Those faces of the compact convex hull of P_N which bound it below in the y direction.

`OuterFaces(N)`

The union of lower faces which aren't inner faces and the faces which bound the compact convex hull of P_N above in the y-direction (ignoring infinite points).

`AllFaces(N)`

The faces of the compact convex hull of P_N.

Example H46E2

Using some of the polygons defined before the different types of faces are illustrated.

```
> Faces(N);
[ <4, 5, 4> ]
> InnerFaces(N);
[ <4, 5, 4> ]
> OuterFaces(N);
[ <0, 1, 0>, <-1, -4, -4>, <-11, -60, -48> ]
> AllFaces(N);
[ <4, 5, 4>, <0, 1, 0>, <-1, -4, -4>, <-11, -60, -48> ]
> Faces(NR);
[ <4, 1, 6>, <2, 1, 4>, <0, 1, 0> ]
> InnerFaces(NR);
[ <4, 1, 6>, <2, 1, 4> ]
> LowerFaces(NR);
[ <4, 1, 6>, <2, 1, 4>, <0, 1, 0> ]
```

For the polynomial over the Puiseux Field it is no coincidence that `InnerFaces` and `Faces` return the same sequences. Similarly, for the polynomial over the local ring `Faces` is defined to be `LowerFaces`. For both, this is the category of faces that gives the most information for the purposes that the polygon is used. It can also be noted that combining `InnerFaces` and `OuterFaces` will give `AllFaces` with no repetitions (though repetitions will occur if the polygon has only one face and this face is an inner face).

`Vertices(N)`

The sequence of vertices of N. The vertices will be listed anticlockwise from the lowest of the leftmost points.

`InnerVertices(N)`

The sequence of vertices which arise as endpoints of inner faces.

`LowerVertices(N)`

The sequence of vertices which arise as endpoints of lower faces.

`OuterVertices(N)`

The sequence of vertices which arise as endpoints of outer faces.

`AllVertices(N)`

The sequence of vertices of the compact convex hull of P_N.

Example H46E3

This example illustrates the types of vertices that can be calculated. Note that the printing of these polygons, created from their defining points, changes as more information is calculated. This would occur in the same manner if faces were being calculated instead of vertices.

```
> InnerVertices(N2);
[ <0, 3>, <2, 0> ]
> N2;
Newton Polygon with vertices {(0, 3), (2, 0)} and defining points {(0, 3), (2,
0), (4, 1)}
> InnerVertices(N6);
[ <1, 4>, <3, 1> ]
> N6;
Newton Polygon with vertices {(1, 4), (3, 1)} and defining points {(1, 4), (1,
6), (2, 4), (2, 7), (3, 1), (4, 5), (4, 7), (5, 2), (5, 9), (6, 1), (6, 6), (7,
7), (7, 9), (8, 4), (8, 6), (8, 8)}
> Vertices(N2);
[ <0, 3>, <2, 0>, <4, 1> ]
> Vertices(N6);
[ <1, 4>, <3, 1>, <6, 1>, <8, 4>, <8, 8>, <7, 9>, <5, 9>, <2, 7>, <1, 6> ]
> AllVertices(N2);
[ <0, 3>, <2, 0>, <4, 1> ]
> N2;
Newton Polygon with vertices {(0, 3), (2, 0), (4, 1)} and defining points {(0,
3), (2, 0), (4, 1)}
> AllVertices(N6);
[ <1, 4>, <3, 1>, <6, 1>, <8, 4>, <8, 8>, <7, 9>, <5, 9>, <2, 7>, <1, 6> ]
> N6;
Newton Polygon with vertices {(1, 4), (3, 1), (6, 1), (8, 4), (8, 8), (7, 9),
(5, 9), (2, 7), (1, 6)} and defining points {(1, 4), (1, 6), (2, 4), (2, 7), (3,
1), (4, 5), (4, 7), (5, 2), (5, 9), (6, 1), (6, 6), (7, 7), (7, 9), (8, 4), (8,
6), (8, 8)}
```

Here `Vertices` has been defined to be `AllVertices`. All the known vertices of the polygon are printed when the polygon is printed. There is some overlap between the inner and outer vertices as is shown below. Every vertex is either an inner vertex or an outer vertex with some being both. Not all defining points are vertices.

```
> OuterVertices(N6);
[ <3, 1>, <6, 1>, <8, 4>, <8, 8>, <7, 9>, <5, 9>, <2, 7>, <1, 6>, <1, 4> ]
> OuterVertices(N2);
[ <2, 0>, <4, 1>, <0, 3> ]
```

`EndVertices(F)`

A sequence containing the two end vertices of the face $F = \langle a, b, c \rangle$.

`FacesContaining(N,p)`

Those faces of the polygon N returned by `Faces` on which the point $p = \langle a, b \rangle$ lies.

Example H46E4

Using some of the example polygons that have been created above, we illustrate the simple use of `EndVertices` and `FacesContaining`.

```
> AN := AllFaces(N);
> AN;
[ <4, 5, 4>, <0, 1, 0>, <-1, -4, -4>, <-11, -60, -48> ]
> A6 := AllFaces(N6);
> A6;
[ <3, 2, 11>, <0, 1, 1>, <-3, 2, -16>, <-1, 0, -8>, <-1, -1, -16>, <0, -1, -9>,
<2, -3, -17>, <1, -1, -5>, <1, 0, 1> ]
> AllVertices(N);
[ <0, 4/5>, <1, 0>, <4, 0>, <3, 1/4> ]
> AllVertices(N6);
[ <1, 4>, <3, 1>, <6, 1>, <8, 4>, <8, 8>, <7, 9>, <5, 9>, <2, 7>, <1, 6> ]
> EndVertices(AN[1]);
[ <0, 4/5>, <1, 0> ]
> EndVertices(AN[4]);
[ <0, 4/5>, <3, 1/4> ]
> EndVertices(A6[1]);
[ <1, 4>, <3, 1> ]
> EndVertices(A6[5]);
[ <7, 9>, <8, 8> ]
> EndVertices(A6[9]);
[ <1, 4>, <1, 6> ]
> FacesContaining(N, <1, 0>);
[ <4, 5, 4> ]
> FacesContaining(N6, <1, 0>);
[]
> FacesContaining(N6, <4, 1>);
[ <0, 1, 1> ]
> FacesContaining(N, <4, 1>);
[]
> FacesContaining(N6, <3, 1>);
[ <3, 2, 11>, <0, 1, 1> ]
```

`GradientVector(F)`

The a and b values of the line describing the face F of the form $a * x + b * y = c$ where a, b and c are integers.

`GradientVectors(N)`

A sequence containing the gradient vectors of the faces of the newton polygon N.

`Weight(F)`

The c value of the line describing the face F of the form $a * x + b * y = c$ where a, b and c are integers.

`Slopes(N)`

The slopes of the faces of the newton polygon N.

`InnerSlopes(N)`

`LowerSlopes(N)`

`AllSlopes(N)`

The slopes of the polygon N corresponding of `InnerFaces`, `LowerFaces` and `AllFaces` respectively.

Example H46E5

In this example `GradientVector` and `Weight` can be seen to be access functions on the components of a face of a polygon.

```
> A := AllFaces(N);
> A;
[ <4, 5, 4>, <0, 1, 0>, <-1, -4, -4>, <-11, -60, -48> ]
> f := A[3];
> GradientVector(f);
<-1, -4>
> Weight(f);
-4
```

The gradient of the face can now be easily computed as shown.

```
> a := GradientVector(f)[1];
> b := GradientVector(f)[2];
> -a/b;
-1/4
```

46.2.3 Tests for Points and Faces

Once more, recall that P_N denotes the finite set of points in the plane used to define the Newton polygon N. Whether or not a point is considered to lie in a polygon depends on what are considered to be its faces. MAGMA always uses the list of faces returned by `Faces(N)` when testing points. Of course, this is not always the case in applications. One must to perform other tests explicitly when there is doubt.

`IsFace(N, F)`

Return `true` if and only if the tuple $F = \langle a, b, c \rangle$ describes a line coinciding with a face of the polygon N as returned by `Faces`.

`IsVertex(N, p)`

Return `true` if and only if the point $p = \langle a, b \rangle$ of the rational plane (given as a tuple) is a vertex of the polygon N as returned by `Vertices`.

`IsInterior(N,p)`

Return `true` if and only if the point $p = \langle a, b \rangle$ given as a tuple lies strictly in the interior of the polygon N.

`IsBoundary(N, p)`

Return `true` if and only if the point $p = \langle a, b \rangle$ given as a tuple lies on the boundary of the polygon N, that is, the point is contained in a face of N.

`IsPoint(N,p)`

Return `true` if and only if the point $p = \langle a, b \rangle$ (given as a tuple) lies on the polygon N.

46.3 Polynomials Associated with Newton Polygons

The polynomial used to define a polygon can be recovered, but more usefully so can those restrictions of that polynomial to parts of the polygon, the so-called face functions in particular.

Note that most of these functions will return an error if N was not defined in terms of a polynomial.

`HasPolynomial(N)`

Return `true` if and only if the polygon N was defined as the Newton polygon of some polynomial.

`Polynomial(N)`

The polynomial used to define the polygon N.

`ParentRing(N)`

The parent ring of the polynomial of the polygon N.

`IsNewtonPolygonOf(N, f)`

Return whether the newton polygon N is defined by the polynomial f.

`FaceFunction(F)`

If the polygon N is defined by a polynomial in two variables f this returns those monomial terms of f whose corresponding Newton points lie on the face F. On the other hand, if N is determined by a univariate polynomial over a series ring, this returns the univariate polynomial supported on the face F.

`IsDegenerate(F)`

Return `true` if the face function along F is not squarefree.

`IsDegenerate(N)`

Return `true` if a face function on some face of N is degenerate.

46.4 Finding Valuations of Roots of Polynomials from Newton Polygons

Newton polygons can be used to find the valuations of roots of the polynomial from which the polygon was created at the prime used in the creation (given implicitly or explicitly). The following functions use Newton polygons to calculate the valuations of the roots of the polynomial paired with the number of roots with that valuation.

`ValuationsOfRoots(f)`

The valuations of the roots of f, where f is a polynomial over a local ring or a series ring.

`ValuationsOfRoots(f, p)`

The valuations of the roots of f with respect to p where p may be either a prime integer, a prime ideal of a number field or a place of a function field.

46.5 Using Newton Polygons to Find Roots of Polynomials over Series Rings

The operations described in this section are relevant for polynomials over series rings. There are two main algorithms involved.

`SetVerbose("Newton", v)`

Set the verbose printing to level v for `PuiseuxExpansion`, `ExpandToPrecision`, `DuvalPuiseuxExpansion`, `Roots` and `ImplicitFunction`. A level of 1 will mean that any partial solutions that could not be expanded to the precision requested will be printed before an error is returned except for `Roots`. The polynomials used in forming extensions will also be printed before the extension is computed. In `Roots`, the algorithm used to compute the expansions will be printed. When Walker's algorithm is being used the current value of the denominator will be printed. For `ImplicitFunction` a warning about a potentially bad value of d will be printed if the value of d given is not divisible by the exponent denominator of some coefficient of f. A level of 2 will print the last polynomials calculated during the newton polygon part of `PuiseuxExpansion` and `DuvalPuiseuxExpansion` and some evaluated polynomials during `ImplicitFunction`.

46.5.1 Operations not associated with Duval's Algorithm

`PuiseuxExpansion(f, n)`

`PreciseRoot`	BoolElt	*Default :* `false`
`TestSquarefree`	BoolElt	*Default :* `true`
`NoExtensions`	BoolElt	*Default :* `false`
`LowerFaces`	BoolElt	*Default :* `true`
`OneRoot`	BoolElt	*Default :* `false`
Verbose	`Newton`	*Maximum :* 2

This function implements the algorithm described in [Wal78].

Return a sequence of partial expansions of the roots of the polynomial f over a series ring as puiseux series. The roots are returned with relative precision at least n/d where d is the least common multiple of exponent denominator for the series expansion and the exponent denominators of the coefficients of the f. An input of $n = 0$ will return the expansions calculated by the newton polygon part of the algorithm and these will be to the precision of what is known. The coefficient ring of the series ring containing the coefficients of f must always be a field and unless extensions are not required it must be able to be extended.

If the coefficient ring of the series ring is a finite field whose characteristic is less than or equal to the degree of the polynomial then the denominators computed in the newton polygon part of the algorithm may not be bounded and the function will return an error. However, it is possible for some polynomials that the denominators will be bounded. This is stated by [Gri95], pg 269 – 272.

Care needs to be taken with polynomials whose coefficients have low precision. The algorithm must extract from f the squarefree part and in doing so lose even more precision. The result is that the algorithm may not have enough precision to calculate the expansions correctly. A solution is to set `TestSquarefree` to `false` if the polynomial is known to have no multiple roots. However this will not solve all precision problems and the answer is only as good as the precision allows it to be.

If `PreciseRoot` is set to `true` then the partial expansions to be returned are checked and if any are exact roots of f they are returned with full precision. If `NoExtensions` is set to `true` then expansions are found within the puiseux series ring only. By default, the coefficient ring of the series ring is extended to find all the partial expansions. If `LowerFaces` is set to `false` then expansions with negative valuations will not be found. If `OneRoot` is set to true then representatives of conjugate roots only will be found instead of each of the roots individually.

Note that it may useful to define the polynomial over an algebraically closed field (via `AlgebraicClosure`), so that all roots may be found.

