are both shown below.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2,X^2+Y^2);
> IsLocallySolvable(C,2);
true (O(2^2) : O(2^2) : 1 + O(2^50))
> IsLocallySolvable(C,2:Smooth);
false
> K<i>:=NumberField(PolynomialRing(Rationals())![1,0,1]);
> CK:=BaseChange(C,K);
> p:=(1+i)*IntegerRing(K);
> IsLocallySolvable(BaseChange(C,K),p:Smooth);
true (O($.1^3) : O($.1^3) : 1 + O($.1^100))
```

`LiftPoint(P, n)`

`Strict`	BoolElt	*Default :* `true`

`LiftPoint(F, d, P, n)`

`Strict`	BoolElt	*Default :* `false`

Let P be in $X(L)$, where X is a scheme over the rationals or over a number field and L is a completion of the base field at a finite prime. This routine attempts to lift P to the desired precision n using quadratic newton iteration. This routine only works if P is distinguishable from all singular points on X. Note that if X is of positive dimension, then the lift is inherently arbitrary.

Due to limited precision used in the computation, it may be impossible to attain the desired precision exactly. By default this leads to an error. If the user specifies `Strict := false` the system silently returns a lift with maximum attainable precision if the desired precision cannot be reached.

The second form provides the same functionality, but requires all input data to be supplied over L. The sequence F should be the defining equations of a scheme over L of dimension d. The sequence P should be coordinates of an approximation of a point on that scheme. The returned sequence is a lift of the point described by P to precision n, if possible.

In principle, a point returned by `IsEmpty` has sufficient precision for `LiftPoint` to work. However, `IsEmpty` may perform nontrivial operations on the scheme. A nonsingular point on a component of X may be singular on X itself.

Example H112E25

A lift of a point in a non empty pointset is given.

```
> P2<X,Y,Z>:=ProjectiveSpace(Rationals(),2);
> C:=Curve(P2,X^2+Y^2-17*Z^2);
> Qp:=pAdicField(2,20);
> bl,P:=IsEmpty(C(Qp));
> LiftPoint(P,15);
(9961 + O(2^15) : O(2^15) : 1 + O(2^20))
```

112.13.4 Searching for Points

The following intrinsic implements a nontrivial method to search for points on any scheme defined over the rationals.

`PointSearch(S,H : parameters)`

`Dimension`	RngIntElt	*Default :* 0
`Primes`	SeqEnum	*Default :* [ ]
`OnlyOne`	BoolElt	*Default :* `false`

Searches for points on the scheme S up to roughly height H. The scheme must be in either an affine space or a non-weighted projective space.

This uses a p-adic algorithm: first find points locally modulo a small prime (or two small primes), then lift these p-adically, and then see if these give global solutions. Lattice reduction is used at this stage, and this makes the method far more efficient than a naive search, for most schemes. Note that points which reduce to singular points modulo p are not necessarily found.

If `OnlyOne` is `true`, then the computation will terminate as soon as one point is found. The algorithm computes the dimension of the scheme unless `Dimension` is set to a nonzero value.

The algorithm chooses its own primes unless `Primes` is non-empty; either one prime or two can be specified. The algorithm slows down considerably in higher dimension — for threefolds, it can take a few hours to search for points up to height 500 or so. For special types of curves (ternary cubics, intersection of quadrics), efficient search methods are implemented under other names (for instance `Points` and `PointsQI`).

Example H112E26

```
> P<a,b,c,d> := ProjectiveSpace(Rationals(),3);
> S := Scheme (P, a^2*c^2 - b*d^3 + 2*a^2*b*c + a*b^3 - a*b^2*c +
>                 7*a*c^2*d + 4*a*b*d^2);
> Dimension(S);
2
> time PS := PointSearch(S,100);
Time: 9.050
> #PS; // not necessarily exhaustive
67571
```

112.14 Maps between Schemes

Given schemes X and Y one can define a map $f : X \to Y$ in a number of ways. The basic method is to give a sequence of polynomials or quotients of polynomials defined on X. If X has an associated function field then function field elements may also be used. Alternative sets of defining polynomials/rational functions may also be given, as long as these represent the same rational map as the original defining set.

Scheme maps in MAGMA represent *rational* maps between schemes. That is, a map $f : X \to Y$ between schemes X and Y actually corresponds to a morphism from a dense Zariski-open subset of X to Y and two maps f and g from X to Y are considered to be equal (and will be so deemed by `eq`, for example) if they are equal as morphisms when restricted to a dense open subset of X that lies in a domain of definition of f and a domain of definition of g. The precise open domain of definition U of a map f is unspecified but in most functional contexts, it is equal to the complement of the base scheme f as returned by `BaseScheme(f)`. This is the set of scheme-theoretic points at which none of the maps given by the defining polynomials/rational functions or any set of alternative defining polynomials are 'naively' defined. `Extend` computes alternative defining equations that reduces the base scheme so that its open complement is equal to the maximal domain of definition of the rational map represented. However, this is a fairly generic implementation that can be computationally very heavy in many cases. When the domain X is a curve with function field and the codomain Y is ordinary projective, the implicit domain of definition for computing the image of points is the maximal domain of definition of f rather than the base scheme. The function field machinery is used here.

Similarly, isomorphisms between schemes can be defined using inverse defining polynomials/rational functions and these represent birational maps rather than actual scheme isomorphisms.

There are some natural functions associated to a map f and some other more complicated functions. The most natural things are, for a point p of X, computing the image point $f(p)$ and, for a subscheme $S \subset Y$ computing the preimage scheme `Pullback(f,S)`. More complicated functions include the standard Gröbner basis algorithm for computing images $f(T) \subset Y$ of subschemes T of X. This is defined when T doesn't lie in the

base scheme of f and the image is actually the scheme theoretic closure of the image of f restricted to the open subset of T on which it is defined.

For some functions such as the image computation just mentioned, it is a requirement that the schemes X and Y be defined over a common base ring and that the map f be defined over the identity map (or coercion map) of this common base ring.

Maps respect point set structures. Indeed, given a map f as above and an extension L of k, the base ring of X, there is a map $f(L) : X(L) \to Y(L)$. The point set of Y is determined by the composition of the map of base rings with the extension map $k \to L$. This map $f(L)$ cannot be created without creating the scheme map f first, and in any case it is not usually explicitly required: the evaluation of $f(p)$ will invoke it in the background, for example. But when the main purpose of f is to transfer a large number of points from $X(L)$ to $Y(L)$ then it is best to assign $g := f(L)$ explicitly and use the map g. In this way the small additional overheads involved in repetitively constructing $f(L)$ are avoided. Perhaps more importantly, it also ensures that the image points all lie in the same point set.

Maps respect projective closures of schemes. That is, given f as above one can compute the projective closure of f which is a map from the projective closure of X to that of Y and which agrees with f where they are both defined.

From V2.16, there is a slight variant on the basic scheme map type (`MapSch`), which we refer to as scheme graph maps and are defined by the graph of the map in the product of the domain and codomain. These currently only have very basic constructors and somewhat less functionality than scheme maps. They will be described in a separate subsection.

Much of the functionality only works for scheme maps f between schemes whose base rings are fields. We usually do not explicitly mention in this documentation when this is a requirement, but the functions will return an error if the base rings are not fields in cases where they must be.

112.14.1 Creation of Maps

The most basic map constructors are described here. It is possible to create maps defined over a map of the base rings of the schemes.

```
map< X -> Y | F >
```

```
map< X -> Y | F, G >
```

```
map< X -> Y | u, F >
```

`Check`	BoolElt	*Default :* `true`
`CheckInverse`	BoolElt	*Default :* `true`

Create the map $X \to Y$ of schemes determined by the sequence F of polynomials or rational functions defined on X. The two schemes X and Y must be defined over compatible base rings, that is, there must exist a ring map u from the base ring of Y to that of X. The polynomials can be elements of the coordinate ring of the ambient space containing X or elements of the coordinate ring of X itself. In any case, the polynomials will be lifted to elements of the coordinate ring of the

ambient space and any ring elements which admit this operation could be used. If the function field of X exists then elements of this may also be used.

The argument u is a map from the base ring of Y to that of X. If it is omitted then natural coercion map is assumed. In practice, the base rings are often identical in which case coercion will simply be the identity map.

A birational inverse specified by polynomials or rational functions on Y can be given as the sequence G.

It is also allowed for F and G to be a sequence of sequences of polynomials or rational functions, giving alternate sets of defining equations (inverse defining equations) that must define the same rational map on X (rational inverse on Y). The base scheme of the map (the inverse) is the intersection of the base schemes of the individual sets of defining equations (inverse defining equations) as described in `BaseScheme`.

There are two parameters `Check` and `CheckInverse` which control exactly what validation checks are carried out.

If the parameter `Check` is set to `false` then no checking occurs at all.

If `Check` is `true` but CheckInverse is `false`, then the map is checked to be well defined from domain to codomain and any inverse to be well defined in the opposite direction. However if there are inverse functions specified, it is not checked that the forward and inverse functions actually define (birational) inverse maps.

If both parameters are `true` then all checks mentioned above are done.

`iso< X -> Y | F, G >`

Create the map $X \to Y$ of schemes determined by the sequence F for which the map $Y \to X$ determined by the sequence G is a birational inverse. The sequences F and G should contain polynomials or rational functions defined on X and Y respectively. The two schemes X and Y must be defined over the same base ring.

The two check parameters for the main map constructor also apply here with the same meaning.

Example H112E27

Map creation is very similar to that for maps between polynomial rings, although here one must put the polynomial arguments into a single sequence.

```
> k := Rationals();
> A<t> := AffineSpace(k,1);
> B<x,y> := AffineSpace(k,2);
> f := map< A -> B | [t^3 + t, t^2 - 3] >;
> f;
Mapping from: Aff: A to Aff: B
with equations :
t^3 + t
```

```
t^2 - 3
```

Features of the map can be computed. Of course, the domain and codomain are trivial attributes of the map while its image requires a Gröbner basis computation.

```
> Domain(f) eq A;
true
Variables : t
> Codomain(f);
Affine Space of dimension 2
Variables : x, y
> Image(f);
Scheme over Rational Field defined by
-x^2 + y^3 + 11*y^2 + 40*y + 48
```

Example H112E28

Defining maps using function field elements directly can be particularly convenient for curves. For example, the user may have a set of such functions coming from some divisor computations. Here is a simple (artificial!) example where a rational map from a projective curve or any of it's affine patchs to the projective line corresponding to a rational function is defined.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^2+y^2-z^2);
> C1 := AffinePatch(C,1);
> C2 := AffinePatch(C,2);
> F := FunctionField(C);
> f := F!(x/y);
> P1 := ProjectiveSpace(Rationals(),1);
> mp1 := map<C->P1 | [f,1]>;
> mp2 := map<C1->P1 | [f,1]>;
> mp3 := map<C2->P1 | [f,1]>;
```

Example H112E29

Maps of the base ring can be included in scheme maps as is the case for maps of polynomial rings. Here we make a Frobenius map.

```
> k<w> := FiniteField(3^2);
> u := hom< k -> k | w^3 >;
> A<t> := AffineSpace(k,1);
> f := map< A -> A | u, [t^3] >;
> f;
Mapping from: Aff: A to Aff: A
with equations :
t^3
and map between base rings
```

```
Mapping from: FldFin: k to FldFin: k given by a rule [no inverse]
```

Notice next how the map f fixes points defined over the prime subfield of k but moves those points with coordinates having nontrivial w component.

```
> p := A ! [w];
> f(p);
(w^3)
> f(A ! [2]);
(2)
```

`IdentityMap(X)`

Create the identity map of the scheme X.

`ConstantMap(X,Y,p)`

`map< X -> Y | Q >`

The map taking all points of the scheme X to the point p of scheme Y where Q is the sequence of coordinates of p.

`Projection(X,Y)`

The linear projection from projective space X to projective space Y that omits the first $\dim X - \dim Y$ coordinates.

`Projection(X, Q)`

`Projection(X)`

`Projection(X, p)`

The projection of the scheme X away from the point p into the projective ambient space Q (if given). If p is not given it is taken to be $(1 : 0 : \ldots : 0)$.

`ProjectionFromNonsingularPoint(X,p)`

The projection of the scheme X from the nonsingular (and rational) point p of X. The projection map is returned as a second value. The image of the blowup of p as a point of X is returned as a third value. If this is a point, it is returned as a point type.

`ProjectiveMap(L, Y)`

`ProjectiveMap(L)`

Given a list L of functions in the function field of X, where X is a projective scheme, return the projective map $X \to Y$ defined by taking those functions as projective coordinates. The scheme Y should be a projective space of dimension one less than the length of L. If Y is not supplied, a new projective space of appropriate dimension is created.

`ProjectiveMap(f, Y)`

`ProjectiveMap(f)`

A short form for `ProjectiveMap([f,1],X,Y)`.

Example H112E30

The above function is illustrated.

```
> P2<X,Y,Z>:=ProjectiveSpace(Rationals(),2);
> C:=Curve(P2,
>      X^4-2*X^3*Y-X^2*Y^2-2*X^2*Y*Z+2*X*Y^3+2*X*Y^2*Z+Y^4-7*Y^3*Z+Y^2*Z^2);
> omega:=CanonicalDivisor(C);
> Degree(omega); //genus 0 curve
-2
> L:=Basis(-omega);
> L;
[
    ($.2 - 4/25) * ($.1^3 - $.1*$.2 + 5/56*$.2^3 + 20/63*$.2^2) * ($.2 - 4) *
    ($.1^3*$.2 - 1/4*$.1^2*$.2^2 - 26/5*$.1^2*$.2 + 4/5*$.1^2 - 7/4*$.1*$.2^3 -
        2*$.1*$.2^2 - 3/4*$.2^4 + 151/20*$.2^3 + 4*$.2^2 - 4/5*$.2)^-1,
    ($.2) * ($.1^2 - 3/14*$.2^2 + 1/63*$.2) * ($.2 - 4) * ($.2 - 4/25) *
    ($.1^3*$.2 - 1/4*$.1^2*$.2^2 - 26/5*$.1^2*$.2 + 4/5*$.1^2 - 7/4*$.1*$.2^3 -
        2*$.1*$.2^2 - 3/4*$.2^4 + 151/20*$.2^3 + 4*$.2^2 - 4/5*$.2)^-1,
    ($.1 + 13/28*$.2 - 8/63) * ($.2 - 4) * ($.2 - 4/25) * ($.2)^2 * ($.1^3*$.2 -
        1/4*$.1^2*$.2^2 - 26/5*$.1^2*$.2 + 4/5*$.1^2 - 7/4*$.1*$.2^3 -
        2*$.1*$.2^2 - 3/4*$.2^4 + 151/20*$.2^3 + 4*$.2^2 - 4/5*$.2)^-1
]
> mp:=ProjectiveMap(L,P2); //anticanonical embedding
> mp;
Mapping from: Crv: C to Prj: P2
with equations :
23/16*X^3 - 113/64*X^2*Y + 5/16*X^2*Z - 71/64*X*Y^2 + 93/16*X*Y*Z + 21/64*Y^3 -
    61/64*Y^2*Z - 5/16*Y*Z^2
-1/8*X^3 + 23/16*X^2*Y + X^2*Z - 19/16*X*Y^2 - 15/8*X*Y*Z - 21/16*Y^3 +
    115/16*Y^2*Z - Y*Z^2
X^3 - 53/32*X^2*Y - 1/8*X^2*Z - 11/32*X*Y^2 - 3/4*X*Y*Z + 21/32*Y^3 -
    13/32*Y^2*Z + 1/8*Y*Z^2
> mp(C);
Curve over Rational Field defined by
X^2 - 15/8*X*Y + 23/4*X*Z - 229/32*Y^2 - 17/16*Y*Z - Z^2
```

`Elimination(X,V)`

The affine scheme obtained by eliminating the ambient variables of the affine scheme X whose indices appear in V from the equations of X. Thus if $V = [2, 5]$ then the result will be a scheme in the affine subspace $u = v = 0$ where u and v are the second and fifth variables of the ambient space of X.

`Inverse(f)`

The inverse of the map of schemes f if inverse defining equations have been included in the definition of f, otherwise an error.

`IsInvertible(f)`

Tests whether the map f between schemes is birational. If so, returns a birational inverse. This function works fairly generically, using Groebner basis computations over standard affine patches of the domain and codomain to compute the closure of the graph of f and retrieve inverse equations from that. It can be very expensive computationally.

`HasKnownInverse(f)`

Returns `true` if the map f has an inverse stored.

Example H112E31

This example shows how `IsInvertible` is more powerful then `Inverse`.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2, X^3*Y^2 + X^3*Z^2 - Z^5);
> Genus(C);
1
> pt := C![1,0,1];
> E,toE := EllipticCurve(C,pt);
> IsInvertible(toE);
true Mapping from: CrvEll: E to Crv: C
with equations :
$.1^3
-3*$.1*$.2*$.3 - 9*$.2*$.3^2
$.1^3 + 3*$.1^2*$.3
and inverse
-3*X^2*Z + 3*X*Z^2
-3*X^2*Y
X^2*Z - 2*X*Z^2 + Z^3
>  Inverse(toE);
>> Inverse(toE);
          ^
Runtime error in 'Inverse': Map has no inverse
```

`g * f`

The composition $g \circ f$, but note the convention for order of composition: the order of mapping is that g acts first and is followed by f. Strictly speaking, one might want to see evaluation of points done on the left to make sense of this, (this can be done using `p @ f` instead of `f(p)`). Since one would usually assign a new identifier to this composition, this is not a large problem. Only simple error checking is done — domain–codomain matching and that the composition doesn't have so many zero components that it is projectively illegal.

Where the expansion of such compositions could be expensive, the resulting map will be stored as a composition. The equivalent expanded map can be created by

```
> gf := g*f;
> dp := DefiningPolynomials(gf);
> dpi := InverseDefiningPolynomials(gf);
> m := map<D -> C | dp, dpi>;
```

where D is the domain of g and C is the codomain of f. The composition will act differently to the expanded map - it will be undefined at all the places each factor is undefined.

`Components(f)`

The maps composed to form f.

Example H112E32

As part of its generic map machinery, MAGMA has a structure for the set of all maps between two given schemes. There is also a structure for the group of all automorphisms of a scheme which is discussed in Section 112.14.6. Using this space one can realise the effect of a map on Hom spaces. We will make two Hom spaces having a common codomain.

```
> k := Rationals();
> P<x,y,z,t> := ProjectiveSpace(k,3);
> A := Scheme(P,Minors(M,2))
>           where M is Matrix(CoordinateRing(P),2,3,[x,y,z,y,z,t]);
> B := Scheme(P,x*t - y*z);
> F<r,s,u,v> := RuledSurface(k,0,0);
> HomAF := Maps(A,F);
> HomBF := Maps(B,F);
> HomAF;
Set of all maps from A to F
```

Given a map $A \to B$ we make the map from `HomBF` to `HomAF` given by composition. Although A lies inside B, we choose a map $A \to B$ which isn't this inclusion.

```
> i := map< A -> B | [y,x,t,z] >;
> ii := map< HomBF -> HomAF | g :-> i * g >;
```

The map ii of Hom spaces realises the composition of maps with i. We test this on a single map $f : B \to F$.

```
> f := map< B -> F | [x,y,z,t] >;
```

```
> Expand(ii(f)) eq Expand(i*f);
true
```

`Restriction(f,X,Y)`

`Check` BoolElt *Default :* `true`

The restriction of the map of schemes f to the scheme X in its domain. The codomain of the new map is considered to be the scheme Y which must either contain the codomain of f, or lie in that codomain but contain the scheme $f(X)$.

By default the program checks these subscheme relationships; this may be time-consuming, and can be skipped by setting the optional parameter `Check` to `false`.

`Expand(phi)`

Given a map ϕ between schemes stored in factored form, return the map in expanded form. Note that if ϕ is a composite of maps, each with many alternative defining polynomials, then computing the expansion can be very expensive. In other situations computing the expansion of ϕ can cause huge (intermediate) expressions and therefore be very expensive as well.

Due to the automatic simplification in map creation, the base scheme of the returned map might be smaller than the base scheme of ϕ.

`Extend(phi)`

Given a map ϕ between schemes, returns an expanded map with extra alternative equations in order to reduce the base scheme as far as possible, i.e. so that the open complement of the base scheme is the maximal domain of definition of the rational map represented by ϕ. This routine is potentially very expensive because it requires Groebner basis computations on several affine graph ideals of ϕ.

`Prune(phi)`

Given a map ϕ between schemes in expanded form, removes alternative equations that do not reduce the base scheme of ϕ. If ϕ has a known inverse, this is returned unaltered.

`Normalization(phi)`

`Normalisation(phi)`

The map created from ϕ by removing common factors from the defining polynomial.

Example H112E33

It is shown below how to convert a map between schemes into a proper morphism.

```
> P2<x,y,z>:=ProjectiveSpace(Rationals(),2);
> C:=Curve(P2,x^3+y^3-2*z^3);
> E,phicomp:=EllipticCurve(C,Place(C![1,1,1]));
> Puvw<u,v,w>:=Ambient(E);
```

We get ϕ as `phicomp` in expanded form.

```
> phi:=Expand(phicomp);
> phi;
Mapping from: Crv: C to CrvEll: E
with equations :
3*x^2*y - 3*x^2*z - 3*x*y^2 + 9*x*y*z - 6*x*z^2 - 6*y^2*z + 15*y*z^2 - 9*z^3
-9*x^2*y + 27*x*y^2 - 54*x*y*z + 18*x*z^2 + 45*y^2*z - 81*y*z^2 + 27*z^3
y^3 - 3*y^2*z + 3*y*z^2 - z^3
```

But ϕ still has a base scheme.

```
> Degree(BaseScheme(phi));
6
```

So we extend ϕ to `phiext` defined on C entirely.

```
> phiext:=Extend(phi);
> phiext;
Mapping from: Crv: C to CrvEll: E
with equations :
3*x^2*y - 3*x^2*z - 3*x*y^2 + 9*x*y*z - 6*x*z^2 - 6*y^2*z + 15*y*z^2 - 9*z^3
-9*x^2*y + 27*x*y^2 - 54*x*y*z + 18*x*z^2 + 45*y^2*z - 81*y*z^2 + 27*z^3
y^3 - 3*y^2*z + 3*y*z^2 - z^3
and alternative equations :
3*x^3 + 6*x^2*z - 6*x*y*z + 9*x*z^2 + 3*y^3 - 15*y*z^2
-18*x^2*z + 54*x*y*z - 27*x*z^2 + 99*y*z^2
x*z^2 + 2*y^2*z - 3*y*z^2
```

And there is no base scheme anymore!

```
> Degree(BaseScheme(phiext));
0
```

This map is invertible.

```
> bl,phii:=IsInvertible(phiext);
> assert bl;
> phii;
Mapping from: CrvEll: E to Crv: C
with equations :
1/6*u^3 - 13/2*u^2*w - 2*u*v*w + 21/2*u*w^2 - 1/6*v^2*w + 3*v*w^2 + 27*w^3
u^2*w - 30*u*w^2 - 3*v*w^2 + 36*w^3
u^2*w - 3*u*w^2 - 18*w^3
```

```
and inverse
3*x^2*y - 3*x^2*z - 3*x*y^2 + 9*x*y*z - 6*x*z^2 - 6*y^2*z + 15*y*z^2 - 9*z^3
-9*x^2*y + 27*x*y^2 - 54*x*y*z + 18*x*z^2 + 45*y^2*z - 81*y*z^2 + 27*z^3
y^3 - 3*y^2*z + 3*y*z^2 - z^3
and alternative inverse equations :
3*x^3 + 6*x^2*z - 6*x*y*z + 9*x*z^2 + 3*y^3 - 15*y*z^2
-18*x^2*z + 54*x*y*z - 27*x*z^2 + 99*y*z^2
x*z^2 + 2*y^2*z - 3*y*z^2
```

But the inverse still has a base scheme.

```
> Degree(BaseScheme(phii));
6
```

So extend `phii`.

```
> phiiext:=Extend(phii);
```

No base scheme left!

```
> Degree(BaseScheme(phiiext));
0
```

Note that the inverse – `phiext` – is still retained. So `phiiext` now really is a morphism.

```
> phiiext;
Mapping from: CrvEll: E to Crv: C
with equations :
1/6*u^3 - 13/2*u^2*w - 2*u*v*w + 21/2*u*w^2 - 1/6*v^2*w + 3*v*w^2 + 27*w^3
u^2*w - 30*u*w^2 - 3*v*w^2 + 36*w^3
u^2*w - 3*u*w^2 - 18*w^3
and inverse
3*x^2*y - 3*x^2*z - 3*x*y^2 + 9*x*y*z - 6*x*z^2 - 6*y^2*z + 15*y*z^2 - 9*z^3
-9*x^2*y + 27*x*y^2 - 54*x*y*z + 18*x*z^2 + 45*y^2*z - 81*y*z^2 + 27*z^3
y^3 - 3*y^2*z + 3*y*z^2 - z^3
and alternative equations :
-1/234*u^3 + 7/26*u^2*w + 5/117*u*v*w - 57/26*u*w^2 + 1/702*v^2*w - 6/13*v*w^2 -
    27/13*w^3
-1/39*u^2*w + 1/117*u*v*w + 21/13*u*w^2 - 1/351*v^2*w + 2/39*v*w^2 - 54/13*w^3
u*w^2 - 1/351*v^2*w + 4/39*v*w^2 + 18/13*w^3
-729/26*u^3 + 3/13*u^2*v + 32805/26*u^2*w + 17/13*u*v^2 + 4293/13*u*v*w -
    19683/26*u*w^2 + 4/39*v^3 + 537/26*v^2*w - 1377/13*v*w^2 + 19683/13*w^3
-27/13*u^2*v + 9/13*u*v^2 + 1233/13*u*v*w + 4/39*v^3 + 132/13*v^2*w -
    1215/13*v*w^2
u*v^2 + 4/39*v^3 - 9/13*v^2*w + 756/13*v*w^2
and alternative inverse equations :
3*x^3 + 6*x^2*z - 6*x*y*z + 9*x*z^2 + 3*y^3 - 15*y*z^2
-18*x^2*z + 54*x*y*z - 27*x*z^2 + 99*y*z^2
x*z^2 + 2*y^2*z - 3*y*z^2
```

112.14.2 Basic Attributes

112.14.2.1 Trivial Attributes

`Domain(f)`

The domain of the map of schemes f.

`Codomain(f)`

The codomain of the map of schemes f.

`DefiningPolynomials(f)`

`DefiningEquations(f)`

The sequence of functions used to define the map of schemes f.

If f is stored as an unexpanded composition then it will be expanded and the defining equations of the expansion returned.

`FactoredDefiningPolynomials(f)`

If the map of schemes f was created by composition (and not expanded) return the sequence of sequences of the defining equations of the maps which were composed to form f otherwise return `DefiningPolynomials` of f.

`InverseDefiningPolynomials(f)`

The sequence of functions used to define the inverse of the map of schemes f.

If f is stored as an unexpanded composition then it will be expanded and the inverse defining equations of the expansion returned.

`FactoredInverseDefiningPolynomials(f)`

If the map of schemes f was created by composition (and not expanded) and has an inverse return the sequence of sequences of inverse defining equations of the maps which were composed to form f otherwise return `InverseDefiningPolynomials` of f.

`AllDefiningPolynomials(f)`

The polynomials of all definitions of the map of schemes f.

`AllInverseDefiningPolynomials(f)`

The polynomials of all definitions of the inverse of the map of schemes f if f has a known inverse.

`AlgebraMap(f)`

The underlying map of polynomial rings determining the map of schemes f. Thus if F is the sequence of defining equations of f and x is the first variable of the codomain then `F[1]` will be the image of x under `AlgebraMap(f)`.

`FunctionDegree(f)`

The degree of the homogeneous polynomials which define the map f of projective schemes. If there are alternative defining polynomials, returns the minimum value over the different sets of defining polynomials.

112.14.2.2 Basic Tests

`f eq g`

Returns `true` if and only if the maps of schemes f and g have the same domain and codomain and define the same rational map.

`IsRegular(f)`

`IsPolynomial(f)`

Returns `true` if and only if the map of schemes f is defined at all points of its domain.

`IsIsomorphism(f)`

Returns `true` if and only if the map of schemes $f : X \to Y$ has inverse defining equations or if they may be easily computed (e.g. the projective closure of the map has inverse defining equations). If so, return a map $g : X \to Y$ which is of the recognised isomorphism type as a second value.

`IsDominant(f)`

Returns `true` if and only if the closure of the image of the map of schemes f is the whole of its codomain.

`IsLinear(f)`

Returns `true` if and only if the map of schemes f is a regular map defined by linear polynomials.

`IsAffineLinear(f)`

Returns `true` if and only if the map of schemes f is a map between affine spaces defined by polynomials of degree at most 1.

112.14.3 Maps and Points

Given a map $f : X \to Y$ of schemes and point p of X outside of the base scheme of f, then the image $f(p)$ is a point of Y. Moreover, given an extension K of the base rings of X and Y, there is a map of point sets $f(K) : X(K) \to Y(K)$. This isn't often needed, but should be used as in the example below, when very many point images are required. Note that it will ensure that all points are returned in the same determined point set. Maps also behave well with respect to sets and sequences of points.

`f(p)`

The point $f(p)$ if the point p is in a point set of the domain of the map of schemes f and doesn't lie in the base scheme of f. An error results if p is in the base scheme (except in the curve case described below). Sets and sequences of points are handled in the same way. If the domain of the map is a curve C with a function field (see Algebraic Curves chapter) and p is in the base scheme of f, then now (from V2.17), MAGMA tries to compute the image of p by working with the function field places over p without having to extend f via `Extend`. If p is non-singular then there is only one place above it and the image will exist if the codomain is projective. If there are several places over p, the image will be computed and returned when the image of all of the places is the same and is defined over p's point set base ring (that must be a field).

`Pullback(f, p)`

The preimage of a point p under the map of schemes f. When f is an isomorphism of schemes with an inverse g, the returned result is the point $g(p)$. Otherwise the pullback is returned as a subscheme of the domain of f. This is identical to `Pullback(f,S)`, where S is the one-point scheme containing p.

When a scheme is returned, it will contain the base scheme of f (which won't map to p under f), but this can be remedied using the (potentially expensive) function call `Difference(Pullback(f,p), BaseScheme(f))`.

`p @@ f`

This is the same as `Pullback(f,p)` *except* when f is an isogeny between elliptic curves. in which case one rational point in the preimage is returned (if none exist, an error results).

`f(K)`

`f(m)`

The map induced by the map of schemes $f : X \to Y$ on point sets $X(K) \to Y(K)$. If m is a ring map from the base ring of X and u is the map of base rings from Y to X then $f(m)$ will be the map of point sets $X(m) \to Y(m(u))$.

Example H112E34

Mapping a single point is easy.

```
> P1<s,t> := ProjectiveSpace(Rationals(),1);
> P3<w,x,y,z> := ProjectiveSpace(Rationals(),3);
> f := map< P1 -> P3 | [s^4,s^3*t,s*t^3,t^4] >;
> p := P1 ! [2,1];
> f(p);
(16 : 8 : 2 : 1)
```

If many points need to be mapped from a fixed point set, a small overhead can be avoided by working with the map of point sets directly.

```
> K := QuadraticField(5);
> g := f(K);
> ims := [];
> for i in [1..100] do
> Append(~ims, g(P1 ! [i,1]));
> end for;
```

This example could also have been handled in one step using a sequence constructor.

```
> pts := [ P1 ! [i,1] : i in [1..100] ];
> f(pts) eq ims;
true
```

An example where the projection from an elliptic curve to the projective line contains the origin in its base scheme but the image under the extension of the projection is computed by using the place machinery without having to globally extend the map.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> E := Curve(P2,Y^2*Z-X^3-X*Z^2);
> p := E![0,0,1];
> f := map<E->P1|[X,Y]>;
> p in BaseScheme(f);
true (0 : 0 : 1)
> f(p);
(0 : 1)
```

112.14.4 Maps and Schemes

The natural operation for maps on schemes is *pullback*, that is, compute the preimage. This is rather trivial. On the other hand, computing the image of schemes under a map requires a Gröbner basis calculation so is much harder. If the map has an inverse this image calculation is automatically replaced by the more simple pullback using the inverse map.

Note that, strictly speaking, the image algorithm computes the closure of the image of the map. We still call it the image, though, and don't worry that there may be some points of the image that are not the set-theoretic image of any point of the domain.

Over a field, the equations of the image of a map in a particular degree can be computed using linear algebra, so a distinct intrinsic is provided for this.

Other schemes related to a map are also discussed here.

`Pullback(f, X)`

The scheme in the domain of the map of schemes f given by the pullback of the equations defining the subscheme X of the codomain of f. The result will contain the base scheme of f (which won't map onto X under f) but this can be remedied using the (potentially expensive) function call `Difference(Pullback(f,X), BaseScheme(f))`.

`Image(f)`

`f(X)`

Let X be a subscheme of the domain of the map of schemes f such that, if U is the open complement of the base scheme of f, $X \cap U$ is Zariski-dense in X. This intrinsic returns the scheme-theoretic closure of $f(X \cap U)$ in the codomain of f, which we refer to simple as the image $f(X)$. For the first signature the image of the entire domain is returned. Moreover, it is stored with the map f so can be called again later without any recomputation. Note that if the domain of f is projective multi-graded, then X is saturated before the computation to ensure the correct result. For computaional efficiency, we do not check that $X \cap U$ is indeed Zariski-dense in X.

`Image(f,X,d)`

A basis of the polynomials of degree d in the codomain of the map of schemes f which contain the image $f(X)$. The scheme X must be a subscheme of the domain of f and d must be a positive integer.

For best results for projective schemes, remove the contribution of the irrelevant ideal corresponding to the zero point from X (normalize the equations of the scheme).

Example H112E35

Consider the embedding of the projective line in 3-space as a quartic. It can be defined as the image of a map determined by a 4-dimensional subspace of the degree 4 monomials on the line, for instance: see [Har77] Chapter II, Example 7.8.6 or the later section here on linear systems.

```
> P1<s,t> := ProjectiveSpace(Rationals(),1);
> P3<w,x,y,z> := ProjectiveSpace(Rationals(),3);
> f := map< P1 -> P3 | [s^4,s^3*t,s*t^3,t^4] >;
> Image(f);
Scheme over Rational Field defined by
-w^2*y + x^3
w*y^2 - x^2*z
-x*z^2 + y^3
-w*z + x*y
> IsNonsingular(Image(f));
true
> f(p) in Image(f) where p is P1 ! [2,1];
true (16 : 8 : 2 : 1)
```

If the Gröbner basis computation is too expensive, or if a partial solution for the image computation would be acceptable, the function `Image(f,C,d)` described above and illustrated in the next example calculates those hypersurfaces of degree d containing $f(C)$. Given a bound on d, the equations of the image could also be calculated using this function.

Example H112E36

A situation where one is really interested in the equations of the image in a particular degree occurs in the case of canonical curves. Usually the ideal is generated in degree 2, but for trigonal curves the degree 2 generators only cut out a surface scroll on which the curve is cut out by a relative equation of degree 3.
Here we simply assert that the curve C has genus 5 and that the map f is the canonical map of the curve C. Chapter 114 describes functions that determine both invariants.

```
> k := Rationals();
> P2<X,Y,Z> := ProjectiveSpace(k,2);
> P4<a,b,c,d,e> := ProjectiveSpace(k,4);
> C := Curve(P2, X^5 + X*Y^3*Z + Z^5);
> f := map< P2 -> P4 | [Y*Z, X*Y, Z^2, X*Z, X^2] >;
> S := Image(f,C,2);
> S;
Scheme over Rational Field defined by
a*d - b*c
a*e - b*d
c*e - d^2
> Dimension(S);
2
> f(C);
Curve over Rational Field defined by
-d^2 + c*e,
-b*d + a*e,
```

```
-b*c + a*d,
a*b^2 + c^2*d + e^3,
a^2*b + c^3 + d*e^2
```

In this case both image computations are fast so the timing difference between them is tiny. But pushing the genus a little higher soon makes the point.
It is easy to see that S is a scroll: its equations are the rank 2 minors of the matrix

$$\begin{pmatrix} a & c & d \\ b & d & e \end{pmatrix}.$$

`BaseScheme(f)`

The subscheme of the domain X of the map of schemes f where the map is 'naively' not defined. When f is expanded, this is equal to the intersection of the base schemes of each of the alternate sets of defining polynomials/rational functions. For a single set of defining polynomials/rational functions, the base scheme is defined by the union of subschemes of X where a denominator of a defining rational function vanishes when the codomain is affine, and by the subset of points of X which are mapped by the given defining polynomials into a null point (with coordinates on which all polynomials in an irrelevant ideal vanish) when the codomain is projective.

`BasePoints(f)`
`BasePoints(f,L)`

If the base scheme of the map of schemes f is finite, this returns a sequence containing those points defined over the base ring which lie in it. Otherwise an error is reported. If a second argument L is included which is an extension field of the base field then base points defined over L are returned.

Example H112E37

We find the base points of a map, although we have to extend the field before we find them all.

```
> k := GF(7);
> P<x,y,z> := ProjectiveSpace(k,2);
> p := x^2 + y^2;
> f := map< P -> P | [p*x,p*y,z^2*(z-x)] >;
> BasePoints(f);
{}
> Degree(BaseScheme(f));
6
> HasPointsOverExtension(BaseScheme(f));
true
```

Clearly we are not seeing all the points of indeterminacy of f. We clumsily extend the base field until we do see enough points. Of course, it is clear that the problem is the polynomial p, so a degree 2 extension will be enough.

```
> BasePoints(f,ext<k|2>);
```

```
{ (1 : $.1^36 : 1), ($.1^12 : 1 : 0), ($.1^36 : 1 : 0), (1 : $.1^12 : 1) }
> HasPointsOverExtension(BaseScheme(f),ext<k|2>);
false
```

Example H112E38

In this example we make an elementary transformation of scrolls.

```
> Q := Rationals();
> F<u,v,x,y> := RuledSurface(Q,2);
> G<a,b,r,s> := RuledSurface(Q,3);
> F;
Rational Scroll of dimension 2
Variables : u, v, x, y
Gradings :
1       1       -2      0
0       0       1       1
> phi := map< F -> G | [u,v,x,y*u] >;
```

Next we find the base points of the map ϕ by hand.

```
> Scheme(F,[u,v]) join Scheme(F,[x,u*y]);
Scheme over Rational Field defined by
u*x
v*x
u*y
> RationalPoints($1);
{ (0 : 1 : 0 : 1) }
```

The map ϕ is the elementary transformation in the point $(0 : 1 : 0 : 1)$ of F. That is, it is the blowup of this point followed by the contraction of the birational transform of the fibre through this point.

112.14.5 Maps and Closure

`ProjectiveClosure(f)`

The map induced by the map of schemes f between the projective closure of its domain and codomain. If either domain or codomain is already projective, then it remains unchanged in the new map. In particular, if both domain and codomain are already projective, then the returned map is simply f itself.

`MakeProjectiveClosureMap(A, P, S)`

`MakePCMap(A, P, S)`

`MakeProjectiveClosureMap(m)`

`MakePCMap(m)`

If A is an affine space and P a projective space and if S is a sequence of polynomials on A defining a map from A to P (or if m is such a map) then this map is set as the projective closure map of A. There is very little functionality for projective closure maps which are not the standard ones, so this intrinsic is usually used in cases where no relationship between A and P yet exists but the user would like A to behave as a standard patch on P so that the closure of a scheme in A is a scheme in P.

`RestrictionToPatch(f,j)`

The restriction of the map f, a map of schemes from an affine scheme to a projective scheme, to a rational map from its domain to the jth standard affine patch of its codomain.

`RestrictionToPatch(f,i,j)`

The restriction of the map f, a map between two projective schemes, to a rational map from the ith standard affine patch of its domain to the jth patch of its codomain.

Example H112E39

The application of closure and patching functions is straightforward. To compute the restriction of a map f to the ith patch of the domain and jth patch of the codomain, essentially set the $\dim+2-i$th coordinate function to 1 and divide by the $\dim+2-j$th defining equation of f.

```
> P<w,x,y,z> := ProjectiveSpace(Rationals(),3);
> f := map< P -> P | [1/w,1/x,1/y,1/z] >;
> f12 := RestrictionToPatch(f,1,2);
> f12;
Map of affine spaces defined by [ $.3/$.1, $.3/$.2, $.3 ]
```

The functions are inevitably rational so cannot be expressed in any coordinates that might already exist on the affine patches. Instead they are expressed in terms of the generators of the function fields.

```
> ProjectiveClosure(f12);
Map of projective spaces defined by [ x*y*z, w*y*z, w*x*z, w*x*y ]
> ProjectiveClosure(f12) eq f;
true
```

However, as seen in the final line above, the relationship between a map and its closure is maintained.

112.14.6 Automorphisms

Automorphisms of schemes defined over a field may be constructed. The main cases where there is significant functionality is for automorphisms of affine and projective spaces and curves. Recall that for projective spaces the only regular automorphisms are the linear maps. However there are many more rational automorphisms, often called *Cremona transformations*. In the case of the projective plane, these form a group generated by linear automorphisms together with a single quadratic transformation. In higher dimensions, the structure of this group is unknown.