`ExpandToPrecision(f, c, n)`

`PreciseRoot`	BoolElt	*Default :* `false`
`TestSquarefree`	BoolElt	*Default :* `true`
Verbose	`Newton`	*Maximum :* 2

Given a polynomial f over a Puiseux series ring and a partial root c of that polynomial (found by `PuiseuxExpansion` for example) continue to expand that root until it has relative precision n/d where d is the least common multiple of the exponent denominator of c and the exponent denominators of the coefficients of f. If c is given to greater precision (or length greater than n if its precision is infinite), the relative precision of c is reduced to n/d. An error results if c is not a partial expansion to precision n/d. If `PreciseRoot` is true then the partial expansion to be returned is checked and if it is an exact root of f it is returned with full precision. All input is checked for being an exact root regardless. If `TestSquarefree` is `false` the polynomial will not be made squarefree. This may avoid some loss of precision but may result in some unique partial roots not being recognized as unique partial roots and as such they cannot be expanded.

An error may result if c is a partial root of f but the exponent denominator of the full expansion is greater than that of c. Therefore for c to be expanded it must have the same denominator as the expansion it is part of. This will rarely be an issue for those partial expansions resulting from `PusieuxExpansion` which did not encounter problems with precision in the newton polygon part since the algorithm for this will find at least as much of the expansion as necessary to compute the exponent denominator.

`ImplicitFunction(f, d, n)`

Verbose	`Newton`	*Maximum :* 2

Return a root of the polynomial f over a series ring. The input d is the denominator (or a multiple of) the exponent denominator of the root. The root is given to absolute precision n/d. The evaluation of f at zero (polynomial) evaluated at zero (series) must be zero but that of its derivative must be nonzero.

Example H46E6

This example illustrates the joint use of `PuiseuxExpansion` and `ExpandToPrecision` which can be used together to gain and improve partial roots of a polynomial. The use of `ExpandToPrecision` following `PuiseuxExpansion` avoids the recalculation of information already known.

```
> P<x> := PuiseuxSeriesRing(Rationals());
> R<y> := PolynomialRing(P);
> f := y^3 + 2*x^-1*y^2 + 1*x^-2*y + 2*x;
> c := PuiseuxExpansion(f, 0);
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> Q<q> := PolynomialRing(A);
> c;
```

```
[
    -2*a^3 + O(a^4),
    -a^-1 + n*a + O(a^2),
    -a^-1 - n*a + O(a^2)
]
> [ExpandToPrecision(f, c[i], 10) : i in [1 .. #c]];
[
    -2*a^3 - 8*a^7 - 56*a^11 + O(a^13),
    -a^-1 + n*a + a^3 + 5/4*n*a^5 + 4*a^7 + O(a^9),
    -a^-1 - n*a + a^3 - 5/4*n*a^5 + 4*a^7 + O(a^9)
]
```

The same results could have been gained using `PuiseuxExpansion` with the required precision in the first place.

```
> c := PuiseuxExpansion(f, 10);
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> c;
[
    -2*a^3 - 8*a^7 - 56*a^11 + O(a^13),
    -a^-1 + n*a + a^3 + 5/4*n*a^5 + 4*a^7 + O(a^9),
    -a^-1 - n*a + a^3 - 5/4*n*a^5 + 4*a^7 + O(a^9)
]
```

However, asking for more precision requires time so that if it is not necessary the extra calculation can be avoided and if more precision happens to be required then it can be gained without recalculation. `ExpandToPrecision` is also called on only one root so that if only one expansion is required using `PusieuxExpansion` and then `ExpandToPrecision` will not calculate any unnecessary information.

```
> time c := PuiseuxExpansion(f, 100);
Time: 2.810
> time c := PuiseuxExpansion(f, 10);
Time: 0.060
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> time ExpandToPrecision(f, c[1], 100);
-2*a^3 - 8*a^7 - 56*a^11 - 480*a^15 - 4576*a^19 - 46592*a^23 -
    496128*a^27 - 5457408*a^31 - 61529600*a^35 - 707266560*a^39 -
    8257566720*a^43 - 97654702080*a^47 - 1167349284864*a^51 -
    14082308833280*a^55 - 171221451538432*a^59 -
    2096081963188224*a^63 - 25814314231136256*a^67 -
    319605795242639360*a^71 - 3975750610806374400*a^75 -
    49666299938073477120*a^79 - 622818862289639178240*a^83 -
    7837247078959687925760*a^87 - 98931046460491133091840*a^91 -
    1252424949872174982758400*a^95 - 158971065678060806587023 36*a^99
    + O(a^103)
```

```
Time: 0.410
```

`IsPartialRoot(f, c)`

Return `true` if the series c can be expanded to at least one root of the polynomial f.

`IsUniquePartialRoot(f, c)`

`TestSquarefree` BoolElt *Default :* `true`

Return `true` if the series c can be expanded to exactly one distinct root of the polynomial f. By default f will have multiple factors removed to allow partial expansions of multiple roots to be recognized as being unique. If `TestSquarefree` is set to `false` then f will be taken as given which may avoid errors due to lost precision but may not pick partial expansions of multiple roots as being unique and as such is best used when f is squarefree or the expansion is known to be of a single root.

Example H46E7

The above 2 functions can be used to reduce the occurrence of errors from `ExpandToPrecision` by checking that the input can be expanded. Errors resulting from a lack of precision which means that the expansion cannot be calculated to the requested precision are the only errors that cannot be removed. Only unique partial roots can be expanded. If a partial root is not unique then calling `PuiseuxExpansion` will provide several further partial expansions of the partial root that will themselves be unique and so can be used to calculate several expansions of the original.

```
> P<x> := PuiseuxSeriesRing(Rationals());
> R<y> := PolynomialRing(P);
> f := (y^2 - x^3)^2 - y*x^6;
> IsPartialRoot(f, x^(3/2));
true
>  ExpandToPrecision(f, x^(3/2), 10);
>> ExpandToPrecision(f, x^(3/2), 10);
                    ^
Runtime error in 'ExpandToPrecision': Element is not a unique partial
root of the polynomial
> IsUniquePartialRoot(f, x^(3/2));
false
> c := PuiseuxExpansion(f, 0);
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> Q<q> := PolynomialRing(A);
> c;
[
    a^(3/2) + 1/2*a^(9/4) + O(a^(5/2)),
    a^(3/2) - 1/2*a^(9/4) + O(a^(5/2)),
    -a^(3/2) + 1/2*n*a^(9/4) + O(a^(5/2)),
```

```
    -a^(3/2) - 1/2*n*a^(9/4) + O(a^(5/2))
]
> IsUniquePartialRoot(f, x^(3/2) + 1/2*x^(9/4));
true
> ExpandToPrecision(f, x^(3/2) + 1/2*x^(9/4), 10);
x^(3/2) + 1/2*x^(9/4) - 1/64*x^(15/4) + O(x^4)
>  ExpandToPrecision(f, x^(3/2) + x^2, 30);
>> ExpandToPrecision(f, x^(3/2) + x^2, 30);
                     ^
Runtime error in 'ExpandToPrecision': Element is not a partial root of
the polynomial
> IsPartialRoot(f, x^(3/2) + x^2);
false
```

So if `IsPartialRoot` returns `false` then no expansion can be made. If `IsUniquePartialRoot` returns `false` (but `IsPartialRoot` returns `true`) then several expansions can be made after calling `PuiseuxExpansion`.

`PuiseuxExponents(p)`

Given a series expansion return the sequence of exponents $[a/b]$ of the non zero terms of the series p up to and including the first one where b is the global denominator for the series.

`PuiseuxExponentsCommon(p, q)`

Given two series return the sequence of exponents $[a/b]$ of the non zero initial terms of the series p and q which are equal up to but not including the first unequal terms.

Example H46E8

This example illustrates how `PuiseuxExponents` and `PuiseuxExponentsCommon` can be used on output from `PusieuxExpansion`. (Similar can be done with related functions and general series).

```
> P<x> := PuiseuxSeriesRing(FiniteField(5, 3));
> R<y> := PolynomialRing(P);
> f := (1+x)*y^4 - x^(-1/3)*y^2 + y + x^(1/2);
> time c := PuiseuxExpansion(f, 5);
Time: 0.030
> c;
[
    4*x^(1/2) + x^(2/3) + 3*x^(5/6) + x^(7/6) + O(x^(4/3)),
    x^(1/3) + x^(1/2) + 4*x^(2/3) + 2*x^(5/6) + O(x^(7/6)),
    4*x^(-1/6) + 2*x^(1/3) + O(x^(2/3)),
    x^(-1/6) + 2*x^(1/3) + O(x^(2/3))
]
> PuiseuxExponents(c[1]);
[ 1/2, 2/3, 5/6 ]
> PuiseuxExponents(c[3]);
```

```
[ -1/6 ]
> P<x> := PuiseuxSeriesRing(FiniteField(5, 3));
> R<y> := PolynomialRing(P);
> f := ((y^2 - x^3)^2 - y*x^6)^2 - y*x^15;
> c := PuiseuxExpansion(f, 0);
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> Q<q> := PolynomialRing(A);
> c;
[
    4*a^(3/2) + 4*a^(9/4) + 4*a^3 + O(a^(13/4)),
    4*a^(3/2) + 4*a^(9/4) + a^3 + O(a^(13/4)),
    4*a^(3/2) + a^(9/4) + 4*a^3 + O(a^(13/4)),
    4*a^(3/2) + a^(9/4) + a^3 + O(a^(13/4)),
    a^(3/2) + 3*a^(9/4) + 4*a^3 + O(a^(13/4)),
    a^(3/2) + 3*a^(9/4) + a^3 + O(a^(13/4)),
    a^(3/2) + 2*a^(9/4) + 4*a^3 + O(a^(13/4)),
    a^(3/2) + 2*a^(9/4) + a^3 + O(a^(13/4))
]
> PuiseuxExponentsCommon(c[1], c[1]);
[ 3/2, 9/4, 3 ]
> PuiseuxExponentsCommon(c[1], c[2]);
[ 3/2, 9/4 ]
> PuiseuxExponentsCommon(c[1], c[3]);
[ 3/2 ]
> PuiseuxExponentsCommon(c[1], c[8]);
[]
```

46.5.2 Operations associated with Duval's algorithm

The following functions have a similar use to those given above but implement a different algorithm, namely that of [Duv89] which is faster and can handle larger degree polynomials. However, it can only be used with polynomials which are essentially over a laurent series ring and the coefficient ring of that laurent series ring has either characteristic zero or characteristic greater than the degrees of the squarefree factors of the polynomial.

`DuvalPuiseuxExpansion(f, n)`

`Version`	MonStgElt	*Default :* "*Rational*"
`TestSquarefree`	BoolElt	*Default :* `true`
`NoExtensions`	BoolElt	*Default :* `false`
`LowerFaces`	BoolElt	*Default :* `true`
`OneRoot`	BoolElt	*Default :* `false`
Verbose	`Newton`	*Maximum :* 2

A sequence of parametrizations of puiseux expansions of roots of f, as puiseux series, where f is a polynomial over a series ring. The expansions will have at least n non zero terms (unless the expansion is finite and has less than n non zero terms), with more than n occurring only if n is less than the number of terms returned by the newton polygon part of the algorithm. The coefficients of f must have exponent denominator 1.

This algorithm is faster than that given by Walker and implemented in `PuiseuxExpansion`, since it doesn't calculate non zero terms explicitly and doesn't make all necessary extensions during the algorithm leaving some to be made when the series is computed from the parametrizations.

If f has coefficients with finite precision then the expansions can only be computed to as many non zero terms as can be known for that expansion. After this limit has been reached, an error results since the next non zero term is not known. If f has roots with finite puiseux expansions then if n is greater than the number of non zero terms in the expansion the expansion is returned with infinite precision.

If `Version` is set to `"Classical"` then the (slower) classical branch of the algorithm will be run which makes all extensions necessary for the computation of the expansions. It is still faster than `PusieuxExpansion` since it does not iterate through and calculate zero terms but will encounter the same problems that `PuiseuxExpansion` does with field extensions over the rationals. The classical version will return as many parametrizations as there are expansions and some of these parametrizations will give the same set of expansions.

If `NoExtensions` is set to `true` then only the expansions which lie in the puiseux series ring corresponding to the coefficient ring of f are calculated. Otherwise, all the expansions of roots of f are calculated regardless of where they lie. `LowerFaces` and `OneRoot` work as for `PuiseuxExpansion`.

This algorithm works with the squarefree part of f only. If any coefficient of f has low precision then this step may make it impossible for any information about the expansions to be gained due to a loss of further precision. A way around this is to set `TestSquarefree` to `false` if the polynomial is known to be squarefree. This may result in some information being returned but such information is only as good as the precision it was allowed.

`ParametrizationToPuiseux(T)`

The series that satisfy the parametrization `T`. These are found by evaluating `T[2]` at t where `T[1]` $= \lambda t^e$.

`PuiseuxToParametrization(S)`

A parametrization of the series S. It is the simplest one which takes the denominator out of S and makes it the exponent of the first entry in the parametrization.

Example H46E9

This example illustrates the use of `DuvalPuiseuxExpansion` and `ParametrizationToPuiseux` to gain the information given by `PuiseuxExpansion` and also compares the performance of the two

algorithms. It also highlights some of the anomalies that may be encountered due to precision concerns.

```
> P<x> := PuiseuxSeriesRing(Rationals());
> R<y> := PolynomialRing(P);
> f := (y^2 - x^3)^2 - y*x^6;
> time D := DuvalPuiseuxExpansion(f, 0);
Time: 0.000
> D;
[
    <16*x^4, 64*x^6 + 256*x^9 + O(x^10)>
]
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.060
> A<a> := Parent(P[1]);
> N<n> := CoefficientRing(A);
> P;
[
    a^(3/2) + 1/2*a^(9/4) + O(a^(5/2)),
    a^(3/2) - 1/2*a^(9/4) + O(a^(5/2)),
    -a^(3/2) + 1/2*n*a^(9/4) + O(a^(5/2)),
    -a^(3/2) - 1/2*n*a^(9/4) + O(a^(5/2))
]
> time c := PuiseuxExpansion(f, 0);
Time: 0.050
```

Here it can be seen that the newton polygon part of the algorithm is substantially faster using Duval's method, though the converting of the parametrization to a series is not as fast. Asking for more terms shows this more substantially.

```
> time D := DuvalPuiseuxExpansion(f, 10);
Time: 0.020
> D;
[
    <16*x^4, 64*x^6 + 256*x^9 - 512*x^15 + 2048*x^18 - 4608*x^21 + 56320*x^27 -
        294912*x^30 + 792064*x^33 - 12082176*x^39 + 68157440*x^42 + O(x^43)>
]
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.129
> time c := PuiseuxExpansion(f, 10);
Time: 0.100
> A<a> := Parent(c[1]);
> N<n> := CoefficientRing(A);
> c;
[
    a^(3/2) + 1/2*a^(9/4) - 1/64*a^(15/4) + O(a^4),
    a^(3/2) - 1/2*a^(9/4) + 1/64*a^(15/4) + O(a^4),
    -a^(3/2) + 1/2*n*a^(9/4) + 1/64*n*a^(15/4) + O(a^4),
    -a^(3/2) - 1/2*n*a^(9/4) - 1/64*n*a^(15/4) + O(a^4)
```

```
]
> A<a> := Parent(P[1]);
> N<n> := CoefficientRing(A);
> P;
[
    a^(3/2) + 1/2*a^(9/4) - 1/64*a^(15/4) + 1/128*a^(9/2) - 9/4096*a^(21/4) +
        55/131072*a^(27/4) - 9/32768*a^(15/2) + 1547/16777216*a^(33/4) -
        11799/536870912*a^(39/4) + 65/4194304*a^(21/2) + O(a^(43/4)),
    a^(3/2) - 1/2*a^(9/4) + 1/64*a^(15/4) + 1/128*a^(9/2) + 9/4096*a^(21/4) -
        55/131072*a^(27/4) - 9/32768*a^(15/2) - 1547/16777216*a^(33/4) +
        11799/536870912*a^(39/4) + 65/4194304*a^(21/2) + O(a^(43/4)),
    -a^(3/2) + 1/2*n*a^(9/4) + 1/64*n*a^(15/4) - 1/128*a^(9/2) -
        9/4096*n*a^(21/4) - 55/131072*n*a^(27/4) + 9/32768*a^(15/2) +
        1547/16777216*n*a^(33/4) + 11799/536870912*n*a^(39/4) -
        65/4194304*a^(21/2) + O(a^(43/4)),
    -a^(3/2) - 1/2*n*a^(9/4) - 1/64*n*a^(15/4) - 1/128*a^(9/2) +
        9/4096*n*a^(21/4) + 55/131072*n*a^(27/4) + 9/32768*a^(15/2) -
        1547/16777216*n*a^(33/4) - 11799/536870912*n*a^(39/4) -
        65/4194304*a^(21/2) + O(a^(43/4))
]
```

It can be seen that the computation of the information is a lot faster using Duval's method. It is only the cosmetic of converting this information into series that could make this algorithm seem slow. But also note that there is much greater information given by Duval's algorithm. The equivalent information is given below.

```
> time D := DuvalPuiseuxExpansion(f, 3);
Time: 0.009
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.049
> A<a> := Parent(P[1]);
> N<n> := CoefficientRing(A);
> P;
[
    a^(3/2) + 1/2*a^(9/4) - 1/64*a^(15/4) + O(a^4),
    a^(3/2) - 1/2*a^(9/4) + 1/64*a^(15/4) + O(a^4),
    -a^(3/2) + 1/2*n*a^(9/4) + 1/64*n*a^(15/4) + O(a^4),
    -a^(3/2) - 1/2*n*a^(9/4) - 1/64*n*a^(15/4) + O(a^4)
]
```

One thing that may be taken for granted from `PuiseuxExpansion` is that all the expansions lie in the same puiseux series ring. However, for `DuvalPuiseuxExpansion` this may not be the case. It will always be true that each of the parametrizations will lie in the same puiseux series ring but series resulting from different parametrizations may not. This occurs since some extensions are left to the stage of calculating the series from the parametrization to be made and for different parametrizations these extensions may be different.

```
> f := (-x^3 + x^4) - 2*x^2*y - x*y^2 + 2*x*y^4 + y^5;
> time D := DuvalPuiseuxExpansion(f, 0);
Time: 0.010
```

```
> D;
[
    <x^2, -x^2 - x^3 + O(x^4)>,
    <x^3, x + O(x^2)>
]
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.000
> P;
[
    -x - x^(3/2) + O(x^2),
    -x + x^(3/2) + O(x^2)
]
> Parent(P[1]);
Puiseux series field in x over Rational Field

Time: 0.030
> A<a> := Parent(P[1]);
> N<n> := CoefficientRing(A);
> P;
[
    a^(1/3) + O(a^(2/3)),
    n*a^(1/3) + O(a^(2/3)),
    (-n - 1)*a^(1/3) + O(a^(2/3))
]
> Parent(P[1]);
Puiseux series field in a over N
> N;
Number Field with defining polynomial $.1^2 + $.1 + 1 over the Rational Field
```

`DuvalPuiseuxExpansion` reacts differently to `PuiseuxExpansion` when given input which has finite expansions either due to finite precision or exact roots. These differences are shown below and are due to the fact that `DuvalPuiseuxExpansion` always looks for the next non zero term in an expansion whereas `PuiseuxExpansion` will calculate zero terms.

```
> f := y - x^3 - x^7 - x^76 + O(x^200);
> D := DuvalPuiseuxExpansion(f, 0);
> D;
[
    <x, x^3 + O(x^4)>
]
> D := DuvalPuiseuxExpansion(f, 3);
> D;
[
    <x, x^3 + x^7 + x^76 + O(x^77)>
]
>  D := DuvalPuiseuxExpansion(f, 4);
>> D := DuvalPuiseuxExpansion(f, 4);
                             ^
Runtime error in 'DuvalPuiseuxExpansion': Insufficient precision to calculate to
```

```
requested precision
> c := PuiseuxExpansion(f, 197);
> c;
[
    x^3 + x^7 + x^76 + O(x^200)
]
>  c := PuiseuxExpansion(f, 200);
>> c := PuiseuxExpansion(f, 200);
                         ^
Runtime error in 'PuiseuxExpansion': Insufficient precision to calculate to
requested precision
> f := y - x^3 - x^7 - x^76;
> D := DuvalPuiseuxExpansion(f, 0);
> D;
[
    <x, x^3 + O(x^4)>
]
> D := DuvalPuiseuxExpansion(f, 3);
> D;
[
    <x, x^3 + x^7 + x^76 + O(x^77)>
]
> D := DuvalPuiseuxExpansion(f, 4);
> D;
[
    <x, x^3 + x^7 + x^76>
]
> c := PuiseuxExpansion(f, 10);
> c;
[
    x^3 + x^7 + O(x^13)
]
> c := PuiseuxExpansion(f, 100);
> c;
[
    x^3 + x^7 + x^76 + O(x^103)
]
> c := PuiseuxExpansion(f, 200);
> c;
[
    x^3 + x^7 + x^76 + O(x^203)
]
> c := PuiseuxExpansion(f, 200 : PreciseRoot := true);
> c;
[
    x^3 + x^7 + x^76
```

```
]
```

The two methods can be combined. Given a series there is no way that Duval's REGULAR algorithm can be used to further the precision of an expansion. But `ExpandToPrecision` can be used to gain the extra precision. Using the REGULAR algorithm would be preferable since it is faster but this is not possible for the type of input that is available. This is explored in the case of our first example.

```
> f := (y^2 - x^3)^2 - y*x^6;
> time D := DuvalPuiseuxExpansion(f, 0);
Time: 0.009
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.050
> A<a> := Parent(P[1]);
> N<n> := CoefficientRing(A);
> P;
[
    a^(3/2) + 1/2*a^(9/4) + O(a^(5/2)),
    a^(3/2) - 1/2*a^(9/4) + O(a^(5/2)),
    -a^(3/2) + 1/2*n*a^(9/4) + O(a^(5/2)),
    -a^(3/2) - 1/2*n*a^(9/4) + O(a^(5/2))
]
> time ExpandToPrecision(f, P[1], 20);
a^(3/2) + 1/2*a^(9/4) - 1/64*a^(15/4) + 1/128*a^(9/2) - 9/4096*a^(21/4) +
    O(a^(13/2))
Time: 0.070
> time D := DuvalPuiseuxExpansion(f, 5);
Time: 0.010
> time P := ParametrizationToPuiseux(D[1]);
Time: 0.059
```

It can be seen that using `ExpandToPrecision` is slower even than rerunning Duval's algorithm from the beginning. Even more so when it is remembered that running Duval's algorithm with the extra precision will give parametrizations of all the expansions of the roots of f and not just one expansion. This seems to still be the case when larger examples are considered so that if more terms of an expansion are required it is probably best to start from the beginning asking for these extra terms.

```
> time p1 := ExpandToPrecision(f, P[1], 50);
> A<a> := Parent(p1);
> N<n> := CoefficientRing(A);
> p1;
a^(3/2) + 1/2*a^(9/4) - 1/64*a^(15/4) + 1/128*a^(9/2) - 9/4096*a^(21/4) +
    55/131072*a^(27/4) - 9/32768*a^(15/2) + 1547/16777216*a^(33/4) -
    11799/536870912*a^(39/4) + 65/4194304*a^(21/2) - 189805/34359738368*a^(45/4)
    + 1584999/1099511627776*a^(51/4) - 2261/2147483648*a^(27/2) + O(a^14)
Time: 0.439
> time D := DuvalPuiseuxExpansion(f, 13);
Time: 0.009
> time P := ParametrizationToPuiseux(D[1]);
```

```
Time: 0.200
```

46.5.3 Roots of Polynomials

This section describes two similar functions that can be used for finding roots of polynomials over series rings in a similar way to finding roots of polynomials over any other ring for which roots can be computed in MAGMA.

```
Roots(f)
```

```
Roots(f, n)
```

Verbose `Newton` *Maximum :* 2

Find the roots of the polynomial f which lie in the coefficient ring of f. The first form of this function can be used on any polynomial over any ring for which MAGMA can compute roots. Since precision is an issue in series rings and some roots may have infinite expansions, the second version of this function which is specific to series rings allows a lower bound for the precision to which these roots will be known to be specified. The first computes the roots to at least the default precision of the ring if that ring has infinite precision otherwise it computes them to at least the precision of the ring. The first version will be enough when all the coefficients of the polynomial have infinite precision. The second version may be required when a precision other than that assumed by the first is sought which may be due to the impossibility of computing the roots to such a high precision as the default. The precision is relative to the least common multiple of the exponent denominators of the coefficients of f and the exponent denominator of the root. Roots which are known to be different but are identical to the precision specified will be returned as two distinct roots.

Duval's algorithm as implemented in `DuvalPuiseuxExpansion` will usually be used. Walker's algorithm as implemented in `PuiseuxExpansion` will be used if the polynomial has coefficients involving fractional powers or the characteristic of the coefficient ring of the series ring is less than the degree of a squarefree factor.

If Walker's algorithm is used and the characteristic of the field is less than the degree of the polynomial then the computation may not finish (see remarks under `PuiseuxExpansion`) and control will return to the user when interrupted.

If verbose printing of partial output that doesn't have enough precision is required the functions `PuiseuxExpansion` and `DuvalPuiseuxExpansion` should be used with the appropriate precision. `Roots` also requires that there is enough precision in the roots so that the multiplicities can be calculated correctly and the parts of the roots that are returned are distinct. Therefore an error will be given if there is not enough precision to calculate the part of the root that results from the newton polygon part of the algorithm and the root is not known to be a single root since the multiplicity may not be able to be calculated correctly. Information at such a low precision can be gained correctly by using the `PuiseuxExpansion` functions and determining the multiplicities manually.

`HasRoot(f)`

Return `true` if the polynomial f has a root in its coefficient ring and that root can be found to the fixed or default precision of the ring as applicable. A root is also returned in this case. If f is irreducible over its coefficient ring then return `false`.