Affine spaces have much more complicated automorphism groups. Decomposition results are known in the case of the affine plane over certain fields (the complex numbers for instance), but otherwise no general statements are known. More information and references can be found in [vdE00], especially in the opening essay.

Although automorphisms can be computed, groups of automorphisms cannot be computed except in a very few cases. For the case of curves, see the `Algebraic Curves` chapter. For ambients, there is currently a function `AutomorphismGroup` which returns a group together with a map matching group elements with the automorphism they represent only in the case of linear automorphisms of projective spaces defined over a finite field.

`Automorphism(X,F)`

The automorphism of the scheme X determined by the sequence of polynomials F defined on X. This function uses a Gröbner basis calculation. If the inverse functions are already known then one can use the `map< | >` constructor and then a type change or the `iso< | >` constructor. This is illustrated in Example H112E40.

`IdentityAutomorphism(X)`

`IdentityMap(X)`

The identity map $X \to X$ on the scheme X.

`IsEndomorphism(f)`

Returns `true` if and only if the domain and range of the maps of schemes f are equal.

`IsAutomorphism(f)`

Returns `true` if and only if the maps of schemes f is an automorphism of its domain. In this case f is returned as an automorphism as the second value.

Example H112E40

In this example we show how to make an automorphism from equations, and also how to include the equations of the inverse map if they are already known. The automorphism is the hyperelliptic involution on a hyperelliptic curve, although we don't use the machinery of hyperelliptic curves here.

```
> A<u,v> := AffineSpace(Rationals(),2);
> f := v^5 + 2*v^3 + 5;
> C := Curve(A,u^2 - f);
> phi := Automorphism(C,[-u,v]);
> Type(phi);
MapAutSch
> phi;
Mapping from: Crv: C to Crv: C
with equations :
-u
v
and inverse
-u
v
```

In this case we clearly know the inverse map in advance. We can make an automorphism of C as follows.

```
> psi := map< C -> C | [-u,v],[-u,v] >;
> psi eq phi;
true
> Type(psi);
MapSch
```

The map ψ is fine, but it is not of the same type as ϕ. We make the type change, if desired, as follows.

```
> bool,psi1 := IsAutomorphism(psi);
> bool;
true
> Type(psi1);
MapAutSch
```

Example H112E41

A standard Gröbner basis exercise is to test particular examples of the Jacobian conjecture. This states that a polynomial map of the plane is invertible if (and only if) its jacobian determinant is everywhere nonzero. The problem here is to calculate the conjectured inverse polynomial map.

```
> A<u,v> := AffineSpace(Rationals(),2);
> f := u^3 + 3*u^2*v^2 + 3*u^2 + 3*u*v^4 + 6*u*v^2 + v^6 + 3*v^4 + v + 3;
> g := u + v^2 + 1;
> J := JacobianMatrix([f,g]);
> Determinant(J);
```

```
-1
> m := map< A -> A | [f,g] >;
> m;
Mapping from: Aff: A to Aff: A
with equations :
u^3 + 3*u^2*v^2 + 3*u^2 + 3*u*v^4 + 6*u*v^2 + v^6 + 3*v^4 + v + 3
u + v^2 + 1
> IsAutomorphism(m);
true
> m;
Mapping from: Aff: A to Aff: A
with equations :
u^3 + 3*u^2*v^2 + 3*u^2 + 3*u*v^4 + 6*u*v^2 + v^6 + 3*v^4 + v + 3
u + v^2 + 1
and inverse
-u^2 + 2*u*v^3 - 6*u*v + 10*u - v^6 + 6*v^4 - 10*v^3 - 9*v^2 + 31*v - 26
u - v^3 + 3*v - 5
> Type(m);
MapSch
> Inverse(m);
Mapping from: Aff: A to Aff: A
with equations :
-u^2 + 2*u*v^3 - 6*u*v + 10*u - v^6 + 6*v^4 - 10*v^3 - 9*v^2 + 31*v - 26
u - v^3 + 3*v - 5
and inverse
u^3 + 3*u^2*v^2 + 3*u^2 + 3*u*v^4 + 6*u*v^2 + v^6 + 3*v^4 + v + 3
u + v^2 + 1
```

The automorphism test returns two values. The first, `true`, confirms that the map m is an automorphism. In doing this test, MAGMA computes the inverse and stores it with m. The second is the same map m, now with its inverse computed, but with the type of an automorphism.

```
> _,maut := IsAutomorphism(m);
> maut;
Mapping from: Aff: A to Aff: A
with equations :
u^3 + 3*u^2*v^2 + 3*u^2 + 3*u*v^4 + 6*u*v^2 + v^6 + 3*v^4 + v + 3
u + v^2 + 1
and inverse
-u^2 + 2*u*v^3 - 6*u*v + 10*u - v^6 + 6*v^4 - 10*v^3 - 9*v^2 + 31*v - 26
u - v^3 + 3*v - 5
> Type(maut);
MapAutSch
```

112.14.6.1 Affine Automorphisms

The first constructor below checks that the proposed map is indeed an automorphism by computing an inverse for the map determined by the arguments. It is a potentially expensive test. The other constructors are all either clearly automorphisms or else require only very simple tests.

`Automorphism(A,F)`

The automorphism of the affine space A determined by the sequence of functions F defined on A.

`Automorphism(A,M)`

The linear automorphism of the affine space A determined by the entries of the matrix of base ring elements M acting from the right on points.

`Translation(A,p)`

The translation map of the affine space A taking the rational point p to the origin.

`PermutationAutomorphism(A, g)`

`Automorphism(A, g)`

The automorphism of the affine space A that permutes its coordinates according to the permutation g.

Example H112E42

Permutations are easy to create as elements of the symmetric group. The symmetric group used must act on the set of n points, where n is the dimension of the affine space, even if it is only intended to permute a few of the coordinates.

```
> A := AffineSpace(Rationals(),5);
> g := SymmetricGroup(5) ! (1,2,3);
> f := PermutationAutomorphism(A,g);
> p := A ! [1,2,3,4,5];
> f(p);
(2, 3, 1, 4, 5)
```

`Automorphism(A,p)`

The automorphism which takes the first coordinate x of the affine space A to $x + p$. The polynomial p must be a function on A which does not involve x.

`AffineDecomposition(f)`

If f is an affine linear endomorphism, that is, an automorphism of some affine space defined by polynomials of degree at most 1, this returns a linear endomorphism ℓ and a translation t such that, in MAGMA notation, `f eq l * t`.

Example H112E43

In this example we make an affine linear map by composing a linear map and a translation. Then we promptly decompose it into these components.

```
> A<x,y,z> := AffineSpace(Rationals(),3);
> f := Automorphism(A,2*y+3*z) * Translation(A,A ! [2,3,5]);
> l,t := AffineDecomposition(f);
> l,t;
Mapping from: Aff: A to Aff: A
with equations :
x + 2*y + 3*z
y
z
and inverse
x - 2*y - 3*z
y
z
Mapping from: Aff: A to Aff: A
with equations :
x - 2
y - 3
z - 5
and inverse
x + 2
y + 3
z + 5
> f eq l * t;
true
```

Note that the composition `l * t` in MAGMA means that the map ℓ is applied first followed by t.

```
> p := A ! [1,2,3];
> f(p);
(12, -1, -2)
> t(l(p));
(12, -1, -2)
```

`NagataAutomorphism(A)`

This intrinsic returns the Nagata automorphism in a standard form:

$$(u, v, w) \mapsto (-u^2w^3 - 2uv^2w^2 - 2uvw + u - v^4w - 2v^3, uw^2 + v^2w + v, w).$$

Recall that this is an automorphism of affine 3-space A which is not known to be tame, that is, admits no known factorisation into automorphisms of the types listed above.

`Projectivity(A,M)`

The restriction to the affine space A of the linear automorphism of its projective closure determined by the matrix M. Note that this map is not usually regular on A but it is an isomorphism where it is defined.

Example H112E44

Most projectivities on an affine space are not regular maps. By definition, the equations which define them are naturally rational polynomials. That is the reason for naming the variables in the field of fractions of the coordinate ring of A in the following code.

```
> k := FiniteField(23);
> A<x,y,z> := AffineSpace(k,3);
> M := Matrix(k,4,4,[1,2,3,-4,2,3,5,6,3,4,5,9,4,5,6,0]);
> phi := Projectivity(A,M);
> KA<u,v,w> := Parent(x/y);
> phi;
Mapping from: Aff: A to Aff: A
with equations :
(6*u + 12*v + 18*w + 22)/(u + 7*v + 13*w)
(12*u + 18*v + 7*w + 13)/(u + 7*v + 13*w)
(18*u + v + 7*w + 8)/(u + 7*v + 13*w)
and inverse
(11*u + 15*v + 5)/(u + 20*w + 2)
(9*u + 16*v + w + 12)/(u + 20*w + 2)
(12*u + 15*v + 3*w + 16)/(u + 20*w + 2)
```

Notice that the inverse of ϕ has also been computed. In fact, ϕ has been returned as an automorphism even though it is not regular.

```
> Type(phi);
MapAutSch
> IsRegular(phi);
false
```

112.14.6.2 Projective Automorphisms

As in the case of affine spaces, a version of the automorphism constructor is provided which takes a sequence of polynomials as second argument. It is included mainly for completeness whereas the other constructors are more appropriate for constructing automorphisms in the contexts in which they often arise.

Projective automorphisms (which are regular) are always linear so they have an associated matrix with respect to the basis of monomials. A function is provided to retrieve this matrix, and conversely automorphisms may be created using matrices. In fact, if the projective space is defined over a finite field, then the automorphism group can be computed (as a group in MAGMA) and its elements can be realised as matrices.

Also included are functions for creating a nonregular birational automorphism of projective space, the standard *quadratic transformation*. When working in the plane, this together with linear automorphisms generates the group of birational automorphisms. An example of factorising a birational automorphism in this group is given.

`Automorphism(P,F)`

The automorphism of the projective space P determined by the sequence of polynomials F defined on P.

`Matrix(f)`

The matrix corresponding to the linear automorphism f of a projective space.

`Automorphism(P,M)`

The linear automorphism of the projective space P determined by the entries of the matrix of base ring elements M acting on the left of coordinates.

`Aut(P)`

The parent of automorphisms of the projective space P.

`AutomorphismGroup(P)`

The automorphism group of the projective space P together with a map from this group to the set of automorphisms of P, that is, the parent of such automorphisms. The space P must be defined over a finite field for this intrinsic. Note that currently the group returned is a general linear group rather than the projectivised version. This will be changed in the future, but in any case does not create much confusion.

Example H112E45

When a projective space is defined over a finite field, then its automorphism group can be realised as a group of matrices in a natural way. First we see how to use standard intrinsics to realise the correspondence between matrices and linear automorphisms of projective space.

```
> P<x,y,z> := ProjectiveSpace(GF(5),2);
> phi := Automorphism(P,[x+y,y,z]);
> M := Matrix(phi);
> M;
[1 0 0]
[1 1 0]
[0 0 1]
> Automorphism(P,M) eq phi;
true
```

Since P is a projective space defined over a finite field, we can actually work with a group which is isomorphic to its automorphism group. The map m computed below maps matrices to automorphisms and conversely its inverse constructs a matrix from an automorphism.

```
> G,m := AutomorphismGroup(P);
> G;
```

```
GL(3, GF(5))
> m;
Mapping from: GrpMat: G to Parent structure for automorphisms of P
> phi eq m(Transpose(M));
true
> Transpose(phi @@ m);
[1 0 0]
[1 1 0]
[0 0 1]
```

The parent of automorphisms is also an object in MAGMA. It can be created using `Aut(P)`.

```
> Aut(P);
Set of all automorphisms of P
> Aut(P) eq Codomain(m);
true
```

`TranslationOfSimplex(P,Q)`

The unique automorphism of the n-dimensional projective space P taking the $n+2$ standard simplex points $(1:0\ldots:0),\ldots$ and $(1:1\ldots:1)$ to the points of the sequence Q. The sequence Q must comprise $n+2$ linearly independent rational points of P.

`Translation(P,Q)`

This function returns an automorphism which translates the standard coordinate points to the points of the sequence Q. The sequence Q must comprise $n+1$ linearly independent rational points of the projective space P where n is the dimension of P. This intrinsic puts no condition on the usual final point $(1:1\ldots:1)$ of the standard simplex. In other words, it creates the automorphism of P by the matrix having the coordinates of the $n+1$ points of Q as its columns. This automorphism is not uniquely determined since $\mathrm{PGL}(n,k)$ is $n+2$ transitive.

`Translation(P,p,q)`

A choice of linear automorphism of the projective space P which takes the rational point p to the rational point q.

`Translation(X,p)`

A choice of linear automorphism of the projective space P taking the point $(0:\ldots:0:1)$ to the rational point p.

Example H112E46

The intrinsic `Translation(X,p)` works in both the affine and the projective context. For an affine scheme, it makes the translation which moves the point p to the origin.

```
> A<u,v> := AffineSpace(Rationals(),2);
> Translation(A,A![1,2]);
Mapping from: Aff: A to Aff: A
with equations :
u - 1
v - 2
and inverse
u + 1
v + 2
```

In the projective case, the resulting translation moves the point p to the image of the origin on the first affine patch. When the point p lies on the first affine patch, then the translation is the obvious one. But when it doesn't a permutation of the coordinates is made first.

```
> P<x,y,z> := ProjectiveSpace(Integers(),2);
> p := P ! [3,2,1];
> f := Translation(P,p);
> f;
Mapping from: Prj: P to Prj: P
with equations :
-x + 3*z
-y + 2*z
z
and inverse
-x + 3*z
-y + 2*z
z
> f(p);
(0 : 0 : 1)
> p := P ! [0,1,0];
> f := Translation(P,p);
> f(p);
(0 : 0 : 1)
> f;
Mapping from: Prj: P to Prj: P
with equations :
-x
-z
y
and inverse
x
-z
y
```

`QuadraticTransformation(P)`

`QuadraticTransformation(P,Q)`

The first function is the standard quadratic transformation of projective space P taking its coordinates to their reciprocals, that is $(x : y : \ldots) \mapsto (1/x : 1/y : \ldots)$. The second conjugates the standard map with a translation of the points of Q to the standard basis vectors. The sequence Q must comprise $n + 1$ linearly independent rational points of P where n is the dimension of P.

`QuadraticTransformation(X)`

`QuadraticTransformation(X,Q)`

The *birational* pullback of the projective scheme X by the quadratic transformation. In the first intrinsic the transformation used is `QuadraticTransformation(P)` while in the second, the transformation is `QuadraticTransformation(P,Q)` where P is the ambient projective space of X. Thus Q must comprise $n+1$ linearly independent rational points of P where n is the dimension of P. Exceptional components in the total pullback of X are removed.

Example H112E47

This example shows how to factorise a simple Cremona transformation. (The reader who knows something about this will note that in this example we take no account of the Nöther–Fano inequalities nor do we analyse infinitely near points. In fact, we are rather lucky to be able to complete the factorisation.)

```
> k := RationalField();
> P<x,y,z> := ProjectiveSpace(k, 2);
> funs := [ 2/3*x^2*y^2 + 2/3*x^2*y*z + x*y^2*z + x*y*z^2,
>     1/3*x^2*y^2 + 4/3*x^2*y*z + x^2*z^2 + 1/2*x*y^2*z + 1/2*x*y*z^2,
>     2/9*x^2*y^2 + 2/3*x^2*y*z + 2/3*x*y^2*z + x*y*z^2 + 1/2*y^2*z^2 ];
> g := map< P -> P | funs >;
> FunctionDegree(g);
4
> RationalPoints(BaseScheme(g));
{@ (3/4 : -1 : 1), (0 : 1 : 0), (0 : 0 : 1), (-3/2 : -1 : 1), (1 : 0 : 0) @}
```

Our aim is to precompose g with quadratic transformations which will reduce the degree of its defining polynomials, currently 4. When the function degree is reduced to 1 the factorisation is complete since the inverse sequence of quadratic transformations will comprise a factorisation of g up to a translation. (Draw the diagram of maps!) That will be done at the end. First a quadratic transformation in the three coordinate points is made since these points are the simplest appearing in the list of base points. (The complete mathematical theory works hard to make the choice of map here the right one: clearly no hard work has been done here in making the choice of coordinate points.)

```
> std_quad := QuadraticTransformation(P);
> g1 := std_quad * g;
> // (Expand and) extend the map to its maximal domain:
```

```
> g1:=Extend(g1);
> FunctionDegree(g1);
2
> S := BaseScheme(g1);
> RationalPoints(S);
{@ (4/3 : -1 : 1), (-2/3 : -1 : 1), (-2/3 : 0 : 1) @}
> HasPointsOverExtension(S);
false
```

Good! With only three non-collinear points of indeterminacy (the final line makes sure there aren't further points defined over some extension of the base ring) we are only one step away from completing the factorisation. We make a quadratic transformation in these three noncollinear points.

```
> tr := Translation(P,[ p : p in $2 ]);
> quad := std_quad * tr;
> g2 := quad * g1;
> g2:=Extend(g2);
> FunctionDegree(g2);
1
```

So g is seen to be the composition of linear translations and standard quadratic transformations: g_2 is itself a linear translation. This sequence of maps is reconstructed in reverse order to get g. All the maps should be inverted, but note that the quadratic transformations are selfinverse so that this is rather easy. Of course, composing the maps in the order they were discovered above produces the birational inverse of g.

```
> f3 := f2 * g2
>     where f2 is f1 * std_quad
>     where f1 is std_quad * Inverse(tr);
> Expand(f3) eq g;
true
```

112.14.7 Scheme Graph Maps

In MAGMA V2.16, we have introduced an alternative to the usual `MapSch` for maps between *ordinary projective* schemes: a new type `MapSchGrph`, which we refer to as graph maps. These are objects whose defining data is the closure of the graph of a rational map, without explicit defining or inverse polynomials. This is a fairly traditional way to consider maps in algebraic geometry and the main motivation for their introduction is for divisor maps of invertible sheaves. These are naturally constructed in graph form and the further derivation of explicit defining polynomials can be quite time-consuming and lead to extremely high degree, ugly results.

As well as being more naturally constructible in certain situations, graph maps have advantages over `MapSch`s in a number of contexts.

1 A graph maps is automatically maximally defined, so `Extend` and alternative equations are unnecessary.

2 Computation of images of subschemes of the domain or of the inverse of a map go, in one way or another, through the graph of the map, so it is more efficient to already have it in graph form.

3 For an invertible graph map, separate inverse equations are not required. It is only necessary to record that it is invertible and consider the "reverse" of the graph.

If $f : X \to Y$ is a rational map, the closure of its graph G naturally lies in $X \times Y$. For computational ease, we take G as lying in the product projective space of the ambients of X and Y, Functionally, it is defined by a bihomogenous ideal in a polynomial ring with $n + m + 2$ variables, where n (resp. m) is the dimension of the ambient of X (resp. Y). There is a primitive basic user constructor described below. Graph maps are more naturally constructed and returned by specialised functions.

Graph maps have most of the functionality of `MapSch` maps including `IsInvertible` and `Expand`. Rather than repeat the list of all of the relevant intrinsics, we note here that the major functionality not currently available for them is

1 No defining or inverse defining polynomials.

2 No pointset map construction: it is not possible to ask for the image or preimage under a graph map of a point in a pointset over a proper extension of the base field. Neither are there images and preimages of rational functions.

3 Restriction to affine patchs of the domain or codomain is not possible (graph maps are only between projective schemes). However, restriction to a closed subscheme of the domain or codomain via `Restriction` is allowable as usual.

4 Any specialised `MapSch` functionality only available for maps between particular scheme types, like maps between curves.

Graph maps can be composed in the usual way for maps, but can not be mixed with `MapSch` maps in composition.

A further minor restriction has been built in for implementational efficiency. It is assumed for the domain X of a graph map that there is no coordinate hyperplane that contains some *but not all* of the irreducible components of X. In particular, there is no problem if X is irreducible.

A graph map f may be converted into normal `MapSch` with an intrinsic given below. If f is known invertible, this also computes inverse defining polynomials. It should be noted that for maps between complicated schemes, this often produces a `MapSch` with extremely high degree defining polynomials and a large base scheme where it is not defined. In such cases, the original `MapSchGrph` can be a functionally much more efficient representation.

`SchemeGraphMap(X, Y, I)`

`Saturated` BoolElt *Default :* `false`

X and Y are ordinary projective schemes with ambients $\mathbf{P}^m$ and $\mathbf{P}^n$ respectively. I is an ideal in an $n + m + 2$ variable polynomial ring R that should have the grevlex ordering. I should define the closure of the graph of a rational map from X to Y if R is identifed with the coordinate ring of the product projective space of $\mathbf{P}^m$ and

$\mathbf{P}^n$ such that the first $m+1$ variables correspond to the variables of the coordinate ring of $\mathbf{P}^m$ in the same order and the last $n+1$ variables correspond to those of $\mathbf{P}^n$ in the same order.

I should thus be bihomogeneous in the first $m+1$ and second $n+1$ variables and be large enough to define the graph of the map, though it doesn't have to be the maximal defining ideal. For example, if a map is explicitly given by defining polynomials $[F_0(x), \ldots, F_n(x)]$ where we use x_i and y_i to denote the variables of R corresponding to the domain and codomain variables, then the ideal generated by

$$y_i F_j(x) - y_j F_i(x) \quad \forall\ 0 \leq i, j \leq n$$

and the defining equations for X will define the graph if the defining polynomials give an everywhere defined map. We give an explicit example below. If there is a non-empty base scheme, it will be necessary to saturate the above ideal by one of the $F_i(x)$ that doesn't vanish on any component of the domain. It is then "domain" saturated.

A defining ideal like the above that *hasn't* been saturated by an $F_i(x)$ is usually not maximal and for functional purposes has to be saturated by an appropriate domain variable using `ColonIdeal`. This is performed internally. If the user already knows that I is domain saturated, he can set the parameter `Saturated` (default `false`) to `true` to avoid this.

This is a simple convenience function that performs practically no checks on the validity of the input data.

`SchemeGraphMapToSchemeMap(f)`

Converts the graph map f into a usual scheme map. As noted in the introduction, if f is a map between fairly complex schemes, this can be quite a computationally heavy procedure and can produce very large degree, non-sparse defining polynomials and the `MapSch` produced can have a large base scheme, even if f is defined everywhere on its domain. If f is known invertible (see below), inverse defining-polynomials are also added to the result.

`IsInvertible(f)`

As for the `MapSch` version, returns whether f is birationally invertible and, if so, also returns the inverse map. This records that f is known invertible internally, as the inverse map just has the graph reversed (also the graph ideal may need to be saturated with respect to a codomain variable, which will be performed here if it is determined that the map is invertible) so no inverse equations are added. The `HasKnownInverse` intrinsic for `MapSch`s, which returns whether the map has already been determined to be invertible, is also available.

Example H112E48

Let X be an elliptic curve, given as an intersection of quadrics in $\mathbf{P}^3$. Here we start with a map from X into $\mathbf{P}^4$, given by cubics, that is birational onto its image. We show how to convert this into a graph map, take restrictions, check for invertibility and various other things.

```
> P3<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> X := Scheme(P3,[x*t-y*z, x^2+y^2-4*z^2+7*t^2]);
> P4<a,b,c,d,e> := ProjectiveSpace(Rationals(),4);
> mp_seq := [x^3,y^3,z^3,t^3,y*z*t]; // polys defining a map to P^4
> mp := map<X->P4|mp_seq>;
> // Will now define the graph map
> R<x1,x2,x3,x4,y1,y2,y3,y4,y5> := PolynomialRing(Rationals(),9,"grevlex");
> hm := hom<CoordinateRing(P3) -> R |[R.i : i in [1..4]]>; // usual map
> grI := ideal<R|[(R.(i+4))*hm(mp_seq[j])-(R.(j+4))*hm(mp_seq[i]):
>   i in [j+1..5] , j in [1..5]] cat [hm(b) : b in Basis(Ideal(X))]>;
> gr_mp := SchemeGraphMap(X,P4,grI); // the graph map
> // check that gr_mp does give mp
> mp eq SchemeGraphMapToSchemeMap(gr_mp);
true
> Y := gr_mp(X);
> Y eq mp(X);
true
> // take restrictions to the image
> gr_mp1 := Restriction(gr_mp,X,Y);
> mp1 := Restriction(mp,X,Y);
> // check that gr_mp1 still gives mp1
> mp1 eq SchemeGraphMapToSchemeMap(gr_mp1);
true
> boo := IsInvertible(gr_mp1);
> boo;
true
> // find the image and preimage of a point
> pt := X![2,0,1,0];
> ipt := gr_mp1(X![2,0,1,0]);
> iminv := ipt @@ gr_mp1;
> Dimension(iminv); Degree(iminv);
0
2
> // the preimage is just pt doubled
> Support(iminv);
{ (2 : 0 : 1 : 0) }
```

112.15 Tangent and Secant Varieties and Isomorphic Projections

The functions in this section relate to the isomorphic projection of schemes in higher-dimensional projective spaces down to lower-dimensional ones. This is achieved through finding points in the ambient projective space which don't lie on either the tangent or secant varieties of the scheme. These varieties are interesting in their own right and we provide functions to compute them as subschemes of the ambient space or to test if a given point lies on them.

112.15.1 Tangent Varieties

For a scheme X in affine or ordinary projective space over a field, the tangent variety TX is a subscheme of the ambient space whose set of closed points is the closure of the union of all tangent spaces of closed points of X. We do not worry if the TX that we construct is necessarily a reduced scheme or not. If X is non-reduced, TX probably won't be and will usually be of larger dimension than expected. If X is projective, the union of tangent spaces is already closed in the ambient space.

`TangentVariety(X)`

`PatchIndex` RngIntElt *Default :* 0

The scheme X must be affine or ordinary projective. If X is projective, the tangent variety can be computed projectively but it is usually quicker to compute the result for an affine patch and then take the projective closure. If the parameter `PatchIndex` is set to $i > 0$ then in the projective case the function will do this, using the ith standard affine patch (see `AffinePatch` on page 3521). This will give the correct result as long as *no component of X lies in the hyperplane complement of the patch.*

`IsInTangentVariety(X,P)`

The computation of the full tangent variety can be quite time consuming except in small dimensional ambient spaces. If the dimension of the ambient space is n, it is effectively calculated as the image of a subscheme in a $2n$-dimensional ambient under projection down to X's ambient space. However, this call gives a much faster way of testing if a particular point P in the ambient space lies in the tangent variety of the scheme X when X is projective.

Example H112E49

```
> P<x,y,z,t> := ProjectiveSpace(RationalField(),3);
> X := Scheme(P,[x*y+z*t,x^2-y^2+2*z^2-4*t^2]);
> Dimension(X);

Time: 0.040
> time IsInTangentVariety(X,P![1,2,3,4]);
false
Time: 0.000
```

112.15.2 Secant Varieties

For a scheme X in affine or ordinary projective space over a field, the secant variety SX is a subscheme of the ambient space whose set of closed points is the closure of the union of all lines joining distinct pairs of closed points of X (secants). Again, we do not worry if the SX that we construct is necessarily a reduced scheme or not. Note that the union of all secants is not necessarily a closed subset of the ambient space even when X is projective.

`SecantVariety(X)`

`PatchIndex` RngIntElt *Default :* 0

The scheme X must be affine or ordinary projective. In the projective case we construct SX by taking the projective closure of the result for an appropriate affine patch (intersecting every component of X). For simplicity, we currently only consider standard affine patchs so the function will fail for X projective if *it has components lying in every standard hyperplane.* As for `TangentVariety`, if the parameter `PatchIndex` is set to $i > 0$ then the ith standard affine patch will be the one used and this saves a little time, avoiding a search. Effectively, the computation consists of finding the image of a subscheme in a projection from a $2n + 1$ dimensional

ambient space down to the (n dimensional) ambient space of X and can be quite lengthy.

`IsInSecantVariety(X,P)`

Again as in the tangent variety case, if the scheme X is projective, this call gives a much faster way of testing if a given ambient point P lies in SX than computing the whole of SX with `SecantVariety`. To be precise, this call actually tells you whether or not P lies in the union of secants rather than its closure SX. Additionally, affine patches are not used, so the above restriction on validity doesn't apply.

Example H112E50

```
> P<a,b,c,d,e> := ProjectiveSpace(RationalField(),4);
> X := Scheme(P,[a*d + c*e, a*c + d*e,
>  a^2 - e^2, c^2*e - d^2*e,
>  b^2 + c*d + e^2]); // union of 3 irreducible curves
> Dimension(X);

> time SecantVariety(X : PatchIndex := 2);
Scheme over Rational Field defined by
a^4*b^2 + a^4*e^2 - a^3*c^2*e - a^3*d^2*e + a^2*b^4 + 2*a^2*b^2*c*d +
    1/4*a^2*c^4 + 1/2*a^2*c^2*d^2 + 1/4*a^2*d^4 - a^2*e^4 + a*c^2*e^3 +
    a*d^2*e^3 - b^4*e^2 - 2*b^2*c*d*e^2 - b^2*e^4 - 1/4*c^4*e^2 -
    1/2*c^2*d^2*e^2 - 1/4*d^4*e^2
Time: 26.890
> Dimension($1);
3
> time IsInSecantVariety(X,P![0,1,0,-3,0]);
true
Time: 0.000
```

112.15.3 Isomorphic Projection to Subspaces

The aim of the functions here is to try to find embeddings of projective schemes which lie in high-dimensional ambient spaces into lower dimensional spaces via projection.

Let X be a scheme in ordinary projective space that is assumed to be *reduced* but not necessarily irreducible or non-singular, d the dimension of X and n the dimension of its ambient space P. The conditions imply that the tangent variety and secant variety of X are finite unions of subschemes of dimension at most $2d + 1$ (*cf* [Har77] IV.3), so while $n > 2d + 1$, we can find points in P lying in neither of these, unless possibly the base field is a finite field. For such a point, projection down to a hyperplane gives an isomorphism of X to its image (*cf. op. cit.*) and we can continue projecting down one dimension at a time until $n = 2d + 1$.

In fact, the tangent and secant varieties of the image of X will be their images under the projection also, which induces a finite map on them (it's quasi-finite since the inverse

image of a point in the image hyperplane is a line through the projecting point pt, which any (closed) subscheme not containing pt must intersect finitely). Hence their images have the same dimensions. If the maximum of these dimensions is $tsd \leq 2d+1$ we can actually project down to a subspace of dimension tsd. Further, the fact that the tangent and secant images correspond under projection shows that if we find a linear change of variables for the coordinates of P, $(x_1, \ldots, x_n) \to (y_1, \ldots, y_n)$, such that $y_1, \ldots, y_{tsd}$ are a set of Noether normalising variables for the defining ideal of the union of the tangent and secant varieties in the coordinate ring of P, then we can project X isomorphically down to the tsd dimensional linear subspace $y_{tsd+1} = 0, \ldots, y_n = 0$ directly.

This would be the most elegant solution. However, in practise it involves computing the full tangent and secant varieties which can be extremely time-consuming once we are in dimensions above around 3 or 4. By contrast, checking if a random point of P lies in the secant or tangent variety is reasonably fast. Therefore, we choose to follow the method of picking random points to project down one dimension at a time and finish when we reach dimension $2d+1$ (when the secant variety generally fills the ambient space anyway).

`IsomorphicProjectionToSubspace(X)`

Verbose `IsoToSub` *Maximum :* 1

As described above, this function projects the scheme X isomorphically down to a linear subspace of its ambient space P of dimension $2d+1$, if $2d+1 < n$. In the case of finite base fields or infinite ones of small characteristic, the process may stop before reaching this dimension but this should be very rare (difficulties finding random points outside the secant/tangent varieties). The return values consist of the image scheme, with the subspace as its ambient space, and the explicit map taking X to this image.

`EmbedPlaneCurveInP3(C)`

Verbose `EmbCrv` *Maximum :* 1

This function embeds a plane curve C as a non-singular projective curve in ordinary 2- or 3-dimensional projective space over the base field. This is effected by first using the function field machinery to give a non-singular projective embedding and then projecting down to a 3-dimensional subspace if necessary. In rare cases with small finite base fields or in small characteristic, the final embedding may still be into a higher-dimensional ambient space. The image scheme is returned along with the mapping of C to it.

Example H112E51

We will embed a genus 5 plane curve into $P3$.

```
> P<x,y,z> := ProjectiveSpace(RationalField(),2);
> f := x^5+x^2*y^3+y^2*z^3+x^2*z^3-y*z^4-z^5;
> C := Curve(P,f);
> Genus(C);
5
```

```
> SetVerbose("IsoToSub",1);
> SetVerbose("EmbCrv",1);
> C1, mp := EmbedPlaneCurveInP3(C);
Curve of genus 5.
Mapping to 4-space by canonical divisor map

```

112.16 Linear Systems

Let $f_1, \ldots, f_r$ be homogeneous polynomials of some common degree d on some projective space $\mathbf{P}$ defined over a field. The set of hypersurfaces

$$a_1 f_1 + \ldots + a_r f_r = 0$$

where the a_is are elements of the base field of $\mathbf{P}$ is an example of a linear system. This can be thought of as being the vector space of elements $(a_1, \ldots, a_r)$ or even the projectivisation of that space (since multiplying the equation above by a constant doesn't change the hypersurface it defines and the equation $0 = 0$ doesn't define a hypersurface at all). The same is true if $f_1, \ldots, f_r$ are a finite collection of polynomials defined on some affine space.

All linear systems in MAGMA arise in a similar way to the above example. It doesn't matter whether the linear system is considered to be the collection of hypersurfaces or the collection of homogeneous polynomials or the vector space of coefficients; MAGMA allows each of these interpretations and the distinction is blurred in the text below. One should note that linear systems in MAGMA are being used in a very elementary way: compare

with the discussion on plane conics and cubics in the first two chapters of Reid's Student Text [Rei88].

Immediate applications of linear systems arise because of their close relationship to maps (consider the map to an $r-1$-dimensional projective space defined by the polynomials $f_1, \ldots, f_r$) and their application to the extrapolation a scheme of some particular degree from a set of points lying on it or some subscheme of it.

More ambitious interpretations, as the zero-th coherent cohomology group of an invertible sheaf for instance, cannot be realised explicitly in MAGMA except inasmuch as the user can understand input and output easily in these terms. There is no analysis of linear systems on general schemes and so, in particular, no analysis of exact sequences of cohomology groups.

We give a brief description of the way in which linear systems work in MAGMA, an approach which echoes the more general definition. The *complete linear system on* $\mathbf{P}$ *of degree* d is the collection of all homogeneous polynomials of degree d on $\mathbf{P}$, or equivalently, the degree d hypersurfaces they define. MAGMA does not consider this to be a unique object: each time such a system is created, a completely new object will be created distinct from any previous creation. Its major attributes include a particular basis of degree d polynomials, which is always the standard monomial basis, and a vector space whose vectors correspond to the coefficients of a polynomial with respect to this basis. The vector space is called the *coefficient space* of the linear system. There are comparison maps: one to produce the vector of coefficients of polynomials with respect to the given basis and one to create a polynomial from a vector of coefficients. Most questions involving the analysis of linear systems are translated into the linear algebra setting, solved there and then translated back.

A general linear system corresponds to some vector subspace of the coefficient space of a complete linear system. The correspondence between vectors of coefficients and polynomials are computed at the level of the complete systems so that any two subsystems interpret coefficient vectors with respect to the same basis of polynomials.

112.16.1 Creation of Linear Systems

In practice, linear systems are not often created explicitly by hand. Typically, the complete linear system of all hypersurfaces of a given degree is created and then restricted by the imposition of geometrical conditions. For example, such a condition could require that all hypersurfaces pass through a particular point.

The creation methods below are split into three classes: (i) explicit initial creation methods; (ii) methods of imposing geometrical conditions; and (iii) creation of subsystems by nominating specific technical data calculated in advance by the user.

112.16.1.1 Explicit Creation

Initially, we present three methods by which a linear system can be created. The complete linear system of degree d whose sections are all monomials of that degree has a special creation function. Alternatively, a sequence of monomials of some common degree can be specified to generate the sections of a linear system. The third constructor is useful for

calculating the images of maps and has been seen before: given a scheme S and a map f it calculates the linear system of hypersurfaces which contain $f(S)$.

`LinearSystem(P,d)`

The complete linear system on the affine or projective space P of degree d. In the projective case, this is the space of all homogeneous polynomials of degree d on P, whereas in the affine case it includes all polynomials of degree no bigger than d. The integer d must be strictly positive.

`LinearSystem(P, d)`

The complete linear system on the affine or projective space P of multi-degree d. The length of d must be the number of gradings of P, i.e. one degree for each grading. In the projective case, this is the space of all homogeneous polynomials of degree d on P, whereas in the affine case it includes all polynomials of degree no bigger than d. The integers in d must be strictly positive.

`LinearSystem(P,F)`

If P is a projective space and F is a sequence of homogeneous polynomials all of the same degree defined on P, or if P is an affine space and F is a sequence of polynomials defined on P this returns the linear system generated by these polynomials. If the polynomials in F are linearly independent they will be used as a basis of the sections of the resulting linear system, otherwise a new basis will be computed.

`MonomialsOfWeightedDegree(X, D)`

Return the monomials in the coordinate ring of the ambient of X having degree $D[i]$ with respect to the ith grading of the ambient of X.

Example H112E52

In this example we construct two linear systems on a projective plane. Although they are created in slightly different ways, MAGMA recognises that they are the same. It does the computation as a subspace equality test in the corresponding 'coefficient spaces'.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> L := LinearSystem(P,1);
> K := LinearSystem(P,[x+y,x-y,z+2*z+3*y]);
> L eq K;
true
```

`ImageSystem(f,S,d)`

The linear system on the codomain of the map of schemes f consisting of degree d hypersurfaces which contain $f(S)$. An error is reported if the scheme S does not lie in the domain of f.

Example H112E53

This example demonstrates how one can use an intrinsic based on linear systems, `ImageSystem`, to find the equations of images of maps. The point is that sometimes the usual Gröbner basis can be very difficult, so if one is interested in the equations of low degree then the linear algebra computation might be more convenient.
The curve C has one singularity analytically equivalent to the cusp $u^2 = v^5$ so is well-known to have genus 4.

```
> Q := RationalField();
> P<x,y,z> := ProjectiveSpace(Q,2);
> C := Curve(P,x^5 + y^4*z + y^2*z^3);
```

The canonical embedding of C is therefore given by four conics having a common tangent with the curve at its singularity.

```
> P3<a,b,c,d> := ProjectiveSpace(Q,3);
> phi := map< P -> P3 | [x^2,x*y,y^2,y*z] >;
```

Unless C is hyperelliptic, its canonical image will be the complete intersection of a conic and a cubic in $\mathbf{P}^3$.

```
> IC2 := Image(phi,C,2);
> IC3 := Image(phi,C,3);
> X := Intersection(IC2,IC3);
> Dimension(X);
1
> IsNonsingular(X);
true
> MinimalBasis(X);
[ a*c - b^2, a^2*b + c^2*d + d^3 ]
```

In this case the Gröbner basis of X has six elements so it is not so helpful for human comprehension. (Compare this with [Hartshorne, IV, Example 5.2.2].)

112.16.1.2 Geometrical Restrictions

Consider the following example. Suppose that L is a linear system on the projective plane whose sections are generated by the monomials x^2, xy, yz and let $p = (1 : 0 : 0)$. The phrase '*one imposes the condition on sections of L that they pass through the point p*' refers to the construction of the subsystem of L, all of whose hypersurfaces pass through p. Explicitly, this involves solving the linear equation in a,b,c obtained by evaluating the equation

$$ax^2 + bxy + cyz = 0$$

at the point p. In this example, the equation is $a = 0$ and the required subsystem is the one whose sections are generated by xy and yz.

The functions described in this section all determine a linear subsystem of a given linear system by imposing conditions on the sections of that system.

`LinearSystem(L,p)`

`LinearSystem(L,S)`

Given a point p or a sequence S of points, create the subsystem of the linear system L comprising those hypersurfaces of L which pass through p or the points of S.

`LinearSystem(L,p,m)`

Create the subsystem of the linear system L comprising hypersurfaces which pass through the point p with multiplicity at least m.

Example H112E54

In this example we make some subsystems of linear systems by imposing conditions at points. In the first example, we construct the family of all curves having singularities with prescribed multiplicities at prescribed points. See Chapter 114 for functions which apply to curves.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> L := LinearSystem(P,6);
> p1 := P ! [1,0,0];
> p2 := P ! [0,1,0];
> p3 := P ! [0,0,1];
> p4 := P ! [1,1,1];
> L1 := LinearSystem(L,p1,3);
> L2 := LinearSystem(L1,p2,3);
> L3 := LinearSystem(L2,p3,3);
> L4 := LinearSystem(L3,p4,2);
> #Sections(L4);
7
> C := Curve(P,&+[ Random([1,2,3])*s : s in Sections(L4) ]);
> IsIrreducible(C);
true
> Genus(C);
0
```

In other words, $L4$ parametrises a six-dimensional family of rational plane curves. (At least, the general element of $L4$ is the equation of a rational plane curve — there are certainly degenerate sections which factorise so don't define an irreducible curve at all.) It would be nice to be able to parametrise one of these curves. The problem is that we need to choose a general one in order that it be irreducible, but on the other hand we have very little chance of finding a rational point of a general curve. However, since this family is nice and big, we can simply impose another point condition on it yielding a rational point on each of the restricted elements.

```
> p5 := P ! [2,1,1];
> L5 := LinearSystem(L4,P![2,1,1]);
> C := Curve(P,&+[ Random([1,2,3])*s : s in Sections(L5) ]);
> IsIrreducible(C);
true
> Genus(C);
0
```

```
> L<u,v> := ProjectiveSpace(Rationals(),1);
> phi := Parametrization(C, Place(C!p5), Curve(L));
> Ideal(Image(phi)) eq Ideal(C);
true
```

To illustrate another feature of imposing point conditions on linear systems, we use a point that is not in the base field of the ambient space. Linear systems on an ambient spaces are defined over its base field, so nonrational points impose conditions as the union of their Galois conjugates.

```
> A<x,y> := AffineSpace(FiniteField(2),2);
> L := LinearSystem(A,2);
> L;
Linear system on Affine Space of dimension 2 Variables : x, y
with 6 sections: 1 x y x^2 x*y y^2
> k1<w> := ext< BaseRing(A) | 2> ;
> p := A(k1) ! [1,w];
> p;
(1, w)
> LinearSystem(L,p);
Linear system on Affine Space of dimension 2
Variables : x, y
with 4 sections:
x^2 + 1
x*y + y
x + 1
y^2 + y + 1
> k2<v> := ext< BaseRing(A) | 3> ;
> q := A(k2) ! [1,v];
> LinearSystem(L,q);
Linear system on Affine Space of dimension 2
Variables : x, y
with 3 sections:
x^2 + 1
x*y + y
x + 1
```

Note the minimal polynomial of the y coordinate of the point $(1, w)$ is of degree 2 so is visible in the restricted linear system. On the other hand, v is of order 3 so it imposes more conditions on the linear system.

`LinearSystem(L,X)`

The subsystem of the linear system L comprising elements of L which contain the scheme X. The sections of this linear system is equal to the polynomials of the defining ideal of X whose homogeneous degree is the same as that of L.

`LinearSystemTrace(L,X)`

The trace of the linear system L on the scheme X which lies in the ambient space of L. This merely simulates the restriction of the linear system L on X by taking the sections of L modulo the equations of X. The result is still a linear system on the common ambient space.

Example H112E55

In this example, we restrict the linear system of cubics in space to a scheme, which is in fact a twisted cubic curve. (The intrinsic `Sections` is defined in Section 112.16.2.2.)

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> L := LinearSystem(P,3);
> X := Scheme(P,[x*z-y^2,x*t-y*z,y*t-z^2]);
> #Sections(L);
20
> L1 := LinearSystemTrace(L,X);
> #Sections(L1);
10
```

Taking the sections of L modulo the equations of X reduces the dimension of the space of sections by 10. Of course, there is a choice being made about which particular trace sections to use — in the end, the computation is that of taking a complement in a vector space of some vector subspace.
Since we recognise this scheme X as the image of a projective line, we can confirm that the result is correct. We make a map from the projective line to the space P which has image X. Then we check that the pullback L and $L1$ are equal on the projective line. In fact, since the linear system embedding the line is the complete system of degree 3, and L comprises degree 3 hypersurfaces on P, both pullbacks should give the complete linear system on the line of degree $3 \times 3 = 9$. (The intrinsic `Pullback` is defined in Section 112.16.3.)

```
> P1<u,v> := ProjectiveSpace(BaseRing(P),1);
> phi := map< P1 -> P | [u^3,u^2*v,u*v^2,v^3] >;
> Ideal(phi(P1)) eq Ideal(X);
true
> Pullback(phi,L) eq Pullback(phi,L1);
true
> Pullback(phi,L1);
Linear system on Projective Space of dimension 1
Variables : u, v
with 10 sections:
u^9 u^8*v u^7*v^2 u^6*v^3 u^5*v^4 u^4*v^5 u^3*v^6 u^2*v^7 u*v^8 v^9
```

112.16.1.3 Explicit Restrictions

`LinearSystem(L,F)`

The subsystem of the linear system L generated by the polynomials in the sequence F. An error results if the polynomials of F are not already sections of L. As before, the polynomials in F are used as a basis of the sections of the resulting linear system provided they are linearly independent, otherwise a new basis is computed.

`LinearSystem(L,V)`

The subsystem of the linear system L determined by the subspace V of the complete coefficient space of L. It is an error to call this if V is not a subspace of the coefficient space of L.

112.16.2 Basic Algebra of Linear Systems

This section presents functions for the following tasks: (i) assessing properties of the data type; (ii) geometrical properties of linear systems; (iii) linear algebra operations.

112.16.2.1 Tests for Linear Systems

`Ambient(L)`
`AmbientSpace(L)`

The projective space on which the linear system L is defined.

`L eq K`

Returns `true` if and only if the linear systems L and K are equal if considered as linear subsystems of some complete linear system. An error results if L and K lie in different complete linear systems.

`IsComplete(L)`

Returns `true` if and only if the linear system L is the complete linear system of polynomials of some degree.

`IsBasePointFree(L)`
`IsFree(L)`

Returns `true` if and only if the linear system L has no base points.

112.16.2.2 Geometrical Properties

`Sections(L)`

A sequence whose elements form basis of the sections of the linear system L. By definition, this is a maximal set of linearly independent polynomials which are elements of L.

`Random(LS)`

If the base field of LS admits random elements then this returns a random element of the space of sections in the linear system LS. If the base field is the rational field, then a section having small random rational coefficients is defined. Otherwise, if there is no random element generator for the base field, the zero section is returned.

`Degree(L)`

The degree of the sections of the linear system L.

`Dimension(L)`

The projective dimension of the linear system L. This is the maximal number of linearly independent sections of L minus 1.

`BaseScheme(L)`

The base scheme of the linear system L. This is simply the scheme defined by the sections of L. This function does not perform any tests on this scheme; it might be empty for example.

`BaseComponent(L)`

The hypersurface common to all the elements of the linear system L.

`Reduction(L)`

The linear system L with its codimension 1 base locus removed. In other words, the linear system defined by the sections of L after common factors are removed.

Example H112E56

If one tries to impose too many point conditions on a linear system, the general elements will no longer be irreducible. From a quick genus calculation one might think that it was possible to impose singularities on multiplicities 2, 3, 4 on projective curves of degree 6 to reveal rational curves — indeed $g = 10 - 1 - 3 - 6 = 0$ if the resulting curves are irreducible.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> L := LinearSystem(P,6);
> p1 := P ! [1,0,0];
> p2 := P ! [0,1,0];
> p3 := P ! [0,0,1];
> L1 := LinearSystem(L,p1,4);
> L2 := LinearSystem(L1,p2,3);
```

```
> L3 := LinearSystem(L2,p3,2);
> Sections(L3);
[ x^2*y^3*z, x^2*y^2*z^2, x^2*y*z^3, x^2*z^4, x*y^3*z^2,
    x*y^2*z^3, x*y*z^4, y^3*z^3, y^2*z^4 ]
> BaseComponent(L3);
Scheme over Rational Field defined by z
```

But notice that every section is divisible by z. So the curve $z = 0$ is in the base locus of this linear system, that is, it is contained in every curve in the linear system $L3$. The intrinsic `BaseComponent` identifies this component. The intrinsic `Reduction` creates a new linear system by removing this codimension 1 base locus, as is seen below. First, however, we look at the complete set of prime components of the base scheme and see that, while there is only one codimension 1 component which we already know, there is another component in higher codimension. When we reduce to remove the base component, this other piece of the base scheme remains, and other codimension 2 components also appear.

```
> MinimalPrimeComponents(BaseScheme(L3));
[
    Scheme over Rational Field defined by
    z,
    Scheme over Rational Field defined by
    x
    y
]
> L4 := Reduction(L3);
> Sections(L4);
[ x^2*y^3, x^2*y^2*z, x^2*y*z^2, x^2*z^3, x*y^3*z, x*y^2*z^2,
    x*y*z^3, y^3*z^2, y^2*z^3 ]
> MinimalPrimeComponents(BaseScheme(L4));
[
    Scheme over Rational Field defined by
    x
    y,
    Scheme over Rational Field defined by
    x
    z,
    Scheme over Rational Field defined by
    y
    z
]
> [ RationalPoints(Z) : Z in $1 ];
[
    {@ (0 : 0 : 1) @},
    {@ (0 : 1 : 0) @},
    {@ (1 : 0 : 0) @}
]
```

The linear system $L4$ has sections which are visibly those of $L3$ but with a single factor of z removed. It still has base locus but now that base locus comprises only points. Not surprisingly, it is exactly the three points which we imposed on curves in the first place.

`BasePoints(L)`

A sequence containing the basepoints of the linear system L if the base locus of L is finite dimensional.

`Multiplicity(L,p)`

The generic multiplicity of hypersurfaces of the linear system L at the point p.

112.16.2.3 Linear Algebra

`CoefficientSpace(L)`

The vector space corresponding to the linear system L whose vectors comprise the coefficients of the polynomial sections of L.

`CoefficientMap(L)`

The map from the polynomial ring that is the parent of the sections of the linear system L to the coefficient space of L. When evaluated at a polynomial f, this map will return vector of coefficients of f as a section of L.

`PolynomialMap(L)`

The map from the coefficient space of the linear system L to the polynomial ring that is the parent of the sections of L. When evaluated at a vector v, this map will return the polynomial section of L whose coefficients with respect to the basis of L are v.

`Complement(L,K)`

A maximal subsystem of the linear system L which does not contain any of the hypersurfaces of the linear system K.

`Complement(L,X)`

A maximal subsystem of the linear system L comprising hypersurfaces not containing X.

Example H112E57

In this example we show to define linear systems by referring to subspaces of a coefficient space. The explicit translation intrinsics between the linear algebra language and the linear system language let one 'see' what is happening in the background. We start by defining a linear system whose chosen sections are clearly not linearly independent.

```
> A<x,y> := AffineSpace(FiniteField(2),2);
> L := LinearSystem(A,[x^2-y^2,x^2,y^2]);
> VL := CoefficientSpace(L);
> VL;
KModule VL of dimension 2 over GF(2)
> W := sub< VL | VL.1 >;
> LinearSystem(L,W);
Linear system on Affine Space of dimension 2
Variables : x, y
with 1 section:
x^2
> phi := PolynomialMap(L);
> [ phi(v) : v in Basis(VL) ];
[
    x^2,
    y^2
]
```

Thus we see that MAGMA has chosen the obvious polynomial basis for the sections of L and disregarded the section $x^2 - y^2$.

`L meet K`

`Intersection(L,K)`

The linear system whose coefficient space is the intersection of the coefficient spaces of the linear systems L and K. An error is reported unless L and K lie in the same complete linear system.

`X in L`

Returns `true` if and only if the scheme X occurs among the hypersurfaces comprising the linear system L.

`f in L`

Returns `true` if and only if the polynomial f is a section of the linear system L. That is, `true` if and only if f is in the linear span of the basis of sections defining L.

`K subset L`

`IsSubsystem(L,K)`

Returns `true` if and only if the coefficient space of the linear system K is contained in that of the linear system L. An error is reported if L and K do not lie in a common linear system.

112.16.3 Linear Systems and Maps

The sequence of sections of a linear system may be used to construct a map from the projective space on which the sections are defined to another having the appropriate dimension. This is done directly using the `map` constructor as in Section 112.14. For example, if L is a linear system on some projective space P then the corresponding map can be created as follows.

```
> map< P -> Q | S >
>              where Q is ProjectiveSpace(BaseRing(P),#S-1)
>              where S is Sections(L);
```

There is not a proper inverse to this operation: there is no reason why a map should be determined by linearly independent polynomials. However, the system determined by the polynomials defining a map is still important. It is sometimes called the *homoloidal system* of the map.

`Pullback(f,L)`

The linear system f^*L on the domain of the map of schemes f where L is a linear system on the codomain of f. This requires care when f is not a regular map: it really produces the system of homaloids, that is, the substitution of the map equations into the linear system's sections.

112.17 Divisors

This section contains functionality for working with divisors on varieties (integral schemes defined over a field) of dimension greater than one. Currently, divisors can only be created on projective schemes X and there is also a restriction that X is ordinary projective for many of the less formal intrinsics that rely on the coherent sheaf code. In a number of places it is also required that a divisor D is Cartier (always true if X is non-singular), which we currently cannot check. There are also a number of intrinsics that are specific to surfaces.

Integral divisors are represented as differences of effective divisors, which are represented as subschemes of the scheme they live on. Factorisation into multiples of irreducibles can also be performed and the result is stored once calculated. It is also possible to work with **Q**-divisors. These are represented internally as factorisations with rational multiplicity of components.

The package of divisor functions is at and early stage and a number of the intrinsics are not as general as they could be and/or could be made more efficient. However, it is useful functionality that seems worth exporting now. There is much further work still to be done.

112.17.1 Divisor Groups

As for curves, there is a divisor group object associated to a variety X, which is the parent of all divisors on X. It is of type `DivSch`.

`DivisorGroup(X)`

The divisor group of variety X.

`Variety(G)`

The variety of the divisor group G.

`G1 eq G2`

True if and only if the divisor groups $G1$ and $G2$ are for the same variety.

112.17.2 Creation Of Divisors

Divisors are of type `DivSchElt`. Internally, an integral, effective divisor D on variety X is stored as an ideal which defines D as a subscheme of X. A general divisor is represented internally in partially factored form as a list of pairs of ideals and rational multiplicities $[\langle I_i, m_i\rangle]$ which represents the **Q**-rational (integral, if all m_i are integers) divisor $\sum_i m_i * D(I_i)$, where $D(I_i)$ is the effective divisor on X defined by the ideal I_i. An integral, effective divisor may also have a factorisation stored. The internal factorisation can change over time with the I_i being decomposed into products of larger ideals. When the I_i are all prime ideals, we say that the factorisation is a prime factorisation of D.

This section contains the basic creation functions for divisors.

`Divisor(X,f)`

`Divisor(X,f)`

`Divisor(X,f)`

These create the integral divisor on X defined by a single global element f. In the first two cases, f is an element of the function field (or the field of fractions of the coordinate ring of) the projective ambient of X. The divisor is non-effective (unless it is zero): the divisor of zeroes of f minus its divisor of poles. In the last case f should be a homogeneous polynomial in the coordinate ring of the ambient and the divisor is the effective divisor defined by the subscheme of X whose ideal is generated by the ideal of X and f.

`Divisor(X,Q)`

`Divisor(X,Y)`

`Divisor(X,I)`

`CheckSaturated`	BoolElt	*Default :* `false`
`CheckDimension`	BoolElt	*Default :* `false`
`UseCodimensionOnePart`	BoolElt	*Default :* `false`

These three intrinsics define an integral, effective divisor on projective variety X defined by an ideal or subscheme. For the first, Q is a sequence of elements in the coordinate ring of X and it is equivalent to passing the ideal generated by the ideal of X and Q. For the second, Y is a subscheme of X that should define an effective divisor on X. For the third, I is an ideal in the coordinate ring of the ambient of X, whose saturation J should contain the ideal of X. The effective divisor is given by the closed subscheme of X whose ideal is J.

`CheckSaturated` can be set to `true` in the third case if it is known that I is already saturated or in the second case if it is known that the ideal of Y is already saturated. `CheckDimension` can be set to `true` in any of the cases if it is known that the subscheme defining the divisor is of pure codimension 1 in X. Otherwise this condition is checked with the following exception. In the third case, if parameter `UseCodimensionOnePart` is set to `true` the non-codimension 1 part of the ideal is ignored in creating the divisor.

`HyperplaneSectionDivisor(X)`

Creates a divisor given by a hyperplane section of projective variety X.

`ZeroDivisor(X)`

The zero divisor on variety X.

`CanonicalDivisor(X)`

A canonical divisor on variety X. X must be ordinary projective and should be a Gorenstein scheme for this to give a correct result. It uses the canonical sheaf on X and the next intrinsic.

`SheafToDivisor(S)`

S is a coherent sheaf that should be invertible (locally free, rank 1) on variety X. S is then isomorphic to $L(D)$ for a (Cartier) divisor D (defined up to rational equivalence) on X. Returns such a divisor D which is effective if possible.

`RoundDownDivisor(D)`

For an integral divisor D just returns D. For a non-integral ($\mathbf{Q}$-rational) divisor with a factorisation into sum of rational multiples of prime components, returns the divisor of the integer multiple sum of primes given by rounding down all of the original rational coefficients.

`RoundUpDivisor(D)`

For an integral divisor D just returns D. For a non-integral ($\mathbf{Q}$-rational) divisor with a factorisation into sum of rational multiples of prime components, returns the divisor of the integer multiple sum of primes given by rounding up all of the original rational coefficients.

`FractionalPart(D)`

Returns $D-$ `RoundDownDivisor`(D).

`IntegralMultiple(D)`

Finds a positive integer N such that $E = N * D$ is an integral divisor. Returns E and N. Doesn't attempt to find the smallest possible N by analysing the full prime factorisation of D.

112.17.3 Ideals and Factorisations

Divisors are stored in ideal or factored form as described in the introduction to the last section. This section contains functions related to these representing structures.

`Ideal(D)`

Returns the defining ideal for an effective, integral divisor D.

`Support(D)`

The subscheme of the variety of effective **Q**-divisor D that gives its support.

`IdealOfSupport(D)`

The ideal in the coordinate ring of the ambient of the variety of the effective **Q**-divisor D that defines it's support.

`SignDecomposition(D)`

The decomposition of D into two effective divisors A and B such that $D = A - B$. A and B are returned. Note that they are not guaranteed to be relatively prime for this intrinsic.

`IdealFactorisation(D)`

Returns the current stored factorisation of D as a sequence of pairs of ideals and rational multiplicities.

`CombineIdealFactorisation(~D)`

Simplify the current ideal factorisation of D by combining terms with the same ideal.

`ComputeReducedFactorisation(~D)`

`ReducedFactorisation(D)`

Replace the ideal factorisation of D with an equivalent reduced factorisation where all ideals occurring are primary. The first intrinsic just does the replacement internally. The second intrinsic also returns the result.

`ComputePrimeFactorisation(~D)`

`PrimeFactorisation(D)`

Replace the ideal factorisation of D with an equivalent prime factorisation where all ideals occurring are prime. The first intrinsic just does the replacement internally. The second intrinsic also returns the result.

`Multiplicity(D,E)`

The multiplicity of prime divisor E in divisor D.

112.17.4 Basic Divisor Predicates

`IsZeroDivisor(D)`

Returns whether D is the zero divisor.

`IsIntegral(D)`

Returns whether D is an integral divisor. If this isn't immediately obvious from the current factorisation, will convert to a prime factorisation and try to combine terms.

`IsEffective(D)`

Returns whether D is an effective divisor. If this isn't immediately obvious from the current factorisation, will convert to a prime factorisation and try to combine terms.

`IsPrime(D)`

Returns whether D is a prime divisor.

`IsFactorisationPrime(D)`

Returns whether the current factorisation of D is a prime factorisation (i.e. all ideals occurring are prime).

`IsDivisible(D)`

Returns whether D is integral and divisible as an integral divisor by an integer $n > 1$. If so, also returns the maximum such n.

112.17.5 Arithmetic of Divisors

```
D1 + D2
D1 + D2
D1 + D2
D1 - D2
D1 - D2
D1 - D2
-D
```

Addition, subtraction and unitary minus on divisors. For addition and subtraction, one argument may be a toric divisor whose toric variety is the variety of the scheme divisor.

```
n * D
r * D
```

Multiplication of a divisor D by an integer n or rational number r. Note that the multiplication by r is the only current primitive method for constructing non-integral divisors.

```
D1 eq D2
```

Returns whether divisors $D1$ and $D2$ lie on the same variety and are equal.

112.17.6 Further Divisor Properties

More complicated predicates on divisors.

```
IsCanonical(D)
```

Returns whether D is a canonical divisor by testing whether its associated sheaf is isomorphic to the canonical sheaf. The variety of D must be ordinary projective here and should be Gorenstein.

```
IsAnticanonical(D)
```

Returns whether D is an anticanonical divisor by testing whether its associated sheaf is isomorphic to the dual of the canonical sheaf. The variety of D must be ordinary projective here and should be Gorenstein.

```
IsCanonicalWithTwist(D)
```

Returns whether D is the sum of a hypersurface divisor of degree d and a canonical divisor by testing whether its associated sheaf is isomorphic to a twist of the canonical sheaf. If so, also returns d. The variety of D must be ordinary projective here and should be Gorenstein.

`IsPrincipal(D)`

Returns whether D with variety X is a principal divisor and, if so, also returns an element f of the function field of the ambient of X such that $D = div(f)$. X should be ordinary projective and D a Cartier divisor here. Uses the Riemann-Roch space of D.

`IsLinearlyEquivalent(D,E)`

Returns whether two divisors D and E on variety X are linearly equivalent and, if so, also returns an element f of the function field of the ambient of X such that $D = E + div(f)$. Uses `IsPrincipal` for the difference between the two divisors, so X must be ordinary projective.

`BaseLocus(D)`

`IsBasePointFree(D)`

`IsMobile(D)`

The first intrinsic computes the base locus of the linear system $|[D]|$ (i.e. the reduced intersection of all effective divisors in the linear system) where $[D]$ is the round down of D . This uses the Riemann-Roch space of $[D]$, which means that this divisor has to be Cartier and the variety X of D has to be ordinary projective.

The second intrinsic returns whether this base locus is empty and the third whether it is of codimension at least two in X (i.e. there are no common divisor components to the full linear system). X and D obviously have to satisfy the same conditions.

`IntersectionNumber(D1,D2)`

$D1$ and $D2$ are divisors on a variety X which must be of dimension 2. One of the two divisors is assumed to be Cartier. Computes the intersection pairing number $D1.D2$.

`SelfIntersection(D)`

The intersection number of D with itself. D and X must satisfy the conditions for the last intrinsic.

`Degree(D)`

`Degree(D,H)`

D (resp. D and H) lies on a variety X of dimension 2. The first computes the intersection number of D with respect to a hyperplane divisor. The second computes the intersection number of D with H (so is just equivalent to `IntersectionNumber(D,H)`).

`IsNef(D)`

D should be a $\mathbf{Q}$-Cartier divisor on a projective surface X. Currently, it also has to be effective. Returns whether D is a nef divisor: i.e. whether it has non-negative intersection with all effective divisors on X.

`IsNefAndBig(D)`

D and X are as above. D must be effective. Returns whether D is a nef divisor AND has positive self-intersection.

`NegativePrimeDivisors(D)`

D and X again should satisfy the same conditions as in `IsNef`. Returns a sequence of prime divisor components of D which have negative intersection with D.

`ZariskiDecomposition(D)`

D and X again should satisfy the same conditions as in `IsNef`. Returns a pair of $\mathbf{Q}$-divisors P and N such that $D = P + N$, P is nef and N has negative-definite support (i.e. the intersection pairing on its prime components is negative definite).

112.17.7 Riemann-Roch Spaces

This section contains functions to compute and work with Riemann-Roch spaces for a divisor D. It is always assumed that X, the variety of D, is an ordinary projective space here. The Riemann-Roch space is the finite-dimensional subspace of the vector space (over the basefield) of rational functions on X consisting of zero and all $f \neq 0$ such that $D + div(f)$ is an effective divisor. Thus, the Riemann-Roch space of D is the same as the Riemann-Roch space of $[D]$, `RoundDownDivisor(D)`. Because the sheaf code is used (or a slight variant for non-effective divisors), it is also required that $[D]$ is Cartier for all relevant intrinsics.

`Sheaf(D)`

The invertible sheaf corresponding to the divisor class of divisor D. If D is not integral, its round down $[D]$ is used. This divisor must be Cartier and its variety X must be ordinary projective. Is effectively the same function as in the Sheaf package when D is effective and uses a slight variant otherwise.

`RiemannRochBasis(D)`
`RiemannRochSpace(D)`

The first returns a basis of the Riemann-Roch space of the round down $[D]$ of divisor D (as a sequence of elements in the function field F of the ambient of D's variety, X). The second returns the Riemann-Roch space as an abstract vector space V over the base field along with a map from V to F. X must be ordinary projective and $[D]$ Cartier. If D is effective, this is the same as using the coherent sheaf function that computes the associated invertible sheaf and Riemann-Roch basis. If D is non-effective a slight variant is used.

`RiemannRochCoordinates(f,D)`

Returns whether f can be coerced into the function field of the ambient of D's variety X and whether f then lies in the Riemann-Roch space of D. If so also returns the coordinates of f with respect to the basis of the Riemann-Roch space returned by `RiemannRochBasis(D)`. As usual, X must be ordinary projective and $[D]$, the round down of D, must be Cartier.

`IsLinearSystemNonEmpty(D)`

Returns whether there is an effective divisor linearly equivalent to D and, if so, returns such a divisor. Uses the Riemann-Roch space of D. The conditions on D and X, its variety, are as for the preceding intrinsics.

112.18 Isolated Points on Schemes

There is now experimental code to try to find isolated points of schemes in $\mathbf{A}(Q)^n$ that are defined by n or more equations. There is no restriction that the scheme itself must be of dimension 0, and in many applications, there is an uninteresting (or degenerate) variety of positive dimension, with the isolated points being the ones of interest.

The first technique to do this is to find points locally modulo some prime, at which the Jacobian matrix is of maximal rank. A separate procedure then lifts such points via a Newton method, and tries to identify them (via LLL) in a number field. If the degree is known (or suspected), this information can be passed to the lifting function, and otherwise it will try a generic method that applies LLL for degrees $3 \cdot 2^n$ and $4 \cdot 2^n$ as n increases, expecting to catch other solutions via a factorization into a smaller field (for instance, a degree 6 solution will show up in degree 8 as the expected minimal polynomial multiplied by a more-or-less random quadratic one).

The running time of such a process is often dominating by the searching for local points, and so various methods can be used to pre-condition the system. Firstly, variables which appear as a linear monomial in one of the equations can be (iteratively) eliminated. Already it is not clear what the best order is, so the user can specify it. In given examples, it is not untypical for later steps to take 10 times as long due to a different choice of eliminations, so some experimenting with this parameter can be useful. Secondly, resultants can be used to try to eliminate more variables, perhaps concentrating on those which appear to a small degree in the equations. By default, if a variable appears to degree 2 or less in all the equations, a resultant step will be applied. The resulting equations can be quite complicated (taking many megabytes to represent them), but it is still often faster to loop over p^{V-1} possible local points compared to p^V. The resultants can introduce extraneous solutions, which are checked when undoing the modifications to the system of equations. An error can occur if the variable elimination reduces the number of equations below the dimension.

Another concern for running time is in the order of the above operations. For instance, computing the resultants can be time-consuming in some examples, and perhaps doing so modulo p for the primes of interest might be a superior method in some cases. A second example is that recognising points over the number fields in question might be faster with

a reduced system and then undoing the resultants and linear eliminations in the number field, though the lifting might be slower in that case. The algorithm as implemented tries to handle the general case well.

Note that the scheme given to the IsolatedPoints routines might also have components of positive dimension, but the techniques here will only work to find the points that do not lie on them.

`LinearElimination(S)`

`EliminationOrder`	SeqEnum	*Default :* [ ]

Given a scheme, iteratively eliminate variables that appear strictly linearly (that is, as a monomial times a constant) in some equation. The `EliminationOrder` vararg allows an ordering to be specified. The results can vary drastically when the order is changed. The returned value is a map from the resulting scheme to the input scheme, with an inverse.

`IsolatedPointsFinder(S,P)`

`LinearElimination`	SeqEnum	*Default :* [ ]
`ResultantElimination`	SeqEnum	*Default :* [ ]
`FactorizationInResultant`	BoolElt	*Default :* `true`

Given a affine n-dimensional scheme defined over the rationals by at least n equations, and a sequence of primes, try to find liftable points of the scheme modulo the primes. The variables given in the `LinearElimination` vararg will be eliminated in that order. If this is non-empty, an automatic procedure will be applied. Similarly with `ResultantElimination`. Finally, by default, computed resultants have `SquarefreeFactorization` applied to them (and repeated factors removed), and this can be turned off.

`IsolatedPointsLifter(S,P)`

`LiftingBound`	RngIntElt	*Default :* 10
`DegreeBound`	RngIntElt	*Default :* 32
`OptimizeFieldRep`	BoolElt	*Default :* `false`
`DegreeList`	SeqEnum	*Default :* [ ]

Given a affine n-dimensional scheme defined over the rationals by at least n equations, and a sequence of finite field elements giving a point (on the scheme) whose Jacobian matrix is of maximal rank, attempt to lift the point via a Newton method and recognise it over a number field. The function returns `false`if a point was not found, and else returns both `true`and the point that was found.

The `LiftingBound` vararg determines how many lifting steps to use, with the default being 10, so that approximately precision $p^{2^{10}}$ is obtained. The `DegreeBound` is a limit on how high of a degree of field extension to check for solutions. The method used only checks for some of the degrees via LLL, as usually smaller degrees will

show up in factors. The `DegreeList` vararg can also be used for this, perhaps when the degree of the solution in question is known. The practical limit is likely around 50 in the degree. Finally, there is the `OptimizeFieldRep` boolean vararg, which determines whether the number field obtained will have its optimised representation computed.

`IsolatedPointsLiftToMinimalPolynomials(S,P)`

`LiftingBound`	RngIntElt	*Default :* 10
`DegreeBound`	RngIntElt	*Default :* 32
`DegreeList`	SeqEnum	*Default :* [ ]

This works as with `IsolatedPointsLifter`, but instead of trying to find a common field containing all the coordinates, simply returns a minimal polynomial for each one.

Example H112E58

This example follows an idea of Elkies to construct "large" integral points on elliptic curves. Let X, Y, A, B be polynomials in t, and let $Q(t)$ be quadratic. The idea is that

$$Q(t)Y(t)^2 = X(t)^3 + A(t)X(t) + B(t)$$

will have infinitely many specialisations with $Q(t)$ square (via solving a Pell equation), and thus yield, perhaps after scaling to clear denominators, integral points on the resulting curves. If the degree of A, B is small enough compared to that of X, the resulting specialisation will be quite notable. However, one must avoid the cases where the resulting discriminant $4A(t)^3 - 27B(t)^2$ is zero, as these points do not yield an elliptic curve. It turns out that such points contribute a positive-dimensional component to the solution space, and we simply want to ignore such solutions in general.
The first case of interest is when the degrees of (X, Y, A, B) are $(4, 5, 0, 1)$, solved by Elkies in 1988. One way of parametrising this, taking into account possible rational changes of the t-variable to simplify the system, is:

$$X(t) = t^4 + t^3 + x_2t^2 + x_1t + x_0, Q(t) = t^2 + q_1t + q,0$$

$$Y(t) = t^5 + y_3t^3 + y_2t^2 + y_1t + y_0, A(t) = a_0, B(t) = b_1t + b_0.$$

Then we get 12 equations from requiring that the 0th to 11th degree coefficients of $X^3 + AX + B - QY^2$ all vanish. It turns out that the desired solution is rational in this case, so that (almost) any prime will suffice. The solution can then be lifted – as a final step (particular to this problem), one would have to scale the resulting point so as to ensure that $Q(t)$ represents squares.

```
> K := Rationals();
> R<a0,b0,b1,q0,q1,x0,x1,x2,y0,y1,y2,y3> := PolynomialRing(K,12);
> _<t> := PolynomialRing(R);
> X := t^4+t^3+x2*t^2+x1*t+x0; Y := t^5+y3*t^3+y2*t^2+y1*t+y0;
> Q := t^2+q1*t+q0; A := a0; B := b1*t+b0;
> L := X^3+A*X+B-Q*Y^2;
```

```
> COEFF:=[Coefficient(L,i) : i in [0..11]];
> S := Scheme(AffineSpace(R),COEFF);
```

For this example, we simply call `IsolatedPointsFinder` directly. Alternatively, we could first use `LinearElimination` if desired.

```
> PTS:=IsolatedPointsFinder(S,[13]); PTS; // 13 is a random choice
[* [ 11, 1, 7, 6, 3, 1, 6, 11, 0, 3, 4, 2 ] *]
> b, sol := IsolatedPointsLifter(S,PTS[1]); sol;
(216513/4096, -3720087/131072, 531441/8192,
 11/4, 3, 311/64, 61/8, 9/2, 715/64, 165/16, 77/16, 55/8)
> _<u>:=PolynomialRing(Rationals());
> X := Polynomial([Evaluate(c,Eltseq(sol)) : c in Coefficients(X)]);
> Y := Polynomial([Evaluate(c,Eltseq(sol)) : c in Coefficients(Y)]);
> Q := Polynomial([Evaluate(c,Eltseq(sol)) : c in Coefficients(Q)]);
> A := Evaluate(A,Eltseq(sol));
> B := Polynomial([Evaluate(c,Eltseq(sol)) : c in Coefficients(B)]);
> assert X^3+A*X+B-Q*Y^2 eq 0;
> Q; // note that Q does not represent any squares, but 2*Q(1/2)=9
u^2 + 3*u + 11/4
> B; // also need to clear 2^17 from denominators
531441/8192*u - 3720087/131072
> POLYS := [2^7*X, 2^9*Y, 2^3*Q, 2^14*A, 2^21*B]; // 2^21 in each term
> [Evaluate(f,u/2) : f in POLYS];
[
    8*u^4 + 16*u^3 + 144*u^2 + 488*u + 622,
    16*u^5 + 440*u^3 + 616*u^2 + 2640*u + 5720,
    2*u^2 + 12*u + 22,
    866052,
    68024448*u - 59521392
]
```

As noted by Elkies, one can clean up the final form of the solution if desired, via rational transformations of the u-variable. Since $Q(1) = 2 + 12 + 22 = 36$, the theory of the Pell equation tells us that there are infinitely many integers u such that $Q(u)$ is integral, and these all give integral points on a suitable elliptic curve.
There are only four choices of (X, Y, A, B) degrees that give the "largest" possible integral points via this method. The second case, of degrees $(6, 8, 1, 1)$ has a solution over a quartic number field, and the third case, of degrees $(8, 11, 1, 2)$ has a nonic solution. Both of these were found by the methods of this section, the former taking only a couple of minutes.

Example H112E59

Another application of the isolated points rotine is to compute Belyi maps, one instance of which is in finding solutions to a polynomial version of Hall's conjecture, concerning how small the degree of $X(t)^3 - Y(t)^2$ can be (if the difference is nonzero). The result is that the degree must be at least $1 + \deg(X)/2$, and there are (up to equivalence) finitely many polynomials of that degree, the count of which can be described in terms of some combinatorics, or in terms of simultaneously conjugacy classes of cycle products of given types in a symmetric group.

In this example, we compute the solution for the case where X has degree 12. It turns out that there are 6 solutions in this case, lying over a sextic number field (we of course ignore "solutions" with $X(t)^3 = Y(t)^2$, though similar to the previous example, they contribute a positive-dimensional component of the solution set). The finding of a suitable local point is not particularly easy, so we just note that

$$X(t) \equiv t^{12} + 14t^{10} + 14t^9 + 9t^8 + 6t^7 + 4t^6 + 7t^5 + 6t^4 + 15t^3 + 7t^2 + 3t + 10$$

gives a solution modulo 17, with $Y(t)$ being (of course) the approximate square root of $X(t)^3$. We shall lift this in a way that keeps the t^{11} as zero and the t^9 and t^{10} coefficients as equal (these are from preliminary transformations of the t-parameter that can be applied to the system).
As noted above, it might be easier to remove the y-variables "by hand", and then undo the linear eliminations in the resulting sextic number field. We chose here to work directly. A theorem of Beckmann says that the number field we obtain can only be ramified at primes less than 36.

```
> SetVerbose("IsolatedPoints",1);
> XVARS := ["x"*IntegerToString(n) : n in [0..9]];
> YVARS := ["y"*IntegerToString(n) : n in [0..17]];
> P := PolynomialRing(Rationals(),28);
> AssignNames(~P,XVARS cat YVARS);
> _<t> := PolynomialRing(P);
> Y := &+[P.(i+11)*t^i : i in [0..17]]+t^18;
> X := &+[P.(i+1)*t^i : i in [0..9]]+(P.10)*t^10+t^12;
> Xpt := [GF(17)|10,3,7,15,6,7,4,6,9,14];
> pt := Xpt cat [0 : i in [11..28]];
> FF := GF(17); _<u> := PolynomialRing(FF);
> Xv := Polynomial([FF!Evaluate(c,pt) : c in Coefficients(X)]);
> Xv3 := Xv^3; Yv := u^18;
> for d:=17 to 0 by -1 do // ApproximateSquareRoot
>     Yv:=Yv+Coefficient(Xv3,d+18)/2*u^d; Xv3:=Xv^3-Yv^2; end for;
> Yv^2-Xv^3; // must be degree 7 or less
8*u^7 + 11*u^5 + 10*u^4 + 3*u^3 + 3*u^2 + 11*u + 4
> pt := Xpt cat [Coefficient(Yv,d) : d in [0..17]];
> SYS := [Coefficient(X^3-Y^2,d) : d in [8..35]]; // 28 vars
> S := Scheme(AffineSpace(P),SYS);
> b, sol := IsolatedPointsLifter(S,pt : LiftingBound:=12, DegreeBound:=10);
> K := OptimisedRepresentation(Parent(sol[1]) : PartialFactorisation); K;
Number Field with defining polynomial
  y^6 - y^5 - 60*y^4 - 267*y^3 - 514*y^2 -  480*y - 180 over the Rationals
> Factorization(Discriminant(Integers(K)));
[ <2, 2>, <5, 1>, <13, 1>, <29, 5> ]
```

An alternative of completing the computation is to first use `LinearElimination` before applying `IsolatedPointsLifter`. In any event, the computation of the local point (which we simply assumed to be given) would be the dominant part of the running time.

```
> mp := LinearElimination(S); // a few seconds to evaluate scheme maps
> rmp := // reduced map
>  map<ChangeRing(Domain(mp),GF(17))->ChangeRing(Codomain(mp),GF(17))
```

```
>     | DefiningEquations(mp),DefiningEquations(Inverse(mp)) : Check:=false>;
> PT := Inverse(rmp)(Codomain(rmp)!(pt));
```

The `IsolatedPointLifter` can now be called on `Domain(mp)` and `Eltseq(PT)` (with varargs if desired), and then the result can be mapped back to the original scheme `S` via `mp`. It is a bit hairy to do this directly, as scheme maps do not naturally deal with finite field inputs in all cases. Due to the way that `IsolatedPointsLifter` uses to choose which coordinate to try to recognise first, it could also be slower in the end.

Example H112E60

Here is an example where finding the common field is quite difficult, but finding minimal polynomials for all the coordinates is rather easy. First, a somewhat generic random scheme in $\mathbf{P}^3$ is chosen, such that each variable appears no more than linearly. This has degree less than 4!, and in the example chosen, it has degree 22. Then two local points are found modulo 5. These are then passed to the lifting function, which returns the desired solution.

```
> P<w,x,y,z> := AffineSpace(Rationals(),4);
> f1 := w*x*y - 6*w*x - 7*w*y*z + w*y - 6*w*z - 3*x*y + y + 6*z;
> f2 := 10*w*x*y*z - 4*w*y*z + 2*w*y - 9*w - x*y*z - 10*x*z + y*z - 7*y;
> f3 := 10*w*x*y*z - 6*w*x*y + 8*w*x*z - 4*w*y*z - 6*w*z - x*z + 9*x + 8*y;
> f4 := 6*w*x*y*z + 3*w*x*z + 19*w*y*z - 7*w*z + 8*x*y*z - 2*x*z + 6;
> S := Scheme(P,[f1,f2,f3,f4]);
> SetVerbose("IsolatedPoints",1);
> PTS := IsolatedPointsFinder(S,[5]);
> Degree(S);
22
> b,POLYS := IsolatedPointsLiftToMinimalPolynomials
>                     (S,PTS[1] : DegreeBound:=22,LiftingBound:=10);
> POLYS[1];
1812403568722098960*x^22 + 6297705584492967832*x^21 +
 6527336365144235612 8*x^20 + 8127120407582645599 2*x^19 +
 1307013696001389696 80*x^18 - 2853763840612678416 22*x^17 -
 8021669561188154716 54*x^16 + 2533254447903279968 45*x^15 -
 1266591733002155213 172*x^14 + 2511386184440323009 0*x^13 +
 5065309674068046314 82*x^12 - 1323179973699695447 463*x^11 +
 1605685921502538803112*x^10 - 1318315736155520576802*x^9 +
 9496491295829584599 58*x^8 - 5274413325441713384 90*x^7 +
 2544636840498666075 12*x^6 - 1000391891985775814 40*x^5 +
 2601441129568647585 6*x^4 - 3177984195514332576*x^3 -
 1852946687180290752*x^2 + 971825485320437760*x - 88506566917263360
```

All of the four polynomials in `POLYS` look approximately like this, and all should determine the same field, but it is difficult to find suitable isomorphisms between them, let alone find an `OptimisedRepresentation`.