Example H46E10

Below are some examples of the use of the `Roots` function.

```
> SetVerbose("Newton", 1);
> P<x> := PuiseuxSeriesRing(Rationals());
> R<y> := PolynomialRing(P);
> f := y^3 + 2*x^-1*y^2 + 1*x^-2*y + 2*x;
> Roots(f);
DUVAL :
[
    <-2*x^3 - 8*x^7 - 56*x^11 - 480*x^15 - 4576*x^19 + O(x^23), 1>
]
> f := f^2;
> Roots(f);
DUVAL :
[
   <-2*x^3 - 8*x^7 - 56*x^11 - 480*x^15 - 4576*x^19 + O(x^23), 2>
]
> f := y^3 + 2*x^-1*y^2 + 1*x^-2*y + 2*x;
> f +:= O(x^20)*(y^3 + y^2 + y + 1);
> f;
(1 + O(x^20))*y^3 + (2*x^-1 + O(x^20))*y^2 + (x^-2 + O(x^20))*y + 2*x + O(x^20)
>  Roots(f);
DUVAL :
>> Roots(f);
        ^
Runtime error in 'Roots': Roots not calculable to default precision
> Roots(f, 10);
DUVAL :
[
   <-2*x^3 - 8*x^7 - 56*x^11 + O(x^13), 1>
]
> f := f^2;
> f;
(1 + O(x^20))*y^6 + (4*x^-1 + O(x^19))*y^5 + (6*x^-2 + O(x^18))*y^4 + (4*x^-3 +
   4*x + O(x^18))*y^3 + (x^-4 + 8 + O(x^18))*y^2 + (4*x^-1 + O(x^18))*y + 4*x^2
   + O(x^21)
> Roots(f, 10);
DUVAL :
[
   <-2*x^3 - 8*x^7 - 56*x^11 + O(x^13), 2>
]
```

```
> f := (y - x^(1/4))*(y - x^(1/3));
> Roots(f);
WALKER :
[
    <x^(1/3) + O(x^2), 1>,
    <x^(1/4) + O(x^(23/12)), 1>
]
```

47 p-ADIC RINGS AND THEIR EXTENSIONS

Chapter 47
p-ADIC RINGS AND THEIR EXTENSIONS

47.1 Introduction

MAGMA supports finite extensions of the ring $\mathbf{Z}_p$ of p-adic integers or the field $\mathbf{Q}_p$ of p-adic numbers. Within this chapter, we mean these objects if we refer to local rings or fields. Section 47.2 provides more background information on the theory behind the p-adics.

MAGMA has two different models for working with these locals: fixed precision rings (`RngPadRes` and `RngPadResExt`, with element types `RngPadResElt` and `RngPadResExtElt`) and free precision rings (`RngPad` and `FldPad`, with element types `RngPadElt` and `FldPadElt`). The merits of each model are discussed in Section 47.3.1.

MAGMA also contains a type of local field where extensions can be made by any irreducible polynomial. For more information on these local fields, see Chapter 51.

47.2 Background

The p-adic field $\mathbf{Q}_p$ arises naturally as the completion of $\mathbf{Q}$ with respect to an absolute value function $|x|_p = p^{-v_p(x)}$, where $v_p(x)$ is the p-adic *valuation* of x (that is, a power of p such that $x = p^{v_p(x)}\frac{a}{b}$ but $p \not| ab$). The *ring of integers* of $\mathbf{Q}_p$, denoted $\mathbf{Z}_p$, is the set of all elements of non-negative valuation. The ring $\mathbf{Z}_p$ has a unique maximal ideal, generated by the prime p; the *residue class field* K is the quotient $\mathbf{Z}_p/p\mathbf{Z}_p$. Any element x of $\mathbf{Q}_p$ can be expressed as a power series in the prime p, so that $x = \sum_{i=v}^{\infty} a_i p^i$, where v is the valuation of x, a_v is non-zero, and each a_i is a lift of an element from the residue class field. In more general terms, $\mathbf{Q}_p$ is a local field, with its ring of integers $\mathbf{Z}_p$ being a local ring. A uniformizer π of $\mathbf{Q}_p$ is the prime p.

More generally, consider an irreducible polynomial over some local field L_1 (such as $\mathbf{Q}_p$). Then the extension given by adjoining a root α of this polynomial to L_1, $L_2 = L_1[\alpha]$, is also a local field. Let π_1 and π_2 be uniformizers of L_1 and L_2, respectively. Then $\pi_2^e = \pi_1 u$, where u is a unit of L_2. The number e is the *ramification degree* of L_2 over L_1, and divides the degree n of the extension. If $e = n$, we say L_2 is *totally ramified* over L_1; if $e = 1$, we say L_2 is *unramified* over L_1. The degree of the residue class field K_2 of L_2 over the residue class field K_1 of L_1 is $f = \frac{n}{e}$. Finite extensions in MAGMA must be either *unramified* or *totally ramified*; MAGMA also allows towers of extensions to be built.

It is well known that up to isomorphism there is only one degree n unramified extension of L, which can be obtained by adjoining a $p^n - 1$-th root of unity ζ to L. This extension is Galois, with Galois group isomorphic to the cyclic group of order n. The Galois group is generated by the Frobenius automorphism σ, which takes ζ to ζ^p. For some applications, it is necessary to have a fast Frobenius action, so MAGMA supports such a representation. However, the defining polynomial in this representation is particularly dense and can be expensive to construct, hence it is ill-suited for general applications. An unramified extension can only be defined by *inertial* polynomials, which are polynomials that are irreducible

over the residue class field. MAGMA allows an unramified extension to be defined by any inertial polynomial.

All totally ramified extensions contain a root of an Eisenstein polynomial of L. An Eisenstein polynomial $f(x) = \sum_{i=0}^{n} a_i x^i$ satisfies $v_\pi(a_n) = 0$, $v_\pi(a_i) \geq 1$ for all $0 < i < n$, and $v_\pi(a_0) = 1$. MAGMA allows a totally ramified extension to be defined by any Eisenstein polynomial; note that this does not allow arbitrary representations of totally ramified extensions to be constructed.

47.3 Overview of the p-adics in MAGMA

47.3.1 p-adic Rings

Since p-adic rings are completions (like the real numbers), it is difficult to represent their elements in an exact form. As described in Section 47.2, any element x of a local ring L can be expressed as a power series in the uniformizing element of L. Most problems can be solved by computing in a finite quotient of L, which is equivalent to truncating the infinite expansion of x at some point. More precisely, we work in the quotient rings $L/\pi^k L$ for non-negative k, which is called the *precision* of the ring L.

Unfortunately, working with finite approximations to elements does have problems. Some operations on these approximations will yield results with reduced precision. For example, in a ring constructed with precision k the quotient of two elements with valuations $v_1 \geq v_2$ lies in the local ring, but can only be determined up to $k - v_2$ digits. Also, it is only possible in general to construct an approximation to the GCD of two polynomials f and g over a local ring.

MAGMA offers two models for computing in a local ring L. The first model (the *fixed precision model*) allows the user to work with the quotient rings defined above. These quotient rings are finite structures, and their elements can easily be represented exactly; hence, many exact algorithms can be applied to them. On the other hand, precision management is left to the user, since operations which may lose precision, such as division, will still return results to the full precision of the ring. In the second model (the *free precision model*), the user works more directly with L, instead of a finite quotient of L. Each element is still represented by a finite approximation, however, these approximations can be of varying precisions, thus freeing the user from precision management. However, these rings are inexact (for instance, there is no zero element of the ring, only approximations to it), and hence many algorithms in MAGMA which are designed for exact rings may cause significant precision loss. The situation is analogous to the support for real numbers in MAGMA.

47.3.2 p-adic Fields

A local field in MAGMA is the field of fractions of a local ring. Representing a local field on a machine causes some trouble, since there is no algebraic structure in which truncations of the elements could be interpreted (as in the case of the finite quotients for the local rings). Moreover, all structural information of a local field is already contained in its ring

of integers, so that the main motivation for supporting local fields is to provide some basic arithmetic.

An element x of a local field L is stored internally as $x = \pi^v u + O(\pi^{v+k})$, where v is the (possibly negative) valuation of x, and u is a unit known to precision k in the ring of integers of L. It can happen that operations in a field yield elements with no known digits at all, since the unit parts may not overlap.

47.3.3 Free Precision Rings and Fields

Free precision rings and fields can be created with bounded or unbounded precision. If they are created with some bounded precision k, then no element in the structure can have precision greater than k. Thus, bounded free precision rings are "inexact" versions of the fixed precision rings. Unbounded precision structures can have elements with arbitrarily large, but not infinite, precision. In general, it is recommended that free precision structures are utilized unless speed is absolutely critical.

47.3.4 Precision of Extensions

In MAGMA, all measurements of precision are made with respect to a valuation function v_π which takes the uniformizer π of the local ring L to unity (throughout this chapter, the subscript will be dropped on v_π where there is no ambiguity). This can have surprising results. For instance, consider a local ring L_1 which extends L_2, such that the ramification degree of L_1 over L_2 is e. Let π_1 and π_2 be the uniformizing elements of L_1 and L_2, respectively. Then, $v_{\pi_1}(\pi_1) = 1$, and $v_{\pi_1}(\pi_2) = e$. Hence, an element of precision k in L_2 will have precision ek in when mapped into L_1. Thus, it is important to always remember in which ring precision is determined.

47.4 Creation of Local Rings and Fields

A local ring in MAGMA can be constructed in two ways: as either a p-adic ring, or as an extension of another local ring. MAGMA supports the construction of towers of extensions of local rings; the only restriction is that each extension must be either unramified or totally ramified. As discussed in Section 47.2, MAGMA requires that the defining polynomial is either inertial or Eisenstein.

Additionally, the user must specify whether to construct a fixed precision or free precision structure, and, if necessary, assign a precision to the structure. For local rings the precision is interpreted as an absolute precision, specifying to what precision the element is known, but for local fields it is interpreted as a relative precision, specifying to what precision the unit part of the element is known.

47.4.1 Creation Functions for the p-adics

`pAdicRing(p, k)`

`pAdicField(p, k)`

Given a prime integer p and non-negative single-precision integer k, construct the bounded free precision ring (field) of p-adic integers with maximum precision k.

`pAdicRing(p)`

`pAdicField(p)`

`Precision` RngIntElt *Default :* 20

Given a prime integer p, construct the unbounded free precision ring (field) of p-adic numbers. The optional parameter `Precision`, which must be a non-negative single precision integer, controls the default precision to which elements are created, e.g., when coercing precise elements such as integers or rationals into the ring.

`pAdicQuotientRing(p, k)`

Given a prime integer p and non-negative single precision integer k, construct the fixed precision quotient ring $\mathbf{Z}_p/p^k\mathbf{Z}_p$.

`quo< L | x >`

Given a local ring L, construct the quotient ring L/xL, where x is an element of L.

Example H47E1

The creation of p-adic rings using the above functions is illustrated below.

```
> R := pAdicRing(5);
> R;
5-adic ring
> R`DefaultPrecision;
20
> R!1;
1 + O(5^20)
> R := pAdicRing(5 : Precision := 20);
> R!1;
1 + O(5^20)
> Q := quo<R | 5^20>;
> Q;
Quotient of the 5-adic ring modulo the ideal generated by 5^20
> Q!1;
1
> Q eq pAdicQuotientRing(5, 20);
true
```

47.4.2 Creation Functions for Unramified Extensions

`UnramifiedExtension(L, n)`

`ext< L | n >`

`Cyclotomic`	BoolElt	*Default :* `false`
`GNBType`	RngIntElt	*Default :* 0

Given a local ring or field L and a positive single precision integer n, construct the default unramified extension of L of degree n. If K is the residue class field of L, then the defining polynomial of the default degree n extension of K is lifted to be an inertial polynomial of L; this polynomial is used as the defining polynomial of the extension. If `Cyclotomic` is `true`, then the lift of the defining polynomial will be such that $p^n - 1$-st root of unity will be adjoined to L (this representation makes computation of the Frobenius automorphism particularly efficient). The angle bracket notation can be used to assign a name to the generator of the extension, e.g. `K<t> := UnramifiedExtension(L, n)`. If `Cyclotomic` is `false` but `GNBType` is $t > 0$ then a Gaussian normal basis of type t is used. This allows extremely fast multiple Frobenius computations but multiplication is slower than the usual or `Cyclotomic` representation if $t > 2$. Because of this, currently only 1 or 2 are legal values for t. Only certain extension degrees will have a Gaussian normal basis of type 1 or 2. To determine if this is true, the `HasGNB` functions described below may be used.

`UnramifiedQuotientRing(K, k)`

Given a finite field K and a non-negative single precision integer k, construct the fixed precision quotient ring which has residue class field K and precision k. The angle bracket notation can be used to assign a name to the generator of the extension, e.g. `L<t> := UnramifiedExtension(K, f)`.

`UnramifiedExtension(L, f)`

`ext< L | f >`

Given a local ring or field L and a polynomial f with coefficients coercible to L, construct the unramified extension of L defined by f. The polynomial f must be an inertial polynomial over L. The angle bracket notation can be used to assign a name to the generator of the extension, e.g. `K<t> := UnramifiedExtension(L, f)`. Free precision rings can only be extended by a polynomial if they are of bounded precision, in which case f must be specified to the maximum precision of the ring.

`IsInertial(f)`

Given a polynomial f with coefficients over a local ring or field L, return `true` if and only if f is an inertial polynomial. A polynomial is inertial over L if it is irreducible over the residue class field of L.

`HasGNB(R, n, t)`

Given a local ring or field, returns `true` iff the unramified extension of degree n can be generated by a Gaussian Normal Basis (GNB) of Type t. A GNB allows particularly fast multiple Frobenius and Norm computations. Multiplication will tend to be slower though, unless $t = 1$.

`CyclotomicUnramifiedExtension(R, f)`

`CyclotomicUnramifiedExtension(R, f)`

`CyclotomicUnramifiedExtension(R, f)`

`CyclotomicUnramifiedExtension(R, f)`

Given a local ring of field R, construct the unramified degree f extension by adjoining a $p^f - 1$-th root of unity to R. Functionally equivalent to calling `UnramifiedExtension(R, f:Cyclotomic := true)`.