In fact, the Gröbner basis machinery is superior for this purpose. Writing one of the coordinates in terms of the other (so as to get the field generators in terms of each other) would necessitate quite high precision in the p-adic lifting to recognise the coefficients, likely $5^{2^{14}}$ or more (this takes

about 5 minutes). The Gröbner basis method, which recognises one coordinate and then back-substitutes into the resulting equations, solving them algebraically, takes only about 15 seconds.

```
> time V := Variety(Ideal(S),AlgebraicClosure()); // about 15s
> MinimalPolynomial(V[22][4]); // deg 22, all coeffs about 25 digits
y^22 - 70869414518205839537/142324397561167099 52*y^21 -
    606754258610022348837 3/569297590244668398 08*y^20 + [...]
    [...] + 166661449939161/1779054969514588744
> MinimalPolynomial(V[22][3]); // deg 22, all coeffs about 25 digits
y^22 - 428567519465749893/68067993818308256*y^21 -
    229592953968800596 15/108908790109293209 6*y^20 + [...]
    [...] + 246916540549044143 1/68067993818308256
> V[22][4]; // given simply as r22, all 22 conjugates are found
r22
> V[22][3]; // third coordinate in terms of the fourth
[output takes about 200 lines, involving 750-digit coordinates]
```

Another way to achieve the result is to plug the known coordinate into the system, and use Gröbner bases (or resultants, if possible) to solve it.

```
> K := NumberField(POLYS[1]); // first coordinate
> _<xx,yy,zz> := PolynomialRing(K,3);
> E := [Evaluate(e,[K.1,xx,yy,zz]) : e in DefiningEquations(S)];
> Variety(Ideal(E)); // about 2 seconds
[again a rather bulky output]
```

Both of these uses of Gröbner bases are somewhat specific to the simplicity of the case here, and in more difficult cases would likely be rather onerous. This example does exemplify that for a generic variety the Gröbner basis methods should be superior. The lifting methods are largely for cases where the problem has special structure.

Example H112E61

Here is an example from N. D. Elkies of a polynomial $f(x) \in K(x)$ for which $f(x) - t$ appears to have Galois group M_{23} over $K(t)$ (this is sometimes called the monodromy group of f). This involves trying to find $f = P_3 P_2^2 P_4^4 = P_7 P_8^2 - c$ for some polynomials P_d of degree d, for some constant c. Upon suitable reductions, one gets a system of 8 variables and equations. With a few additional considerations, the search space can be reduced a bit further. As noted by M. Zieve, the equation should have 4 solutions, and thus likely be in a quartic field K that is an extension of $\mathbf{Q}(\sqrt{-23})$. This is indeed the case.

```
> Q := Rationals();
> R<a2,c,b1,b2,c1,c2,c3,c4,d1,d2,d3,d4,d5,d6,d7,
>   e1,e2,e3,e4,e5,e6,e7,e8> := PolynomialRing(Q,(3-1)+2+4+7+8);
> _<t> := PolynomialRing(R);
> P3 := t^3 + a2*t + a2/(26/-27); // normalisation
> P2 := t^2 + b1*t + b2;
> P4 := t^4 + c1*t^3 + c2*t^2 + c3*t + c4;
> P7 := t^7 + d1*t^6 + d2*t^5 + d3*t^4 + d4*t^3 + d5*t^2 + d6*t + d7;
> P8 := t^8 + e1*t^7 + e2*t^6 + e3*t^5 + e4*t^4 +
```

```
>             e5*t^3 + e6*t^2 + e7*t + e8;
> Q := P3 * P2^2 * P4^4 - P7 * P8^2 - c;
> S := Scheme(AffineSpace(R),Coefficients(Q));
> SetVerbose("IsolatedPoints",1);
> v:=[GF(101) | 26, 1,  -26,21,  -19,-27,-22,8, // known point
>              -14,12,26,-3,-37,-43,-22,  44,-11,-13,-21,45,-45,32,46];
> b, pt := IsolatedPointsLifter
>           (S,v : DegreeList:=[4], LiftingBound:=15, OptimizeFieldRep);
> K := Parent(pt[1]);
> DefiningPolynomial(K);
y^4 - 2*y^3 - 10*y^2 + 11*y + 36
> Factorization(Discriminant(Integers(K)));
[ <3, 1>, <23, 3> ]
```

The above code lifts the given point to precision $101^{2^{11}}$, and recognises it in the field K. Next we can compute the polynomial $f(x)$ in question, and see that reductions (modulo 269, say) of $f(x) - i$ do indeed correspond to cycle structures of M_{23}. However, to prove that this really is the Galois group (over the function field) seems to require a more difficult monodromy calculation. A more theoretical (topological) construction was given by P. Müller in 1995, but did not explicitly produce f. It is also still an open question whether there is a polynomial over the *rationals* with Galois group M_{23}.

```
> X := P3 * P2^2 * P4^4;
> f := Polynomial([Evaluate(e,Eltseq(pt)) : e in Coefficients(X)]);
> p := 269;
> P := Factorization(p * Integers(K))[1][1]; assert Norm(P) eq p;
> _, mp := ResidueClassField(P);
> fp := Polynomial([mp(c) : c in Coefficients(f)]);
> D := [[Degree(u[1]) : u in Factorization(fp-i)] : i in [1..p]];
> Sort(SetToSequence(Set([Sort(d) : d in D | &+d eq 23])));
[
    [ 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2 ],
    [ 1, 1, 1, 1, 1, 3, 3, 3, 3, 3, 3 ],
    [ 1, 1, 1, 2, 2, 4, 4, 4, 4 ],
    [ 1, 1, 1, 5, 5, 5, 5 ],
    [ 1, 1, 7, 7, 7 ],
    [ 1, 2, 2, 3, 3, 6, 6 ],
    [ 1, 2, 4, 8, 8 ],
    [ 1, 11, 11 ],
    [ 2, 7, 14 ],
    [ 3, 5, 15 ],
    [ 23 ]
]
> load m23; // G is M23
> C := [g : g in ConjugacyClasses(G) | Order(g[3]) ne 1];
> S := Set([CycleStructure(c[3]) : c in C]);
> Sort([Sort(&cat[[s[1] : i in [1..s[2]]] : s in T]) : T in S]);
[
    [ 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2 ],
```

```
    [ 1, 1, 1, 1, 1, 3, 3, 3, 3, 3, 3 ],
    [ 1, 1, 1, 2, 2, 4, 4, 4, 4 ],
    [ 1, 1, 1, 5, 5, 5, 5 ],
    [ 1, 1, 7, 7, 7 ],
    [ 1, 2, 2, 3, 3, 6, 6 ],
    [ 1, 2, 4, 8, 8 ],
    [ 1, 11, 11 ],
    [ 2, 7, 14 ],
    [ 3, 5, 15 ],
    [ 23 ]
]
```

112.19 Advanced Examples

This section contains examples of the use of the scheme machinery that are broader than those brief illustrations of intrinsics in the main text. They show how these functions can be used in collaboration with one another to build computer experiments which back up mathematical intuition.

112.19.1 A Pair of Twisted Cubics

This example constructs a cluster as the intersection of two twisted cubics in space. It uses a pair of curves whose equations are very closely related. Their union admits an automorphism which interchanges the two curves, fixing the cluster.

Example H112E62

We start by making the two twisted cubics, $C1$ and $C2$, as the minors of a pair of 2×3 matrices. It is clear straight away that these curves are closely related; it is a shame that we lose the "format" of the equations, in fact. On the other hand, if one tries to make other interesting examples by such tricks, one does not automatically come up with something so slick (and Gorenstein).

```
> k := Rationals();
> P<x,y,z,t> := ProjectiveSpace(k,3);
> M1 := Matrix(CoordinateRing(P),2,3,[y,t,x,t,x,z]);
> M2 := Matrix(CoordinateRing(P),2,3,[y,x,t,x,t,z]);
> C1 := Scheme(P,Minors(M1,2));
> C2 := Scheme(P,Minors(M2,2));
> Z := Intersection(C1,C2);
> MinimalBasis(Z);
[
    x*t - y*z,
    x*z - t^2,
    x*y - t^2,
    -x^2 + z*t,
    -x^2 + y*t
```

```
]
```

Anyone knowing about Pfaffians can have fun trying to realise these equations as the five maximal Pfaffians of a skew-symmetric 5×5 matrix. Although this example is a bit degenerate, it is reasonable to think of it as a hyperplane section of an elliptic curve of degree 5 (living in $\mathbf{P}^4$) so the ideal of equations will be Gorenstein. Given the Buchsbaum–Eisenbud structure theorem for Gorenstein codimension 3 rings, we are not surprised to see this Pfaffian format. In this example we will settle for confirming that this scheme Z is a cluster of degree 5 and finding its support.

```
> IsCluster(Z);
true
> Degree(Z);
5
> IsReduced(Z);
true
> RationalPoints(Z);
{@ (1 : 1 : 1 : 1), (0 : 0 : 1 : 0), (0 : 1 : 0 : 0) @}
> HasPointsOverExtension(Z);
true
```

As expected, the scheme Z is zero-dimensional and has degree 5. Since it is reduced, its support will comprise five separate points over some extension of the base field. We locate these points by hand by considering the Gröbner basis of the ideal of Z. The last element of a lexicographical Gröbner basis usually suggests a field extension that is relevant to the scheme. So we extend the base field by roots of this polynomial and look for the support over that field.

```
> GB := GroebnerBasis(ChangeOrder(Ideal(Z),"lex"));
> GB[#GB];
z^3*t - t^4
> L<w> := ext< k | U.1^2 + U.1 + 1 > where U is PolynomialRing(k);
> RationalPoints(Z,L);
{@ (w : -w - 1 : -w - 1 : 1), (-w - 1 : w : w : 1),
(1 : 1 : 1 : 1), (0 : 1 : 0 : 0), (0 : 0 : 1 : 0) @}
> HasPointsOverExtension(Z,L);
false
```

The final line confirms that we have found all the points of Z. That was already clear since Z has degree 5 and we see five points, but in other cases, especially when the cluster is not reduced, it might not be so obvious.
Now we look at the union of the two twisted cubics.

```
> C := Union(C1,C2);
> C;
Scheme over Rational Field defined by
x^3 - x*y*t - x*z*t + t^3
-x*t + y*z
```

This curve C is a $2,3$ complete intersection, numerology that is familiar from canonical curves of genus 4. We already know that C is not such a curve since it has two components. Indeed, we

already know that these components are nonsingular and meet in five points. Clearly these points must be singular points of C.

```
> SC := SingularPointsOverSplittingField(C);
> SC;
{ (1 : 1 : 1 : 1), (-r2 - 1 : r2 : r2 : 1), (0 : 0 : 1 : 0),
(-r1 - 1 : r1 : r1 : 1), (0 : 1 : 0 : 0) }
> Ring(Universe(SC));
Algebraically closed field with 2 variables
Defining relations:
[
    r2^2 + r2 + 1,
    r1^2 + r1 + 1
]
```

MAGMA has automatic Gröbner basis based machinery for working in the algebraic closure of the rationals (the so-called *D5 method*). Here we see it in action. The roots that we made explicitly when computing with Z are the new symbols $r1$ and $r2$ — they are the two conjugate roots of the quadratic equation list as the 'Defining relations'. Since $r1 \neq r2$, we see that the singular points really are the points of Z as expected.
From the definition of the matrices $M1$ and $M2$ we can see that the union and intersection of $C1$ and $C2$ should be invariant under the automorphism of P which exchanges x and t. We realise that automorphism here and confirm what we expect by comparing various ideals.

```
> phi := iso< P -> P | [t,y,z,x],[t,y,z,x] >;
> IsAutomorphism(phi);
true
> Ideal(C2) eq Ideal(phi(C1));
true
> Z eq phi(Z);
true
> Ideal(Z) eq Ideal(phi(Z));
true
```

Note that the basic equality test 'eq' for schemes returns `true` in the penultimate line, even though the two arguments were created independently.
The five points of Z obviously have Sym_5 as their permutation group (or $\mathrm{Sym}_2 \times \mathrm{Sym}_3$ over the rationals). How much of that is realised by automorphisms of the union C? We try to realise some elements of this symmetric group.

```
> S5 := SymmetricGroup(5);
> QL := RationalPoints(Z,L);
> rho := S5 ! [ Index(QL,phi(p)) : p in QL ];
> rho;
(1, 2)
```

Of course, this permutation is simply the action of the Galois group of L.

```
> GaloisGroup(L);
Permutation group acting on a set of cardinality 2
```

```
    (1, 2)
```

We make another automorphism: using C explicitly in the constructor ensures that the image of the map is contained in C.

```
> psi := iso< C -> C | [x,z,y,t],[x,z,y,t] >;
> eta := S5 ! [ Index(QL,psi(p)) : p in QL ];
> eta;
(4, 5)
> G := sub< S5 | rho,eta >;
> #G;
4
```

Since these two permutations commute and the small collection of five points is already partitioned by a Galois group action, this example is too simple to use MAGMA's substantial group theory machinery. But one can imagine at this stage finding complicated elements of G and realising them by compositions of the easily recognised automorphisms ρ and η.

112.19.2 Curves in Space

In this example, we construct something that we know is an elliptic curve in space. The point is to realise that within MAGMA by making a new curve of the right type and understanding the translation between the two types, at least to some degree. Something very similar would also works for the canonical models of curves of genus 4, although one has to take care handling the image of the natural projection.

Example H112E63

The first thing to do is to make a curve in space and to choose a nonsingular rational point on that curve. The question of whether or not a rational point is part of the input or part of the algorithm is always tricky since finding good points is often the heart of a problem. That is certainly the case here, so we do not pretend that this is a particularly powerful example.

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> X := Scheme(P,[x*y-z*t,x^2 + 2*z^2 - y*t]);
> Dimension(X);
1
> IsNonsingular(X);
true
> p := X ! [0,1,0,0];
```

Next we simply project from this given point p.

```
> Y,pr,q := ProjectionFromNonsingularPoint(X,p);
> bool,C := IsCurve(Y);
> bool;
true
> q := C ! q;
> q;
(0 : 1 : 0)
```

```
> Degree(C);
3
> IsNonsingular(C);
true
> P2<a,b,c> := Ambient(C);
> C;
Curve over Rational Field defined by
a^3 + 2*a*b^2 - b*c^2
```

Since there was a conic (two, in fact) among the equations of the scheme X, the projection from p is necessarily birational to a plane curve. And since p is a nonsingular point, it has a definite rational image point on the projection which is called q above. Since we know that X has genus 1 (as an external fact) and that the projection is birational we already know that the image curve C is the plane elliptic curve we desire. (It is interesting to try this calculation with a curve of higher genus, like the canonical model of a curve of genus 4.)
But we have made no effort to find a good model for C. At this point we can use MAGMA intrinsics to find a better model for C since we have the rational point q lying on C.

```
> EllipticCurve(C,q);
Elliptic Curve defined by y^2 = x^3 + 32*x over Rational Field
Mapping from: Crv: C to Elliptic Curve defined by y^2 = x^3 + 32*x over
Rational Field given by a rule
Mapping from: Elliptic Curve defined by y^2 = x^3 + 32*x over Rational Field to
Crv: C given by a rule
```

The result is a very nice model of an elliptic curve in Weierstraß form. The mapping types returned by this function are not yet fully integrated Scheme maps. But this will be added to MAGMA in due course, after which computations can be done on the good elliptic model and related to the original scheme X.

113 COHERENT SHEAVES

Chapter 113
COHERENT SHEAVES

113.1 Introduction

This chapter describes the MAGMA functionality for working with coherent sheaves on ordinary projective schemes. The emphasis in this initial version is on invertible sheaves and on computing associated cohomological invariants and explicit divisor maps. Important examples include canonical and anticanonical maps and adjunction maps on varieties of arbitrary dimension. The tools provided in MAGMA enable the user to compute these in a general and reasonably efficient way. There is also functionality for computing an invertible sheaf corresponding to the class of an effective Cartier divisor given as a closed subscheme as well as a basis for the Riemann-Roch space of that divisor as ambient rational functions. The correspondence between divisors (or their classes) and invertible sheaves will be expanded in later releases. A standard reference for the definition and basic properties of coherent sheaves on Noetherian schemes is Section 5, Chapter II of [Har77].

The package is based on MAGMA's functionality for graded modules over polynomial rings and relies heavily on Gröbner basis computations. A coherent sheaf is represented by a graded module over the coordinate ring of the ambient projective space. The key difference between the category of sheaves and the category of modules is that a sheaf is not represented uniquely. However, there is a unique *maximal* graded module representing it, which is finitely generated (with certain provisos). For certain algorithms – computing cohomology, for example – any module representing the sheaf may be used. However for other calculations, such as explicit Riemann-Roch spaces or divisor maps, the full maximal module, containing the full space of global sections of the sheaf and its small Serre twists, is often required.

One of the basic operations, therefore, is the computation of the maximal module of a sheaf from its initial defining module. We have tried to do this efficiently in reasonable generality. The basic condition is that the support of the sheaf has irreducible components all of the same non-zero dimension. This will be described in more detail in the function descriptions that follow. The user does not have to explicitly make a call to perform the computation, but it may be carried out in the background and the result stored by several other functions.

A coherent sheaf $\mathcal{S}$ is defined by a graded module M over the polynomial ring $R = k[x_0, \ldots, x_n]$ and a subscheme X of $\mathbf{P}^n = Proj(R)$ on which M is supported. That is, the defining ideal $I \subseteq R$ of X annihilates M. In some contexts, X is unimportant and it doesn't matter whether $\mathcal{S}$ is thought of as a sheaf on X or on $\mathbf{P}^n$. In other cases, X plays a role: we can test whether $\mathcal{S}$ is locally free as a sheaf on X or take its dual. The sheaf $\mathcal{S}$ is just the coherent sheaf $\tilde{M}$ on X as described in Prop. 5.11, Section 5, Chapter II of [Har77], with M considered as a graded module over the homogeneous coordinate ring of X.

Sheaves are of type `ShfCoh`. There is also a type `ShfHom` for homomorphisms between sheaves supported on the same scheme X.

The algorithms used in the package are based on a number of computational commutative algebra tricks well-known to the experts.

113.2 Creation Functions

The general creation function for sheaves takes a graded module representing the sheaf and a scheme X on which it is supported. Special constructors are provided in the cases of the structure sheaf of X and the canonical sheaf of X, when X is locally Cohen-Macaulay and equidimensional. The user may also ask for Serre twists of a given sheaf. Other constructions deriving new sheaves from existing sheaves will be described in later sections.

`Sheaf(M, X)`

Given an ordinary projective scheme X and a module M over the coordinate ring of the ambient of X, such that M is annihilated by the defining ideal of X, this function returns the sheaf defined by graded module M on scheme X.

`StructureSheaf(X)`

`StructureSheaf(X, n)`

Given an ordinary projective scheme X, this function returns the structure sheaf $\mathcal{O}_X$ for X, which is the sheaf defined by the coordinate ring R_X of X, as a module. If the intrinsic is called with a second integer-valued argument n, the object returned is a twisted version of the sheaf, that is, Serre's twisting sheaf $\mathcal{O}_X(n)$, which has $R_X(n)$ as its associated graded module (see Section 5, Chapter II of [Har77]). These are all invertible sheaves on X and $\mathcal{O}_X(1)$ is the sheaf $\mathcal{O}_X(H)$ corresponding to the class of a hyperplane divisor H on X.

`CanonicalSheaf(X)`

`CanonicalSheaf(X, n)`

Given an ordinary projective scheme X, this function returns the canonical sheaf K_X for X. The scheme X should be an ordinary projective scheme which is equidimensional and locally Cohen-Macaulay. That is, all of the primary components of X should have the same dimension and its local rings should all be Cohen-Macaulay rings. These conditions aren't checked by MAGMA as the necessary computations can be very expensive in general. A non-singular variety always satisfies these conditions, and many singular normal varieties do also. For example, any curve or normal surface will be equidimensional and locally Cohen-Macaulay. The stronger condition of being *arithmetically* Cohen-Macaulay, can be checked by invoking the intrinsic `IsArithmeticallyCohenMacaulay` with the structure sheaf of X as argument.

Under these conditions, X has a canonical sheaf K_X, defined up to isomorphism, which acts as a dualising sheaf. See Section 7, Chapter III of [Har77] and Chapter

21 of [Eis95] for the module-theoretic background. For non-singular varieties, the canonical sheaf is the usual one: the highest alternating power of the sheaf of Kahler differentials. The function returns the canonical sheaf of X. It is computed from the dual complex to the minimal free resolution of the coordinate ring of X.

If the intrinsic is invoked with an additional integer argument n, it returns the nth Serre twist (see below) of the canonical sheaf $K_X(n)$. For a non-singular variety of dimension d, the map into projective space corresponding to $K_X(d-1)$ is the important *adjunction map*.

`Twist(S, n)`

Given a sheaf S, the function returns the nth Serre twist of $\mathcal{S}$, $\mathcal{S}(n) \cong \mathcal{S} \otimes_{\mathcal{O}_X} \mathcal{O}_X(n)$. If M is a module giving $\mathcal{S}$, then $M(n)$ gives $\mathcal{S}(n)$.

Example H113E1

We construct some sheaves associated with the smooth cubic surface defined by $x^3+y^3+z^3+t^3$ in P^3.

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> R := CoordinateRing(P);
> X := Scheme(P,x^3+y^3+z^3+t^3);
> OX := StructureSheaf(X);
```

We first examine the underlying graded module of the structure sheaf.

```
> Module(OX);
Reduced Module R^1/<relations>
Relations:
[x^3 + y^3 + z^3 + t^3]
```

Observe that the canonical sheaf KX of X is isomorphic to the twist $OX(-1)$ of the structure sheaf.

```
> KX := CanonicalSheaf(X);
> Module(KX);
Reduced Module R^1/<relations> with grading [1]
Relations:
[x^3 + y^3 + z^3 + t^3]
> Module(StructureSheaf(X,-1));
Reduced Module R^1/<relations> with grading [1]
Relations:
[x^3 + y^3 + z^3 + t^3]
```

Note that the module column weights are the negations of the Serre twist indices!

```
> Module(Twist(OX,-1));
Reduced Module R^1/<relations> with grading [1]
Relations (Groebner basis):
```

```
[x^3 + y^3 + z^3 + t^3]
```

The equations $x = z, y = t$ define an (exceptional) line in X. We can get its structure sheaf as a sheaf on X using the basic `Sheaf` constructor. The associated invertible sheaf $\mathcal{L}(Y)$ of Y as a divisor on X can be obtained from the `DivisorToSheaf` intrinsic described later in the chapter.

```
> IY := ideal<R|[x+z,y+t]>; // ideal of line
> OY := Sheaf(QuotientModule(IY),X);
> Module(OY);
Graded Module R^1/<relations>
Relations:
[x + z],
[y + t]
> Scheme(OY);
Scheme over Rational Field defined by
x^3 + y^3 + z^3 + t^3
```

`SheafOfDifferentials(X)`

`Maximize` BoolElt *Default :* `false`

Given an ordinary projective scheme X, this function returns the sheaf of 1-differentials on X, $\Omega^1_{X/k}$. The function computes the natural representing module for the sheaf coming from the embedding of X in projective space (see Section 8, Chapter II of [Har77]). If the parameter `Maximize` is `true`, then the maximal module representing this sheaf is computed and used to define it (see next section).

`TangentSheaf(X)`

`Maximize` BoolElt *Default :* `false`

For an ordinary projective scheme X, this function returns the sheaf of tangent vectors for X. The function computes the natural representing module for these sheaves coming from the embedding of X in projective space (see Section 8, Chapter II of [Har77]). If the parameter `Maximize` is `true`, then the maximal module representing this sheaf is computed and used to define it (see next section).

Combining either of the above intrinsics with the `IsLocallyFree` intrinsic, this gives an alternative method for checking non-singularity on varieties that are known to be (locally) Cohen-Macaulay. It is best to use the sheaf of differentials since that is generally easier to compute. This approach can be much faster for varieties having high codimension than the usual Jacobian method.

`HorrocksMumfordBundle(P)`

The projective space P should be ordinary projective 4-space $\mathbf{P}^4$ over a field. The function returns the locally free rank 2 sheaf on P which represents the Horrocks-Mumford bundle (see [HM73]). The scheme of vanishing of a general global section of this sheaf is a two dimensional Abelian variety in P.

113.3 Accessor Functions

The following functions provide an interface to conveniently extract the basic data from a coherent sheaf.

`Module(S)`

Returns the graded module that was used to define sheaf S.

`Scheme(S)`

Returns the ordinary projective scheme X on which the sheaf S is defined.

`FullModule(S)`

Computes and returns the maximal module M_{max} giving sheaf S. The nth graded piece of M_{max} is equal to the global sections of the Serre twist $S(n)$ as a finite dimensional vector space over k, the base field of the scheme X of S. Thus $M_{max} \cong \oplus_{n \in \mathbf{Z}} H^0(X, S(n))$ as in [Har77]. Here, it is implicitly assumed that the exact support of S on X has no irreducible components of dimension 0 and that there are no embedded associated prime places of dimension 0. More concretely, if M is a defining module for S with a possible non-zero finite torsion module for the redundant maximal ideal having been divided out, then no (homogeneous) associated prime of M has dimension 1. This assumption means that the terms in the above direct sum are 0 for $n[[0$ or equivalently that M_{max} is a finitely-generated module.

As mentioned in the introduction, a further assumption, which isn't checked, for the computation of M_{max} is that S is equidimensional, so that M actually has no embedded associated primes and the irreducible components of its exact support have the same non-zero dimension. It may be possible to avoid this assumption with more complex (and computationally heavy) code that works with an equidimensional decomposition of the defining module, but it suffices for many cases of interest (e.g., sheaves with trivial annihilator on a variety or equidimensional scheme).

The method used is basically the computation of the double dual of the defining module over an appropriate polynomial algebra A. A possible approach is to take A as the exact "supporting" algebra $k[x_0, \ldots, x_n]/I$ where the polynomial ring is the coordinate ring of the ambient of X and I is the exact annihilator of M. This would involve stronger assumptions on the support of S and the computation of the dualising module for this A. We choose instead to work with A as a *Noether normalisation* of the above A, which means that A is a simple polynomial ring and is its own dualising module (up to a shift in grading). Then M is re-expressed as a module over this A, M_{max} is computed as a module over A and finally is recovered as a module over $k[x_0, \ldots, x_n]$ by keeping track of the multiplication maps by the x_i variables which don't occur in A.

The module M_{max} is stored so that it is only computed once.

`GlobalSectionSubmodule(S)`

Given a sheaf S, this function returns the submodule of the maximal module M_{max} generated in degrees ≥ 0, that is $\oplus_{n\geq 0} H^0(X, S(n))$.

`SaturateSheaf(~S)`

Procedure to compute and store (but not return) the maximal module M_{max} of the sheaf S.

Example H113E2

The classic example of a natural module which is unsaturated (non-maximal) defining a sheaf is the coordinate ring R of a non-projectively normal non-singular projective variety X. The ring R defines the structure sheaf as usual, but not maximally. By definition, R isn't integrally closed. Its integral closure R_1 is an extension ring, inheriting its natural grading and agreeing with R in all but finitely many graded parts. In fact, R_1 considered as an R-module is precisely the maximal graded module of the structure sheaf!
Such a situation can very commonly arise when a non-singular variety is projected down isomorphically into a subspace of its ambient projective space. The projected down image X is then not even linearly-normal: the degree one graded part of its coordinate ring is missing coordinates that were eliminated in the projection. These must reoccur in the graded R-module that is computed as the maximal module of the structure sheaf.
In the following example, X is taken as the non-singular projection into P^3 of a degree 4 rational normal curve (which naturally lives in P^4). We can see the difference between the maximal module of the structure sheaf and the coordinate ring using Hilbert series. In fact, they just differ by dimension 1 in the 1-graded part, corresponding to that missing coordinate!

```
> P3<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> X := Scheme(P3,[
> y^3 - y*z^2 - 2*y^2*t - 2*x*z*t - 3*y*z*t + z^2*t - y*t^2 + 2*z*t^2 + 2*t^3,
> x^2*z + x*z^2 + y*z^2 + 3*x*z*t + 2*y*z*t - z^2*t + y*t^2 - 2*z*t^2 - 2*t^3,
> y^2*z - y*z^2 + y^2*t - x*z*t - 4*y*z*t + z^2*t - 3*y*t^2 + 2*z*t^2 + 2*t^3,
> x*y - x*z - x*t + y*t]);
> OX := StructureSheaf(X);
> M1 := Module(OX);
> M2 := FullModule(OX);
> h1 := HilbertSeries(M1); h1;
(-t^3 + 2*t^2 + 2*t + 1)/(t^2 - 2*t + 1)
> h2 := HilbertSeries(M2); h2;
(3*t + 1)/(t^2 - 2*t + 1)
> h2-h1;
t
```

113.4 Basic Constructions

The following functions give some basic constructions on sheaves.

`TensorProduct(S, T)`

`Maximize` BoolElt *Default :* `false`

`TensorPower(S, n)`

`Maximize` BoolElt *Default :* `true`

The first intrinsic gives the tensor product (over $\mathcal{O}_X$) of two sheaves on the same scheme X. The second gives the nth tensor power of S if $n > 0$, the $(-n)$th tensor power of the dual (see below) of S if $n < 0$ and the structure sheaf $\mathcal{O}_X$ if $n = 0$.

Defining modules for these constructions are taken as the appropriate tensor products of modules for the constituent sheaves when the parameter `Maximize` is `false`. The user should note that this is the archetypal case where the module constructed to define the resulting sheaf can be far from maximal, even when the defining modules of S and T are maximal. The rank of the presentation of the tensor power of a module rises rapidly with n. Thus, it is usually a good idea to set `Maximize` to `true`, which means that the maximal module of the result is computed and also used as its defining module.

`Dual(S)`

For the sheaf S on a scheme X, the function returns the dual sheaf $\mathrm{Hom}_{\mathcal{O}_X}(S, \mathcal{O}_X)$.

`SheafHoms(S, T)`

For S and T sheaves on the same scheme X, the function returns the sheaf $H = \mathrm{Hom}_{\mathcal{O}_X}(S, T)$. The module defining H is $\mathrm{Hom}(M_{\max}, N_{\max})$, where $M_{\max}$ and $N_{\max}$ are the maximal modules of S and T. This module, M_H, is the maximal module of H.

Also returned is a map that takes a homogeneous element of M_H (which can be recovered with `Module(H)` or `FullModule(H)`) of degree d to the sheaf homomorphism of degree d that it represents (see the next section for information about sheaf homomorphisms). All sheaf homomorphisms can be obtained this way.

`DirectSum(S, T)`

For S and T sheaves on the same scheme X, this function returns the sheaf direct sum $S \oplus T$.

`Restriction(S, Y)`

`Check` BoolElt *Default :* `true`

Given a sheaf S on a scheme X and a subscheme Y of X, the function returns the restriction of S to Y. A check that Y is a subscheme of X will be performed only if the parameter `Check` is `true` (the default).

Example H113E3

We look at the well-known example of a ruling L on a (singular) projective quadric cone X in P^3. We find the associated invertible sheaf $O_X(L)$ using the `DivisorToSheaf` intrinsic. The tensor square of this sheaf is $O_X(2L)$ which is just isomorphic to the $O_X(1)$ Serre twist of the structure sheaf, as $2L$ is a hyperplane section. We verify this by getting the tensor and inspection. Of course we need to saturate the result, illustrating that the basic tensor power of maximal modules usually does not result in a maximal module.

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> R := CoordinateRing(P);
> X := Scheme(P,x*y-z^2); // singular projective quadric
> IL := ideal<R|z,y>;     // line y=z=0 on X
> OL := DivisorToSheaf(X,IL); // associated sheaf O(L)
```

We first make sure that OL is saturated.

```
> SaturateSheaf(~OL);
> Module(OL);
Graded Module R^2/<relations>
Relations:
[ y, -z],
[ z, -x]
> O2L := TensorProduct(OL,OL); // or TensorPower(OL,2)
> Module(O2L);
Graded Module R^4/<relations>
Relations:
[ y,  0, -z,  0],
[ 0,  y,  0, -z],
[ z,  0, -x,  0],
[ 0,  z,  0, -x],
[ y, -z,  0,  0],
[ z, -x,  0,  0],
[ 0,  0,  y, -z],
[ 0,  0,  z, -x]
```

Finally, we get the maximum module – just that of OX(1)!

```
> FullModule(O2L);
Reduced Module R^1/<relations> with grading [-1]
Relations:
[x*y - z^2]
```

113.5 Sheaf Homomorphisms

This section describes some basic functionality for homomorphisms between sheaves defined on the same scheme. A sheaf homomorphism is represented by a module homomorphism between representing modules (defining, maximal or global section modules) for the two sheaves. Strictly, only (degree 0) homomorphisms that preserve the module gradings should be allowed but, for flexibility, we allow "homogeneous" homomorphisms that uniformly shift the grading by d and should be thought of as sheaf homomorphisms from the domain sheaf to the dth Serre twist of the codomain sheaf. We then say that the homomorphism is of degree d as for module homomorphisms.

There are some basic constructors and accessor functions, a function to "expand" a chain of homomorphisms to a single homomorphism and image, kernel and cokernel functions. The type of a sheaf homomorphism is `ShfHom`. Note that this is NOT a `Map` subtype, so that a sheaf homomorphism doesn't automatically inherit all of the usual map properties.

`SheafHomomorphism(S, T, h)`

Given sheaves S and T on the same scheme X and a module homomorphism h between M_0 and N_0, this function returns a sheaf homomorphism from S to T. Here M_0 is one of the defining, maximal or global section modules of S and N_0 is a similar module for T. The homomorphism h must be a homogeneous module homomorphism as returned by `IsHomogeneous` and if d is its degree then the homomorphism returned is really one from S to $T(d)$ in the category of $\mathcal{O}_X$-sheaves.

For the construction of sheaf homomorphisms see also `SheafHoms`.

`Domain(f)`

The domain of the sheaf homomorphism f.

`Codomain(f)`

The codomain of the sheaf homomorphism f.

`Degree(f)`

The degree of the sheaf homomorphism f as defined in the introduction to this section.

`ModuleHomomorphism(f)`

The underlying homogeneous graded module homomorphism of the sheaf homomorphism f.

`Kernel(f)`

Given a sheaf homomorphism f, this function returns the kernel of f and its inclusion homomorphism into the domain of f.

`Image(f)`

Given a sheaf f, this function returns the image, I, of f and two sheaf homomorphisms g and h. If f has degree d and S, T are its domain and codomain, then I is a subsheaf of $T(d)$. The second return value g is the restriction of f from S to I and the third return value h is the inclusion of I in $T(d)$, so that g also has degree d and h has degree 0.

`Cokernel(f)`

Given a sheaf homomorphism f, this function returns the cokernel of f and also the quotient homomorphism from the codomain to it.

Strictly speaking, if f has degree d and S, T are its domain and codomain, here we are taking f to be a homomorphism from $S(d) \leftarrow T$ rather than from $S \leftarrow T(d)$.

`Expand(hms)`

If $hms = [h_1, \ldots, h_n]$ is a sequence of sheaf homomorphisms, then this function returns the composition of homomorphisms $h_1 * h_2 * \ldots h_n$. The domain of h_2 must be the codomain of h_1 etc. and the stronger condition that the underlying module homomorphisms must be composable also holds. So the domain of `ModuleHomomorphism(h2)` must be the codomain of `ModuleHomomorphism(h1)` etc.

113.6 Divisor Maps and Riemann-Roch Spaces

As stated at the beginning of the chapter, one of our main initial aims in introducing sheaf machinery has been to provide a way of computing the (rational) maps associated to invertible sheaves in reasonable generality (see Section 7, Chapter 2 of [Har77]) and similarly for effective Cartier divisors (as closed subschemes) in the form of the map or their Riemann-Roch spaces. This section describes the main intrinsics. We hope to add further functionality to capture the correspondence between divisors and invertible sheaves in future releases.

`DivisorMap(S)`

`graphmap` BoolElt *Default :* `false`

Given an invertible sheaf S on the scheme X this function returns the rational map from X into the projective space associated to S. For efficiency, the invertibility of S is not checked, so that if the user is unsure whether a potential S actually is invertible (ie, locally free of rank one) he should apply the `IsLocallyFree` intrinsic.

The rational map that is returned can be thought of as $X \to Proj(R) \to \mathbf{P}^r$ where R is the graded k-subalgebra of the graded ring $\oplus_{n \geq 0} H^0(X, S^{\otimes n})$ generated by the weight 1 subspace $H^0(X, S)$ – the space of global sections of S – and the map to $\mathbf{P}^r$, where $r+1$ is the dimension of the space of global sections, is that induced by choosing a basis for the global sections. The divisor map, as usual, is only unique up to a linear change of coordinates of the codomain. The map is defined on the open subscheme of X where S is generated by global sections. Also returned is the image of the map on X.

In most cases, the map returned is a graph map of type `MapSchGrph` (see Section 112.14.7). This computation naturally computes the graph of the map and, in complicated situations, it is not particularly efficient to convert this to the more usual `MapSch` which will be defined by very nasty, high degree polynomials (often with a large base scheme) without some further specialised reduction routine. The user can however convert to a `MapSch` using `SchemeGraphMapToSchemeMap`. In cases when the sheaf has been constructed from a divisor using the `DivisorToSheaf` intrinsic below with the `GetMax` parameter `true`, so that a Riemann-Roch space has been stored, a traditional `MapSch` is returned. If in doubt, the user can distinguish using the `Type` intrinsic. Sometimes the user may still want a `MapSchGrph` in the latter case (e.g. because it is maximally defined, it is good for getting the genuine inverse image of a point/subscheme without components of the base scheme which appear for a non-maximally defined `MapSch`). This can be forced by setting the parameter `graphmap` to `true`.

The major stage of the computation is the determination of the graph of the map. An ideal defining the graph can be written down directly from the relation matrix of a minimal presentation of the global section submodule M_0 of S, and this ideal then only needs to be saturated with respect to an appropriate domain variable. The submodule M_0 is computed (and stored) as described earlier in the chapter.

`DivisorToSheaf(X, I)`

`GetMax` BoolElt *Default :* `true`

`RiemannRochBasis(X, I)`

Given an ordinary, projective scheme X and an ideal I of the coordinate ring of the ambient of X that defines a subscheme D of X that is an effective Cartier (locally principal) divisor of X, this function returns the invertible sheaf corresponding to the divisor class of D, commonly denoted $\mathcal{L}(D)$ (see Section 6, Chapter 2 of [Har77]). The conditions require D to be purely of codimension 1 in X and that it is everywhere locally defined by a single equation. Again for efficiency, Magma does not perform the computationally expensive checks to verify that D is locally principal within X. If X is a non-singular variety, then a closed subscheme of codimension 1 is automatically Cartier.

If `GetMax` is `true`, then the maximal module of $\mathcal{L}(D)$ is computed and an explicit basis for the Riemann-Roch space $L(D)$ is computed and stored along the way. This basis is of the form $[G_1/G, \ldots, G_n/G]$, where G and the G_i are homogeneous polynomials of some degree d on the ambient of X and the G_i/G are the usual rational functions restricted to X.

If instead of `DivisorToSheaf`, the intrinsic `RiemannRochBasis` is called, then the above procedure is carried out and a basis of the Riemann Roch space is returned as the sequence of numerators $[G_1, \ldots, G_n]$ and the denominator G, along with the sheaf $\mathcal{L}(D)$. If $\mathcal{L}(D)$ has been computed from `DivisorToSheaf` and returned as S, then the RiemannRoch basis can be recovered at a later stage from the *attribute*

of S, `rr_space`. This attribute, if assigned, contains a pair consisting of the above sequence of numerators and the denominator.

The algorithm used is based on the following observation. If we choose $r > 0$ such that I contains a homogeneous polynomial G of degree r that doesn't lie in the ideal of X, I_X (which is a proper subideal of I), then there is a "complementary" divisor E of X such that $rH \sim D + E$, where H is a hyperplane divisor of X. Then $\mathcal{L}(D) \simeq \mathcal{L}(-E)(r)$ and $\mathcal{L}(-E)$ is represented by the module I_E/I_X, where I_E is the ideal of E, a subscheme of X (see Prop 6.18 of the above reference). Once a suitable G is found, I_E is computed by invoking intrinsics `ColonIdeal` and `Saturation` a few times. If the `GetMax` option is on, r is chosen large enough so that $H^1(I_X(m)), m \geq r$ vanishes, which guarantees that we end up with a maximal representing module and can get a full basis of Riemann-Roch numerators with G as the denominator.

Example H113E4

As a simple example, we consider a degree 3 rational scroll in $\mathbf{P}^4$. This is a ruled surface that contains a family of disjoint lines. If l is a line in the family, then the divisor map for $\mathcal{L}(l)$ is a map to the projective line, the fibres of which are the lines of the family. We take such a scroll X and line l and get the Riemann-Roch space $L(l)$ and the divisor map down to $\mathbf{P}^1$.

```
> P4<a,b,c,d,e> := ProjectiveSpace(Rationals(),4);
> X := Scheme(P4,[a*b - c^2, a*d - c*e, c*d - b*e]);
> Il := ideal<CoordinateRing(P4)|[a,c,e]>; // ideal of l
> rr_seq,G, Sl := RiemannRochBasis(X,Il);
> rr_seq; G;
[
    d,
    e
]
e
```

Thus, 1 and d/e are a basis for the rational functions in $L(l)$.