Example H47E2

The creation of unramified extensions of local rings using the above functions is illustrated below.

```
> R1 := pAdicRing(2, 20);
> R2 := ext<R1 | 5>;
> R2;
Unramified extension defined by the polynomial x^5 + x^2 + 1
 over 2-adic ring mod 2^20
> DefiningPolynomial(R2);
x^5 + x^2 + 1
> R3 := ext<R1 | 5 : Cyclotomic>;
> R3;
Cyclotomic unramified extension of degree 5 over 2-adic ring mod 2^20
> DefiningPolynomial(R3);
x^5 + 426248*x^4 - 14172*x^3 - 147105*x^2 + 293314*x - 1
> R3.1^(2^5-1);
1
> P1<x> := PolynomialRing(R1);
> f1 := x^3 + 3*x + 1;
> IsInertial(f1);
true
> R4 := ext<R1 | f1>;
> R4;
Unramified extension defined by the polynomial x^3 + 3*x + 1
 over 2-adic ring mod 2^20
> P2<y> := PolynomialRing(R2);
> f2 := y^3 + 3*y + 1;
> IsInertial(f2);
true
> ext<R2 | f2>;
Unramified extension defined by the polynomial x^3 + 3*x + 1
```

```
over Unramified extension defined by the polynomial x^5 + x^2 + 1
over 2-adic ring mod 2^20
```

47.4.3 Creation Functions for Totally Ramified Extensions

`TotallyRamifiedExtension(L, f)`

`ext< L | f >`

Given a local ring or field L and a polynomial f with coefficients coercible to L, construct the totally ramified extension of L defined by f. The polynomial f must be an Eisenstein polynomial, that is, the leading coefficient is a unit, the constant coefficient has valuation 1 and all other coefficients have valuation greater than or equal to 1. The angle bracket notation can be used to assign a name to the generator of the extension, e.g. `K<t> := TotallyRamifiedExtension(L, f)`. Free precision rings can only be extended by a polynomial if they are of bounded precision, in which case f must be specified to the maximum precision of the ring.

`IsEisenstein(f)`

Given a polynomial f with coefficients over a local ring or field L, return `true` if and only if f is an Eisenstein polynomial over L. An Eisenstein polynomial satisfies the following properties: the leading coefficient is a unit, the constant coefficient has valuation 1 and all other coefficients have valuation greater than or equal to 1.

Example H47E3

The creation of totally ramified extensions of local rings using the above functions is illustrated below.

```
> L1<a> := ext<pAdicRing(5, 20) | 4>;
> L1;
Unramified extension defined by the polynomial x^4 + 4*x^2 + 4*x + 2
 over 5-adic ring mod 5^20
> L2<b> := ext<L1 | x^4 + 125*x^2 + 5>;
> L2;
Totally ramified extension defined by the polynomial x^4 + 125*x^2 + 5
 over Unramified extension defined by the polynomial x^4 + 4*x^2 + 4*x + 2
 over 5-adic ring mod 5^20
> P<y> := PolynomialRing(L2);
> L3<c> := TotallyRamifiedExtension(L2, y^3 + b^4*a^5*y + b*a^2);
> L3;
Totally ramified extension defined by the polynomial x^3 + ((500*a^3 + 500*a^2 +
    250*a)*b^2 + 20*a^3 + 20*a^2 + 10*a)*x + a^2*b
 over Totally ramified extension defined by the polynomial x^4 + 125*x^2 + 5
 over Unramified extension defined by the polynomial x^4 + 4*x^2 + 4*x + 2
```

```
 over 5-adic ring mod 5^20
```

If the precision of the base ring is only 1, then it is not possible to construct a ramified extension, as there is not enough precision to allow the constant coefficient to be non-zero to that precision.

```
> R<x> := PolynomialRing(Integers());
> L<a> := UnramifiedExtension(pAdicRing(5, 1), 3);
>  TotallyRamifiedExtension(L, x^4 + 5);
>> TotallyRamifiedExtension(L, x^4 + 5);
                           ^
Runtime error in 'TotallyRamifiedExtension': Polynomial must be Eisenstein
> L<a> := UnramifiedExtension(pAdicRing(5, 2), x^5 + x^2 + 2);
> TotallyRamifiedExtension(L, x^4 + 5);
Totally ramified extension defined by the polynomial x^4 + 5 over Unramified
extension defined by the polynomial x^5 + x^2 + 2 over 5-adic ring mod 5^2
> ext<L | x^4 + 125*x^2 + 5>;
Totally ramified extension defined by the polynomial x^4 + 5 over Unramified
extension defined by the polynomial x^5 + x^2 + 2 over 5-adic ring mod 5^2
```

47.4.4 Creation Functions for Unbounded Precision Extensions

Suppose we have an unbounded precision local ring or field L, and we wish to create a finite extension of it. If we need the default degree n unramified extension, then we can use the construction functions defined in Section 47.4.2 to construct this extension. However, suppose we wish to define the extension by some polynomial f. As there is no upper bound on the precision of elements of L, it is impossible for us to represent the polynomial f sufficiently precisely, and hence we cannot use the creation functions defined in previous sections for this task. To allow such extensions to be created, MAGMA allows extensions to be defined by a map $\phi : \mathbf{Z}_{\geq 0} \to R[x]$, where R is a ring whose elements are coercible to the quotient rings $L/\pi^k L$ for all $k \in \mathbf{Z}_{\geq 0}$. The map ϕ, given an input precision k, returns the defining polynomial of the extension to precision k. Internally, whenever MAGMA needs to represent an element of the extension to some precision, it will use ϕ to compute the defining polynomial up to this precision. MAGMA may call ϕ on any precision between zero and the precision of the most precise element created by the user.

`ext< L | m >`

Given a free precision local ring or field L and a map m with domain $\mathbf{Z}$ and codomain $R[x]$, where elements of R are coercible to the quotient rings $L/\pi^k L$ for all $k \in \mathbf{Z}_{\geq 0}$, construct an extension of L defined by m. Given a non-negative single precision integer k, the map m must return the defining polynomial of the extension to precision k, as a polynomial over R. The map m's behaviour for other input values is undefined. Internally, MAGMA will coerce the value returned by the map m to be a polynomial over $L/\pi^k L$. Examples of suitable codomains R include the integers, rationals, or L itself.

Example H47E4

The creation of extensions of local rings using maps is illustrated below. We show how it is possible to define an extension of a free precision ring using an "exact" polynomial.

```
> R := pAdicRing(2);
> Z := Integers();
> P<x> := PolynomialRing(Z);
> m := map<Z -> P | k :-> x^3 + x + 1>;
> R2 := ext<R | m>;
> R2;
Unramified extension defined by a map over 2-adic ring
> DefiningPolynomial(R2);
(1 + O(2^20))*$.1^3 + O(2^20)*$.1^2 + (1 + O(2^20))*$.1 + 1 + O(2^20)
> R2`DefaultPrecision := 1000;
> DefiningPolynomial(R2);
(1 + O(2^1000))*$.1^3 + O(2^1000)*$.1^2 + (1 + O(2^1000))*$.1 + 1 + O(2^1000)
```

47.4.5 Miscellaneous Creation Functions

`IntegerRing(F)`

`Integers(F)`

`RingOfIntegers(F)`

Given a local field F, construct the ring of integers R of F. The ring R is the set of elements of F of non-negative valuation.

`RingOfIntegers(R)`

Given a ring R, this function simply returns it, it is provided to support generic functionality for finite extensions of rings and fields.

`FieldOfFractions(R)`

Given a local ring R, construct the field of fractions F of R. The relative precision of F is equal to the precision of R.

`SplittingField(f, R)`

Given a polynomial f over the integers and a p-adic ring R, compute an extension S over R such that f splits into linear factors over S. The algorithms uses the R4-methods as developed by Pauli ([Pau01b]).

`AbsoluteTotallyRamifiedExtension(R)`

Given a tower of ramified extensions over some unramified ring S, compute a more efficient representation of R, ie. an extension of S that is totally ramified and defined by a single Eisenstein polynomial. The map returned allows to convert between the new and old representations.

47.4.6 Other Elementary Constructions

`Composite(R, S)`

For two p-adic fields that are normal over $\mathbf{Q}_p$, compute the compositum of R and S, ie. the smallest field containing both R and S.

47.4.7 Attributes of Local Rings and Fields

There is only one attribute for local rings and fields that is accessible to the user.

`L‘DefaultPrecision`

Used to retrieve or set the default precision of the local ring or field L. This attribute is only relevant if L is an unbounded free precision ring, in which case this will change the precision with which elements are created by default. For bounded precision structures, the default precision of the ring is equal to the upper bound on precision; attempting to set this attribute will result in an error in this case.

47.5 Elementary Invariants

These functions return some simple information partially defining a local ring.

`Prime(L)`

Given a local ring or field L, return the prime p defining the p-adic ring or field underlying L. This is also the characteristic of the residue class field of L.

`InertiaDegree(L)`

Return the inertia degree of the local ring or field L over its coefficient ring.

`InertiaDegree(K, L)`

Return the inertia degree of the local ring or field K relative to its subring L.

`AbsoluteInertiaDegree(L)`

Return the inertia degree of the local ring or field L over the p-adic ring.

`RamificationDegree(L)`

`RamificationIndex(L)`

Return the ramification degree of the local ring or field L over its coefficient ring.

`RamificationDegree(K, L)`

`RamificationIndex(K, L)`

Return the ramification degree of the local ring or field K relative to its subring L.

`AbsoluteRamificationDegree(L)`

`AbsoluteRamificationIndex(L)`

Return the ramification degree of the local ring or field L over the p-adic ring.

`AbsoluteDegree(L)`

The degree of L over $\mathbf{Z}_p$.

`Degree(L)`

Return the degree of the local ring or field L over its coefficient ring.

`Degree(K, L)`

Return the degree of the local ring or field K relative to its subring L.

`DefiningPolynomial(L)`

Return the minimal polynomial of the generator of L over its coefficient ring. If L is p-adic, the polynomial $x - 1$ is returned. For free precision rings and fields, the coefficients of the defining polynomial are given to the default precision of L.

`DefiningMap(L)`

Given a free precision local ring or field L, return the map that was used to define the extension (see Section 47.4.4 for information on defining extension by maps). If a map was not used, then an error is raised.

`HasDefiningMap(L)`

Given a free precision local ring or field L, return `true` if L is defined by a map; if so, the defining map is also returned.

`PrimeRing(L)`

`PrimeField(L)`

`pAdicRing(L)`

`pAdicField(L)`

Given a local ring or field L, return the p-adic ring or field which is a subring of L.

`BaseRing(L)`

`CoefficientRing(L)`

`BaseField(L)`

`CoefficientField(L)`

`BaseRing(L)`

Given a local ring or field L, return the base ring of L.

`ResidueClassField(L)`

Given a local ring or field L, return the residue class field K of L, and a map from L to K.

`ResidueSystem(R)`

Given a p-adic ring or field R, compute a set of representatives of the residue class field of R as elements of R.

`UniformizingElement(L)`

Given a local ring or field L, return the uniformizing element of L.

`L . 1`

Given a local ring or field L, return an element α of L such that if K is L's base ring or field, then the powers of α give a basis of L as a vector space over K.

`Precision(L)`

Given a local ring or field L, return the precision with which L has been created. If L is a local ring this is the maximum absolute precision to which its elements can be created. If L is a local field this is the maximum relative precision to which its elements can be created. If L is an unbounded free precision ring or field, then infinity is returned.

`HasPRoot(R)`

Given a local ring R extending $\mathbf{Z}_p$ for some prime p, decide if R contains a primitive p-th root of unity.

`HasRootOfUnity(L, n)`

Given a local ring L and some positive integer n, decide if L contains a primitive nth root of unity.

`Discriminant(R)`

Compute the discriminant of the local ring R over its coefficient ring. Since R is defined by either an inertial polynomial or an Eisenstein one, this is equivalent to computing the discriminant of the defining polynomial.

`Discriminant(K, k)`

Given p-adic rings K/k, compute the discriminant of K as an extension of k.

`AdditiveGroup(R)`

The additive group of the p-adic quotient R as an abelian group and the isomorphism from this group back to R.

Example H47E5

We illustrate the functions in this section for rings. Similar constructions can be used for fields.

```
> Zp := pAdicRing(5, 20);
> I<a> := UnramifiedExtension(Zp, 3);
> R<x> := PolynomialRing(I);
> L<b> := ext<I | x^3 + 5*a*x^2 + 5>;
> Prime(L);
5
> InertiaDegree(L);
1
```

The inertia degree of L is returned as 1 because L has been defined as a totally ramified extension of I. However, the inertia degree of L over Z_p is 3, because I itself is an unramified extension of Z_p.

```
> InertiaDegree(L, Zp);
3
> Degree(L);
3
> Degree(L, Zp);
9
> DefiningPolynomial(L);
x^3 + 5*a*x^2 + 5
> P<y> := PolynomialRing(Zp);
> DefiningPolynomial(I);
y^3 + 3*y + 3
> BaseRing(L);
Unramified extension defined by the polynomial x^3 + 3*x + 3
 over 5-adic ring mod 5^20
> PrimeRing(L);
5-adic ring mod 5^20
> PrimeRing(I);
5-adic ring mod 5^20
> ResidueClassField(L);
Finite field of size 5^3
Mapping from: RngPad: L to GF(5^3)
> ResidueClassField(I);
Finite field of size 5^3
Mapping from: RngPad: I to GF(5^3)
```

Here, we see that the residue class fields of I and L are identical. This is due to the fact that L is a totally ramified extension of I.

```
> UniformizingElement(L);
b
> Precision(L);
60
> Precision(I);
20
```

```
> R<a> := ext<pAdicRing(2) | 2>;
> DefiningPolynomial(R);
(1 + O(2^20))*$.1^2 + (1 + O(2^20))*$.1 + 1 + O(2^20)
> Precision(R);
Infinity
```

47.6 Operations on Structures

`AssignNames(~L, S)`

`AssignNames(~L, S)`

Assign a name to the generator of L. The sequence must have only one element, which must be a string. This element is assigned to be the name of the generator when L is considered as a linear associative algebra over its base ring.

`Characteristic(L)`

`Characteristic(L)`

`Characteristic(L)`

The characteristic of the local ring or field L.

`#L`

The number of elements in the local ring or field L. The cardinality is finite only if L is a quotient ring or a bounded free precision ring.

Iterating over the elements of a local ring is possible if it is bounded, but it will take time in proportion to the cardinality of L. It is recommended only in the case of "small" local rings (i.e., rings for which the precision is be very small).

`Name(L, k)`

Given a local ring or field L and an integer k, return the generator of L if k is 1; otherwise, raise an error.

`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`
`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`
`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`
`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`
`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`
`ChangePrecision(L, k)`
`ChangePrecision(~L, k)`

Given a local ring or field L and a non-negative single precision integer k, change the maximum precision with which elements can be created to be k. Depending on how L and its subrings have been constructed, there may be an upper bound (possibly infinite for free structures) on the precision to which L can be changed. For instance, the precision to which a defining polynomial has been given places a bound on the precision of the extension — no defining polynomial can be expanded beyond the precision with which it was originally specified.

`L eq K`

Given local rings or fields L and K, return whether or not L and K are the same object.

`L ne K`

Given local rings or fields L and K, return whether or not L and K are different objects.

Example H47E6

```
> Zp := pAdicRing(5, 20);
> I<a> := UnramifiedExtension(Zp, 3);
> R<x> := PolynomialRing(I);
> L<b> := ext<I | x^3 + 5*a*x^2 + 5>;
> ChangePrecision(Zp, Infinity());
5-adic ring
> L;
Totally ramified extension defined by the polynomial x^3 + 5*a*x^2 + 5
 over Unramified extension defined by the polynomial x^3 + 3*x + 3
 over 5-adic ring mod 5^20
```

```
> ChangePrecision(~L, 50);
> L;
Totally ramified extension defined by the polynomial x^3 + 5*$.1*x^2 + 5
 over Unramified extension defined by the polynomial x^3 + 3*x + 3
 over 5-adic ring mod 5^17
> #L;
875811540203010669327330989556197582050l\
63713672822357348167677431119426678662870\
59291488677263259887695312 5
> AssignNames(~L, ["t"]);
> L.1;
t
> b;
b
> L eq ChangePrecision(L, 10);
false
```

Note that b is an element of the original ring L with precision 60 which is why it retains its print name.

47.6.1 Ramification Predicates

IsRamified(R)

IsUnramified(R)

IsTotallyRamified(R)

Return whether the local ring or field extension R is ramified, unramified or totally ramified.

IsTamelyRamified(R)

IsWildlyRamified(R)

Return whether the local ring or field extension R is tamely ramified (the prime does not divide the ramification degee) or wildly ramified (the prime does divide the ramification degree).

47.7 Element Constructions and Conversions

Local ring elements are implemented using a balanced mod representation. This allows small negative elements x to be represented as x rather than $p^k - x$ where k is a p-adic precision.

47.7.1 Constructions

To simplify the creation of elements in a local ring, various coercions are provided. The most obvious is to regard the integer ring or rational field as embedded in the p-adic ring or field. But there is a range of coercions available, including that of elements from the residue class field.

To create an element of a local field not lying in the local ring, constructors are provided that create an element coercible into the ring, and which increase or decrease this element's valuation in the field.

`Zero(L)`

Given a local ring or field L, create the additive identity of L. Note that if L is an unbounded precision structure, this will only be the zero element to the default precision of the ring, and hence only an approximation to the additive identity of L.

`One(L)`

Given a local ring or field L, create the multiplicative identity of L. Note that if L is an unbounded precision structure, this will only be the one element to the default precision of the ring, and hence only an approximation to the multiplicative identity of L.

`Random(L)`

Given a local ring or field L, return a random element of L, which must be a quotient ring or bounded precision ring. The element will have the default precision of the ring.

`Representative(L)`

Return an element of the local ring or field L.

`elt< L | u >`

`L ! u`

Coerce the object u into the local ring or field L. The resulting element will have as much precision as possible. The element u is allowed to be one of the following:

(i) An integer.

(ii) An element of $\mathbf{Z}/p^m\mathbf{Z}$; (where m is a precision).

(iii) An element of the residue class field of L.

(iv) An element of a local ring or field with something in common with L.

(v) A rational number. If L is a ring then u must not have valuation in the denominator.

(vi) An element of a valuation ring over the rationals with the same prime as L.

(vii) A sequence s. In this case, the sequence s is coerced to a sequence t over the base ring or field of L. This sequence is coerced to $\sum_{i=1}^{\#t} t[i]L.1^{i-1}$.

`elt< L | u, r >`

Create an element of the local ring or field L by coercing u into L and returning with it precision r.

`elt< L | v, u, r >`

Create an element of the local ring or field L by coercing u into L, multiplying by the v-th power of the uniformizing element and returning it with precision r.

`BigO(x)`

`O(x)`

For an element x of a local ring or field L of valuation v, create an element of valuation v and relative precision 0. For rings this is the zero element in the quotient $L/\pi^v L$.

`UniformizingElement(L)`

Given a local ring or field L, return the uniformizing element of L to the default precision of L.

Example H47E7

Here we illustrate the usage of element constructors for local fields and imprecise zeros.

```
> Zp := pAdicRing(5, 20);
> I<a> := UnramifiedExtension(Zp, 3);
> R<x> := PolynomialRing(I);
> L<b> := ext<I | x^3 + 5*a*x^2 + 5>;
> K<pi> := ext<BaseField(FieldOfFractions(L)) | x^2 + 5>;
> K;
Totally ramified extension defined by the polynomial x^2 + 5
 over Unramified extension defined by the polynomial x^3 + 3*x + 3
 over 5-adic field mod 5^20
> elt<K | 64>;
64 + O(pi^40)
> P := PrimeField(K);
> elt<K | 2, 3/4, 6>;
pi^2*7 + O(pi^6)
> 4*$1;
pi^2*3 + O(pi^6)
> K!3/5;
pi^-2*3 + O(pi^38)
> O(K!40^200);
O(pi^400)
```

```
> Precision($1);
0
> O(K!0);
O(pi^40)
> O(K!1);
O(1)
> R<x> := PolynomialRing(Integers());
> K<pi> := ext<pAdicField(5, 100) | x^2 + 5>;
> elt<K | 64>;
64 + O(pi^200)
> Precision($1);
200
> K!3/10;
-pi^-2*39443045261050590270586428264139311483660321755451150238513946533203 11 +
O(pi^198)
```

Example H47E8

There is a subtle interplay between the default precision of rings and fields and coercion of sequences, which we demonstrate here. We construct the 5-adic field P, and an unramified extension of R. We set the default precision of R to be higher than that of P.

```
> P := pAdicRing(5);
> R := ext<P | 2>;
> P`DefaultPrecision;
20
> R`DefaultPrecision := 40;
> x := Random(R);
> x;
-157980184343196320136914558 7*R.1 - 68057573045897503903339476 9 + O(5^40)
> s := [-68057573045897503903339476 9, -157980184343196320136914558 7];
> R!s;
-13585890629962*R.1 + 47482939261481 + O(5^20)
> P`DefaultPrecision := 40;
> R!s;
-157980184343196320136914558 7*R.1 - 68057573045897503903339476 9 + O(5^40)
```

As can be seen from the above, it is the default precision of the base ring, not the ring itself, which determines the precision of elements created by sequences.

47.7.2 Element Decomposers

`ElementToSequence(x)`

`Eltseq(x)`

`Coefficients(x)`

Given an element x of a degree n extension K of L, these functions return a sequence s of elements of L such that $x = \sum_{i=1}^{n} s[i]K.1^{i-1}$.

`Coefficient(x, i)`

Equivalent to, but more efficient than, `Coefficients(x)[i]`.

Example H47E9

We want to perform a Galois descent for a polynomial, i.e. we interpret the product of the Galois conjugates of a polynomial in a subring.

```
> p := 3;
> L<a> := UnramifiedExtension(pAdicRing(p), 4 : Cyclotomic);
> R<x> := PolynomialRing(L);
> g := x^2 + (a+a^-2)*x + (a^-1+a^3+1);
> g;
(1 + O(3^20))*x^2 + (-151999392*a^3 - 428033534*a^2 + 1509587217*a - 64512399 +
    O(3^20))*x + 2*a^3 + 307453058*a^2 - 1732356354*a - 151999391 + O(3^20)
> a2 := a^(p^2);
> g2 := R ! [ &+[Eltseq(c)[i]*a2^(i-1) : i in [1..4]] : c in Eltseq(g) ];
```

Here `Eltseq` is being used to replace occurrences of a in the element by a_2.

```
> h := g * g2;
> h;
(1 + O(3^20))*x^4 + (774759822*a^3 - 1559939781*a^2 + 644136111*a + 143311364 +
    O(3^20))*x^3 + (73899384*a^3 - 333497478*a^2 + 1655979363*a + 158024680 +
    O(3^20))*x^2 + (989668189*a^3 - 661853000*a^2 - 1685887308*a + 122035547 +
    O(3^20))*x - 1630826887*a^3 - 328410694*a^2 - 175290219*a + 1601599448 +
    O(3^20)
```

The polynomial g_2 is the image of g under the automorphism induced by the square of the Frobenius automorphism. The product $h = gg_2$ has coefficients in the unramified extension of degree 2, which is the fixed field under the square of the Frobenius and is generated by a^{10}. Next, we determine a representation for the polynomial h with coefficients lying in this unramified extension of degree 2.

```
> K<b> := UnramifiedExtension(pAdicRing(p), 2 : Cyclotomic);
> S<y> := PolynomialRing(K);
> M := RMatrixSpace(PrimeRing(L), 2, 4) ! 0;
> V := RSpace(PrimeRing(L), 4);
> M[1] := V ! Eltseq(a^0);
> M[2] := V ! Eltseq(a^10);
> sol := [ Solution(M, V ! Eltseq(c)) : c in Eltseq(h) ];
```

```
> h2 := S ! [ K ! Eltseq(s) : s in sol ];
> h2;
(1 + O(3^20))*y^4 + (-1237301755*b + 505889265 + O(3^20))*y^3 + (-542504216*b +
    1258167831 + O(3^20))*y^2 + (-280210015*b - 1205051127 + O(3^20))*y +
    1213139407*b + 1602993886 + O(3^20)
```

47.8 Operations on Elements

47.8.1 Arithmetic

For local ring elements the usual operations are available. The quotient of two elements can be computed when the result lies in the ring (i.e. the valuation of the dividend is not smaller than that of the divisor). The precision of the result is reduced by the valuation of the divisor. The result of an operation with elements of reduced precision will have as much precision as possible. For addition and subtraction this is the minimum of the precisions of the two elements. For multiplication it is the minimum of $v_1 + k_2$ and $v_2 + k_1$, where v_i and k_i are the valuations and precisions of the two elements, respectively.

For local field elements the operations are performed with the maximum precision possible. For multiplication and division this is the minimum of the (relative) precisions of the two elements. For addition and subtraction of elements x and y with valuations v_x and v_y and precisions k_x and k_y the precision of $x \pm y$ is $\min(v_x + k_x, v_y + k_y) - v_p(x \pm y)$, which may even be 0.

`-x`

The negative of the element x.

`x + y`

The sum of the elements x and y.

`x - y`

The difference of the elements x and y.

`x * y`

The product of the elements x and y.

`x ^ k`

The k-th power of the element x. If k has valuation (when coerced) and x has precision less than that of its parent ring, the power x^k will have more precision than x.

`x div y`

The quotient of the elements x and y. For elements of a local ring, this results in an error if the valuation of x is smaller than that of y.

`x div:= y`

Mutation operation: replace the element x by its quotient upon division by y. For elements of a local ring, this results in an error if the valuation of x is smaller than that of y.

`x / y`

The quotient of the elements x and y. For elements of a local ring, the result will be returned in its field of fractions.

`IsExactlyDivisible(x, y)`

Return `true` if x can be exactly divided by y; in this case also return the quotient.

Example H47E10

Division of non-units in the ring will yield a result in the field of fractions. In that case the result has reduced precision. To ensure that the result is returned as a ring element, the operator `div` should be used.

```
> R := pAdicRing(2);
> pi := UniformizingElement(R);
> pi;
2 + O(2^20)
> 1 / pi;
2^-1 + O(2^18)
> Parent($1);
2-adic field
>  1 div pi;
>> 1 div pi;
     ^
Runtime error in 'div': Division is not exact
> IsExactlyDivisible(1, pi);
false
> IsExactlyDivisible(pi^2, pi);
true 2 + O(2^20)
```

47.8.2 Equality and Membership

It is possible to test whether two local ring or field elements are equal only in quotient rings. Equality testing in free precision rings is disabled, as there are several reasonable definitions of equality in an imprecise ring.

`x eq y`

Given local ring or field elements x and y, return `true` if and only if x and y are identical in value. This operator is only defined in fixed precision rings.

`x ne y`

Given local ring or field elements x and y, return `true` if and only if x and y are not identical in value. This operator is only defined in fixed precision rings.

`x in L`

Return `true` if and only if x lies in the local ring or field L.

`x notin L`

Return `true` if and only if x does not lie in the local ring or field L.