```
> fib_mp := DivisorMap(Sl);
> fib_mp;
Mapping from: Sch: X to Projective Space of dimension 1
Variables: $.1, $.2
with equations :
d
e
```

Here the divisor map is not a graph map and is not maximally defined. So we extend it to make it so. Note that the fibres are lines.

```
> fib_mp := Extend(fib_mp);
> (Codomain(fib_mp)![1,0])@@fib_mp;
Scheme over Rational Field defined by
a,
```

```
c,
e,
a*b - c^2,
a*d - c*e,
c*d - b*e
> (Codomain(fib_mp)![0,1])@@fib_mp;
c,
b,
d,
a*b - c^2,
a*d - c*e,
c*d - b*e
```

Alternatively, we could ask for `fib_mp` as a `MapSchGrph` and not have to extend it.

```
> fib_mp := DivisorMap(Sl : graphmap := true);
> Type(fib_mp);
MapSchGrph
> (Codomain(fib_mp)![1,0])@@fib_mp;
Scheme over Rational Field defined by
a,
c,
e,
a*b - c^2,
a*d - c*e,
c*d - b*e
```

Example H113E5

As a second example, we consider the degree 3 Del Pezzo surface example from the Del Pezzo chapter. There we mapped it to a degree 6 Del Pezzo surface by blowing down 3 disjoint lines in an explicit fashion. We do the same thing here using the sheaf machinery.

First we get the surface X_3 and the union of the 3 lines L_{123}:-

```
> R3<x,y,z,t> := PolynomialRing(Rationals(),4,"grevlex");
> P3 := Proj(R3);
```

We set up the equation defining the degree 3 surface:

```
> F := -x^2*z + x*z^2 - y*z^2 + x^2*t - y^2*t - y*z*t + x*t^2 + y*t^2;
> X3 := Scheme(P3,F);
```

Get the ideal defining the union of the 3 lines:

```
> I1 := ideal<R3|[x,y]>; // line 1 L1
> I2 := ideal<R3|[z,t]>; // line 2 L2
> I3 := ideal<R3|[x-z,y-t]>; //line 3 L3
```

```
> I := I1*I2*I3; // (non-saturated) ideal of L1+L2+L3 = L123
```

Now we blow down to get the degree 6 Del Pezzo in $\mathbf{P}^6$. The divisor we need for the map is $H + L_{123}$ where H is a hyperplane section. We get this simply by twisting the sheaf corresponding to L_{123} once.

```
> S123 := DivisorToSheaf(X3,I);
> H6 := Twist(S123,1); // sheaf of H+L123
> mp, X := DivisorMap(H6);
> X;
Scheme over Rational Field defined by
y[1]*y[2] - y[2]*y[3] - y[4]*y[5] + y[1]*y[6] + 3*y[2]*y[6] - y[4]*y[6] + y[6]^2
    + y[1]*y[7] + 2*y[2]*y[7] - y[4]*y[7] - y[5]*y[7] + 3*y[6]*y[7],
y[2]^2 - y[2]*y[3] + 2*y[2]*y[6] + y[6]^2 + 2*y[2]*y[7] + 3*y[6]*y[7],
y[1]*y[3] - y[2]*y[3] + 2*y[2]*y[6] - y[5]*y[6] + y[6]^2 + y[2]*y[7] - y[4]*y[7]
    + 3*y[6]*y[7],
y[2]*y[4] - y[2]*y[6] + y[4]*y[6] + y[4]*y[7] + y[5]*y[7],
y[3]*y[4] - y[2]*y[6] - y[6]^2 - y[6]*y[7] + y[7]^2,
y[4]^2 - y[4]*y[6] + y[5]*y[6] + y[1]*y[7] - y[2]*y[7] + y[4]*y[7] + y[5]*y[7],
y[2]*y[5] - y[4]*y[6] + y[5]*y[6] - y[2]*y[7] + y[4]*y[7] + y[5]*y[7],
y[3]*y[5] - y[6]^2 - y[2]*y[7] - y[7]^2,
y[5]^2 - y[1]*y[6] + y[2]*y[6] - 2*y[4]*y[6] + y[5]*y[6] + y[1]*y[7] - y[2]*y[7]
> Dimension(X); Degree(X);
2
6
```

113.7 Predicates

This subsection describes tests for several important properties of coherent sheaves. It contains an isomorphism test that, combined with `DivisorToSheaf`, can be used as a test for linear equivalence of Cartier divisors.

`IsLocallyFree(S)`

`UseFitting` BoolElt *Default :* `true`

Given a sheaf S on ordinary projective scheme X, this function returns `true` if and only if S is a locally free sheaf on X of constant rank and, if so, also returns its rank.

Our original implementation was very fast but unfortunately incorrect! We have modified it to the algorithm described below which uses an "étale stratification" of X.

The more straightforward method uses Fitting ideals of the module M (or M_{max}) of S. If the possible rank is d (as determined from Hilbert polynomials), it is required to check that the saturation of the dth Fitting ideal is the full ring and that the $(d-1)$th lies in the saturated ideal of X. This is now the default method, but can be extremely slow and use a large amount of memory. Our alternative method is much

slower than it was but we still find that it can be much faster than the Fitting ideal method for a low dimensional X in a high dimensional ambient and a sheaf S whose (maximal) module has a presentation with a reasonably large minimal number of both generators and relations.

To use the alternative method, the user can set the `UseFitting` parameter to `false`. For this method, it is assumed that X is equidimensional (all of its primary components have the same dimension), (locally) Cohen-Macaulay and connected. MAGMA does not check these conditions. The alternative method is described below.

The equidimensional and locally Cohen-Macaulay assumptions imply that X is faithfully flat over $P_0 = Proj(R_0)$ for a Noether normalisation R_0 of the coordinate ring of X. Standard flatness properties mean that S being locally free over X implies that it is locally free as a sheaf over P_0, which is just a full projective space. Serre's criterion (see [Ser55]) states that the latter is true if and only if all intermediate cohomology rings $H^i(P_0, S(q))$ vanish for $q[[0$. If M_{max} is the maximal graded module of S, this translates to all intermediate $Ext(M_{max}, R_0)$ R_0-modules being finite length, which in turn translates to the dual complex to the minimal free resolution of M_{max} as an R_0-module, having finite-length homology groups at all intermediate places. Rather than actually computing homology modules, we can further translate this condition into a number of equality tests for Hilbert polynomials of cokernels of the maps between free modules in the dual complex. This operation seems to be fairly fast and efficient in practise.

The above gives a necessary condition for local freeness over X (and gives the rank) but it is only sufficient over the Zariski open subset of X over which $X \to P_0$ is unramified. We have adapted it to be applied inductively over a chain of closed subschemes of X, which is what we refer to as the étale stratification of X. At each level, we have a subscheme Y of X and a possibly empty collection of polynomials $\{F_i\}$ which are non-zero divisors on Y and such that a chosen Noether normalisation of Y is unramified (equivalently, étale) outside of the subschemes Y_i defined by F_i adjoined to the equations of Y. These subschemes lie at the next level down. The conditions imply that all of the Y_i are equidimensional and Cohen-Macaulay. For Y_i of positive dimension, we apply the above test to the restriction of S to Y_i, checking that the rank is the same as the rank determined for X at the top level if the test is passed and also that F_i is not a zero-divisor on the module of the restricted sheaf. For Y_i of dimension 0, we perform a more direct test.

The overall algorithm generally takes much longer than just applying the main test to X. The étale stratification can take some time to compute when X lies in higher dimensional ambients. However, the main problem is that the degrees of the Y_i increase as we go down the chain (the subscheme defined by F_i has the degree of Y_i multiplied by the degree of F_i as its degree) and in practice (mainly working with surfaces X), the most time is taken in the bottom level checks on high degree zero-dimensional subschemes. Once computed, the étale stratification is stored with X, so does not need to be recomputed for tests on other sheaves. However, it relies on finding Noether normalisations at each level that are generically unramified, i.e. separable. Currently we do not check the condition and it can fail in small positive

characteristic leading to a crash or wrong results.

`IsIsomorphic(S, T)`

`IsIsomorphicWithTwist(S, T)`

For S and T coherent sheaves on the same base scheme X, this function returns `true` if and only if S is isomorphic to T or (for the second intrinsic) to a Serre twist $T(d)$ of T. In either case, an isomorphism is returned, if one exists and for the second intrinsic, the twist d is also returned as the second return value (so the isomorphism is between S and $T(d)$).

For the implementation, we first do a quick Hilbert polynomial check and then a Betti number check for the maximal modules M_{max} and N_{max} of S and T. This gives necessary conditions for an isomorphism and the possible d in the "with twist" case. Then we look for an isomorphism in the finite dimensional space of homomorphisms between M_{max} and N_{max}. We could have chosen to work with the homomorphisms between the truncated modules with gradings greater than or equal to N, for some N greater than or equal to the regularity of any defining modules for the two sheaves, but these have much larger presentations in general so the computation of homomorphisms is slower.

To look for isomorphisms, we look at the "zero degree" subblocks of the matrices giving a basis to the space of all homomorphisms. This reduces the problem to determining whether there is an invertible matrix in a space of $n \times n$ matrices over the base field. This is known to be a difficult problem in general and currently our implementation is rather weak at this point. We hope to improve it for future releases.

`IsArithmeticallyCohenMacaulay(S)`

Given a sheaf S on an ordinary projective scheme X, this function returns `true` if and only if the maximal graded module M_{max} of S is a Cohen-Macaulay module over the coordinate ring of X.

A scheme X is called arithmetically Cohen-Macaulay if and only if its coordinate ring is a Cohen-Macaulay ring. This is then true if and only if its coordinate ring is equal to the maximal module of $\mathcal{O}_X$ and the intrinsic returns `true`for $\mathcal{O}_X$.

This is a fairly straightforward computation once M_{max} has been determined. If we already know the structure of M_{max} as a module over a Noether normalisation of the coordinate ring of X, it is an immediate freeness check. Otherwise it is a straightforward depth calculation from a minimal free resolution of M_{max} as a graded module over the coordinate ring of the ambient of X.

113.8 Miscellaneous

`CohomologyDimension(S, r, n)`

Given a sheaf S and integers r and n, this function returns the dimension over the base field of the r-th cohomology group of the n-th Serre twist of S, $H^r(X, S(n)$.

This just calls the equivalent function for the maximal module of S or its defining module, if the maximal module has not yet been computed. Note that, in practice, it may often be much faster to use the maximal module so it may be desirable to call `SaturateSheaf` before doing any cohomology computations.

`DimensionOfGlobalSections(S)`

This returns the same dimension as `CohomologyDimension(S,0,0)` – the dimension of the space of global sections of S – but it is computed in a different way that is usually faster. It uses some straightforward linear algebra to compute the dimension of the zero-th graded part of the maximal module of S given as a presentation module.

`IntersectionPairing(S, T)`

If S and T are invertible sheaves on a nonsingular surface X, representing divisor classes D and E, this function returns the surface intersection number $D.E$.

Only minimal checks are made on the validity of the input data. The computation is a standard one using the Hilbert polynomials of S, T and their tensor product.

`ZeroSubscheme(S, s)`

The sheaf S should be a locally free sheaf on a scheme X (local freeness is *not* checked). The element s should be a homogeneous element of the defining, maximal or global section modules of S. Then s represents a global section of the twisted sheaf $S(d)$ if s is homogeneous of degree d. The intrinsic returns the vanishing subscheme of s: the largest subscheme of X on which s restricts to a zero section. If S is invertible of the form $\mathcal{L}(D)$, for example, s represents an effective divisor D_s in the linear system $|D + dH|$ (if it is non-zero) and the vanishing subscheme is D_s as a subscheme of X. Locally, for a Zariski-open set U over which there is an isomorphism $S(d)_U \cong \mathcal{O}_{X\,U}^{\,n}$, $s|_U$ corresponds to an n-tuple of functions $(f_1, \ldots, f_n)$ on U and the vanishing subscheme restricted to U is the closed subscheme of U defined by the ideal $\langle f_1, \ldots, f_n \rangle$.

113.9 Examples

In this section we present some extended examples illustrating various features of the sheaf machinery.

Example H113E6

In this example, we consider a surface X from a special family of rational surfaces of degree 10 in $\mathbf{P}^4$. This family is described by Decker, Ein and Schreyer in Section 2.1 of [DES93]. They have sectional genus 9 and are isomorphic to the plane blown up in 18 points in special position which give 18 exceptional curves in X. The embedding into $\mathbf{P}^4$ is such that four of these exceptional curves are of degree 3, seven curves are of degree 2 and seven curves are of degree 1.

The adjunction map on X is the map corresponding to the divisor $K_X + H$, where K_X is a canonical divisor and H is a hyperplane section, or, equivalently to the sheaf $\mathcal{K}_X(1)$ where $\mathcal{K}_X$ is the canonical sheaf. In our example, the adjunction map maps X to a smooth surface X_1 of degree 13 in $\mathbf{P}^8$ blowing down the seven degree 1 exceptional curves to points and reducing the degrees of the others by 1. The adjunction map on X_1 blows down the seven exceptional curves originally of degree 2 to points and maps X_2 to an anticanonically embedded degree 5 Del Pezzo surface in $\mathbf{P}^5$.

We take a randomly generated surface from this family over a small finite field ($\mathbf{F}_{17}$) and illustrate this process by explicitly computing the adjunction maps and images X_1 and X_2. We show that the intersection pairings of the canonical divisor and hyperplane sections on X, X_1, X_2 are as expected and that X_2 really is an anticanonically embedded Del Pezzo surface. We also expand the composition of the two divisor maps and show that the resulting map is indeed a birational map from X onto X_2.

These surfaces X are defined by one degree 4 and ten degree 5 polynomials in $\mathbf{P}^4$. The embedding is quite a complex one and it is hard to construct one with defining polynomials which are at all sparse. This makes it fairly challenging for explicit computation and also means that an example takes up a lot of page space! An example with relatively small coefficients over $\mathbf{Q}$ can also be processed, though the total running time is a few minutes. Also, the resulting X_2 tends to have very large coefficients. Here we get no coefficient blow-up and X_2 is a much simpler looking surface than X.

>        7*x[1]^2*x[2]*x[4]*x[5] + 8*x[1]*x[2]^2*x[4]*x[5] + 2*x[2]^3*x[4]*x[5] +
>        16*x[1]^2*x[3]*x[4]*x[5] + 9*x[1]*x[2]*x[3]*x[4]*x[5] +
>        15*x[1]*x[3]^2*x[4]*x[5] + 3*x[2]*x[3]^2*x[4]*x[5] + 5*x[3]^3*x[4]*x[5]
>        + 10*x[1]^2*x[4]^2*x[5] + 10*x[2]^2*x[4]^2*x[5] + x[1]*x[3]*x[4]^2*x[5]
>        + x[2]*x[3]*x[4]^2*x[5] + 15*x[3]^2*x[4]^2*x[5] + 15*x[1]*x[4]^3*x[5] +
>        14*x[2]*x[4]^3*x[5] + 3*x[3]*x[4]^3*x[5] + 13*x[4]^4*x[5] +
>        4*x[1]^3*x[5]^2 + 13*x[1]^2*x[2]*x[5]^2 + 16*x[1]*x[2]^2*x[5]^2 +
>        14*x[2]^3*x[5]^2 + 3*x[1]^2*x[3]*x[5]^2 + 16*x[1]*x[2]*x[3]*x[5]^2 +
>        11*x[2]^2*x[3]*x[5]^2 + 8*x[1]*x[3]^2*x[5]^2 + 10*x[2]*x[3]^2*x[5]^2 +
>        x[3]^3*x[5]^2 + 5*x[1]^2*x[4]*x[5]^2 + 15*x[1]*x[2]*x[4]*x[5]^2 +
>        9*x[2]^2*x[4]*x[5]^2 + 10*x[1]*x[3]*x[4]*x[5]^2 +
>        9*x[2]*x[3]*x[4]*x[5]^2 + 12*x[3]^2*x[4]*x[5]^2 + 12*x[1]*x[4]^2*x[5]^2
>        + 3*x[2]*x[4]^2*x[5]^2 + 6*x[3]*x[4]^2*x[5]^2 + 15*x[4]^3*x[5]^2 +
>        3*x[1]^2*x[5]^3 + 10*x[1]*x[2]*x[5]^3 + 14*x[2]^2*x[5]^3 +
>        12*x[1]*x[3]*x[5]^3 + 6*x[2]*x[3]*x[5]^3 + 4*x[3]^2*x[5]^3 +
>        8*x[1]*x[4]*x[5]^3 + 4*x[3]*x[4]*x[5]^3 + 9*x[1]*x[5]^4 + 14*x[2]*x[5]^4
```

```
>        + 12*x[3]*x[5]^4 + x[4]*x[5]^4 + 9*x[5]^5]);
```

We check a few of the invariants of X.

```
> Dimension(X);
2
> IsNonsingular(X);
true
> ArithmeticGenus(X);
0
> // Get the sectional genus of X -- ie the genus of a hyperplane section.
> ArithmeticGenus(X meet Scheme(P,P.1));
9
```

Now we construct the canonical sheaf and hyperplane sheaf and check intersection numbers.

```
> KX := CanonicalSheaf(X);
> HX := StructureSheaf(X,1); // hyperplane sheaf
> IntersectionPairing(HX,HX); // should be 10 = Degree(X)
10
> Degree(X);
10
> IntersectionPairing(KX,HX); // should be 6
6
> IntersectionPairing(KX,KX); // should be -9 : lots of exceptional curves!
-9
```

We now get the adjunction map as a divisor map, compute its image X_1 and check some of the invariants of X_1 as well as its corresponding intersection numbers.

```
> mp1,X1 := DivisorMap(Twist(KX,1));
> Dimension(Ambient(X1)); Dimension(X1);
8
2
> KX1 := CanonicalSheaf(X1);
> HX1 := StructureSheaf(X1,1); // hyperplane sheaf of X1
> IntersectionPairing(HX1,HX1); // should be 13 = degree X1
13
> IntersectionPairing(KX1,HX1); // should be -3
-3
> IntersectionPairing(KX1,KX1); // should be -2 : fewer exceptional curves!
-2
```

We construct a second adjunction map to get X_2 and check it as above.

```
> mp2,X2 := DivisorMap(Twist(KX1,1));
> Dimension(Ambient(X2)); Dimension(X2);
5
2
> KX2 := CanonicalSheaf(X2);
> HX2 := StructureSheaf(X2,1); // hyperplane sheaf X2
```

```
> IntersectionPairing(HX2,HX2); // = degree X2 = 5
5
> IntersectionPairing(KX2,HX2); // should be -5
-5
> IntersectionPairing(KX2,KX2); // should be 5
5
```

Now X_2 should be a degree five Del Pezzo surface with $\mathcal{K}_X \simeq \mathcal{O}_X(-1)$. This last isomorphism can be verified by checking that there is a degree -2 isomorphism from $\mathcal{K}_X$ to $\mathcal{O}_X(1)$! The scheme X_2 is much simpler than X: it is defined by five degree 2 polynomials.

```
> boo,d := IsIsomorphicWithTwist(KX2,HX2);
> boo; d;
true
-2
> MinimalBasis(Ideal(X2));
Scheme over GF(17) defined by
y[1]^2 + y[3]^2 + y[1]*y[4] + 15*y[2]*y[4] + 8*y[3]*y[4] + 6*y[4]^2 +
    2*y[1]*y[5] + 12*y[2]*y[5] + y[3]*y[5] + 4*y[4]*y[5] + 4*y[5]^2 +
    6*y[1]*y[6] + 10*y[2]*y[6] + 7*y[3]*y[6] + 7*y[5]*y[6] + 16*y[6]^2,
y[1]*y[2] + 13*y[3]^2 + 3*y[1]*y[4] + 14*y[2]*y[4] + 13*y[3]*y[4] + 5*y[4]^2 +
    14*y[1]*y[5] + 10*y[2]*y[5] + 2*y[3]*y[5] + 9*y[4]*y[5] + 6*y[5]^2 +
    4*y[1]*y[6] + 13*y[2]*y[6] + 10*y[3]*y[6] + 3*y[4]*y[6] + y[5]*y[6] +
    12*y[6]^2,
y[2]^2 + 16*y[3]^2 + 15*y[1]*y[4] + 3*y[3]*y[4] + y[4]^2 + 10*y[1]*y[5] +
    12*y[2]*y[5] + 10*y[3]*y[5] + 11*y[4]*y[5] + 9*y[5]^2 + 5*y[1]*y[6] +
    3*y[2]*y[6] + 2*y[3]*y[6] + 15*y[4]*y[6] + 12*y[5]*y[6] + 5*y[6]^2,
y[1]*y[3] + 13*y[3]^2 + y[1]*y[4] + 11*y[3]*y[4] + y[4]^2 + 16*y[1]*y[5] +
    y[2]*y[5] + 15*y[3]*y[5] + 3*y[4]*y[5] + 7*y[1]*y[6] + 3*y[2]*y[6] +
    9*y[3]*y[6] + 10*y[4]*y[6] + 8*y[5]*y[6] + 6*y[6]^2,
y[2]*y[3] + 16*y[3]^2 + 14*y[1]*y[4] + 3*y[2]*y[4] + y[3]*y[4] + y[4]^2 +
    12*y[1]*y[5] + 9*y[3]*y[5] + 6*y[4]*y[5] + 2*y[5]^2 + 13*y[3]*y[6] +
    9*y[4]*y[6] + 13*y[5]*y[6] + 12*y[6]^2
```

Finally we get the composed map from X to X_2 and check that it is (birationally) invertible.

```
> mp1r := Restriction(mp1,X,X1);
> mp2r := Restriction(mp2,X1,X2);
> mpc := Expand(mp1r*mp2r);
> boo := IsInvertible(mpc);
> boo;
true
```

Example H113E7

In this example, we show how the sheaf machinery can be effectively used as an alternative method to normalise the projective coordinate ring of a normal, but not projectively normal, projective variety. Here the coordinate ring is locally normal at all primes except at the maximal homogeneous ideal.

Our chosen variety is C, an elliptic curve that has been embedded as a degree 8 subvariety of $\mathbf{P}^3$ over $\mathbf{Q}$. The curve C can be thought of as having been embedded in $\mathbf{P}^7$ by a complete linear system of degree 8 and then (isomorphically) projected down into $\mathbf{P}^3$. Such genus one curves embedded as degree 8 curves in $\mathbf{P}^3$ actually arise fairly naturally as models of homogeneous spaces arising in eight-descents.

We wish to recover the full embedding as a projective normal curve in $\mathbf{P}^7$. The coordinate ring of this is isomorphic to the normalisation of the coordinate ring of C in $\mathbf{P}^3$. From a sheaf-theoretic point of view, this is straightforward. The full embedding is the image of the divisor map corresponding to a hyperplane section of C or, equivalently, to the Serre twisting sheaf $\mathcal{O}_X(1)$. The maximal module of $\mathcal{O}_X(1)$ is isomorphic to the normalisation as an R-module, where R is the coordinate ring of C in $\mathbf{P}^3$, and it can be recovered as an algebra by taking the image of its associated divisor map. The global sections of $\mathcal{O}_X(1)$ correspond to the full Riemann-Roch space of the divisor on the abstract curve given by a certain hyperplane divisor on C.

This example also illustrates another interesting point. In situations similar to these, the dimension of the full space of global sections of the Serre twisting sheaf can be computed from cohomology of the coordinate ring R. However, it is faster in this case to explicitly compute the full maximal module of $\mathcal{O}_X(1)$, the zero-th graded part of this corresponding to the space of global sections and having the dimension of the zeroth cohomology group. In fact, though we only need to compute the dimension of this part, it is actually much quicker to compute the maximal module and compute its cohomology than to compute the cohomology of the original defining module, which is R twisted once. This probably reflects to some extent the fact that polynomial ring Groebner basis computations are much more highly tuned currently in MAGMA than the alternating algebra ones used in the cohomology computations. But the maximal module of a sheaf is generally a nicer object than a submodule with bits missing in the lower-graded pieces and has a smaller Castelnuevo-Mumford regularity etc. So, as we see in this example, it is often worth making sure that the maximal module of a sheaf is available before making cohomology calls.

```
> P<x,y,z,t> := ProjectiveSpace(Rationals(),3);
> C := Curve(P,[ x^2*y^2 - 23/59*x*y^3 + 9/59*y^4 + 27/59*x^3*z - 23/59*x^2*y*
> z - 6/59*x*y^2*z + 6/59*y^3*z - 10/59*x^2*z^2 + 5/59*x*y*z^2 - 3/59*y^2*z^2 +
> 1/59*x*z^3 - 74/59*x^3*t + 115/59*x^2*y*t - 83/59*x*y^2*t + 3/59*y^3*t -
> 105/59*x^2*z*t + 1/59*x*y*z*t - 2/59*y^2*z*t + 36/59*x*z^2*t + 4/59*y*z^2*t -
> 3/59*z^3*t + 297/59*x^2*t^2 - 135/59*x*y*t^2 + 52/59*y^2*t^2 + 68/59*x*z*t^2 -
> 11/59*y*z*t^2 - 18/59*z^2*t^2 - 315/59*x*t^3 + 42/59*y*t^3 + 96/59*t^4,
> x^3*y - 833/354*x*y^3 - 11/236*y^4 - 1633/708*x^3*z - 4675/708*x^2*y*z -
> 2633/708*x*y^2*z - 27/236*y^3*z + 805/354*x^2*z^2 + 223/59*x*y*z^2 -
> 4/59*y^2*z^2 - 38/59*x*z^3 + 3359/708*x^3*t + 3811/354*x^2*y*t +
> 1445/708*x*y^2*t + 303/118*y^3*t - 715/177*x^2*z*t - 527/177*x*y*z*t +
> 211/118*y^2*z*t + 347/354*x*z^2*t - 195/236*y*z^2*t - 4/59*z^3*t -
> 127/236*x^2*t^2 - 8237/708*x*y*t^2 + 65/708*y^2*t^2 + 1973/708*x*z*t^2 +
> 123/59*y*z*t^2 - 24/59*z^2*t^2 - 1753/354*x*t^3 + 873/236*y*t^3 + 128/59*t^4,
> x^4 + 269/354*x*y^3 + 35/236*y^4 + 1849/708*x^3*z + 4255/708*x^2*y*z -
> 247/708*x*y^2*z + 43/236*y^3*z - 727/354*x^2*z^2 - 82/59*x*y*z^2 +
> 2/59*y^2*z^2 + 19/59*x*z^3 - 5603/708*x^3*t - 3469/354*x^2*y*t -
> 1637/708*x*y^2*t - 63/118*y^3*t + 328/177*x^2*z*t - 769/177*x*y*z*t -
> 17/118*y^2*z*t + 151/354*x*z^2*t + 127/236*y*z^2*t + 2/59*z^3*t +
> 1391/236*x^2*t^2 + 7865/708*x*y*t^2 + 823/708*y^2*t^2 - 1901/708*x*z*t^2 +
```

```
> 86/59*y*z*t^2 + 12/59*z^2*t^2 + 493/354*x*t^3 - 761/236*y*t^3 - 64/59*t^4]);
```

Next the hyperplane sheaf of C is constructed and the dimension of the space of global sections is confirmed to be 8 using `DimensionOfGlobalSections` (which also saturates the sheaf).

```
> OC1 := StructureSheaf(C,1);
> DimensionOfGlobalSections(OC1);
8
```

Finally, the projective normal embedding into P^7 is created and we check that the image X is defined by 20 quadrics.

```
> norm_mp, X := DivisorMap(OC1);
> ArithmeticGenus(X);
1
> B := MinimalBasis(Ideal(X));
> #B;
20
> [TotalDegree(f) : f in B];
[ 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2 ]
```

114 ALGEBRAIC CURVES

Chapter 114
ALGEBRAIC CURVES

114.1 First Examples

This chapter describes functions for constructing and studying algebraic curves. The first section below contains elementary examples to help with getting started. The biggest obstacle is being able to create geometric objects. After that one should be able to consult the later sections for off-the-shelf functions to apply to the curves.

Within MAGMA, curves are realised as a specialised type of scheme, themselves covered in Chapter 112. As schemes they may be defined over any ring, although most functions will require this to be at least a domain and often a field.

In previous versions of MAGMA, curves were restricted to lie in some plane for the dedicated functions below to apply to them. However, we have now generalised the curve definition to apply to any one-dimensional scheme. The general type is `Crv` and the plane curve now has sub-type `CrvPln`. As before, for the vast majority of the specialist functionality to apply to a curve, it has to be integral (reduced and irreducible) and defined over a field.

114.1.1 Ambients

One usually starts by defining an affine or projective space over some base ring in which our curves will live, although it is not absolutely necessary. Normal affine and projective spaces are the commonest, although product or weighted projective spaces may also be used. This space is often referred to as the *ambient space* and these are more fully described in the general chapter on schemes referred to above. A two-dimensional ambient is referred to as a plane. Plane curves - the ones of subtype `CrvPln` - are those whose ambient space is a plane (and these are defined by a single polynomial equation). If you intend later to create several curves and would like them to be taken to lie in the same space, then deliberately creating their common ambient space in advance is certainly the surest way. It is important to be aware that any two ambients that have been created independently will always be distinct. For example, if one wants to intersect two plane curves, the curves are not allowed to lie in distinct planes, even if one might consider the planes to be mathematically equivalent.

The basic creation function takes two arguments. The first is the intended base ring, the second the intended dimension. In the code fragment below we make an affine plane (of dimension 2). The x, y delineated by diamond brackets determine the names of the coordinates. This syntax is just the same as that for analogous structures such as polynomial rings.

```
> k := Rationals();
> A<x,y> := AffineSpace(k,2);
```

```
> A;
Affine space of dimension 2 with coordinates x,y
```

One can retrieve the characteristic data related to a particular plane as in the following examples.

```
> BaseRing(A);
Rational Field
> Dimension(A);
2
> CoordinateRing(A);
Polynomial ring of rank 2 over Rational Field
Lexicographical Order
Variables: x, y
```

The variables x and y are named on A, but are really elements of the coordinate ring of A. Thus, `A.1`, the first variable of A which in this case is x, is synonymous with `CoordinateRing(A).1`. Higher dimensional affine ambients are precisely analogous, the difference being that there are more variables.

114.1.2 Curves

Algebraic curves are schemes of dimension one. That is, they are described by the vanishing of a set of polynomials or an ideal in the coordinate ring of their ambient space A and this set of zeros has algebraic dimension 1.

Plane curves are described by the vanishing of a single polynomial equation $f = 0$ in some plane A. In other ambients of dimension d, at least $d-1$ polynomials are needed and usually more (when $d-1$ suffice, we refer to the curve as a global complete intersection).

The polynomials or ideal must belong to the coordinate ring of A and be homogeneous when A is projective. In practical terms, this means that one should usually write the polynomial using the variables of A. When using most of the creation functions below, one must be explicit about the ambient in which the curve lies.

Given some affine plane A with coordinates u, v, define a curve C as the zero locus of a polynomial f in u, v.

```
> A<u,v> := AffineSpace(FiniteField(32003),2);
> f := u^2 - v^5;
> C := Curve(A,f);
> C;
Curve over GF(32003) defined by u^2 + 32002*v^5
```

As we see next, the curve C remains in the ambient space A in which it was constructed. It will always lie in that particular space.

```
> AmbientSpace(C);
Affine space of dimension 2 with coordinates u,v
> AmbientSpace(C) eq A;
true
```

```
> BaseField(C);
Finite field of size 32003
```

MAGMA can solve systems of polynomial equations over a given field (or even over a domain using resultants). In particular, it can find the singular points of C defined over the current base field.

```
> SingularPoints(C);
{ (0,0) }
> HasSingularPointsOverExtension(C);
false
```

The function `HasSingularPointsOverExtension()` above returns `false` if and only if there are no additional singular points defined over some extension of the base field of C. (It calculates the radical of the Jacobian algebra to check whether the singularities over the current base field account for the whole algebra.) So the origin really is the only singularity of C defined over this field. There are functions which help one find the singularities of C over an extension if they exist.

114.1.3 Projective Closure

MAGMA maintains a close connection between a curve and its projective closure. Here we illustrate some of the nice results of this.

In this example we define an affine curve in coordinates x, y and take its projective closure. For clarity, we name the homogeneous coordinates on projective space X, Y, Z. These names are really maintained by the projective space containing D even though they appear to have been created with D. Any other curve in this projective space will be expressed in terms of these variables. Names are not automatically given to the projective space. In this example the choice is made at the first opportunity, but it can be made or changed at any time.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,(y^2 - x^3)^2 - y*x^6);
> D<X,Y,Z> := ProjectiveClosure(C);
> D;
Curve over Rational Field defined by
X^6*Y - X^6*Z + 2*X^3*Y^2*Z^2 - Y^4*Z^3
```

Conversely one can retrieve the affine patches of a projective curve. The standard patches are usually the ones of interest, although others can be recovered. The first line below checks that the first patch really is C. Again, variable names are not automatically determined for curves lying in spaces that have not already been created. As seen below, the only result of not assigning names to variables is that the printing is a little unreadable: the first coordinate function is referred to as `$.1` and so on.

```
> AffinePatch(D,1) eq C;
true
> C2 := AffinePatch(D,2);
```

```
> C2;
Curve defined by -$.1^6*$.2 + $.1^6 + 2*$.1^3*$.2^2 - $.2^3
```

We name the coordinate functions and check that C_2 really is a patch of D.

```
> A2<u,v> := AmbientSpace(C2);
> C2;
Curve defined by -u^6*v + u^6 + 2*u^3*v^2 - v^3
> ProjectiveClosure(C2);
Curve defined by -X^6*Y + X^6*Z - 2*X^3*Y^2*Z^2 + Y^4*Z^3
```

114.1.4 Points

Points have already arisen as the singular points of a curve. In this chapter we always think of points as being a sequence of coordinates that satisfies the equations of a curve rather than as a zero-dimensional scheme. While the coordinates of a point often lie in the base ring of the curve, they may lie in any extension of that base ring. Technically, the parent of points is not considered to be the curve at all, but instead a *point set*. Point sets are characterised by two pieces of information. The first piece of information is some scheme, in this case a curve C. The second is some algebra over the base ring. (Note that while we say *algebra* here to emphasise the mathematical point, in MAGMA one uses any ring which admits a map from the base ring rather than an explicit MAGMA algebra type as the second piece of information.) In other words, given an extension L of the base ring k of a curve C, there is a set, $C(L)$, of points of C with coordinates in L. You can consider the point set $C(L)$ literally to be the set of points of C with coordinates in L, although this set does not actually compute or list all its elements since there are often infinitely many.

Thus points can be thought of as being the closest thing to the notion of point that one uses colloquially: "Is the curve C singular at the point p?", for example, can be translated as `IsSingular(C,p)`.

Creating points is easy. For sequences of coordinates of the base ring of a curve, the expression `C ! [1,2]`, for example, creates the point $(1, 2)$ on the scheme C (assuming that coordinate sequences of length 2 are appropriate for C and that $(1, 2)$ satisfies the equations of C). If the coordinates are in some extension, or if you really want a particular point set as parent, you must be explicit about the point set and write `C(L) ! [1,2]`.

Points may belong to the point sets either of a curve or of the ambient plane of the curve. When a point and a curve are both arguments to a function then this difference isn't visible — in the background the function will check that the point really does lie on the curve if that is what is mathematically required — although being careful about where points lie is good practice. Often one is allowed to omit the curve argument in such functions, in which case one must be clear that the point really does lie exactly where one wants it to lie: `IsNonsingular(p)` is an example of function that is rather susceptible to returning confusing results if one isn't careful about where the point lies.

The `!` operator is MAGMA's usual coercion operator. It can be used in a variety of situations where one might hope to make natural reinterpretations of objects. Here it is

used to reinterpret a sequence of numbers as the coordinates of a point in a plane or a curve.

```
> A<x,y> := AffineSpace(FiniteField(23),2);
> p := A ! [1,2];
> p;
(1, 2)
> q := Origin(A);
> q;
(0, 0)
```

So now it is possible to analyse particular points of a curve.

```
> C := Curve(A,x^2 + 2*x*y^2 - y^5);
> C;
Curve over GF(23) defined by
x^2 + 2*x*y^2 + 22*y^5
> p in C;
true (1, 2)
> IsSingular(C,p);
false
> TangentLine(C,p);
Curve over GF(23) defined by
10*x + 20*y + 19
```

Notice that the statement `p in C` is evaluated in a generous way: p is really in a point set of the plane but it happens to satisfy the equation of the curve and that is what is checked. There are two ways to force the parent of the point to be a point set of C: either use the coercion operator or test it with the standard `IsCoercible()` function. The tangent line to C at p is interpreted as a linear curve embedded in the same plane as C and intersecting it at p. These tangent lines are only defined for plane curves C and are themselves plane curves. In particular, functions which can take a curve as argument can take this tangent line as argument. The tangent line is given the name T in the discussion below and used as an argument in a function which takes two curves and a point. Recall that the tangent line to a curve C at a nonsingular point p is the unique line having intersection number at least 2 with C at p.

```
> T := $1;
> IntersectionNumber(C,T,p);
2
```

114.1.5 Choosing Coordinates

One way to express a curve C after a change of coordinates is to make a map — an automorphism of the ambient space — which realises the change of coordinates and then compute the image of C under this map.

Here is a hands-on analysis of a singularity on a curve which involves changes of coordinates. The example is again a plane curve and involves several functions still only available for such: `TangentCone` and `Blowup`. The singularity is first moved to the origin where coordinates are chosen so that the tangent directions lie along the coordinate axes.

```
> A<x,y> := AffineSpace(GF(11,2),2);
> C := Curve(A,-x^6 + x*y^2 - 2*x*y + x + (y - 1)^3);
> SingularPoints(C);
{ (0, 1) }
> p := Representative(SingularPoints(C));
> f := Translation(A,p);
> C1 := f(C);
> q := Origin(A);
> TangentCone(C1,q);
Curve over GF(11^2) defined by x*y^2 + y^3
> g := Automorphism(A,y);
> C2 := g(C1);
> TangentCone(C2,q);
Curve over GF(11^2) defined by x*y^2
```

The singularity is now in a suitable form for study. The following could be the first steps in an analysis. It can be skipped over by anyone not familiar with the language; otherwise see Chapter 46.

```
> D,E := Blowup(C2);
> IsSingular(D,q),IsSingular(E,q);
true false
> TangentCone(D,q);
Curve over GF(11^2) defined by y^2
> Faces(NewtonPolygon(D));
[ <2, 3, 6> ]
```

So the singularity is almost resolved. One more blowup of the cusp at the origin of D will make a resolution.

114.1.6 Function Fields and Divisors

If C is an integral curve then the field of fractions of its coordinate ring (or the homogeneous part of degree 0 in the projective case), is known as the *function field* of C. The function field allows us to conveniently perform many different computations with the curve. The function fields of an affine curve and its projective closure are isomorphic and are identified in MAGMA (with the projective version).

In fact, there are two MAGMA function fields associated to the curve, both abstractly isomorphic to its field of rational functions. What we refer to as the function field here has type `FunFldFracSch` and is associated with more general schemes. Additional information may be found in Chapter 112. This provides the basic user interface for curve functions when they are explicitly needed. For the most part, functions apply to the curve directly

with the function field being used in the background. The second function field is an algebraic function field (see Chapter 42). This provides much of the deeper functionality associated to the curve but lies even further in the background and most users should never need to access it directly.

Divisors — loosely speaking, formal sums of points of a curve — are an important part of the technology having many substantial applications. Any nonzero rational function determines a divisor: take the formal sum of zeros of the function on the curve (counted with multiplicity) minus the poles of the function. Divisors of this form are called principal divisors. Conversely, divisors arising in this way determine the function which defined them up to a scalar multiple.

There are two important groups in which divisors are often considered: the divisor group in which addition is simply coefficient-wise, and the divisor class group which is the divisor group modulo the subgroup of principal divisors. In the case of elliptic curves, the class group provides a formal setup in which to interpret the group law.

If you want to see it explicitly, the function field of a curve may be accessed.

```
> k := FiniteField(17);
> P<x,y,z> := ProjectiveSpace(k,2);
> E := Curve(P, y^2*z - x^3 - 4*x*z^2);
> E1<u,v> := AffinePatch(E,1);
> F<a,b> := FunctionField(E);
> F;
Function Field of Curve over GF(17) defined by
16*x^3 + 13*x*z^2 + y^2*z
> Genus(E);
1
```

But often you don't need the function field in your hands since the function you want can be called directly with the curve as argument.

Divisors are constructed by referring to the curve on which they should lie together with some characteristic data for them.

```
> Div := DivisorGroup(E);
> Div;
Group of divisors of Curve over GF(17) defined by
16*x^3 + 13*x*z^2 + y^2*z
> p := E ! [0,0,1];
> L := TangentLine(E,p);
> D := Divisor(E,L);
> D;
Divisor of Curve over GF(17) defined by
16*x^3 + 13*x*z^2 + y^2*z
> Decomposition(D);
[
    <Place at (0 : 0 : 1), 2>
```

```
    <Place at (0 : 1 : 0), 1>,
]
```

A little explanation is required. Firstly, the divisor D constructed here is really the divisor of the rational function with zero along L and pole along the line at infinity. Secondly, the basic printing of D is not so helpful: the point is to ensure that potentially lengthy calculations are avoided so it is not immediately printed in 'factorised' form. Next, once factorised, the divisor refers to places of the curve. Since the curve could be singular and divisor computations are done on the nonsingular model, the language of places is used. Note that when printing a place, a point corresponding to the place is shown. Of course, this point does not uniquely characterise the place. If p is a singular point of a curve it is possible to have unequal places that both display p as their support.

In this case, the curve is nonsingular so everything is above board: D is literally the divisor $2p_1 + p_2$ where p_1 is the prime divisor at the point $(0 : 0 : 1)$ and p_2 is the prime divisor at the point $(0 : 1 : 0)$. Now, after defining these prime divisors, we define a new divisor of degree 0.

```
> p1 := Divisor(p);
> p2 := Divisor(E![0,1,0]);
> D2 := D - 3*p1;
> Decomposition(D2);
[
    <Place at (0 : 0 : 1), -1>
    <Place at (0 : 1 : 0), 1>,
]
> Degree(D2);
0
```

The natural question to ask of a divisor of degree 0 is whether or not it is principal.

```
> IsPrincipal(D2);
false
> IsPrincipal(2*D2);
true 1/a
```

So D_2 is not principal but two times D_2 is principal. Moreover, the rational function $1/a$ defines $2 \times D_2$. (This corresponds to the rational function z/x on P.)

Now we look at the class group of E. This function requires that E be defined over a finite field. All the operations above apply to a curve defined over any field.

```
> Cl, _, phi := ClassGroup(E);
> Cl;
Abelian Group isomorphic to Z/4 + Z/4 + Z
Defined on 3 generators
Relations:
    4*Cl.1 = 0
    4*Cl.2 = 0
```

```
> phi;
Mapping from: DivCrv: D to GrpAb: Cl given by a rule
> phi(D2);
2*Cl.2
```

114.2 Ambient Spaces

In this section we show how to create various spaces that can be used as ambient spaces for curves. They can be specified in a number of different ways. Typically, different constructions of such spaces will be taken to be different objects, even if they are defined over the same ring. Names for the coordinates can be defined by using the diamond bracket notation in the same way as for polynomial rings.

The discussion here is rather brief, giving just enough functions to create some basic ambients, their functions and points in them. Consult Chapter 112 for more constructors and functions.

`AffineSpace(k,n)`

`AffinePlane(k)`

Create affine n-dimensional space (resp. the 2-dimensional affine plane) over the ring k.

`ProjectiveSpace(k,n)`

`ProjectivePlane(k)`

Create n-dimensional projective space (resp. the 2-dimensional projective plane) over the ring k.

`DirectProduct(A,B)`

If A and B are both one-dimensional projective spaces (defined using the intrinsic `ProjectiveSpace(k,1)` for example) this forms the product $A \times B$ and also returns a sequence containing the two projection maps.

`RuledSurface(k,n)`

`RuledSurface(k,a,b)`

The rational ruled surface over the ring k which has a curve of self-intersection $-n$ or $\pm(a-b)$. The integer arguments must all be nonnegative. It has four variables, the ratio of the first two defining the structure map to $\mathbf{P}^1$, the second two being homogeneous coordinates on the $\mathbf{P}^1$ fibres of this map.

`CoordinateRing(A)`

The coordinate ring of the ambient space A. This is a multivariate polynomial ring over the base ring of A. The number of variables possessed by the ring will depend upon the space. If A is an affine n-space, the function will return a ring with n variables; an ordinary or weighted projective n-space will result in $n+1$ variables; a ruled surface will result in four variables. The gradings that are implicit on various spaces will not be reflected by the polynomial ring. Indeed, at present, there is no way to impose two different gradings on a polynomial ring in MAGMA.

`FunctionField(A)`

Return the function field of the ambient space A. This is a field isomorphic to the field of fractions of the coordinate ring of A. Its generators can be assigned names in the usual way and, typically, one writes elements of this function field in terms of those generators. Polynomials of the coordinate ring of A can be coerced into this function field.

`A ! [a,...]`

`A(L) ! [a,...]`

For elements $a, \ldots$ in the base ring of the ambient space (or any other scheme) A the expression `A ! [a,...]` creates the set-theoretic point, eg, (a, b) in the affine plane case, $(a : b : c)$ in the projective plane case, or $(a : b : c : d)$ in the product or ruled surface case. If L is an extension ring of the base ring of A then the expression `A(L) ! [a,...]` creates the point with coordinates $(a, \ldots)$ where these coordinates are elements of L (or the base ring of A).

`Origin(A)`

The point $(0, 0, \ldots, 0)$ of the affine space A.

`Coordinates(p)`

`p[i]`

The complete sequence of base ring elements corresponding to the coordinates of the point p or the ith coordinate or p alone.

Example H114E1

In this example we make some points of an affine plane A. The first exhibits the constructor which creates points in the point set of the base ring of A. The second creates a point in some extension of the base ring of A.

```
> k := FiniteField(2);
> A := AffineSpace(k,3);
> p := A ! [1,2,3];
> p;
(1, 0, 1)
> L<w> := ext< k | 2 >;
```

```
> q := A(L) ! [1,2,w];
> q[3];
w
```

114.3 Algebraic Curves

A general curve C (type `Crv`) is defined by the vanishing of a finite number of polynomials $f_1, \ldots, f_n$ or a polynomial ideal I in a general ambient space. As a scheme, this must have dimension 1.

A plane curve C (type `CrvPln`) is defined by the vanishing of a single polynomial f in one of the available ambient planes:

$$C : (f_1 = f_2 = \ldots = f_n = 0) \subset A.$$

The polynomials or ideal must lie in the coordinate ring of A. The notation C for a curve and f or $f_1, \ldots, f_n$ for its defining equation(s) will be maintained. The coefficient ring of the parent of polynomials will be denoted k. Irrespective of type, the ambient space will be denoted A.

114.3.1 Creation

In this section the most basic methods of creating a curve are presented. For specialised types — conics, elliptic curves, hyperelliptic curves — there are additional functions documented in the corresponding chapters. Curves may also be created implicitly, such as when they arise as the images of maps.

`Curve(A,f)`

`Nonsingular`	BoolElt	*Default :* `false`
`Reduced`	BoolElt	*Default :* `false`
`Irreducible`	BoolElt	*Default :* `false`
`GeometricallyIrreducible`	BoolElt	*Default :* `false`
`Saturated`	BoolElt	*Default :* `false`

Create the plane curve $f = 0$ in the ambient plane A where f is a polynomial in the coordinate ring of A.

`Curve(A,I)`

`Nonsingular`	BoolElt	*Default :* `false`
`Reduced`	BoolElt	*Default :* `false`
`Irreducible`	BoolElt	*Default :* `false`
`GeometricallyIrreducible`	BoolElt	*Default :* `false`
`Saturated`	BoolElt	*Default :* `false`

Create the curve in the ambient space A determined by the ideal I of the coordinate ring of A. An error results if the result

`Curve(X,S)`

`Nonsingular`	BoolElt	*Default :* `false`
`Reduced`	BoolElt	*Default :* `false`
`Irreducible`	BoolElt	*Default :* `false`
`GeometricallyIrreducible`	BoolElt	*Default :* `false`
`Saturated`	BoolElt	*Default :* `false`

Create the curve defined by the sequence S in the ambient space of X, where S is a sequence of polynomials in the coordinate ring. Here X can be any scheme, not necessarily an ambient space itelf. An error results if the result is not actually a 1-dimensional scheme.

Note: An important special case is when A is an affine or a projective space of dimension 1 and S is empty. This gives the affine or projective line as a curve - as a scheme it is just the ambient space A. Alternatively, the constructor `Curve(A)` described below may be used. Note that the initial construction of A never returns it as a `Crv` type, even though it is 1-dimensional. This is for internal technical reasons – a `Crv` cannot be considered as an ambient space by Magma. is not a 1-dimensional scheme.

`IsCurve(X)`

Returns `true` if and only if X is a one-dimensional scheme.

`Curve(X)`

The smallest scheme in the inclusion chain above the scheme X which is a curve. If X is a curve (ie 1-dimensional) then X will be returned as a `Crv` type. If X has been created as a subscheme of a curve then this curve will be returned.

`Line(C,p,q)`

`Line(P,S)`

The line through the distinct points p, q on the curve C, or the points of S as a subscheme of the projective space P if they are collinear. If the points are points of a curve rather than the ambient space, the line will be interpreted as the tangent line in the case that the points are equal.

`Conic(P,S)`

Given a projective plane P and a set S of points in P, this function returns the conic P through the points of the set S if such a conic exists and is unique. The traditional setup corresponds to the case where S is a set of 5 points in general position, that is, no three of them are collinear. If the resulting conic curve is nonsingular, then it will be returned as a special type. See Chapter 119 for details of the special functions that apply in that case.

`Union(C,D)`

Create the union of the curves C and D. The result will usually be non-irreducible, so although it will be interpreted as a curve, most of the advanced functions below will not apply to it.

114.3.2 Base Change

Let A be some ambient space in MAGMA. For example, think of A as being the affine plane. Let k be its base ring and R_A its coordinate ring. If $m : k \to L$ is a map of rings (a coercion map, for instance) then there is a new ambient space denoted A_L and called the *base change of A to L* which has coordinate ring R_A but with coefficients L instead of k. (Mathematically, one simply tensors R_A with L over k. In MAGMA the equivalent function at the level of polynomial rings is `ChangeRing`.) There is a base change function described below which takes A and L (or the map $k \to L$) as arguments and creates this new space A_L. Note that there is a map from the coordinate ring of A to that of A_L determined by the map m.

This operation is called *base extension* since one often thinks of the map m as being an extension of fields. Of course, the map m could be many other things. One key example where the name *extension* is a little unusual would be when m is the map from the integers to some finite field.

Now let X be a scheme in MAGMA. Thus X is defined by some polynomials $f_1, \ldots, f_r$ on some ambient space A. Given a ring map $k \to L$ there is a base change operation for X which returns the *base change of X to L*, denoted X_L. This is done by first making the base change of A to L and then using the map from the coordinate ring of A to that of A_L to translate the polynomials f_i into polynomials defined on A_L. These polynomials can then be used to define a scheme in A_L. It is this resulting scheme which is the base change of X to L.

If one has a number of curves in the same ambient space and wants to base change them all at the same time, a little care is required. The function which takes a curve and a

map of rings as argument will create a new ambient space each time so should be avoided. A better approach is to apply base change to the ambient space and then invoke the base change function which takes the curve and the desired new ambient space as argument. (This latter base change function appears to be different to the other. In fact it is not. We described base change above as a function of maps of rings. Of course, there is a natural extension to maps of schemes. With that extension, this final base change intrinsic really is base change with respect to map of ambient spaces.)

`BaseChange(C, K)`

The base change of the curve C to the new base ring K. This is only possible if elements of the current base ring of C can be coerced automatically into K. The resulting curve will lie in a newly created plane (see the example below).

`BaseChange(C, m)`

The base change of the curve C by the map of base rings m. The resulting curve will lie in a newly created plane.

`BaseChange(C, A)`

`BaseChange(C, A, m)`

The base change of the curve C to a curve in the new ambient space A. The space A must be of the same type as the ambient of C and its base ring must either admit coercion from the base ring of C or have the map m between the two explicitly given.

`BaseChange(C, n)`

The base change of C, where the base ring of C is a finite field to the finite field which is a degree n extension of the base field of C.

Example H114E2

We give an example of a singular curve, over the rationals, whose singular points are only defined over the field extension given by adjoining a square root of -1.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,y^2 - (x^2+1)^3);
> SingularPoints(C);
{}
> HasSingularPointsOverExtension(C);
true
```

Here we assume that the user knows which extension to move to. The first method of finding the points is to search in the particular point set as follows.

```
> Qi<i> := QuadraticField(-1);
> SingularPoints(C,Qi);
```

```
{ (i, 0), (-i, 0) }
```

The second method is to create a new curve by base change and to search the base ring point set for that curve. For a single calculation this method is rather clumsy, but if further computation were to take place at these points it might be preferable.

```
> B<u,v> := BaseChange(A,Qi);
> Ci := BaseChange(C,B);
> SingularPoints(Ci);
{ (i, 0), (-i, 0) }
```

114.3.3 Basic Attributes

The first few functions below recover data from the ambient space of the curve (and could equally well be applied to the ambient space). Any curves lying in the same ambient space will return identical results when evaluated in these functions. The remaining functions recover data about the equation defining the curve.

The coordinate ring of a curve is described here, but its function field is discussed much later in Section 114.8.

`AmbientSpace(C)`

The ambient space containing the curve C.

`BaseRing(C)`

`CoefficientRing(C)`

`BaseField(C)`

The base ring of the curve C. This is recovered as the base ring of the ambient plane. The third function will report an error if the base ring is not a field.

`DefiningPolynomial(C)`

The defining polynomial of the plane curve C.

`DefiningIdeal(C)`

The defining ideal of the curve C, as an ideal in the coordinate ring of its ambient space.

`CoordinateRing(C)`

The coordinate ring of the curve C. Even creating this requires the use of Gröbner basis techniques.

`Degree(C)`

The degree of the of the curve C which must be defined in an ordinary projective ambient space.

`JacobianIdeal(C)`

The ideal of partial derivatives of the defining polynomials of the curve C.

`JacobianMatrix(C)`

The matrix of partial derivatives of the defining polynomials of the curve C.

`HessianMatrix(C)`

The symmetric matrix of second partial derivatives of the defining polynomial of the plane curve C.

Example H114E3

In this example we start by creating a plane curve C and check that its ideal really is principal. We have chosen an example which is in Weierstrass form.

```
> A<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(A,z*y^2 - x^3 - x*z^2 - z^3);
> IsNonsingular(C);
true
> DefiningIdeal(C);
Ideal of Polynomial ring of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
Basis:
[
    -x^3 - x*z^2 + y^2*z - z^3
]
> IsPrincipal($1);
true x^3 + x*z^2 - y^2*z + z^3
```

Next we compute the determinant of the Hessian matrix of C. That is a polynomial which we use to create another curve D. The intersection of C and D are the points of inflection, or *flexes*, of C. Over an algebraic closure there will be nine of these, but we only see one — the family "flex at infinity" — over the rationals.

```
> M := HessianMatrix(C);
> Determinant(M);
24*x^2*z + 24*x*y^2 + 72*x*z^2 - 8*z^3
> D := Curve(A,Determinant(M));
> IntersectionPoints(C,D);
{ (0 : 1 : 0) }
```

114.3.4 Basic Invariants

`IsReduced(C)`

Returns `true` if and only if the ideal defining the curve C is reduced.

`IsIrreducible(C)`

Returns `true` if and only if the curve C is irreducible (as a scheme).

`IsSingular(C)`

Returns `true` if and only if the curve C contains at least one singularity over an algebraic closure of its base field.

`IsNonsingular(C)`

Returns `true` if and only if the curve C has no singularities over an algebraic closure of its base field.

114.3.5 Random Curves

This section described several functions for the generation of random curves of given degree and/or genus over finite fields and the rationals. The implementations follow [ST02].

`RandomNodalCurve(d, g, P)`

`RandomBound` RngIntElt *Default :* 9

Generates a random plane curve in the projective plane P of degree d and genus g with only nodes as singularities. The genus g must satisfy $g \leq (d-1)(d-2)/2$ and then the number of nodes will be $(d-1)(d-2)/2 - g$. These nodes are chosen as a random set of points in P. At the same time g must be $\geq 1 + (d(d-6)/3)$ to guarantee a non-empty linear system for a general set of nodes. For $0 \leq g \leq 10$, a good choice to obtain a general curve of genus g is to take $d = g + 2 - [g/3]$ (see [ST02]).

The base field may be a finite field or $\mathbf{Q}$. Over $\mathbf{Q}$, the construction uses polynomials which will have integer coefficients randomly chosen in the range $[-r \ldots r]$, where r is the value of `RandomBound`. Over a finite field, `RandomBound` is ignored.

`IsNodalCurve(C)`

Given a plane curve C, this function returns `true` if either C is non-singular or C only has nodes as singularities.

`RandomOrdinaryPlaneCurve(d, S, P)`

`Adjoint`	BoolElt	*Default :* `true`
`Proof`	BoolElt	*Default :* `true`
`RandomBound`	RngIntElt	*Default :* 9

Generates a random plane curve in the projective plane P of degree d and with ordinary singularities specified by the sequence *sings* as follows: If $S = [s_2, s_3, s_4, \ldots]$ then the curve will have s_2 nodes, s_3 triple points, s_4 ordinary singularities of multiplicity 4, etc. For example $[2, 0, 1]$ specifies 2 nodes and one ordinary quadruple point.

For such a curve to exist we require $\binom{d-1}{2} \geq \sum_i s_i \binom{i+1}{2}$.

If `Proof` is `false` then the full check that the singularities are ordinary is skipped.

If `Adjoint` is `true` then the adjoint ideal, an ideal of the coordinate ring of P, is also computed and returned as a second value. The r-th graded parts of this homogeneous ideal realises the linear system $K + (r - d + 3)H$ on the normalisation of the curve, where K is the canonical divisor and H is the hyperplane section divisor corresponding to the (singular) embedding into P. This can be used to compute various adjoint maps (for example, $r = d - 3$ gives the canonical map) and its computation by this function is more efficient than using the general method of blowing-up in `Adjoints` (this function now also tests for ordinariness and uses the adjoint ideal by default).

The base field can be finite or $\mathbf{Q}$ and `RandomBound` is as before.

`RandomCurveByGenus(g, K)`

`RandomBound`	RngIntElt	*Default :* 9

Given a positive integer g and a field K this function generates a random projective curve over K of genus g, for $0 \leq g \leq 13$. When $g \leq 10$, a plane nodal curve is returned as given by the function `RandomNodalCurve` with degree $g + 2 - [g/3]$. For $11 \leq g \leq 13$, a curve in $\mathbf{P}^3$ is returned, computed by syzygy computations as described in [ST02].

The field K must be a finite field or $\mathbf{Q}$. The parameter `RandomBound` applies when K is chosen to be $\mathbf{Q}$. Note that, although $\mathbf{Q}$ is allowed in all cases, for the higher values of g, particularly for $g \geq 11$, the heights of the coefficients of the defining polynomials for the curve produced tend to be very large, even for small values of `RandomBound`.

Example H114E4

```
> SetSeed(1);
> C := RandomCurveByGenus(4, Rationals());
> C;
Curve over Rational Field defined by
x^5 + 34965/512*x*y*z^3 - 59355/512*x*z^4 + y^5 - 16705/48*y^3*z^2 -
    1831885/1536*y^2*z^3 - 1553135/2304*y*z^4 + 655145/4608*z^5
```

```
> Genus(C);
4
> C := RandomCurveByGenus(8, GF(23));
> C;
Curve over GF(23) defined by
17*x^8 + 5*x^7*y + 5*x^7*z + 13*x^6*y^2 + 11*x^6*y*z + 8*x^6*z^2 + 16*x^5*y^3 +
    17*x^5*y^2*z + 22*x^5*y*z^2 + 6*x^5*z^3 + 3*x^4*y^4 + 2*x^4*y^3*z +

114.3.6 Ordinary Plane Curves

The term ordinary plane curve refers to a curve in the projective plane all of whose singularities are ordinary. This means that a singularity of multiplicity $m \geq 2$ has m "distinct tangent directions" – the equation of the curve expanded in local coordinates at the singularity begins with a binary form of degree m which splits into m distinct linear factors over the algebraic closure of the ground field.

A significant property of such curves is that all of their singularities are resolved by a single blow-up. Their adjoint linear systems/adjoint ideal can be computed in a more direct fashion than for more general plane curves. These linear systems give important projective maps such as the canonical map for curves of genus at least 2 and embeddings as rational normal curves for curves of genus 0.

This section contains some functions relating to ordinary curves and, in particular, to nodal curves, all of whose singularities are ordinary of multiplicity 2 (nodes). The list of functions is likely to be extended in future versions of Magma.

`HasOnlyOrdinarySingularities(C)`

`Adjoint` BoolElt *Default :* `true`

Given a plane curve C this function returns `true` in C has only ordinary singularities. If that is the case it also returns the maximum of the multiplicities of the singularities of C (1 means that C is non-singular). Further, if C is ordinary and if `Adjoint` is `true`, then the (saturated) adjoint ideal is also computed and returned as the third value.

`HasOnlyOrdinarySingularitiesMonteCarlo(C)`

Given a plane curve C defined over $\mathbf{Q}$ perform a Monte Carlo test for ordinariness. This will generally be faster than the intrinsic `OnlyOrdinarySingularities`. The function does not compute the adjoint ideal. Five primes are chosen for which the mod p reduction of C is still a curve and which has Jacobian ideal of the same degree as that of C. The five reductions are tested for ordinary singularities. If all pass, then `true` is returned. Otherwise `false` is returned. If `false` is returned, then C is definitely not ordinary. If it succeeds, then C is very likely to be ordinary but this is not 100% guaranteed.

`AdjointIdeal(C)`

Returns the (saturated) adjoint ideal of an ordinary plane curve C. If C is not ordinary then an error results.

`AdjointIdealForNodalCurve(C)`

`AdjointLinearSystemForNodalCurve(C, d)`

Given a plane curve C that is *assumed* to be nodal, these are slightly faster intrinsics for computing the adjoint ideal and adjoint linear system, respectively. The first function returns the adjoint ideal I and the second returns the degree d adjoint linear system, which is the linear subsystem of the complete plane linear system of degree d given by the degree d graded part of I.

`AdjointLinearSystemFromIdeal(I, d)`

Given an ideal I and a positive integer d, this function returns the degree d adjoint linear system for a plane curve whose (saturated) adjoint ideal is I.

`CanonicalLinearSystemFromIdeal(I, d)`

Given an ideal I and a positive integer d, this function returns the canonical linear system for a plane curve of degree d whose (saturated) adjoint ideal is I. This is the same as intrinsic `AdjointLinearSystemFromIdeal` with I and $d-3$ as arguments. It will be empty if the curve has genus 0.

`CanonicalLinearSystem(C)`

`AdjointLinearSystem(C)`

`Adjoints(C,d)`

Given a plane curve C the first two functions return the canonical linear system for any plane curve C and the third gives the general degree d adjoint linear system. If C is ordinary, then the functions compute the adjoint ideal and takes its graded piece as above. If not, they have to work out in detail the graph of the full resolution of singularities of C, which can take some time.

Example H114E5

In this example, we generate a random ordinary plane curve of degree 7 with 3 nodes and one ordinary singularity of order 4. We use its adjoint ideal to get the canonical map and compute its canonical image in $\mathbf{P}^5$. The computation of the canonical map this way is generally faster and gives a much simpler map description than the computation for general curves using the function field machinery.

114.4 Local Geometry

Here we discuss some basic functions providing analysis of a point p lying on a curve C. Firstly we describe how to create points on curves and their basic access functions. One should also refer to the comments in Section 112.7 of the general schemes chapter about the point sets of point arguments of these functions where there is a fuller discussion of point sets.

Most functions usually have two arguments, a curve and a point on that curve. In fact, the point need not actually be in a point set of the curve since coercion will be attempted if it is not. Moreover, the curve argument is not strictly necessary either, since if the point does lie in a point set of the curve, it can be recovered automatically. So these functions also work with the curve argument omitted. However, omitting the curve argument should be thought of merely as a convenient shorthand and should be used with care — it is very easy to use a point from some other space for which the function still makes sense but returns a misleading answer.

114.4.1 Creation of Points on Curves

Points of a curve C, and indeed points of any scheme in MAGMA, lie in point sets associated to C rather than C itself. Each point set is the parent of points whose coordinates lie in a particular extension ring of the base ring of the curve. Thus, if k is the base ring of the curve C, points whose coordinates lie in k are elements of the "base ring point set" denoted $C(k)$. If L is an extension ring of k (in the sense of admitting coercion from k or being the codomain of a ring homomorphism from k) then points with coordinates in L lie in the point set $C(L)$.

Here we give the basic point creation methods and access functions. For more information, consult the discussion of points and point sets in Section 112.7 of Chapter 112 on schemes.

`C ! [a,...]`

For a sequence of elements $a, \ldots$ of the base ring of C, this creates the point of C with coordinates $(a, \ldots)$. The parent of the resulting point is the base point set of the curve C rather than C itself.

`C(L) ! [a,...]`

For a sequence of elements $a, \ldots$ of the extension ring L of the base ring of C, this function creates the point of C with coordinates $(a, \ldots)$. The parent of the resulting point is the point set $C(L)$ of the curve C rather than C itself. The phrase 'extension ring' here means that either L admits automatic coercion from the base ring of C, or that L is the codomain of a ring homomorphism from that base ring.

`Curve(p)`

The smallest scheme in the inclusion chain above the scheme on which the point p lies which is a curve. If p lies on a curve then the curve will be returned.

`Curve(P)`

The smallest scheme in the inclusion chain above the scheme P is a point set of which is a curve. If P is a point set of a curve then this curve will be returned.

`Coordinates(p)`

The sequence of ring elements corresponding to the coordinates of the point p.

`p[i]`

`Coordinate(p,i)`

The ith coordinate of the point p.

`p eq q`

Returns `true` if and only if the two points p and q lie in schemes contained in a common ambient space, have coordinates that can be compared (either by lying in the same ring, or by an automatic coercion) and these coordinates are equal.

`FormalPoint(P)`

Given a non–singular point P in $C(K)$, where C is a curve and K is some extension of the field of definition of C, returns a point in `C(LaurentSeriesRing(K))`, such that specializing the variable to 0 yields P.

114.4.2 Operations at a Point

Most of the functions in this section report an error if p does not lie on C. Functions having arguments C, p allow the omission of C as long as the parent of p is a point set of C. A few of the functions apply only to plane curves.

`p in C`

`S in C`

Returns `true` if and only if the point p or the sequence of coordinates S lies on the curve C. That is, return `true` if and only if the coordinates of p satisfy the equation of C.

`IsNonsingular(C,p)`

Returns `true` if and only if p is a nonsingular point of the curve C.

`IsSingular(C,p)`

Returns `true` if and only if the point p is a singular point on the curve C.

`IsInflectionPoint(C,p)`

`IsFlex(C,p)`

Returns `true` if and only if the point p is a flex of the plane curve C. An error is reported if p is a singular point of C. The second return value is the order of the flex, that is, the local intersection number at p of C with its tangent line at p.

`TangentLine(p)`

`TangentLine(C,p)`

The tangent line to the curve C at the point p embedded as a curve in the same space; an error if p is a singular point of C.

`TangentCone(C,p)`

The tangent cone to the curve C at the point p embedded in the same ambient space.

`IsTangent(C,D,p)`

Returns `true` if and only if the plane curves C and D are nonsingular and tangent at the point p.

114.4.3 Singularity Analysis

These functions report an error if p is not a singular point of C. Again, the arguments can be abbreviated to just the point if care is taken about its parent.

`Multiplicity(C,p)`

The multiplicity of the curve C at the point p.

`IsDoublePoint(C,p)`

Returns `true` if and only if the point p is a double point of the curve C.

`IsOrdinarySingularity(C,p)`

Returns `true` if and only if the point p is a singular point of the curve C with reduced tangent cone.

`IsNode(C,p)`

Returns `true` if and only if the point p is an ordinary double point of the curve C.

`IsCusp(C,p)`

Returns `true` if and only if the point p is a nonordinary double point of the curve C.

`IsAnalyticallyIrreducible(C,p)`

Returns `true` if and only if the plane curve C has exactly one place at the point p, or equivalently if the resolution of singularities is injective above p.

Example H114E6

Each of the two curves in this example has a double point at the origin. One of these is a node and one is a cusp.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,x^2-y^3);
> p := Origin(A);
> IsCusp(C,p);
true
> IsDoublePoint(C,p);
true
> IsReduced(TangentCone(C,p));
false
> D := Curve(A,x^2 - y^3 - y^2);
> IsAnalyticallyIrreducible(D,p);
false
> IsNode(D,p);
true
```

114.4.4 Resolution of Singularities

Again, all functions in this section only apply to plane curves.

`Blowup(C)`

Given the affine plane curve C, return the two affine plane curves lying on the standard patches of the blowup of the affine plane at the origin. Note that the two curves returned are the *birational* transforms of C on the blowup patches. The patches are contained in the same affine space as the curve itself. If C does not contain the origin this returns an error message.

`Blowup(C,M)`

This returns the weighted blowup of the plane curve C at the origin defined by the 2×2 matrix of integers M. Again, the birational transform of C is returned inside the ambient plane of C. An error is reported if M does not have determinant ± 1.

Example H114E7

It often happens that one can replace a string of ordinary blowups used to resolve a curve singularity by a single weighted blowup.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A,y^2 - x^7);
> f := map< A -> A | [x^2*y,x^7*y^3] >;
> C @@ f;
Curve over Rational Field defined by
x^14*y^7 - x^14*y^6
```

```
> M := Matrix(2,[2,1,7,3]);
> Blowup(C,M);
Curve over Rational Field defined by
-y + 1
14 6
```

The blowup function takes the total pullback as the underlying map and then removes all copies of the x and y axes. The pair of numbers displayed in the final line is the multiplicity of these factors in the total pullback. The curve returned is the birational pullback of C on some patch of a rational surface arising by a number of blowups above the origin of A. It is clearly nonsingular — it's linear! — so this map resolves the singularity at the origin of C.
In fact, MAGMA has machinery for interpreting strings of blowups in terms of a graph, the *resolution graph*.

```
> ResolutionGraph(C);
The resolution graph on the Digraph
Vertex  Neighbours
1 ([ -2, 7, 4, 0 ])     2 ;
2 ([ -1, 14, 8, 1 ])    3 ;
3 ([ -3, 6, 3, 0 ])     4 ;
4 ([ -2, 4, 2, 0 ])     5 ;
5 ([ -2, 2, 1, 0 ])     ;
```

Consult Chapter 115 for the full interpretation of this graph. Briefly, one should see this as representing a chain of five blowups which resolve the curve. Each vertex of the graph corresponds to one of the exceptional curves coming from these blowups. The curve extracted by the weighted blowup we saw above corresponds to vertex number 2. Indeed, we can see the multiplicity 14 in the total pullback as the second entry of the labelling sequence. (The multiplicity 6 which we saw above is the corresponding entry in exceptional curve 3.) The fourth entry of that sequence, 1, reports that the birational transform of C to the blownup surface intersects the exceptional curve with multiplicity 1. This is the only nonzero fourth entry of any vertex label, so we conclude that there is exactly one place above the singularity at the origin. This can be confirmed (more quickly!) by the divisor machinery which will be discussed in Section 114.9.

```
> Places(C ! Origin(A));
[
    Place at (0 : 0 : 1)
]
> Degree($1[1]);
1
```

114.4.5 Log Canonical Thresholds

For background on log canonical singularities, see for example [Kollár 1997, Singularities of pairs] or [Kollár 1998, Birational geometry of algebraic varieties].

Let V be a variety with at worst log canonical singularities, P a point on V and D an effective $\mathbf{Q}$-Cartier divisor on V. Then the *log canonical threshold* (lct) of the log pair (V, D) at P is the number

$$\mathrm{lct}_P(V, D) = \sup\{\lambda \in \mathbf{Q} \mid (V, \lambda D) \text{ is log canonical at } P\} \in \mathbf{Q} \cup \{+\infty\}.$$

We can also consider the lct of D along the whole of V:

$$\begin{aligned}\mathrm{lct}(V, D) &= \inf\{\mathrm{lct}_P(V, D) \mid P \in V\} \\ &= \sup\{\lambda \in \mathbf{Q} \mid (V, \lambda D) \text{ is log canonical}\}.\end{aligned}$$

`LogCanonicalThreshold(C)`

The log canonical threshold of the curve C computed at its singular k-points, where k is the base field of C.

`LogCanonicalThresholdAtOrigin(C)`

The local log canonical threshold of the affine curve C computed at the origin.

`LogCanonicalThreshold(C, P)`

The local log canonical threshold of the curve C computed at the point P.

`LogCanonicalThresholdOverExtension(C)`

The log canonical threshold of the curve C computed at all singular points including those defined over some base field extension.

Example H114E8

Consider a cubic curve C on the projective plane, then the singularities of C resemble one of the following examples: a smooth curve, e.g.,

```
> P2<x,y,z> := ProjectiveSpace(Rationals(),2);
> A := Curve(P2,x^3-y^2*z-3*x*z^2);
> IsNonsingular(A);
true
```

a curve with ordinary double points (i.e. nodes), e.g.,

```
> B := Curve(P2,x^3-y^2*z-3*x*z^2+2*z^3);
> IsNodalCurve(B);
true
```

a curve with one cuspidal point, e.g.,

```
> C := Curve(P2,x^3-y^2*z);
> #SingularPoints(C) eq 1;
```

```
true
> IsCusp(C,SingularPoints(C)[1]);
true
```

a conic and a line that are tangent, e.g.,

```
> D := Curve(P2,(x^2+(y-z)^2-z^2)*y);
> #PrimeComponents(D) eq 2;
true
> TangentCone(PrimeComponents(D)[1],P2![0,0,1]) eq PrimeComponents(D)[2];
true
```

three lines intersecting at one (Eckardt) point, e.g.

```
> E := Curve(P2,x*y*(x-y));
> IsOrdinarySingularity(E,P2![0,0,1]);
true
> Multiplicity(E,P2![0,0,1]);
3
```

a curve whose support consists of two lines, e.g.,

```
> F := Curve(P2,x^2*y);
> IsReduced(F);
false
> #SingularPoints(ReducedSubscheme(F)) eq 1;
true
> IsNodalCurve(Curve(ReducedSubscheme(F)));
true
```

or a curve whose support consists of three lines, e.g.,

```
> G := Curve(P2,x^3);
> IsReduced(G);
false
> IsNonsingular(ReducedSubscheme(G));
true
```

It is known that a curve is log canonical whenever its singularities are at worst nodal, thus $\mathrm{lct}(P^2, A) = \mathrm{lct}(P^2, B) = 1$. For the remaining reduced curves we can resolve their singularities and calculate their discrepancies to find their log canonical thresholds.

```
> curves := [* A,B,C,D,E,F,G *];
> [LogCanonicalThreshold(curve) : curve in curves];
```

It follows that $\mathrm{lct}(P^2, -K_{P^2}) \leq \frac{1}{3}$. In fact, it is not hard to see that equality holds.

Example H114E9

Here we exhibit a curve C over the rationals, $\mathbf{Q}$, that has singularities defined over a splitting field, k, where $\mathrm{lct}(C)$ (over k) $< \mathrm{lct}(C)$ (over $\mathbf{Q}$). We take a curve C in the projective plane $P2$ with one ordinary double point and two triple point singularities. Such a curve can be obtained by calling:

```
> P2<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := RandomPlaneCurve(6,[1,2],P2);
```

For this example we use the fixed curve C defined below.

```
> f := x*y^5 + y^6 + x^5*z + x^2*y^3*z + 2095/3402*y^5*z + x^4*z^2 -
>      6244382419/8614788*x^3*y*z^2 -
>      28401292681/8614788*x^2*y^2*z^2 -
>      89017753225/25844364*x*y^3*z^2 -
>      243243649115/232599276*y^4*z^2 -
>      2798099890675/70354102*x^3*z^3 -
>      22754590185549/281416408*x^2*y*z^3 -
>      7190675316787/140708204*x*y^2*z^3 -
>      75304687887883/7598243016*y^3*z^3 +
>      17778098933653/140708204*x^2*z^4 +
>      6098447759659/35177051*x*y*z^4 +
>      24308031251845/422124612*y^2*z^4 -
>      4694415764252/35177051*x*z^5 -
>      77497995284599/844249224*y*z^5 +
>      6592790982389/140708204*z^6;
> C := Curve(P2,f);
> IsSingular(C);
true
> LogCanonicalThreshold(C);
1
> IsNodalCurve(C);
false
```

Thus C must have singularities defined over some field extension.

```
> HasSingularPointsOverExtension(C);
true
> LogCanonicalThresholdOverExtension(C);
2/3
```

114.4.6 Local Intersection Theory

The main function here for a single point uses a standard Euclidean algorithm to calculate local intersection numbers at points where two plane curves meet. It was taken from unpublished lecture notes of Franz Winkler, "Introduction to Commutative Algebra and Algebraic Geometry"; the same algorithm is in Fulton's book [Ful69]. These numbers are also called *intersection multiplicities* in the literature. In the following sections there are functions for finding the intersection points of two curves.

There is now a variant that uses an algorithm of Jan Hilmar and Chris Smyth described in [HS10]. This computes all intersection points of the two curves as a set of Galois conjugacy classes and their intersection numbers in a single computation. The implementation, adapted into MAGMA from code contributed by Chris Smyth, returns the sequence of points along with the corresponding local intersection multiplicities.

`IsIntersection(C,D,p)`

Returns `true` if and only if the point p lies on both curves C and D.

`IsTransverse(C,D,p)`

Returns `true` if and only if the point p is a nonsingular point of both plane curves C and D and the curves have distinct tangents there.

`IntersectionNumber(C,D,p)`

The local intersection number $I_p(C, D)$ of the plane curves C and D at the point p. This reports an error if C or D have a common component at p.

`IntersectionNumbers(C,D)`

`IntersectionNumbers(F,G)`

`Global` BOOLELT *Default :* `false`

These intrinsics use the algorithm of Hilmar and Smyth to compute in one go a list of all intersection places along with the corresponding local intersection multiplicities of two projective plane curves C and D defined over k: a finite field, an algebraic field or the rationals $\mathbf{Q}$. Here, intersection place means a point in $\mathbf{P}^2(K)$, where $\mathbf{P}^2$ is the ambient of C and D and K is a finite extension of k, which represents a Galois conjugacy class of ($[K : k]$) points in the intersection of C and D.

The first intrinsic takes C and D as arguments (which must have no common irreducible component) and returns the result as a list of pairs $\langle p, m\rangle$, where p is an element of a pointset $\mathbf{P}^2(K)$ giving a place in the intersection and m is the corresponding local intersection multiplicity.

The second intrinsic avoids the use of pointsets. It takes two homogeneous polynomials F and G which are relatively prime and lie in the same multivariate polynomial ring $P = k[x, y, z]$. They represent two plane curves in $Proj(P)$ and the result is a list of intersection places of these curves with intersection multiplicity. The elements of the list are again pairs $\langle p, m\rangle$, but here p is represented as in Hilmar and Smyth's paper [HS10], p is a list of three elements of one of three types:

i) $[*1, 0, 0*]$. Represents the plane projective point with these homogeneous coordinates.

ii) $[*f(y), 1, 0*]$ with $f(y)$ an irreducible polynomial in $k[y]$. Represents the conjugate points with homogeneous coordinates $[\alpha, 1, 0]$ where α ranges over the roots of f.

iii) $[*h(x, y), g(y), 1*]$ with $g(y)$ an irreducible polynomial in $k[y]$ and $h(x, y)$ a polynomial in $k[x, y]$ whose image in $(k[y]/(g(y)))[x]$ is irreducible. Represents the conjugate points with homogeneous coordinates $[\gamma, \beta, 1]$ where β ranges over the roots of g and, for each β, γ ranges over the roots of $h(x, \beta)$.

The parameter `Global` applies to the polynomial version. If it takes its default value `false`, both the two-variable and one-variable polynomial rings used in the type ii) and iii) representations will be non-global versions with the y and x, y labelling of variables as shown. This may have the disadvantage that elements returned by *different* calls to the intrinsic cannot be directly compared because they lie in different rings. If `Global` is `true`, the global one- and two-variable polynomial rings are used but in this case the variables are not labelled by the intrinsic.

Example H114E10

The local intersection of two curves at a point where they share a common tangent is calculated. If the curves did not share a tangent, the intersection would be the product of multiplicities which it is not in this case.

```
> A<x,y> := AffineSpace(Rationals(),2);
> C := Curve(A, y^2 - x^5);
> D := Curve(A, y - x^2);
> p := Origin(A);
> IntersectionNumber(C,D,p);
4
> Multiplicity(C,p) * Multiplicity(D,p);
2
```

These intersection numbers are often defined to be the length of a particular affine algebra. (See [Har77] Chapter I, Exercise 5.4.) Below it is checked that this definition produces the same result in this case. Note that the algebra is not localised at p so the length calculated is the sum of intersection numbers at all intersection points. At the end one sees that the discrepancy of 1 is accounted for by a single transverse intersection away from the origin.

```
> RA := CoordinateRing(A);
> I := ideal< RA | DefiningPolynomial(C), DefiningPolynomial(D) >;
> Dimension(RA/I);
5
> IP := IntersectionPoints(C,D);
> IP;
{@ (0, 0), (1, 1) @}
> IsTransverse(C,D,IP[1]);
false
> IsTransverse(C,D,IP[2]);
```

```
true
```

Example H114E11

This example is taken from the paper of Hilmar and Smyth. We use the polynomial version for which the output is more explicit.