Example H47E11

We demonstrate how an unramified extension can be constructed from a given degree. The idea is to interpret the minimal polynomial of a primitive element in the residue class field as a polynomial over $\mathbf{Z}_p$. The quotient of $\mathbf{Z}_p[x]$ by the ideal generated by this polynomial is isomorphic to the unramified extension and $a := \overline{x}$ is a first approximation for the $p^f - 1$-th root of unity. This is improved by iterating $a \mapsto a^{p^f}$ until this remains fixed.

```
> p := 2;
> f := 5;
> Zp := pAdicRing(p, 25);
> R<x> := PolynomialRing(Zp);
> g := R ! MinimalPolynomial(GF(p,f).1);
> Q<r> := quo<R | g>;
> a := [ r, r^(p^f) ];
> while a[#a] ne a[#a-1] do
>     print a[#a];
>     Append(~a, a[#a]^(p^f));
> end while;
34*r^4 - 44*r^3 + 58*r^2 - 23*r + 36
12522914*r^4 + 12522004*r^3 - 12174790*r^2 - 8200343*r - 10407260
8242594*r^4 + 12409364*r^3 + 5143098*r^2 + 15781737*r - 3636572
5490082*r^4 + 8804884*r^3 - 11109830*r^2 + 11456361*r + 11698852
-15481438*r^4 - 5875180*r^3 + 5667386*r^2 + 7262057*r - 884060
> [ Minimum([ Valuation(c) : c in Eltseq(a[i] - a[i-1]) ]) : i in [2..#a-1] ];
[ 1, 6, 11, 16, 21 ]
```

The last statement demonstrates the convergence of the process. The polynomial defining the unramified extension could now easily be obtained as the minimal polynomial of the fixed element.

```
> U := ext<Zp | f>;
> MinimalPolynomial(U ! Eltseq(a[#a]));
x^5 - 13205240*x^4 - 3159900*x^3 - 13778593*x^2 + 9730498*x - 1
```

47.8.3 Properties

Local ring and field elements can be tested for certain properties. However, note that in free precision rings and fields, exact zero, one, and minus one elements do not exist, only approximations to such elements — in these cases, the predicates will always return `false`.

`IsZero(x)`

Given an element x of a local ring or field, return `true` if and only if x is the zero element of its parent ring or field.

`IsOne(x)`

Given an element x of a local ring or field, return `true` if and only if x is the one element of its parent ring or field.

`IsMinusOne(x)`

Given an element x of a local ring or field, return `true` if and only if x is the minus one element of its parent ring or field.

`IsUnit(x)`

Given an element x of a local ring or field, return `true` if and only if x is a unit, that is, x has valuation 0.

`IsIntegral(x)`

Given an element x of a local ring or field, return `true` if and only if x has non-negative valuation.

47.8.4 Precision and Valuation

The parent of a local element can be retrieved, its precision accessed and changed, its valuation computed and its denominator returned.

`Parent(x)`

Return the parent local ring or field of the element x.

`Precision(x)`

For a local ring element x, returns the precision to which it is known; for a local field element x, returns the precision to which its unit part is known.

`AbsolutePrecision(x)`

Returns the precision of a local ring or field element x.

`RelativePrecision(x)`

Returns the difference between the absolute precision and the valuation of the local ring or field element x.

`ChangePrecision(x, k)`

`ChangePrecision(∼x, k)`

`ChangePrecision(x, k)`

`ChangePrecision(∼x, k)`

Given a local ring or field element or polynomial over a local ring or field x and a non-negative single precision integer k, change the precision of x to k. If k is smaller than the precision of x, x is truncated; if k is larger, then an element y is returned such that $v(x-y) \geq k$. Note that the precision of an element cannot be changed to be greater than its parent. Any attempt to do so will result in the element gaining the precision of its parent.

`Expand(x)`

Change the precision of the local ring or field element x to be the maximum precision allowed by its parent. This results in an error if x is an element of an unbounded free precision ring.

`Valuation(x)`

Return the valuation of the local ring or field element x. This is always bounded by the absolute precision of the element.

Example H47E12

The uses and properties of relative and absolute precision for field elements are illustrated here, as well as the results of `Expand`.

```
> R<x> := PolynomialRing(Integers());
> K<d> := ext<ext<pAdicField(5, 100) | 2> |  x^2 + 5>;
> x := d + d^7;
> x;
-d*124 + O(d^200)
> AbsolutePrecision(x);
200
> RelativePrecision(x);
199
> RelativePrecision(x + O(d^10));
9
> AbsolutePrecision(x + O(d^10));
10
> RelativePrecision(ChangePrecision(x, 19));
19
> RelativePrecision(ChangePrecision(x, 10));
10
> AbsolutePrecision(ChangePrecision(x, 10));
11
> Expand(ChangePrecision(x, 10));
```

```
d*3001 + O(d^201)
> Valuation(x);
1
> ChangePrecision(x, 20) - (x + O(d^21));
O(d^21)
```

The last two lines show that changing the precision of an element is equivalent to adding imprecision to the element effectively cancelling off all terms beyond that of relative valuation 20.

47.8.5 Logarithms and Exponentials

Logarithms and exponentials can also be calculated for certain elements.

`Log(x)`

The logarithm of the local ring or field element x, returned to the precision of x. Note that the power series of the logarithm function only converges if the valuation of $x-1$ is positive. For ring elements x, the answer lies in the ring (and not its field of fractions) only if the valuation of $x-1$ is greater than or equal to the ramification degree of the ring divided by the prime.

The rate of convergence of `Log` is dependent on the valuation of $x-1$. The greater the valuation the faster the convergence, as is illustrated in the example below.

`Exp(x)`

The exponential of the local ring or field element x, returned to the precision of x. Note that the power series of the exponential function only converges if the valuation of x is strictly larger than $e/(p-1)$, where e is the ramification degree of the parent ring of x.

Example H47E13

This example illustrates the relative timings of the `Log` function and the `Exp` function for rings and fields and for various valuations of $x-1$ or x as appropriate.

```
> K := ext<pAdicField(3, 20) | x^3 + x^2 + x + 2>;
> K<d> := ext<K | x^3 + 3*x^2 + 3*x + 3>;
> L<b> := IntegerRing(K);
> x := 1 + b;
> time Log(x);
Time: 0.070
> x := 1 + b^5;
> time Log(x);
874050819*b^2 + 1624571442*b - 914550768
Time: 0.010
> Valuation(Exp(Log(x)) - x);
60
> x := b^2;
```

```
> time Exp(x);
1418565628*b^2 + 1334033745*b + 905945461
Time: 0.170
> Valuation(Log(Exp(x)) - x);
60
> x := b^6;
> time Exp(x);
1700312013*b^2 - 72781965*b + 1129064707
Time: 0.020
> Valuation(Log(Exp(x)) - x);
60
```

47.8.6 Norm and Trace Functions

The norm, trace and minimal polynomial of an element can be calculated. A function returning the image of an element under a power of the Frobenius automorphism is also provided.

`Norm(x)`

Given a local ring or field element x, return the norm of x over the base ring of its parent. The norm is the product of all conjugates of x.

`Norm(x, R)`

Given a local ring or field element x, return the norm of x over the local ring or field R. The ring R must be a subring of the parent of x. The norm is the product of all conjugates of x.

`Trace(x)`

Given a local ring or field element x, return the trace of x over the base ring of its parent. The trace is the product of all conjugates of x.

`Trace(x, R)`

Given a local ring or field element x, return the trace of x over the local ring or field R. The ring R must be a subring of the parent of x. The trace is the sum of all conjugates of x.

`MinimalPolynomial(x)`

Given a local ring or field element x, return the minimal polynomial of x over the base ring of its parent.

`MinimalPolynomial(x, R)`

Given a local ring or field element x, return the minimal polynomial of x over the local ring or field R. The ring R must be a subring of the parent of x.

`CharacteristicPolynomial(x)`

Given a local ring element x, return the characteristic polynomial of x over the base ring of its parent.

`CharacteristicPolynomial(x, R)`

Given a local ring or field element x, return the characteristic polynomial of x over the local ring or field R. The ring R must be a subring of the parent of x.

`GaloisImage(x, i)`

Given a local ring or field element x, return the image of x under the Frobenius automorphism composed with itself i times, that is, $a \mapsto a^{(p^i)}$ where a is a $p^f - 1$st root of unity of the parent of x.

Example H47E14

One important application of the p-adics is to counting points on elliptic curves over finite fields. This example demonstrates how a simple version of the Arithmetic-Geometric Mean (AGM) algorithm could be implemented in MAGMA.

```
> d := 50;
> FF := GF(2^d);
> E := EllipticCurve([FF | 1, 0, 0, 0, Random(FF)]);
> assert Degree(sub<BaseRing(E) | jInvariant(E)>) gt 2;
>
> n := (d + 1) div 2 + 3;
> R := ext<pAdicRing(2) | d>;
> R`DefaultPrecision := n;
>
> a6 := elt<R | jInvariant(E)^-1, 1>;
> lambda := 1 + 8 * a6;
>
> for k in [4..n] do
>     ChangePrecision(~lambda, k + 2);
>     lambda := (1 + lambda) * InverseSqrt(lambda) div 2;
> end for;
> lambda := 2 * lambda div (1 + lambda);
> Exp(Trace(Log(lambda)));
32196193 + O(2^26)
> Trace(E) mod 2^26;
32196193
```

47.8.7 Teichmüller Lifts

Another important operation is the determination of the canonical *Teichmüller lift* of an element u in the residue field of a p-adic ring. By definition this is the unique root of unity of order prime to p which reduces to u modulo the maximal ideal.

`TeichmuellerLift(u, R)`

For a fixed precision quotient ring R of the p-adics or an unramified extension and a finite field element u, the function attempts to coerce u into the residue class field of R and then computes and returns its Teichmüller lift to R. This uses a fast iterative lifting method of Harley described in Chapter 12 of [C$^+$05]. For unramified extensions this works most efficiently with `Cyclotomic` or `Gaussian Normal` bases since it uses the Frobenius operation.

47.9 Linear Algebra

All linear algebra over local rings and fields in MAGMA is implemented in terms of the fixed precision model. Internally, linear algebra over free precision models is performed over an appropriate quotient ring. The advantage of this method is that exact algorithms can be used to solve linear systems; the disadvantage is that the answer may be returned to less precision than is theoretically possible.

47.10 Roots of Elements

Roots of local ring and field elements can be found to some precision.

`SquareRoot(x)`

`Sqrt(x)`

Given a local ring or field element x, return a square root of x. An error results if x is not a square. The result may have less precision than x.

`IsSquare(x)`

Return whether the local ring or field element x is the square of an element in its parent and if it is, the square root is returned. The result may have less precision than x.

`InverseSquareRoot(x)`

`InverseSqrt(x)`

Given a local ring or field element x, return an inverse square root of x. The element x must be a unit. An error results if x is not a square. The result may have less precision than x.

`InverseSquareRoot(x, y)`

`InverseSqrt(x, y)`

Given local ring or field elements x and y, return an inverse square root of x lifted from an initial approximation y. The element x must be a unit. An error results if x is not a square, or if y is not a valid initial approximation to an inverse square root of x. The result may have less precision than x.

`Root(x, n)`

Return an n-th root of x if one exists. An error results if x is not an n-th power. The result may have less precision than x.

`IsPower(x, n)`

Return whether x is an n-th power of some element belonging to its parent and if it is return an n-th root. The result may have less precision than x.

`InverseRoot(x, n)`

Given a local ring or field element x, return an inverse n-th root of x. The element x must be a unit. An error results if x is not an n-th power. The result may have less precision than x.

`InverseRoot(x, y, n)`

Given local ring or field elements x and y, return an inverse n-th root of x lifted from an initial approximation y. The element x must be a unit. An error results if x is not an n-th power, or if y is not a valid initial approximation to an inverse n-th root of x. The result may have less precision than x.

47.11 Polynomials

Various simple operations for polynomials as well as root finding and factorization functions have been implemented for polynomials over local rings and fields.

47.11.1 Operations for Polynomials

A number of functions for polynomials in general are applicable for polynomials over local rings and fields. Arithmetic functions, including `div` and `mod` can be used with such polynomials (though there may be some precision loss), as well as all the elementary functions to access coefficients and so forth. Derivatives can be taken and polynomials over local rings and fields can be evaluated at elements coercible into the coefficient ring. Along with GCD for these polynomials, the LCM of two polynomials can also be found.

Although the ring of polynomials over a local ring is not a principal ideal domain, it is useful to have a GCD function available. For example, for polynomials which are coprime over the local field, the ideal generated by the two polynomials contains some power of the uniformizing element of the local ring. This power determines whether an approximate factorization can be lifted to a proper factorization.

`GreatestCommonDivisor(f, g)`

`Gcd(f, g)`

`GCD(f, g)`

Determine the greatest common divisor of polynomials f and g where f and g are over a free precision local ring or field. The GCD returned is such that the cofactors of the polynomials will have coefficients in the ring (if the polynomial is not over a field). The process of computing the GCD of two polynomials may result in some inaccuracy. The GCD is computed by echelonizing the Sylvester matrix of f and g.