```
> P<x,y,z> := PolynomialRing(Rationals(),3,"grevlex");
> A := (y-z)*x^5+(y^2-y*z)*x^4+(y^3-y^2*z)*x^3+(-y^2*z^2+y*z^3)*x^2+
>   (-y^3*z^2+y^2*z^3)*x-y^4*z^2+y^3*z^3;
> B := (y^2-2*z^2)*x^2+(y^3-2*y*z^2)*x+y^4-y^2*z^2-2*z^4;
> c := IntersectionNumbers(A,B);
> c;
[* <[* x + y, y^2 + 1, 1 *], 1>, <[* x - y^3, y^4 + 1, 1 *], 1>,
  <[* y^2 + y + 1, 1, 0 *], 2>, <[* x^2 + x + 2, y - 1, 1 *], 1>,
  <[* 1, 0, 0 *], 2>, <[* x^2 + x*y + 2, y^2 - 2, 1 *], 1>,
  <[* x^3 - y, y^2 - 2, 1 *], 1>  *]
```

114.5 Global Geometry

In this section functions which determine global properties of curves such as their genus and whether their equation has a particular form are presented.

114.5.1 Genus and Singularities

`Genus(C)`

`GeometricGenus(C)`

The topological genus of the curve C. More precisely, this is the arithmetic genus of the projective normalisation $\tilde{C}$, which is unique up to k-isomorphism, where k is the basefield of C. C must be an integral curve (reduced and irreducible as a scheme).

Note that, if k is not a perfect field, $\tilde{C}$ may have singularities over an inseparable extension field of k (in technical terms, $\tilde{C}$ is a non-singular scheme, but it may not be k-smooth), in which case the genus of C may drop after some (inseparable) basefield extensions.

`ArithmeticGenus(C)`

The arithmetic genus of the curve C or its projective closure if C is affine. In the case of a plane projective curve of degree d, this number is just $(d-1)(d-2)/2$.

This is really the arithmetic genus of (projective) scheme C and not of its normalisation.

`NumberOfPunctures(C)`

The number of punctures of the affine plane curve C over an algebraic closure of its ground field, that is, the number of points supporting its reduced scheme at infinity. This is just the reduced degree of the polynomial of C at infinity.

`SingularPoints(C)`

The singular points of the curve C which are defined over the base field of C.

`HasSingularPointsOverExtension(C)`

Returns `false` if and only if the scheme of singularities of the curve C has support defined over the base field of C. This function requires that C be reduced.

`Flexes(C)`

`InflectionPoints(C)`

For a plane curve C, this returns the subscheme of C defined by the vanishing of the determinant of the Hessian matrix. This contains the "flex points" of C, which by definition are the nonsingular points at which the tangent line intersects C with multiplicity at least 3.

`C eq D`

Returns `true` if and only if the curves C and D are defined by identical ideals in the same ambient space. (For plane curves, this simply compares defining polynomials of the two curves up to a factor so Gröbner basis calculations are avoided.)

`IsSubscheme(C,D)`

Returns `true` if and only if the curve C is contained (scheme-theoretically) in the curve D.

Example H114E12

We take a plane affine cubic C with a single cusp and non-singular at infinity. Here the projective normalisation of C is isomorphic to the projective line with genus 0, although the arithmetic genus of C is 1.

```
> A<x,y> := AffineSpace(GF(3),2);
> C := Curve(A,y^2 - x^3 - 1);
> Genus(C);
0
> ArithmeticGenus(C);
1
```

Now we consider a similar cubic over the non-perfect field $K = k(t)$ with a single cuspidal singularity defined over an inseparable cubic extension. Now C is a normal and non-singular scheme (but non-smooth), which only loses its normality after an inseparable basefield extension. Here both the genus and arithmetic genus are 1.

```
> K<t> := RationalFunctionField(GF(3));
```

```
> A<x,y> := AffineSpace(K,2);
> C := Curve(A,y^2 - x^3 - t);
> Genus(C);
1
```

114.5.2 Projective Closure and Affine Patches

In MAGMA, any affine space has a unique projective closure. This may be assigned different variable names just like any projective space. The projective closure functions applied to affine curves will return projective curves in the projective closure of the affine ambient. Conversely, a projective space has standard affine patches. These will also appear as the ambient spaces of the standard affine patches of a projective curve.

`ProjectiveClosure(A)`

The projective space that is the projective closure of the ambient A. Unless A is already expressed as a particular patch on some projective space, this is the standard closure defined by the homogenisation of the coordinate ring of A with a new coordinate and unit weights.

`ProjectiveClosure(C)`

The closure of the curve C in the projective closure of its ambient affine space.

Example H114E13

Since the closure of the ambient space is unique, the ambient space of the closure of curves lying in a common affine space is independent of how it is constructed. Here is an odd example but one that occurs in practice when curves and spaces are passed between functions: the functions `ProjectiveClosure()` and `AmbientSpace()` commute!

```
> A<a,b> := AffineSpace(GF(5),2);
> C := Curve(A,a^3 - b^4);
> AmbientSpace(ProjectiveClosure(C)) eq ProjectiveClosure(AmbientSpace(C));
true
```

`LineAtInfinity(A)`

The line which is the complement of the affine plane A embedded in the projective closure of A.

`PointsAtInfinity(C)`

The set of points at infinity defined over the base field of the curve C. The number of these points can also be recovered by the `NumberOfPunctures()` function in the plane case.

`AffinePatch(C,i)`

The i-th affine patch of the projective curve C. For ordinary projective space, the first patch is the one centred on the point $(0 : 0 : \ldots : 0 : 1)$, the second at the point $(0 : 0 : \ldots : 1 : 0)$ and so on.

Example H114E14

Usually one looks at the first affine patch of a curve. If the curve is described, as below, using homogeneous coordinates x,y,z then this is often realised by "setting $z = 1$". Note that we have to assign names to the coordinates explicitly on the affine patches if we want them.

```
> P<x,y,z> := ProjectiveSpace(GF(11),2);
> C := Curve(P,x^3*z^2 - y^5);
> AffinePatch(C,1);
Curve over GF(11) defined by 10*$.1^3 + $.2^5
> C1<u,v> := AffinePatch(C,1);
> C1;
Curve over GF(11) defined by 10*u^3 + v^5
> SingularPoints(C);
{ (1 : 0 : 0), (0 : 0 : 1) }
```

One can also look at other patches. Indeed, sometimes it is necessary. In this example, the curve C has an interesting singularity "at infinity", the point $(1 : 0 : 0)$. If we want to view it on an affine curve then we must take one of the other patches.

```
> C3<Y,Z> := AffinePatch(C,3);
> C3;
Curve over GF(11) defined by Y^5 + 10*Z^2
> IsSingular(C3 ! [0,0]);
true
```

Both affine curves $C1$ and $C3$ have the projective curve C as their projective closure.

```
> ProjectiveClosure(C1) eq ProjectiveClosure(C3);
true
```

114.5.3 Special Forms of Curves

The functions in this section check whether a curve is written in a particular normal form, and also whether it belongs to one of the more specialised families of curve.

`IsEllipticWeierstrass(C)`

Returns `true` if the curve C is nonsingular plane curve of genus 1 in Weierstrass form. This tests the coefficients of the polynomial of C. The conditions guarantee a flex at the point $(0 : 1 : 0)$ either on C or on its projective closure. These are precisely the conditions required by the linear equivalence algorithms for divisors in a later section.

`IsHyperellipticWeierstrass(C)`

Returns `true` if the curve C is a hyperelliptic curve in plane Weierstrass form. The conditions chosen are that the (a) first affine patch be nonsingular, (b) the point $(0:1:0)$ is the only point at infinity and has tangent cone supported at the line at infinity and (c), the projection of C away from that point has degree 2.

`EllipticCurve(C)`

`EllipticCurve(C,p)`

`EllipticCurve(C,p)`

See the description of `EllipticCurve` in Chapter 120.

`IsHyperelliptic(C)`

`Eqn`	BoolElt	*Default :* `true`

`IsGeometricallyHyperelliptic(C)`

`Map`	BoolElt	*Default :* `true`
Verbose	`IsHyp`	*Maximum :* 2

The second function determines whether the curve C is a hyperelliptic curve over the algebraic closure of its base field. If so and if `Map` is `true`, a plane conic or the projective line and a degree 2 map from C to it (all defined over the base field) are returned. The map is to the line if the genus of C is even and to a conic if the genus is odd.

The first function determines whether the curve C is hyperelliptic over its base field K (ie has a degree 2 map to the projective line defined over K). If so, and if the `Eqn` parameter is `true`, it also returns a hyperelliptic Weierstrass model H over K and an isomorphic scheme map from C to H.

Here, hyperelliptic entails genus ≥ 2.

The basic method in both cases is to find the image of C under the canonical map (using functions to be described later) and to check if this is of arithmetic genus zero. If so, this image curve (which is rational normal) is mapped down to a plane conic or the line by repeated adjunction maps. For the second function, the final equation is determined by differential computations in the function field of C once the explicit map to the projective line, which gives the base x function, has been determined.

Example H114E15

```
> P<a,b,c,d,e,f> := ProjectiveSpace(Rationals(),5);
> C := Curve(P,[
> a^2 + a*c - c*e + 3*d*e + 2*d*f - 2*e^2 - 2*e*f - f^2,
> a*c - b^2,
> a*d - b*c,
> a*e - c^2,
```

```
> a*e - b*d,
> b*e - c*d,
> c*e - d^2
> ] );
> boo,hy,mp := IsHyperelliptic(C);
> boo;
true
> hy;
Hyperelliptic Curve defined by y^2 = x^8 + x^6 + x - 1 over Rational Field
> mp;
Mapping from: Sch: C to CrvHyp: hy
with equations :
c*e - d^2 + d*f
-d*f + e*f + f^2
e*f
```

114.6 Maps and Curves

114.6.1 Elementary Maps

The first group of functions create selfmaps of the affine plane. Such a map f can be used to move a curve around the plane simply by applying it to the curve. See Chapter 112 on schemes for more details about maps.

`IdentityAutomorphism(A)`

`Translation(A,p)`

`FlipCoordinates(A)`

`Automorphism(A,q)`

These are the basic automorphisms of the affine plane A taking (x, y) to (x, y), $(x - a, y - b)$, (y, x) and $(x + q(y), y)$ respectively, where p is the point (a, b) and q is a polynomial on A involving y only.

`TranslationToInfinity(C,p)`

The image of C under the change of coordinates which translates p to the point $(0 : 1 : 0)$ in the projective plane and makes the tangent line there equal to the line at infinity. An error is reported if p is a singular point of C. The change of coordinates map is given so that other curves can be mapped by the same change of coordinates.

Example H114E16

In this example we show how one could begin to work out a Weierstrass equation for a Fermat cubic. First we define that cubic curve C in the projective plane and choose a point p on C.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^3 + y^3 + z^3);
> p := C ! [1,-1,0];
> IsFlex(C,p);
true 3
```

The point we have chosen is a flex — the second return value of 3 is the local intersection number of the curve C with its tangent line at p. We use the intrinsic `TranslationToInfinity` to make an automorphism of P which takes the point p to the point $(0 : 1 : 0)$ and takes the curve C to a curve which has tangent line $z = 0$ at the image of p.

```
> C1,phi := TranslationToInfinity(C,p);
> phi(p);
(0 : 1 : 0)
> C1;
Curve over Rational Field defined by
x^3 + 3*y^2*z - 3*y*z^2 + z^3
```

This is almost in Weierstrass form already. It is a pleasant exercise to make coordinate changes which "absorb" some of the coefficients. Alternatively, one can use the intrinsic `EllipticCurve` to perform the entire transformation in one step.

`EvaluateByPowerSeries(m, P)`

Given a map $m : C \to D$, and a nonsingular point P on C, where C is a curve, return $m(P)$, evaluating $m(P)$ using a power series expansion if necessary. This allows a rational map on C to be evaluated at nonsingular base points.

Example H114E17

The following example shows a map evaluated at a point using power series methods.

```
> P2<X,Y,Z>:=ProjectiveSpace(Rationals(),2);
> C:=Curve(P2,X^3+Y^3-2*Z^3);
> D:=Curve(P2,Y^2*Z-X^3+27*Z^3);
> phi:=map<C->D|[-6*X^2-6*X*Z+6*Y^2+6*Y*Z,
>                9*X^2+18*X*Y+18*X*Z+9*Y^2+18*Y*Z+36*Z^2,
>                X^2-2*X*Z-Y^2+2*Y*Z
>               ]>;
> P:=C![-1,1,0];
> P in BaseScheme(phi);
true (-1 : 1 : 0)
> Q:=EvaluateByPowerSeries(phi,P);
> Q;
(3 : 0 : 1)
```

```
>  phi(P);
>> phi(P);
      ^
Runtime error in map application: Image of map does not lie in the codomain
> pullbackQ:=Q@@phi;
> pullbackQ;
Scheme over Rational Field defined by
-9*X^2 + 9*Y^2,
9*X^2 + 18*X*Y + 18*X*Z + 9*Y^2 + 18*Y*Z + 36*Z^2,
X^3 + Y^3 - 2*Z^3
> IsSubscheme(BaseScheme(phi), pullbackQ);
true
> P in pullbackQ;
true (-1 : 1 : 0)
> Degree(BaseScheme(phi))+1 eq Degree(pullbackQ);
true
```

114.6.2 Maps Induced by Morphisms

Given a non-constant map $\phi : D \to C$ between curves, there are several induced maps between the function fields of C and D and the divisor groups $\mathrm{Div}(C)$ and $\mathrm{Div}(D)$. We refer to the contravariant maps ϕ^* as *Pullback*s and to the covariant maps ϕ_*, corresponding to the Norm between the function fields, as *Pushforward*s. Divisor groups and other function field related items are discussed in Section 114.8.

`Degree(m)`

Returns the degree of a non-constant dominant map m between curves.

`RamificationDivisor(m)`

Returns the ramification divisor of a non-constant dominant map m between irreducible curves.

`Pullback(phi, X)`

Given a map $\phi : D \to C$ between curves and a function, differential, place or divisor X on C, this function returns the pullback of X along ϕ.

`Pushforward(phi, X)`

Given a map $\phi : D \to C$ between curves and a function, place or divisor X on C, this function returns the pushforward of X along ϕ. In older versions, the function applied to a place used to only work with the image of the point (or cluster) below the place for speed and would give an error when ϕ was undefined there. Now, if this is true, the function reverts to working entirely with places and should never fail.

Example H114E18

As an illustration of these routines, consider the following example

```
> Puvw<u,v,w>:=ProjectiveSpace(Rationals(),2);
> Pxyz<x,y,z>:=ProjectiveSpace(Rationals(),2);
> D:=Curve(Puvw,u^4+v^4-w^4);
> C:=Curve(Pxyz,x^4-y^4+y^2*z^2);
> phiAmb:=map<Puvw->Pxyz|[y*z,z^2,x^2]>;
> phi:=Restriction(phiAmb,D,C);
> KC:=FunctionField(C);
> KD:=FunctionField(D);
> Omega:=BasisOfHolomorphicDifferentials(C)[1];
```

Here we see a holomorphic differential pulls back to holomorphic.

```
> IsEffective(Divisor(Pullback(phi,Omega)));
true
```

Ramification divisors are actually quite easy to compute.

```
> RamificationDivisor(phi) eq
>     Divisor(Pullback(phi,Omega))-Pullback(phi,Divisor(Omega));
true
```

Verifying Riemann-Hurwitz:

```
> 2*Genus(D)-2 eq Degree(phi)*(2*Genus(C)-2)+Degree(RamificationDivisor(phi));
true
```

Pulling back and pushing forward is taking powers on the function field.

```
> f:=KC.1;
> Pushforward(phi,Pullback(phi,f)) eq f^Degree(phi);
true
```

`Divisor` and `Pushforward` commute.

```
> g:=KD.1;
> Divisor(Pushforward(phi,g)) eq Pushforward(phi,Divisor(g));
true
```

114.7 Automorphism Groups of Curves

MAGMA now (V2.13) contains functionality for computing the automorphism group of a (reduced and irreducible) curve over a variety of base fields. New structures have been added to aid the user in working with these groups. An automorphism group is of type `GrpAutCrv` and there may be several of these associated to a given curve: the full automorphism group or a subgroup generated by a given set of automorphisms. The automorphism group structure acts as a container for a permutation group representation of the group of curve automorphisms along with the map between the representing group and a list of the actual automorphisms stored in a compressed format.

Elements of the group are of type `GrpAutCrvElt`, a subtype of `MapAutSch`. For these, all of the usual scheme-map operations are available. However, a number of these are specially implemented for the new type and there are also several new operations. In particular, composition and powering of elements makes use of the internal group representation for speed and there are functions for the actions on points, places, divisors etc. which are more efficient than those for a general (finite) map between curves. There is also a function to compute the matrix representation of an automorphism group on the space of holomorphic differentials of the curve.

The full automorphism group is computed at function field level. The algebraic function field versions of some of the functions here are described in Section 42.7.2.

It should be stressed that these groups are groups of *birational* automorphisms of a curve C, in the usual way. This means that they are correspond to actual automorphisms (ie, everywhere defined with an everywhere defined inverse) of the unique normalisation of C and the full automorphism group is the full automorphism group of this normalisation. However, if C is singular, then some of these automorphisms may not be defined at particular singular points.

There are also functions for computing isomorphisms between distinct curves.

All functions require C to have a function field, whether the full group of automorphisms is computed or not.

All of the functions computing the full set of automorphisms require the base field to be perfect (characteristic zero or finite).

114.7.1 Group Creation Functions

`AutomorphismGroup(C)`

Given a reduced, irreducible projective curve C, this function returns the full automorphism group of C over its base field. If the genus of C is less than 2, an error results unless the base field is finite. Note that the full automorphism group is cached so is only ever computed once.

`AutomorphismGroup(C,auts)`

With C as above, this function returns the automorphism group of C generated by the sequence of automorphisms *auts*. The sequence *auts* can consist of either scheme automorphisms of C of type `MapAutSch` or `GrpAutCrvElt` elements lying in

a previously constructed automorphism group of C. The same restrictions on the genus apply.

`Automorphisms(C)`

`Bound` RngIntElt *Default :* ∞

For C as above, this function computes at most `Bound` automorphisms of C over its base field and returns them as a sequence of scheme maps (type `MapSch`). If `Bound` is `Infinity` or at least the order of the full automorphism group, all automorphisms will be returned.

`IsIsomorphic(C, D)`

Given irreducible curves C and D this function returns `true` is C and D are isomorphic over their common base field. If so, it also returns a scheme map giving an isomorphism between them. The curves C and D must be reduced. Currently the function requires that the curves are not both genus 0 nor both genus 1 unless the base field is finite.

`Isomorphisms(C, D)`

`Bound` RngIntElt *Default :* ∞

Given reduced, irreducible curves C and D this function returns at most `Bound` isomorphisms from C to D over their common base field. These are returned as a sequence of scheme maps. The genus restrictions are as for `IsIsomorphic`.

114.7.2 Automorphisms

`A . i`

Let A be a group of automorphisms of curve C and let i be an integer such that $-n \leq i \leq n$, where n is the number of generators of A. This operator returns the i-th generator for A. A negative subscript indicates that the inverse of the generator is to be created. Finally, $A.0$ denotes the identity of A.

Note that if A is an automorphism group that was generated from a list of specified automorphisms, *auts*, then the generators of A will not necessarily be these "user" generators, but will be those coming from the permutation representation of A.

`Identity(A)`

`Id(A)`

`A ! 1`

The identity element of the automorphism group A.

`A ! f`

Let A be an automorphism group of a curve C. Given a scheme map f from C to C or an element of some (other) automorphism group of C, this function returns the `GrpAutCrvElt` element of A corresponding to f. An error will result if f is not in A.

`Order(f)`

The order of the curve automorphism f.

`Inverse(f)`

The inverse of the curve automorphism f.

`f * g`

The product of the curve automorphisms f and g in automorphism group A. If f and g are regarded as maps, this function returns their composite: first apply f, then apply g. Note that this composition uses the permutation representation of A and is generally performed faster than the usual scheme map composition.

`f ^ n`

The nth power of the curve automorphism f. The integer n may be positive or negative. Again, this uses the permutation representation of A, the parent of f.

`g eq h`

Given curve automorphisms g and h belonging to automorphism groups of the same curve C, return `true` if g and h represent the same automorphism, `false` otherwise. Note that g and h do not have to belong to the same automorphism group.

`g ne h`

The logical negation of the preceding function.

`SchemeMap(f)`

It is sometimes useful for the user to convert a curve automorphism back to an object of plain scheme isomorphism type. This is a convenience function that simply returns the curve automorphism f as a `MapAutSch`.

114.7.3 Automorphism Group Operations

`Curve(A)`

The curve of which A is a group of automorphisms.

`Order(A)`

The order of A.

`FactoredOrder(A)`

The factored order of A.

`NumberOfGenerators(A)`

`Ngens(A)`

The number of generators of A. If A was defined as the group generated by a given sequence of automorphisms, this sequence will not necessarily coincide with the set of generators, which is determined by the internal permutation representation.

`Generators(A)`

The generators of A - a small set of `GrpAutCrvElt` elements of A, which generate it as a group - returned in a sequence.

`PermutationGroup(A)`

The permutation group of A which gives the abstract group representation of the automorphism group.

`PermutationRepresentation(A)`

The permutation group representation of A consisting of the actual permutation group G and an invertible map which takes elements of G to the corresponding curve automorphism (as a `GrpAutCrvElt` element).

`MatrixRepresentation(A)`

For an automorphism group A on a curve C of genus at least 2, computes the matrix representation of A acting on the space of holomorphic differentials by pullback. The differentials are represented by row vectors with respect to a basis B and the matrix associated to $g \in A$ gives the pullback action of g by right multiplication of the row vectors. The (finite) matrix group image G is returned along with a map from A to G giving the representation and an enumerated sequence containing the basis of differentials B used.

`a in A`

Returns whether a curve automorphism, given as a `GrpAutCrvElt` or `MapSch`, is equal to an automorphism lying in A.

`A subset B`

Returns whether A is actually a subgroup of B as automorphism groups of the same curve.

114.7.4 Pullbacks and Pushforwards

For `GrpAutCrvElt` elements, pullbacks and pushforwards (images) of functions, places, divisors and differentials of the curve C are handled more directly than for general curve maps. The functions to perform these operations use the more direct `f(x)` and `x @@ f` syntax and these should be used in preference to the `Pushforward` and `Pullback` functions in Section 114.6.2.

In addition, the computation of images of points on C by a curve automorphism is handled slightly differently. If the point doesn't lie in the original domain of definition of the scheme map giving the automorphism, the image is still computed without extending the map (although for some singular points of the curve model, the image may still not exist for the "birational" automorphism).

`f(X)`
`X @ f`

Given a curve automorphism f of curve C and a point, function, differential, place or divisor X on C, this function returns the image (or pushforward) of X under f.

`X @@ f`

Given a curve automorphism f of curve C and a function, differential, place or divisor X on C, this function returns the inverse image (or pullback) of X under f.

Example H114E19

Here are some examples of the above functions applied to the genus 3 Fermat curve in characteristic 0.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^4+y^4+z^4);
> L := Automorphisms(C);
> #L;
24
> // to get all automorphisms, we base change to Q(zeta_8)
> K := CyclotomicField(8);
> C1 := BaseChange(C,K);
> L1 := Automorphisms(C1);
> #L1;
96
> // next, we get the automorphism as a group
> G := AutomorphismGroup(C1);
> g := G!iso<C1 -> C1 | [y,z,x],[z,x,y]>;
> Gp,rep := PermutationRepresentation(G);
> Gp;
Permutation group Gp acting on a set of cardinality 12
Order = 96 = 2^5 * 3
    (2, 4)(3, 5)(6, 8)(7, 10)
    (2, 5, 10, 8, 4, 3, 7, 6)(11, 12)
    (1, 2, 3)(4, 5, 9)(6, 11, 7)(8, 12, 10)
```

```
> rep(g);
(1, 8, 4)(2, 9, 6)(3, 10, 11)(5, 7, 12)
> Inverse(rep)(Gp.2);
Mapping from: CrvPln: C1 to CrvPln: C1
with equations :
zeta_8^2*$.1^3*$.3
$.1^3*$.2
$.2^4 + $.3^4
and inverse
zeta_8^2*$.1^3*$.3
-zeta_8^2*$.1^3*$.2
$.2^4 + $.3^4
> $1 eq G.2;
true
```

Example H114E20

In the next example we look at a superelliptic curve over $GF(7^2)$ with isomorphism group a central extension of $PGL_2(\mathbf{F}_7)$ by a cyclic group of order 4.

```
> SetSeed(1);
> k := GF(7^2);
> A<x,y> := AffineSpace(k,2);
> C := ProjectiveClosure(Curve(A,y^4-x^7+x));
> G := AutomorphismGroup(C);
> Gp,rep := PermutationRepresentation(G);
> Gp;
Permutation group G acting on a set of cardinality 192
Order = 1344 = 2^6 * 3 * 7
> [Order(G.i) : i in [1..Ngens(G)]];
[ 7, 24, 2 ]
> Z := Centre(Gp); Z;
Permutation group Z acting on a set of cardinality 192
Order = 4 = 2^2
> (Z.1)@@rep;
Mapping from: CrvPln: C to CrvPln: C
with equations :
$.1
k.1^12*$.2
$.3
and inverse
$.1
k.1^36*$.2
$.3
> Gp1 := quo<Gp|Z>;
> boo := IsIsomorphic(Gp1,PGL(2,GF(7)));
> boo;
true
```

```
> // Find the representation on the 176 Weierstrass places.
> // Only need the action of the generators of Gp (or G)
> wpls := WeierstrassPlaces(C);
> wpls_perms := [[Index(wpls,g(w)) : w in wpls]: g in Generators(G)];
> G_wpls := SymmetricGroup(#wpls);
> weier_rep := hom<Gp->G_wpls|[G_wpls!p : p in wpls_perms]>;
> //Check that its faithful
> K := Kernel(weier_rep);
> #K;
1
```

Example H114E21

The next example illustrates the use of `IsIsomorphic` in finding an isomorphism between the well-known plane model of genus 3 curve $X(7)$ and a degree 6 model of it in $\mathbf{P}^3$. The isomorphism between C and D is only computed in one direction, but we can then use `IsInvertible`.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2,x^3*y+y^3*z+z^3*x);
> P3<a,b,c,d> := ProjectiveSpace(Rationals(),3);
> D := Curve(P3,[b^2-a*d,a*b*c+b*d^2+c^3]);
> boo,im := IsIsomorphic(C,D);
> boo;
true
> im;
Mapping from: CrvPln: C to Crv: D
with equations :
x^2
x*z
y*z
z^2
> _,imi := IsInvertible(im);
> Inverse(imi);
Mapping from: CrvPln: C to Crv: D
with equations :
x^2
x*z
y*z
z^2
and inverse
b
c
d
```

We now compute the automorphism group of C over $GF(11^3)$ where the full set of 168 automorphisms exists (the group is isomorphic to $PSL_2(\mathbf{F}_7)$) and generate some subgroups.

```
> P2<x,y,z> := ProjectiveSpace(GF(11^3),2);
> C := Curve(P2,x^3*y+y^3*z+z^3*x);
```

```
> G := AutomorphismGroup(C);
> Order(G);
168
> [Order(g) : g in Generators(G)];
[ 7, 3, 7 ]
> G1 := AutomorphismGroup(C,[G.1,G.2]);
> Order(G1);
21
> PermutationGroup(G1);
Permutation group acting on a set of cardinality 8
Order = 21 = 3 * 7
    (2, 4, 3, 7, 5, 8, 6)
    (3, 5, 4)(6, 8, 7)
> // can also find the normaliser of <G.3> via the
> // permutation rep
> Gp,rep := PermutationRepresentation(G);
> H := Normaliser(Gp,sub<Gp|Gp.3>);
> #H;
21
> Hgens := [g@@rep : g in Generators(H)];
> [Order(g) : g in Hgens];
[ 3, 7 ]
> h := Hgens[1];
> //check directly that h normalises <g> in G
> g := G.3;
> Index([g^i : i in [1..7]],h*g*(h^-1));
4
```

114.7.5 Quotients of Curves

For G an arbitrary group of automorphisms of a curve C of genus $>= 2$, the main intrinsic in this section computes a model of the quotient curve C/G along with the explicit projection map $C \to C/G$.

`CurveQuotient(G)`

G is a group of automorphisms of a curve C/k, which must be of genus $g >= 2$. The function computes a projective, non-singular model of C/G, the scheme theoretic quotient of C by G. This is returned with the G-invariant projection map from C down to it.

If $k(C)$ is the function field of C then C/G can be thought of as the curve with function field $k(C)^{G^*}$ where G^* is the group of field automorphisms of $k(C)/k$ induced by G under function pull-back.

The implementation utilises MAGMA's Function Field and Invariant Theory functionality and uses a variety of methods. There is no restriction on the characteristic p

and the function works in positive characteristic as long as the following assumption is true:

$$C \to C/G \text{ is tamely ramified when genus}(C/G) > 1$$

This is equivalent to saying that, for all points P on (the non-singular, projective model of) C, the subgroup G_P of G fixing P has order prime to p. In practise, this will only be a problem for very small $p > 0$ when $p|\#G$.

The algorithm used is slightly different depending on g_G, the genus of the quotient curve.

When $g_G >= 2$ and the quotient is non-hyperelliptic, the canonical image of C/G is computed and this is the model returned. This uses function field functionality only.

The case $g_G >= 2$ and the quotient is hyperelliptic is similar, only extra work is needed to find the "y-coordinate". Again everything is done purely with function fields. The model returned is a `CrvHyp` Weierstrass model if the quotient is hyperelliptic over k, or a bi-quadratic model in P^3 if it is only geometrically hyperelliptic.

When g_G is 0 or 1, the canonical map methodology used in the above cases fails and we use a combination of Invariant theory and function field methods instead.

For $g_G = 0$, the model returned for C/G is either the projective line P^1 or a conic in P^2. In this case, the function does not automatically search for k-rational points so, if a conic is returned, the quotient may still be isomorphic to P^1 over k.

For $g_G = 1$, the model returned is a projectively normal embedding by quadrics in P^n, $n >= 3$, or a cubic in P^2. Again, the function does not search for k-rational points in order to try to convert the quotient into elliptic curve form.

Example H114E22

We start with our old friend the Klein quartic again - this time over Q. The quotient by an automorphism of order 3 is a genus 1 curve. We find this quotient and produce an isomorphism from this to an elliptic curve using the rational point that is the projection of $(0 : 0 : 1)$.

```
> P2<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2,x^3*y+y^3*z+z^3*x);
> phi := iso<C->C|[y,z,x],[z,x,y]>;
> // we will take the quotient by phi
> G := AutomorphismGroup(C,[phi]);
> CG,prj := CurveQuotient(G);
> CG;
Curve over Rational Field defined by
x[1]^2 - 13*x[1]*x[2] + 8*x[1]*x[3] + 10*x[2]*x[3] - 6*x[3]^2 + 15*x[1]*x[4] +
    3*x[2]*x[4] - 6*x[3]*x[4] - 6*x[4]^2,
x[1]^2 - 12*x[1]*x[2] + 3*x[2]^2 + 8*x[1]*x[3] + 12*x[1]*x[4]
> Genus(CG);
1
> // find an minimal elliptic Weierstrass model
> ptCG := prj(C![0,0,1]);
> E1, psi1 := EllipticCurve(CG,ptCG);
```

```
> E, psi := MinimalModel(E1);
> prj := Expand(prj * psi1 * psi); // get the composite map C -> E
> E;
Elliptic Curve defined by y^2 + x*y = x^3 - x^2 - 2*x - 1 over Rational Field
> prj;
Mapping from: CrvPln: C to CrvEll: E
with equations :
-2*x^2*y^8 + 2*x*y^8*z - 2*y^9*z - 2*x*y^7*z^2 - 2*x^2*y^5*z^3 + 2*x*y^6*z^3 -
    2*y^7*z^3 + 2*x^2*y^4*z^4 - 2*x^2*y^3*z^5 - 2*y^4*z^6 + 2*y^3*z^7 -
    2*y^2*z^8
4*x^2*y^8 - 2*x*y^9 - 2*x^2*y^7*z - 2*x*y^8*z + 4*y^9*z + 2*x^2*y^6*z^2 +
    4*x*y^7*z^2 - 2*y^8*z^2 + 2*x^2*y^5*z^3 - 4*x*y^6*z^3 + 4*y^7*z^3 -
    4*x^2*y^4*z^4 + 2*x*y^5*z^4 - 2*y^6*z^4 + 4*x^2*y^3*z^5 + 2*y^5*z^5 -
    2*x^2*y^2*z^6 + 2*y^4*z^6 - 4*y^3*z^7 + 4*y^2*z^8 - 2*y*z^9
2*x*y^8*z - 2*x^2*y^5*z^3 - 2*y^4*z^6
> Conductor(E);
49
```

In fact, C is the modular curve $X(7)$ and E is $X_0(49)$. That C/G and E are isogenous elliptic curves also follows from modular form theory.

Example H114E23

As a second example we consider the genus 4 modular curve $X_0(54)$ with the two commuting Atkin-Lehner involutions W_2, W_{27}. We compute the quotients by $< W_2 >$, $< W_{27} >$ and $< W_2, W_{27} >$ which respectively have genera 2,1,0.

```
> P<[x]> := ProjectiveSpace(Rationals(),3);
> X054 := Curve(P,[
>   x[2]*x[3] - x[1]*x[4], 4*x[1]^2*x[2] + 2*x[1]*x[2]^2 +
>       x[2]^3 - x[3]^3 + x[3]^2*x[4] - x[3]*x[4]^2]);
> W2 := iso<X054->X054|[1/2*x[4],-x[3],-x[2],2*x[1]],
>                 [1/2*x[4],-x[3],-x[2],2*x[1]]>;
> W27 := iso<X054->X054|
> [
>     -1/3*x[1] - 1/3*x[2] - 1/3*x[3] - 1/3*x[4],
>     -2/3*x[1] - 2/3*x[2] + 1/3*x[3] + 1/3*x[4],
>     -2/3*x[1] + 1/3*x[2] - 2/3*x[3] + 1/3*x[4],
>     -4/3*x[1] + 2/3*x[2] + 2/3*x[3] - 1/3*x[4]
> ],
> [
>     -1/3*x[1] - 1/3*x[2] - 1/3*x[3] - 1/3*x[4],
>     -2/3*x[1] - 2/3*x[2] + 1/3*x[3] + 1/3*x[4],
>     -2/3*x[1] + 1/3*x[2] - 2/3*x[3] + 1/3*x[4],
>     -4/3*x[1] + 2/3*x[2] + 2/3*x[3] - 1/3*x[4]
> ]>;
> // 1. Quotient by <W2>
> G := AutomorphismGroup(X054,[W2]);
> CG,prj := CurveQuotient(G);
```

```
> CG;
Hyperelliptic Curve defined by y^2 + (-x^2 - 1)*y = 387*x^6 + 999*x^5 + 785*x^4
    + 294*x^3 + 58*x^2 + 6*x over Rational Field
> Genus(CG);
2
> // 2. Quotient by <W27>

114.8 Function Fields

An integral curve C has a coordinate ring that is an integral domain. The function field of the curve is the corresponding field of fractions in the affine case and the homogeneous degree 0 part of this in projective cases. The function field of an affine curve is isomorphic to that of its projective closure. As with schemes generally, a function field is attached to projective curves and the same object represents the function field of all of its affine patchs.

Furthermore, in the curve case, there is a unique (up to abstract scheme isomorphism) (ordinary) projective non-singular curve $\tilde{C}$ which is birationally equivalent to C (ie there are maps from C to $\tilde{C}$ which are defined at all but finitely many points and whose composite is the identity where defined) $\Leftrightarrow \tilde{C}$ has the same function field (up to isomorphism) as C.

When C is projective, $\tilde{C}$ is just the *normalisation* of C. The normalisation $\tilde{C}$ differs from C only at singular points of the latter and C can be thought of as a singular model of $\tilde{C}$ and, as is usual with curves, most of the functionality provided by the function field and the objects attached - places, divisors etc. - can be more properly thought of as relating to $\tilde{C}$. The first section below treats function fields and some basic functions related to them and their elements.

From now on we assume that the reader is familiar with the notion of divisor, linear equivalence and their relationship with function fields. If not, there are very brief discussions of them at the beginning of each section and also in the introduction to this chapter, but you may also consult standard texts such as [Har77] Chapter II, 6 (especially from page 136) and Chapter IV for a more serious treatment.

For functions working with elements of a function field of a scheme and the scheme itself see Section 112.6.

114.8.1 Function Fields

For the purposes of this section, function fields are fields of rational functions on a curve C. Let f be an element and p a nonsingular rational point of C. Then one can evaluate f at p and compute the order of a zero or a pole of f at p, an integer which is positive for zeros and negative for poles. This allows points of the curve to be considered as valuations of the function field.

In fact, the proper language for discussing valuations and function fields is that of *places* and *divisors*, which really correspond to points of the projective normalisation $\tilde{C}$ of C and formal sums of these, and they are discussed in later sections. Functions in this section which take a point of a curve as an argument are convenient shorthands for functions taking a place and are only allowed when there is no ambiguity about which place is intended, which is why p is required to be non-singular. Functions which compute the zeros and poles of rational functions properly return divisors, so will be discussed later.

Finally, function fields and divisor groups are cached so that recomputation is avoided. Although it is transparent in practice, it is worth remembering that the function fields and divisor groups are always attached to the projective model of a curve, rather than to any of the affine models. Since these are all tightly related, it doesn't make any difference. The support points of divisors will be returned as points on the projective model since they can quite easily lie at infinity on any particular affine model. For a completely clean treatment, it is possible to work exclusively with the projective model, although it is certainly not necessary. Indeed, for some time the elliptic curve machinery in MAGMA has happily presented affine models of curves together with projective points.

```
FunctionField(C)
```

The function field of the curve C, a field isomorphic to the field of fractions of the coordinate ring of C. It can be assigned generator names using the diamond bracket notation, as in the example below. The function field will only exist when C is integral (reduced and irreducible) and this can be checked directly or by calling the function below if it is in doubt.

```
HasFunctionField(C)
```

```
Curve(F)
```

The curve used to create the function field F, or the projective closure of that curve (if it was affine). The function field is stored on projective curves so that the same field is returned whenever it is called for from any patch of the projective curve.

```
F ! r
```

Coerce the ring element r into the function field F of a scheme. For the coercion to be successful r must be in a ring related to the scheme of F, e.g. the base ring or coordinate ring of (or a field of fractions of) the scheme or one of its affine patches or a subscheme or super scheme.

`ProjectiveFunction(f)`

Return the function f in the function field of a scheme as a function in projective coordinates (as an element in the field of fractions of the coordinate ring of the projective scheme having function field the parent of f).

Example H114E24

After creating a curve in the usual way we make its function field F.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^4 + 2*x*y^2*z + 5*y*z^3);
> F<a,b> := FunctionField(C);
> F;
Function Field of Curve over Rational Field defined by
x^4 + 2*x*y^2*z + 5*y*z^3
> Curve(F);
Curve over Rational Field defined by
x^4 + 2*x*y^2*z + 5*y*z^3
> b^2;
b^2;
```

Once constructed, the function field will be stored with the curve (or its projective closure). Thus the same field will be returned from multiple function calls.

```
> FunctionField(C) eq FunctionField(AffinePatch(C,3));
true
```

`p @ f`

`f(p)`

`Evaluate(f, p)`

The ring element $f(p)$ where f is an element of the function field of the curve on which p is a point. If f has a pole at p the value infinity is returned.

`Expand(f, p)`

Given an element f on a curve C and a place p of C return a series which is the expansion of f at p and the uniformizing element of p.

`Completion(F, p)`

`Precision` RngIntElt *Default :* 20

The completion of the function field F of the curve C at the place p of C and a map from F into its completion.

`Degree(f)`

Given an element f of the function field of a curve, return the degree of f. This is the degree of the map given by f to $\mathbf{P}^1$ or the degree of the numerator and denominator of the principal divisor of f. If f is constant, then 0 is returned.

`Valuation(f, p)`

The degree of the zero of the function f at the point p where f is a function on the curve on which p is a point. A negative value indicates there is a pole of f at p.

`Valuation(p)`

The valuation of the function field of the curve on which p lies centred at the point p. This is a map from the function field to the integers.

`UniformizingParameter(p)`

A rational function on the curve of the nonsingular point p which having valuation 1 at p.

`Module(S)`

`Preimages`	BoolElt	*Default :* `false`
`IsBasis`	BoolElt	*Default :* `false`

Given a sequence S of elements of a function field of a curve C return the module over the base ring of C generated by the elements of S. Also return the map from the module to the function field and a sequence of preimages of the elements of S if `Preimages` is `true`.

If `IsBasis` is `true` then the elements of S will be assumed to be a basis of the module.

`Relations(S)`

`Relations(S, m)`

Given a sequence S of elements of a function field of a curve C return the module over the base ring R of C of R-linear relations between the elements of S.

`Genus(C)`

The genus of the curve C.

`FieldOfGeometricIrreducibility(C)`

Return the algebraic closure of the base ring of C in the function field of C along with the map including the closure in the function field.

`IsAbsolutelyIrreducible(C)`

Returns `true` if the field of geometric irreducibility of the curve C is the base ring of C.

`DimensionOfFieldOfGeometricIrreducibility(C)`

The dimension of the field of geometric irreducibility of the curve C over the base ring of C.

Example H114E25

Having made a curve and its function field we make an element of the function field using its named generators a, b. The function is put into a convenient form which, for this F, ensures that the denominator is a polynomial in a alone.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^4 + 2*x*y^2*z + 5*y*z^3);
> F<a,b> := FunctionField(C);
> f := a/b;
> f;
(-2*a*b - 5)/a^3
```

Now we choose a point of the curve and find that f has a pole there of order 3.

```
> p := C ! [0,0,1];
> Evaluate(f,p);
Infinity
> Valuation(f,p);
-3
```

Computing the valuations of the generators we notice that a is a uniformising parameter at p — indeed, it is the parameter automatically returned. Clearly the valuation of $f = a/b$ at p should be $1 - 4 = -3$ as computed in the previous line.

```
> vp := Valuation(p);
> vp(a), vp(b);
1 4
> UniformizingParameter(p);
a
```

`GapNumbers(C)`

The gap numbers of the curve C.

`WronskianOrders(C)`

The Wronskian orders of the curve C.

`NumberOfPlacesOfDegreeOverExactConstantField(C, m)`

`NumberOfPlacesDegECF(C, m)`

The number of places of degree m of the curve C defined over a finite field. Contrary to the `Degree` function the degree is here taken over the field of geometric irreducibility.

`NumberOfPlacesOfDegreeOneOverExactConstantField(C)`

`NumberOfPlacesOfDegreeOneECF(C)`

The number of places of degree one of the curve C defined over a finite field. Contrary to the `Degree()` function the degree is here taken over the field of geometric irreducibility.

`NumberOfPlacesOfDegreeOneOverExactConstantField(C, m)`

`NumberOfPlacesOfDegreeOneECF(C, m)`

The number of places of degree one in the constant field extension of degree m of the curve C. Contrary to the `Degree()` function the degree is here taken over the field of geometric irreducibility.

`NumberOfPlacesOfDegreeOneECFBound(C)`

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(C)`

`NumberOfPlacesOfDegreeOneECFBound(C, m)`

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(C, m)`

An upper bound on the number of places of degree one in the constant field extension of degree m (if given) of the curve C. Contrary to the `Degree` function the degree is here taken over the respective exact constant fields.

`DivisorOfDegreeOne(C)`

Return a divisor of the curve C of degree 1 over its field of geometric irreducibility.

`SerreBound(C)`

`SerreBound(C, m)`

`IharaBound(C)`

`IharaBound(C, m)`

The Serre and Ihara bounds of the number of places of degree 1 over the field of geometric irreducibility of the curve C over the extension of degree m of the base ring of C, which must be a finite field.

`LPolynomial(C)`

`LPolynomial(C, m)`

`ZetaFunction(C)`

`ZetaFunction(C, m)`

The L-polynomial and the ζ function of the curve C over the extension of degree m of the base ring of C, which must be a finite field.

114.8.2 Representations of the Function Field

The function field of a scheme has very little direct functionality. But when the scheme is a curve the function field is isomorphic to an algebraic function field as described in Chapter 42. This isomorphism is used internally in many computations for curves. Although the isomorphic algebraic function field can be retrieved from the function field of the scheme, this should not be necessary during ordinary usage of the curves.

`AlgorithmicFunctionField(F)`

Given the function field F of a curve C, this function returns the background algebraic function field, AF. As this is the object where such calculations as those involving places, divisors and differentials are performed, we refer to it as the algorithmic or arithmetic function field. Since there are curve functions which provide an interface to most of the functionality of this field via C, F and its elements, the user can usually avoid accessing AF directly. However, when it is required, it is also usually necessary to translate between elements of F and AF. A map from F to AF is thus also returned. This map is invertible and its inverse is used to map elements the other way.

`FunctionFieldPlace(p)`
`CurvePlace(C, p)`
`FunctionFieldDivisor(d)`
`CurveDivisor(C, d)`
`FunctionFieldDifferential(d)`
`CurveDifferential(C, d)`

Return the place, divisor or differential of the algebraic function field corresponding to the place, divisor or differential of a curve or convert the place p, divisor or differential d of an algebraic function field into a place, divisor or differential of the curve C.

114.8.3 Differentials

The space of differentials in MAGMA is the vector space of elements df over the function field of a curve, where f is any element of the function field and where the operator d satisfies the usual derivation conditions. This vector space is called the *differential space* and corresponds to the Kähler differentials of [Har77], II.8. Note that the differential space is not explicitly a vector space in MAGMA. Rather, as so often when there are many different structures to be considered, a vector space together with a map to the space of differentials is given. (Of course, basic vector space arithmetic works on the space of differentials.) In fact, this is appropriate: after all, Kähler differentials are merely a model of an object which one might prefer to define by its universal properties.

114.8.3.1 Creation of Differentials

`DifferentialSpace(C)`

The space of differentials of the curve C.

`SpaceOfDifferentialsFirstKind(C)`

`SpaceOfHolomorphicDifferentials(C)`

Given a curve C, this function returns a vector space V and a map from V to the space of differentials of C with image the holomorphic differentials on C.

`BasisOfDifferentialsFirstKind(C)`

`BasisOfHolomorphicDifferentials(C)`

Given a curve C, this function returns a basis for the space of holomorphic differentials of C.

`DifferentialSpace(D)`

Given a divisor D associated with curve C, this function returns a vector space V and a map from V to the space of differentials of the curve C containing the divisor D with image the differentials of $\omega_C(D)$. Colloquially, this refers to the differentials whose zeros are at least the positive (or effective) part of D and whose poles are no worse than the negative part of D.

`DifferentialBasis(D)`

Given a divisor D on a curve, this function returns the basis of the differential space of D.

`Differential(a)`

The exact differential $d(a)$ of the function field element a.

114.8.3.2 Operations on Differentials

The space of differentials admits vector space operations over the function field of the curve. As such, it is one-dimensional so one can even divide two non-zero differentials to recover an element of the function field.

`Identity(S)`

The identity differential of the differential space S of a curve.

`Curve(S)`

The curve for which S is the space of differentials.

`Curve(a)`

The curve to which the differential a belongs.

`f * x` `x * f` `x + y` `- x` `x - y` `x / r` `x / y`

The basic arithmetic in the space of differentials. Thought of as a vector space over the function field, this space is one-dimensional. The final operation uses this fact to return a function field element as the quotient of two differentials.

`S eq T`

Returns `true` if and only if the two spaces of differentials S and T are the same.

`a eq b`

Returns `true` if and only if the differentials a and b are equal.

`a in S`

Returns `true` if and only if a is an element of the differential space S of a curve.

`IsExact(a)`

Returns `true` if and only if a is known to be an exact differential, that is, if it is known to be of the form df. If this is not already known, no further attempt is made to determine that.

`IsZero(a)`

Returns `true` if and only if the differential a is the zero differential.

`Valuation(d, P)`

The valuation of the differential d of a curve at the place P of the same curve.

`Residue(d, P)`

The residue of the differential d of a curve at the place P of the same curve.

`Divisor(d)`

The divisor $(f) + (dx)$ of the differential $d = f dx$ of a curve.

`Module(L)`

`IsBasis`	BoolElt	*Default :* `false`
`PreImages`	BoolElt	*Default :* `false`

Given a sequence L of differentials of a curve C, return the module over the base ring of C generated by the differentials in L as an abstract module and a map from the module into the space of differentials of C.

If the parameter `IsBasis` is set to `true` then the elements in L are assumed to be a basis for the module returned. If `PreImages` is set to `true` then a sequence of the preimages of the basis elements is also returned.

`Relations(L)`

`Relations(L, m)`

Given a sequence L of differentials of a curve C, return the module over the base ring R of C of R-linear relations between the elements of L. If given, the argument m is used to compute a generating system for the relation module such that the corresponding generating system of $\{ \sum_{i=1}^{m} v_i a_i \mid v = (v_i)_i \in V \}$ consists of "small" elements where a_i are the elements of L.

`Cartier(a)`

`Cartier(a, r)`

Given a differential a belonging to a curve C and a positive integer r, this function returns the result of applying the Cartier divisor to a r times (or just once if the argument r is omitted). More precisely, let C be a curve over the perfect field k with function field F, $x \in F$ be a separating variable and $a = g\,dx \in \Omega(C)$ with $g \in F$ be a differential. The Cartier operator is defined by

$$CA(a) = \left(-d^{p-1}g/dx^{p-1}\right)^{1/p} dx.$$

This function computes the r-th iterated application of CA to a.

`CartierRepresentation(C)`

`CartierRepresentation(C, r)`

Given a curve C and a positive integer r, this function determines a row representation matrix for action of the Cartier operator on a basis of the space of holomorphic differentials of C, (applied r times). More precisely, let C be a curve over the perfect field k, $\omega_1, \ldots, \omega_g \in \Omega(C)$ be a basis for the holomorphic differentials and $r \in \mathbf{Z}^{\geq 1}$. Let $M = (\lambda_{i,j})_{i,j} \in k^{g \times g}$ be the matrix such that

$$CA^r(\omega_i) = \sum_{m=1}^{g} \lambda_{i,m}\omega_m$$

for all $1 \leq i \leq g$. This function returns M and $(\omega_1, \ldots, \omega_g)$.

Example H114E26

In this example we create a curve known to have genus 3 (a nonsingular plane quartic). So it should have a three-dimensional space of holomorphic differentials.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^4+y^4+z^4);
> Omega_C,phi := SpaceOfHolomorphicDifferentials(C);
> Omega_C;
KModule of dimension 3 over Rational Field
> F<a,b> := FunctionField(C);
```

```
> phi;
Mapping from: ModFld: Omega_C to Space of differentials of F
```

That is good. Now we make a differential and check whether it is exact (which it obviously is since that's how we made it).

```
> f := a/b;
> df := Differential(f);
> df;
(-a/(b^6 + b^2)) d(b)
> Curve(df) eq C;
true
> IsExact(df);
true
```

114.9 Divisors

We work implicitly on the resolution of a particular, usually singular, model of a curve C that has been referred to as $\tilde{C}$. To handle prime divisors at the singularities properly we use the notion of *places* of the curve and devote the first section below to their construction. Places include the case of prime divisors at points of degree greater than 1, that is, points whose coordinates do not lie in the base ring. Following this are sections on constructions of divisors and their basic arithmetic. It may seem a little strange at first to distinguish places from other divisors, but in practice when doing arithmetic the difference is not noticeable.

The most important invariant associated with a divisor D is its *Riemann–Roch* space, often denoted by $L(D)$ or $H^0(D)$. This is a vector subspace of the function field of a curve. Its computation has an enormous number of applications. One we give as an illustration is the computation of the canonical embedding of C (in the case that C is non-hyperelliptic).

This section, together with Section 114.10, is devoted to MAGMA's facility to work with divisors on curves. A *divisor* on a nonsingular curve C is a formal sum of points $\Sigma n_i p_i$, where each $p_i \in C$ and each n_i is an integer. It is clear that divisors form a group under componentwise addition. This group, and various variants of it, is an important invariant of the curve C. For a singular (but still irreducible) curve, one can make a similar definition in which *points* are replaced by *places*, a notion that makes precise the vague idea that singularities arise in different ways, both by "gluing" nonsingular points together and by "pinching" tangent vectors at a particular point. The sections of this chapter contain very brief discussions which will help to orient the user who already knows something about divisors. For a more complete account one should consult an advanced textbook such as [Har77] Chapter II 6, or [Ful69] Chapter 8.

We start with a description of *prime divisors* or *places*. Then we show how to create divisor groups and divisors in them and go on to explain the basic arithmetic of divisors. All of the functions here are based on equivalent functions which apply to algebraic function fields. All calculations are done in that context using the functionality of Chapter 42.

A translation is made in the background for all functions described here. For information about function fields, their representations and translations see Section 114.8. The translations should not be explicitly needed in the ordinary course of working with curves and their divisors.

The main concern when working with divisors is with questions of linear equivalence. In this respect, one should at least have in mind that the most substantial calculations really make sense on projective curves. However, the functions below allow constructions using an affine curve and its points which are reinterpreted in terms of the projective closure.

Section 114.10 describes those functions which are related to linear equivalence of divisors. A divisor is called *principal* if it is linearly equivalent to the zero divisor. In the case of a curve defined over a finite field, we can compute the class group, that is, the group of divisors modulo principal divisors. In fact, we compute a finitely presented abelian group isomorphic to the class group and a map which transforms elements between the divisor group and the class group.

For any divisor on any curve, there are functions to compute Riemann-Roch spaces and a host of related entities.

114.9.1 Places

A *place* is a point of the resolution of a curve or, equivalently, a valuation of the function field of a curve. It is characterised by a point on the curve and, if that point is singular, some data that distinguishes a single resolved point above it.

114.9.1.1 Sets of Places

`Places(C)`

The set of places of the curve C.

`Curve(P)`

The curve on which the places in the set of places P lie. This will be a projective curve.

`P eq Q`

`P ne Q`

Returns `true` if and only if the sets of places P and Q are (not) equal.

114.9.1.2 Places

There are some explicit methods for constructing places. As we show later, places arise implicitly as components of divisors and this is a common way of getting hold of them.

`Places(C, m)`

A sequence of all places of degree m on C, a curve defined over a finite field, where m is a positive integer.

`HasPlace(C, m)`

`RandomPlace(C, m)`

If a place of degree m exists on the curve C over a finite field, then this returns `true` and a single such place, where m is a positive integer. Otherwise it returns `false`.

`Place(p)`

The place corresponding to the nonsingular point p of some curve.

`Places(p)`

A sequence containing the places corresponding to the point p of some curve.

`Place(C, I)`

Return the place of the curve C defined by the ideal I of the coordinate ring of C.

`WeierstrassPlaces(C)`

The Weierstrass places of the curve C, which are the Weierstrass places of the zero divisor of C.

`Place(Q)`

The place of a curve C determined by the sequence of elements of the sequence Q, which should all be contained in the function field of C.

`Ideal(P)`

Given a place P of a curve C return the prime ideal of the coordinate ring of the ambient of C of coordinate functions which vanish at the place P.

`TwoGenerators(P)`

Return two elements of the function field of P which determine the place P. The sequence containing these two elements can be used as input to `Place` to create a place equal to P.

Example H114E27

In this example we show how to use rational functions to create a place on a curve. This is not directly a very geometric operation. However, it is very useful since a pair of rational functions which determine a place form a very concise description of that place. Thus one often uses this method to recreate a given place on a curve in one step. We illustrate that by first finding a place and later recreating it from rational functions.

```
> P2<x,y,z> := ProjectivePlane(FiniteField(17));
> C := Curve(P2,x^5 + x^2*y^3 - z^5);
> p := C ! [1,0,1];
> Places(p);
[
    Place at (1 : 0 : 1)
]
```

```
> P := $1[1];
> P:Minimal;
Place at (1 : 0 : 1)
> TwoGenerators(P);
$.1 + 16
$.1^2*$.2
```

So now we have a place and some rational functions. As usual, these functions are elements of the function field of the curve C, so to be able to read them conveniently we assign names to that function field.

```
> FC<a,b> := FunctionField(C);
> TwoGenerators(P);
a + 16
a^2*b
```

We can use this sequence to recreate the place P. The real convenience of the first line of code below is that it could be in a different MAGMA session in which only the curve C has been defined together with the names a, b of its function field. (You can confirm this by running the four relevant lines in a separate MAGMA session.) The final line is simply to confirm that we really have created the same place P as we started with.

```
> Place([a+16,a^2*b]);
Place at (1 : 0 : 1)
> Place([a+16,a^2*b]) eq P;
true
> Place([a+16,a*b,a^2*b^2]) eq P;
true
```

Notice that in the final line we create exactly the same place using more than the two elements that `TwoGenerators` returned.

`Zeros(f)`

`Poles(f)`

A sequence of places of the curve C containing the zeros or poles of f where f is an element of the function field of C.

`Zeros(C, f)`

`Poles(C, f)`

A sequence of places of the curve C containing the zeros or poles of f where f is some function on C, i.e. f is coercible into the function field of C.

`CommonZeros(L)`

`CommonZeros(C, L)`

Given a sequence L of elements of the function field of some curve C or a curve C and a sequence L of functions on C, return the zeros which are common to all elements of L as places of C.

Example H114E28

The second argument to the intrinsic `Poles(C,f)` can be either an element of the function field of the curve C or an element of the function field of its ambient space.

```
> A<x,y> := AffineSpace(GF(2),2);
> C := Curve(A,x^8*y^3 + x^3*y^2 + y + 1);
> FA<X,Y> := FunctionField(A);
> FC<a,b> := FunctionField(C);
> Poles(C,X/Y);
[
    Place at (1 : 0 : 0)
]
> Poles(C,a/b);
[
    Place at (1 : 0 : 0)
]
> $1 eq $2;
true
```

In particular, we did not use the ambient coordinates x, y in the arguments.

`p1 + p2` `- p1` `p1 - p2` `k * p`
`p div k` `p mod k` `Quotrem(p1, k)`

`Curve(P)`

The projective curve on which the place P lies.

`RepresentativePoint(P)`

A representative point of the projective model of the curve underlying the place.

`P eq Q`
`P ne Q`

Returns `true` if and only if the two places are (not) the same.

`P in S` `P notin S`

`Valuation(f, P)`

The order of vanishing of the function f on the curve C at the place P of C. A negative value indicates a pole at P.

`Valuation(P)`

The valuation of the function field centred at the place P. This is a map from the function field to the integers.

`Valuation(a, P)`

The valuation of the differential a at the place P.

`Residue(a, P)`

The residue of the differential a at the degree 1 place P.

`UniformizingParameter(P)`

A function on the curve of the place P having valuation 1 at P.

`IsWeierstrassPlace(P)`
`IsWeierstrassPlace(D, P)`

Returns `true` if and only if the place P (which must have degree 1) is a Weierstrass place (of divisor D if given).

`ResidueClassField(P)`

The residue class field of the place P.

`Evaluate(a, P)`

Evaluate the element a in the function field of the curve of the place P, returning an element of the residue class field of P.

`Lift(a, P)`

Lift the element a of the residue class field of the place P (including infinity) to a function on the curve of P.

`Degree(P)`

The degree of the place P of a curve over the base ring of the curve of P.

`GapNumbers(C, P)`
`GapNumbers(P)`

The gap numbers of the curve C at the degree 1 place P.

`Parametrization(C, p)`
`Parametrization(C, p, P)`

Returns a map parametrizing the rational curve C at the rational point p or place p of degree 1. If p is a *singular* point on C, then it must have a unique place above it of degree 1. If P is also given it must be the projective line of dimension 1 as a curve (ie of type `Crv`) and then the domain of the map will be P.

114.9.2 Divisor Group

A curve has an associated group of divisors which is simply the formal abelian group generated by the places of the curve C. Divisors are elements of this group. In other words, divisors are expressions of the form $\Sigma n_i p_i$ where n_i are integers, p_i are places of the curve which one usually assumes to be distinct. Each term np is called a *summand* of d or the *component of d corresponding to p*. The integer n will be called the *coefficient* or *multiplicity* of the summand.

Divisors are created by specifying the curve for which they will a divisor (if that is not clear) and then giving sufficient data to identify precisely the divisor in question. This data could be a list of points or places together with integers, but there are many other creation methods. Divisors are printed as a linear combination of the places which support them, if such a combination is known. However, giving this information can be extremely expensive so often printing simply refers to the curve.

`DivisorGroup(C)`

The group of divisors of the curve C. This curve may be either an affine or projective curve.

`Curve(Div)`

The curve that was used to create the divisor group Div, or its projective model.

`Div1 eq Div2`

`Div1 ne Div2`

Returns `true` if and only the divisor groups $Div1$ and $Div2$ are (not) equal.

114.9.3 Creation of Divisors

`DivisorGroup(D)`

The divisor group in which the divisor D lies.

`Curve(D)`

The (projective) curve on which the divisor D lies.

`Identity(D)`

`Id(D)`

`D ! 0`

The zero divisor of the divisor group D of a curve.

`Div ! p`

`Divisor(p)`

The prime divisor in the divisor group Div of the curve C corresponding to the place or nonsingular point p of some curve C.

`Divisor(D, S)`

`Divisor(C, S)`

`Divisor(S)`

The divisor of the curve C or the curve of the divisor group D described by the factorization sequence S. The sequence should contain tuples of the form `<place,integer>`.

Example H114E29

One can use the intrinsic `Divisor(S)` to reconstruct a divisor from concise data related to it. The intrinsics `Support` and `CanonicalDivisor` are defined below.

```
> P<x,y,z> := ProjectivePlane(FiniteField(17));
> C := Curve(P,x^5 + x^2*y^3 - z^5);
> F<a,b> := FunctionField(C);
> K := CanonicalDivisor(C);
> supp, exps := Support(K);
> Q := [ < RationalFunctions(supp[i]),exps[i] > : i in [1..#supp] ];
> Q;
[
    <[ a, 2*a^2*b^2 + 4*a*b ], 2>,
    <[ a + 16, a^2*b ], 2>,
    <[ a^4 + a^3 + a^2 + a + 1, a^2*b ], 2>,
    <[ 1/a, (a + b)/a ], -2>,
    <[ 1/a, (a^2 + 16*a*b + b^2)/a^2 ], -2>
]
> K;
Divisor 2*Place at (0 : 1 : 0) + 2*Place at (1 : 0 : 1) + 2*Place at
($.1 : 0 : 1) - 2*Place at (16 : 1 : 0) - 2*Place at (16*$.1 + 1 : 1 : 0)
```

Now we can reconstruct the divisor K using this sequence.

```
> Divisor([<Place(f[1]), f[2]> : f in Q]);
Divisor on Curve over GF(17) defined by
x^5 + x^2*y^3 + 16*z^5
> K eq $1;
true
```

`PrincipalDivisor(C, f)`
`PrincipalDivisor(D, f)`
`PrincipalDivisor(f)`
`Divisor(C, f)`
`Divisor(D, f)`
`Divisor(f)`

The principal divisor corresponding to f, that is, the divisor of the curve C of zeros and poles of the function field element f, where C is the curve of the divisor group D if given.

`Divisor(a)`

The divisor of the curve C corresponding to the differential a of C.

`Divisor(C, X)`
`Divisor(D, X)`

The divisor described by intersection of the curve C with the scheme X, (where C is the curve of the divisor group D if the group is given instead of the curve).

`Divisor(C, p, q)`
`Divisor(D, p, q)`

The principal divisor corresponding to the line through points p and q (the tangent line to the curve C there if they coincide) where C is the curve of the divisor group D if given.

`Divisor(C, I)`
`Divisor(D, I)`

The divisor of the curve C defined by the ideal I of the ambient coordinate ring where C is the curve of the divisor group D if given.

`Decomposition(D)`

The decomposition sequence of D as a sequence of tuples of the form `<place, multiplicity>` characterizing the divisor D.

`Support(D)`

The sequence of places in the support of D, followed by their sequence of multiplicities in D.

Example H114E30

A curve, its divisor group and some divisors are created.

```
> P<x,y,z> := ProjectiveSpace(GF(7), 2);
> C := Curve(P,y^2*z - x^3 - x*z^2 - z^3);
> Div := DivisorGroup(C);
> Div;
Group of divisors of Curve over GF(7) defined by
6*x^3 + 6*x*z^2 + y^2*z + 6*z^3
> FP<a,b> := FunctionField(P);
> D := Divisor(C,a);
> D;
Divisor of Curve over GF(7) defined by
6*x^3 + 6*x*z^2 + y^2*z + 6*z^3
> Decomposition(D);
[
    <Place at (0 : 1 : 0), -2>,
    <Place at (0 : 6 : 1), 1>,
    <Place at (0 : 1 : 1), 1>
]
> D;
Divisor -2*Place at (0 : 1 : 0) + 1*Place at (0 : 6 : 1) + 1*Place at (0 : 1 : 1)
```

The support of a divisor is written in the style of the factorization of other objects in MAGMA; compare with the factorization of the integer 84 below. This expression is called the *factorization* of a divisor and provides a method of accessing the individual components.

```
> Factorization(84);
[ <2, 2>, <3, 1>, <7, 1> ]
> Support(D)[2];
Place at (0 : 6 : 1)
```

One can access the point underlying a given place.

```
> p := Support(D)[1];
> p;
Place at (0 : 1 : 0)
> RepresentativePoint(p);
(0 : 1 : 0)
```

`CanonicalDivisor(C)`

A divisor in the canonical divisor class of the curve C.

`RamificationDivisor(C)`

The ramification divisor of the curve C.

114.9.4 Arithmetic of Divisors

`D + E` `- D` `D - E` `n * D` `D div n` `D mod n`

Basic formal arithmetic of divisors; D and E are divisors (or places) and n is an integer.

`Quotrem(D, n)`

The quotient and remainder on dividing the divisor D by the integer n.

`Degree(D)`

The sum of coefficients of the divisor D multiplied by the degrees of the places of the corresponding components.

`IsEffective(D)`
`IsPositive(D)`

Returns `true` if and only if all coefficients of the divisor D are nonnegative.

`Numerator(D)`
`Denominator(D)`

The numerator, respectively denominator, of the divisor D of a curve. The numerator and denominator are both positive divisors such that D is the difference between numerator and denominator.

`SignDecomposition(D)`

The minimal effective divisors A and B such that the equality of divisors $D = A - B$ holds.

Example H114E31

The sign decomposition of the previous example is calculated.

```
> P<x,y,z> := ProjectiveSpace(GF(7),2);
> C := Curve(P,y^2*z - x^3 - x*z^2 - z^3);
> Div := DivisorGroup(C);
> phi := hom< Parent(x/z) -> FP | [FP.1,FP.2,1] >
>             where FP is FunctionField(P);
> D := Divisor(Div,phi(x/z));
> Decomposition(D);
[
    <Place at (0 : 1 : 0), -2>,
    <Place at (0 : 6 : 1), 1>,
    <Place at (0 : 1 : 1), 1>
]
> Decomposition(D div 2);
[
    <Place at (0 : 1 : 0), -1>
```

```
]
> A, B := SignDecomposition(D);
> IsEffective(A);
true
> IsEffective(B);
true
> A - B eq D;
true
```

`d in D` `d notin D`

`D eq E`
`D ne E`

Returns `true` if and only the divisors D and E are (not) equal. Note that this means equality in the group of divisors and is not the same as being linearly equivalent.

`D lt E` `D le E` `D gt E` `D ge E`

`IsZero(D)`

Returns `true` if and only if all coefficients of the divisor D are zero.

`IsCanonical(D)`

Returns `true` if and only if the divisor D is the divisor of a differential, in which case also return a differential realising this.

`GCD(D1, D2)`
`Gcd(D1, D2)`
`GreatestCommonDivisor(D1, D2)`

The greatest common divisor of the divisors $D1$ and $D2$. This is the divisor supported on the places common to the support of both divisors with coefficients the minimum of those occurring in $D1$ and $D2$.

`LCM(D1, D2)`
`Lcm(D1, D2)`
`LeastCommonMultiple(D1, D2)`

The least common multiple of the divisors $D1$ and $D2$. This is the divisor supported on all the places in the supports of $D1$ and $D2$ with coefficients the maximum of those occurring in the input divisors.

Example H114E32

We find that a given divisor is actually a canonical divisor.

```
> P<x,y,z> := ProjectiveSpace(GF(7),2);
> C := Curve(P,y^2*z - x^3 - x*z^2 - z^3);
> Div := DivisorGroup(C);
> phi := hom< Parent(x/z) -> FP | [FP.1,FP.2,1] >
>               where FP is FunctionField(P);
> D := Divisor(Div,phi(x/z));
> IsCanonical(D);
true (($.1) ^ 1 * ($.1^3 + $.1 + 1) ^ -1 * ($.1) ^ 1) d($.1)
```

The printing of the differential in the last line above is not very clear since names have not been assigned, but nonetheless, it can be used as an argument to intrinsics.

```
> _, dd := IsCanonical(D);
> Valuation(dd,Support(D)[1]);
-2
```

114.9.5 Other Operations on Divisors

`Ideal(D)`

Given a divisor D of a curve C, return the ideal of the coordinate ring of the ambient of C of coordinate functions which cuts out D.

`Valuation(D,p)`

`Valuation(D,P)`

The coefficient of the divisor summand of the divisor D corresponding to the point p or place P.

`ComplementaryDivisor(D,p)`

`ComplementaryDivisor(D,P)`

The divisor after removing from the divisor D the component corresponding to the point p or place P.

114.10 Linear Equivalence of Divisors

114.10.1 Linear Equivalence and Class Group

`IsPrincipal(D)`

Returns `true` if and only if the divisor D is the divisor of zeros and poles of some rational function. A rational function which performs that role will also be returned. Recall that any two such functions differ only by a scalar factor.

`IsLinearlyEquivalent(D1,D2)`

Returns `true` if and only if the difference $D1 - D2$ of the two divisor arguments is a principal divisor. In that case return also the rational function giving this equivalence.

`IsHypersurfaceDivisor(D)`

For an effective hypersurface divisor D on an ordinary projective curve C, returns `true` if and only if D is the scheme theoretic intersection of C with a hypersurface H of the ambient projective space. If so, also returns an equation for H and the degree of H.

Example H114E33

We check that an effective canonical divisor on a non-singular degree 4 plane curve is indeed a divisor coming from the intersection of the curve with a hyperplane.

```
> P<x,y,z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P,x^3*y+y^3*z+z^3*x);
> D0 := CanonicalDivisor(C);
> f := Basis(D0)[1];
> D := D0+PrincipalDivisor(f);
> IsEffective(D);
true
> IsHypersurfaceDivisor(D);
true -2/9*x
1
```

`ClassGroup(C)`

The *divisor class group*, or simply *class group* of a curve is the group of divisors modulo principal divisors. If C is a curve defined over a finite field, then this function returns an abelian group isomorphic to its divisor class group, a map of representatives from the class group to the divisor group and the homomorphism from the divisor group onto the class group. The second map has an inverse, so translation between the group and the divisors can be achieved using only this map.

`ClassNumber(C)`

The order of the class group of the curve C.

`GlobalUnitGroup(C)`

The group of global units of the function field of the curve C, that is the multiplicative group of the field of geometric irreducibility of C as an abelian group together with the map into the function field of C.

Example H114E34

We compute the class group of a curve defined over a finite field. The calculation takes a few seconds.

```
> A<x,y> := AffineSpace(GF(2,5),2);
> C := Curve(A,x^7 + x^4*y^3 + x*y^2 + y);
> Genus(C);
3
> Cl, _, phi := ClassGroup(C);
> Cl;
Abelian Group isomorphic to Z/26425 + Z
Defined on 2 generators
Relations:
    26425*Cl.1 = 0
```

We can use the map ϕ to pull elements of the abelian group back to the divisor group. For curves over finite fields, this is one way of constructing interesting divisors.

```
> Div := DivisorGroup(C);
> Div eq Domain(phi);
true
> D := Cl.1 @@ phi;
> D;
Divisor of Curve over GF(2^5) defined by
x^7 + x^4*y^3 + x*y^2 + y
```

The unpleasant printing with the dollar signs is happening because no names have yet been assigned to the projective closure of C. Notice that the printing is rather uninformative. This is because a factorization of d is not yet known and could be an extremely expensive computation.

```
> Decomposition(D);
[
    <Place at (0 : 0 : 1), -3>,
    <Place at ($.1 : $.1^10*$.1^2 + $.1^26*$.1 + $.1^22 : 1), 1>
]
> Degree(D);
0
```

The degree function simply returns the sum of the integer valuations in the factorization. Those valuations can be seen as the second entry of each tuple in the support.

`ClassGroupAbelianInvariants(C)`

The abelian invariants of the curve C.

`ClassGroupPRank(C)`

The p-rank of the class group of C.

`HasseWittInvariant(C)`

The Hasse–Witt invariant of the curve C.

114.10.2 Riemann–Roch Spaces

If D is a divisor on C then colloquially speaking the Riemann–Roch space $L(D)$ is the finite dimensional vector subspace of the function field of C consisting of functions with poles no worse that D (and at least as many zeros as the negative part of D if D is not effective). To be precise, we say that

$$L(D) = \{f \in k(C) \mid \mathrm{div}(f) + D \geq 0\}$$

where $\mathrm{div}(f)$ is the principal divisor of zeros and poles of f and the condition ≥ 0 is simply shorthand to mean that the left-hand side is an effective divisor.

For any divisor on a projective curve defined over a field this vector space is finite dimensional. Its dimension $\ell(D)$ appears in the Riemann–Roch formula

$$\ell(D) - \ell(K_C - D) = \deg(D) + 1 - g$$

where K_C is the canonical divisor and g is the genus of C.

The space of *effective* divisors linearly equivalent to D, the complete linear system of D, is the projectivisation of the Riemann–Roch space $L(D)$. This can be used to create a map from the curve C to a projective space of dimension $\ell(D) - 1$.

`Reduction(D)`

`Reduction(D, A)`

Let D be a divisor. Denote the result of both functions by $\tilde{D}$, r, A and a (for the second function the input A always equals the output A). A has (must have) positive degree and the following holds:

(i) $D = \tilde{D} + rA - (a)$,

(ii) $\tilde{D} \geq 0$ and $\deg(\tilde{D}) < g + \deg(A)$ (over the field of geometric irreducibility),

(iii) $\tilde{D}$ has minimal degree among all such divisors satisfying (i), (ii).

`RiemannRochSpace(D)`

A vector space V and an isomorphism from V to the Riemann–Roch space of D in the function field of the curve on which the divisor D lies.

`Basis(D)`

A sequence containing a basis of the Riemann-Roch space $L(D)$ of the divisor D.

`ShortBasis(D)`

A sequence containing a basis of the Riemann-Roch space $L(D)$ of the divisor D in short form.

`Dimension(D)`

The dimension $\ell(d)$ of the Riemann-Roch space of the divisor D.

`DifferentialSpace(D)`

Returns a vector space V and a map from V to the space of differentials of the curve C containing the divisor D with image the differentials of $\omega_C(D)$. Colloquially, this means the differentials whose zeros are at least the positive (or effective) part of D and whose poles are no worse than the negative part of D.

`DifferentialBasis(D)`

A basis of the space of differentials of the divisor D.

`IndexOfSpeciality(D)`

The index of speciality of the divisor D, that is the dimension $\ell(K_C - D)$ appearing in the Riemann–Roch formula.

`IsSpecial(D)`

Returns `true` if and only if the divisor D is special.

`GapNumbers(D)`
`GapNumbers(D,p)`

The gap numbers of the divisor D, at the place p if included.

`GapNumbers(p)`

The gap numbers of the nonsingular point p.

`WeierstrassPlaces(D)`
`WeierstrassPoints(D)`

A sequence containing the Weierstrass places (or underlying points) of the divisor D.

`WronskianOrders(D)`

The Wronskian orders of the divisor D.

`RamificationDivisor(D)`

The ramification divisor of the divisor D.

`DivisorMap(D)`

`DivisorMap(D,P)`

A map from the curve of the divisor D to the projective space P (which will be created in the background if not given as an argument). The dimension of P must be $\ell(D) - 1$.

`CanonicalMap(C)`

`CanonicalMap(C,P)`

The canonical map from the curve C to the projective space P (which will be created in the background if not given as an argument). This is the map determined by (a basis of the) Riemann–Roch space of the canonical divisor K_C. In particular, the dimension of P must be $\ell(K_C) - 1 = g - 1$.

`CanonicalImage(C, phi)`

`CanonicalImage(C, eqns)`

These functions compute the canonical image of a projective curve C of genus at least 2 much more efficiently than the generic image machinery applied to the canonical map. In the first function, the second argument should be the canonical map and in the alternative it should be a sequence of polynomials defining the canonical map.

A second return value is a boolean which is true if and only if the image is a rational curve or equivalently if and only if C is a hyperelliptic curve. Note that these functions may also be used for computing the rational normal curve image of a genus 0 curve C under the map given by any (non-trivial) complete linear system.

Example H114E35

We first make a curve and compute its genus.

```
> P2<X,Y,Z> := ProjectiveSpace(Rationals(),2);
> C := Curve(P2,X^7 + X^3*Y^2*Z^2 + Z^7);
> Genus(C);
3
```

If C is not hyperelliptic then its canonical map will embed it as a nonsingular quartic curve in the projective plane. We make the canonical map. We even include the plane $P2$ that we have already created as an argument so that it will be set as the codomain of the map.

```
> phi := CanonicalMap(C,P2);
> phi;
Mapping from: Prj: P2 to Prj: P2
with equations :
X^2 X*Z Z^2
> phi(C);
```

```
Curve over Rational Field defined by -X*Z + Y^2
```

That curve is certainly not a plane quartic. Indeed, it is evidently a rational curve, so C must have been hyperelliptic.

```
> D := phi(C);
> Genus(D);
0
```

The bicanonical map will embed C since its genus is strictly bigger than 2.

```
> D := 2 * CanonicalDivisor(C);
> phi2 := DivisorMap(D);
> Dimension(Codomain(phi2));
5
> P5<a,b,c,d,e,f> := Codomain(phi2);
> phi2(C);
Scheme over Rational Field defined by
a^2 + b^2 + e*f
-b*d + c^2
-b*e + c*d
-b*f + d^2
-b*f + c*e
-c*f + d*e
-d*f + e^2
> Dimension(phi2(C));
1
> IsNonsingular(phi2(C));
true
```

If you are familiar with the equations of rational normal curves, you will recognise this as a quadric section of a standard scroll—the cone on the rational normal curve of degree 4—which misses the vertex of the cone. This is exactly what gives the curve its hyperelliptic structure. One could go on to make a ruled surface with a map to $\mathbf{P}^5$ with this scroll as its image and pull back the curve to the ruled surface on which the ruling cuts out the degree 2 linear system of the hyperelliptic curve. This is carried out for a particular trigonal curve later in Section 114.11.1.

114.10.3 Index Calculus

MAGMA contains functionality to compute discrete logarithms in the degree 0 divisor class group of plane curves over finite fields. The algorithm used for this is Diem's version of index calculus [Die06], which looks for relations by considering lines through the points of the factor base. In order to use this algorithm, the group order must be know and given as input.

As is always the case with index calculus, the algorithm consists of two main stages: the sieving stage, during which relations are obtained and stored in a matrix, and the linear algebra stage, during which a non-trivial element of the kernel of this matrix is computed. It is possible to only do the sieving and compute the matrix. For this it is not necessary

to know the group order. This can be used to obtain information on how fast sieving can be done. Generally, the linear algebra stage will be the bottle neck for larger examples.

The running time of the algorithm mainly depends on the degree of the curve. In [Die06] it is explained how one can obtain a model of a given curve with relatively low degree. This can greatly speed up the running time of the algorithm.

The algorithm will not work if the field is too small, as there will not be enough lines to produce relations in that case. One requires that at least $q \geq d!$ for a degree d curve over $GF(q)$.

Elements in the degree 0 class group can be represented by divisors of degree 0. But we also allow divisors of non-zero degree D as input, together with a fixed divisor $D0$ of degree 1. This will be interpreted as representing the divisor class $D - \deg(D)D0$. Note that once $D0$ is fixed, and D is effective of minimal degree, then D is uniquely determined by the divisor class. Starting out with an arbitrary divisor E, this unique D can be computed with the `Reduction(E,D0)` command.

`IndexCalculus(D1, D2, D0, np)`

`IndexCalculus(D1, D2, D0, np, n, rr)`

Compute the discrete logarithm of $D2 - \deg(D2)D0$ with base $D1 - \deg(D1)D0$. The group order np must be given. Optionally, one can also give n as approximate size of the factor base to be used, and rr as the number of required relations.

`IndexCalculusMatrix(D1, D2, D0, n, rr)`

Find the sparse matrix with relations found in the sieving stage. Input is the same as for `IndexCalculus`, except that the group order is not given. Outputs M, pos, fb, Da, Db, a, b, where M is the sparse relation matrix. Da and Db are divisors that split over the factor base, and $Da - \deg(Da)D0$ and $Db - \deg(Db)D0$ are linearly equivalent to $a(D1 - \deg(D1)D0)$ and $b(D2 - \deg(D2)D0)$, respectively. fb is a sequence of points that contains the support of Da, Db and $D0$. pos is a sequence of integers that indicates the position of the points of fb in the factor base. The last two rows of M correspond to the divisors $Da - \deg(Da)D0$ and $Db - \deg(Db)D0$.

`MultiplyDivisor(n, D , D0)`

Effective divisor E of minimal degree such that $E - \deg(E)D0$ is equivalent to $n(D - \deg(\mathrm{D})D0)$.

Example H114E36

In this example we compute a discrete logarithm in the class group of a curve of degree 6. The curve is over $GF(2^{13})$, but it is a base change of a curve over $GF(2)$

```
> A2<x,y>:=AffinePlane(GF(2));
> C1:=ProjectiveClosure(Curve(A2,x^5*y + x*y^2 + y^6 + y + 1));
> L:=LPolynomial(C1);
> Evaluate(L,1);
```

```
752
> K<z>:=CyclotomicField(13);
> np:=Numerator(Norm(Evaluate(L,z)));
> Factorisation(np);
[ <175310448404461045718069548360655837, 1> ]
```

So the class group of $C1$ has order 752 over $GF(2)$, and is has order $752np$ over $GF(2^{13})$, where np is a large prime. Now we create some divisors, and make sure that $D2 - \deg(D2)D0$ is in the subgroup generated by $D1 - \deg(D1)D0$.

```