`f div g` `f mod g` `LeastCommonMultiple(f, g)`

`Coefficient(f, i)` `LeadingCoefficient(f)`

`Derivative(f)` `Evaluate(f, x)`

Example H47E15

This example illustrates the usage and results of the GCD functions. Note the precision loss in the answer.

```
> L := pAdicRing(5, 20);
> R<x> := PolynomialRing(L);
> elts := [Random(L) : i in [1..3]];
> f := (x - elts[1])^3 * (x - elts[2])^2 * (x - elts[3]);
> f;
x^6 + 31722977012336*x^5 - 34568128687249*x^4 +
    4655751767246*x^3 + 11683626356181*x^2 -
    29833674388290*x + 32360011367900
> GCD(f, Derivative(f));
(1 + O(5^18))*x^3 - (934087632277 + O(5^18))*x^2 -
    (89130566204 + O(5^18))*x + 1178670674955 + O(5^18)
> f mod $1;
O(5^18)*x^5 + O(5^18)*x^4 + O(5^18)*x^3 + O(5^18)*x^2 +
    O(5^18)*x + O(5^19)
> (x - elts[1])^2 * (x - elts[2]);
x^3 + 14324701430223*x^2 + 26613750293171*x +
    31696248799955
> ChangePrecision($1, 18);
(1 + O(5^18))*x^3 - (934087632277 + O(5^18))*x^2 -
    (89130566204 + O(5^18))*x + 1178670674955 + O(5^18)
```

`ShiftValuation(f, n)`

Shifts the valuation of each coefficient of f by n, ie. scales the polynomial by π^n.

47.11.2 Roots of Polynomials

Roots of polynomials can be found to some precision by applying the Hensel lift to an approximation or by factorizing the polynomial and looking for linear factors from which the roots can be read off.

47.11.2.1 Hensel Lifting of Roots

Roots of a polynomial f defined over a local ring or field can be found by first determining their valuation (using the Newton polygon), finding a first approximation over the finite field and finally improving this approximation until the Hensel condition $v(f(a)) > 2v(f'(a))$ is satisfied.

`NewtonPolygon(f)`

The Newton polygon of a polynomial $f = \sum_{i=0}^{n} c_i x^i$ (over a local ring or field) is the lower convex hull of the points $(i, v(c_i))$. The slopes of the Newton polygon determine the valuations of the roots of f in a splitting ring and the number of roots with that valuation. The faces of the Newton polygon can be determined using the function `Faces` which returns the faces expressed as the line $mx + ny = c$ which coincides with the face. The function `GradientVector` will return the m and n values from the line so that the valuation (gradient) can be calculated. The function `EndVertices` will return the end points of the face, the x coordinates of which will give the number of roots with valuation equal to the gradient of the face.

Newton polygons are discussed in greater detail in Chapter 46 and are illustrated below.

`ValuationsOfRoots(f)`

Return a sequence containing pairs which are valuations of roots of f and the number of roots of f which have that valuation.

Example H47E16

For a polynomial of the form $g := \prod(x - r_i)$ we demonstrate that the Newton polygon determines the valuations of the roots of g.

```
> Z3 := pAdicRing(3, 30);
> R<y> := PolynomialRing(Z3);
> pi := UniformizingElement(Z3);
> roots := [ pi^Random([0..3]) * Random(Z3) : i in [1..10] ];
> [ Valuation(r) : r in roots ];
[ 3, 1, 6, 3, 0, 3, 2, 3, 3, 2 ]
> g := &* [ y - r : r in roots ];
> N := NewtonPolygon(g);
> N;
Newton Polygon of y^10 + 44594997030169*y^9 - 85346683389318*y^8 +
    76213593390537*y^7 + 74689026811236*y^6 - 48671968754502*y^5 -
    58608670426020*y^4 - 63609139981179*y^3 + 77334553491246*y^2 +
    39962036019861*y - 94049035648173 over pAdicRing(3, 30)
```

```
> F := Faces(N);
> F;
[ <6, 1, 26>, <3, 1, 23>, <2, 1, 17>, <1, 1, 9>, <0, 1, 0> ]
> [GradientVector(F[i]) : i in [1 .. #F]];
[ <6, 1>, <3, 1>, <2, 1>, <1, 1>, <0, 1> ]
> [$1[i][1]/$1[i][2] : i in [1 ..#$1]];
[ 6, 3, 2, 1, 0 ]
> [EndVertices(F[i]) : i in [1 .. #F]];
[
    [ <0, 26>, <1, 20> ],
    [ <1, 20>, <6, 5> ],
    [ <6, 5>, <8, 1> ],
    [ <8, 1>, <9, 0> ],
    [ <9, 0>, <10, 0> ]
]
> [$1[i][2][1] - $1[i][1][1] : i in [1 .. #$1]];
[ 1, 5, 2, 1, 1 ]
```

So there is one root of valuation 6, five of valuation 3, two of valuation 2, one of valuation 1 and one root with valuation zero. This information could also have been gained using `ValuationsOfRoots`.

```
> ValuationsOfRoots(g);
[ <6, 1>, <3, 5>, <2, 2>, <1, 1>, <0, 1> ]
```

`HenselLift(f, x)`

`HenselLift(f, x, k)`

Return a root of the polynomial f over a local ring or field by lifting the approximate root x to a root with precision k (or the default precision of the structure if not specified). This results in an error, if the Hensel condition $v(f(x)) > 2v(f'(x))$ is not satisfied.

Example H47E17

This examples illustrates how Hensel lifting is used to compute square roots.

```
> Zx<x> := PolynomialRing(Integers());
> L1<a> := ext<pAdicRing(3, 20) | 2>;
> L2<b> := ext<L1 | x^2 + 3*x + 3>;
> R<y> := PolynomialRing(L2);
> c := (a+b)^42;
> r := L2 ! Sqrt(ResidueClassField(L2) ! c);
> r;
a
> rr := HenselLift(y^2-c, r);
> rr;
(-1513703643*a - 1674232545)*b - 1219509587*a + 760894776
> Valuation(rr^2 - c);
```

```
40
> ChangePrecision(rr, 1);
a + O(b)
```

For $p = 2$ the situation is a bit more difficult, since the derivative of $y^2 - c$ is not a unit at this point.

```
> Zx<x> := PolynomialRing(Integers());
> L1<a> := ext<pAdicRing(2, 20) | 2>;
> L2<b> := ext<L1 | x^2 + 2*x + 2>;
> R<y> := PolynomialRing(L2);
> c := (a+b)^42;
> r := L2 ! Sqrt(ResidueClassField(L2) ! c);
> r;
1
>  HenselLift(y^2-c, r);
>> HenselLift(y^2-c, r);
             ^
Runtime error in 'HenselLift': Hensel lift condition is not satisfied
```

We have to find a better approximation for the square root first.

```
> for d in GF(2,2) do
>     if Valuation((r + b*L2!d)^2 - c) gt 4 then
>         print L2!d;
>     end if;
> end for;
a + 1
> r +:= b * (a+1);
> HenselLift( y^2-c, r );
(-199021*a + 100463)*b + 204032*a - 31859 + O(b^38)
> ChangePrecision($1, 1);
1 + O(b)
> ChangePrecision($2, 2);
(a + 1)*b + 1 + O(b^2)
```

The square root is an element of reduced precision, since the proper root is only guaranteed to coincide with the approximation up to valuation 18.

47.11.2.2 Functions returning Roots

These functions determine the roots of a polynomial from the factorization of the polynomial.

`Roots(f)`

`Roots(f, R)`

`IsSquarefree` BoolElt *Default :* `false`

Return the roots of the polynomial f over a local ring or field R as a sequence of tuples of elements in R and multiplicities. If R is not specified it is taken to be the

coefficient ring of f. If the polynomial is known to be squarefree, the root-finding algorithm may run considerably faster.

`HasRoot(f)`

Try to find a root of the polynomial f over a local ring or field. If a root is found, this function returns `true` and a root as a second value; otherwise it returns `false`.

Example H47E18

We generate the ramified extensions of $\mathbf{Z}_2$ of degree 2 by looping over some Eisenstein polynomials with small coefficients and checking whether a new polynomial has a root in one of the already known rings.

```
> Zx<x> := PolynomialRing(Integers());
> RamExt := [];
> for c0 in [2, -2, 6, -6] do
> for c1 in [0, 2, -2, 4, -4, 6, -6] do
>     g := x^2 + c1*x + c0;
>     new := true;
>     for L in RamExt do
>         if HasRoot(PolynomialRing(L)!g) then
>             new := false;
>             break L;
>         end if;
>     end for;
>     if new then
>         print "new field with polynomial", g;
>         Append(~RamExt, ext<pAdicRing(2, 20) | g>);
>     end if;
> end for;
> end for;
new field with polynomial x^2 + 2
new field with polynomial x^2 + 2*x + 2
new field with polynomial x^2 + 4*x + 2
new field with polynomial x^2 + 2*x - 2
new field with polynomial x^2 + 4*x - 2
new field with polynomial x^2 + 6
```

These are all such extensions, since the extensions of $\mathbf{Q}_2$ of degree 2 are in bijection to the 7 non-trivial classes of $\mathbf{Q}_2^*/(\mathbf{Q}_2^*)^2$ and one of these classes yields the unramified extension.

47.11.3 Factorization

It is possible to factorize (to some precision) polynomials over a local ring or field. Approximate factorizations can also be lifted to a factorization to greater precision.

`HenselLift(f, s)`

Given a sequence s of polynomials with coefficients that can be coerced into the coefficient ring of f such that $f \equiv \prod_{i=1}^{\#s} s[i]$ modulo π, $s[i]$ and $[j]$ are co–prime modulo π for all i and j, and $s[i]$ is monic for all i, find a more accurate factorization $t[1], t[2], \ldots t[\#s]$ such that $f \equiv \prod_{i=1}^{\#s} t[i]$ modulo π^k, where k is the minimum precision of the coefficients of f.

Example H47E19

If the reduction of a polynomial over the residue class field is not a power of an irreducible polynomial, the factorization into powers of different irreducibles can be lifted to a factorization over the local ring.

```
> Z2 := pAdicRing(2, 25);
> R<x> := PolynomialRing(Z2);
> f := &* [ x - i : i in [1..8] ];
> F2 := ResidueClassField(Z2);
> Factorization( PolynomialRing(F2)!f );
[
    <$.1, 4>,
    <$.1 + 1, 4>
]
> h1 := x^4;
> h2 := (x+1)^4;
> h := HenselLift(f, [h1, h2]);
> h[1], h[2], f - h[1]*h[2];
x^4 - 20*x^3 + 140*x^2 - 400*x + 384
x^4 - 16*x^3 + 86*x^2 - 176*x + 105
0
```

`IsIrreducible(f)`

Given a polynomial f with coefficients lying in a local ring or field L, return `true` if and only if f is irreducible over L. Currently, this only works over p-adic rings, unramified extensions of p-adic rings, totally ramified extensions of p-adic rings, and totally ramified extension of unramified extensions of p-adic rings.

`SquareFreeFactorization(f)`

Return a sequence of tuples of polynomials and multiplicities where the polynomials are not divisible by any square of a polynomial. The product of the polynomials to the corresponding multiplicities is the polynomial f (to some precision). Currently, this only works over p-adic rings, unramified extensions of p-adic rings, totally ramified extensions of p-adic rings, and totally ramified extension of unramified extensions of p-adic rings.

`Factorization(f)`

`LocalFactorization(f)`

`Certificates`	BoolElt	*Default :* `false`
`IsSquarefree`	BoolElt	*Default :* `false`
`Ideals`	BoolElt	*Default :* `false`
`Extensions`	BoolElt	*Default :* `false`

Return the factorization of the polynomial f over a local ring or field into irreducible factors as a sequence of pairs, the first entry giving the irreducible factor and the second its multiplicity.

Precision is important since for polynomials over rings of relatively small precision a correct factorization may not be possible and an error will result. A lower bound on the precision needed for the factorization to succeed is given by `SuggestedPrecision`; this precision may still be insufficient, however.

The precision the factorization is returned to is reduced for multiple factors.

The optional parameter `IsSquarefree` can be set to `true`, if the polynomial is known to be square-free. The `Certificates` parameter can be set to `true` to compute certificates for the irreducibility of the individual factors returned. This information can be used to compute the p-maximal order of the equation order defined by the factor. If the `Extensions` parameter is set to `true` then certificates will be returned which will include an extension given by each factor.

`SuggestedPrecision(f)`

For a polynomial f over a local ring or field, return a precision at which the factorization of f as given by `Factorization(f)` will be Hensel liftable to the correct factorization.

The precision returned is not guaranteed to be enough to obtain a factorization of the polynomial. It may be that a correct factorization cannot be found at that precision but may be possible with a little more precision.

Currently, this only works over p-adic rings, unramified extensions of p-adic rings, totally ramified extensions of p-adic rings, and totally ramified extension of unramified extensions of p-adic rings.

`IsIsomorphic(f, g)`

Given two irreiducible polynomials over the same p-adic field, test if the extensions defined by them are isomorphic.

`Distance(f, g)`

Given two Eisenstein polynomials of the same degree and discriminant compute their distance, i.e. the minimal weighted valuation of the difference of the coefficients.

Example H47E20

The use of `SuggestedPrecision` along with `Factorization` is illustrated below for a few different cases.

```
> L<b> := ext<ext<pAdicRing(5, 20) | 2> |  y^2 + 5*y + 5>;
> R<x> := PolynomialRing(L);
> f := (x - 1)^3*(x - b)^2*(x - b^2 + b - 1);
> SuggestedPrecision(f);
80
> Factorization(f);
[
    <x - b + O(b^40), 2>,
    <x - 1 + O(b^40), 3>,
    <x + 6*b + 4 + O(b^40), 1>
]
1 + O(b^40)
> f := (x + 2)^3*(x + b)*(x + 3)^4;
> f;
x^8 + (b + 18 + O(b^40))*x^7 + (18*b + 138 + O(b^40))*x^6 + (138*b + 584 +
    O(b^40))*x^5 + (584*b + 1473 + O(b^40))*x^4 + (1473*b + 2214 + O(b^40))*x^3
    + (2214*b + 1836 + O(b^40))*x^2 + (1836*b + 648 + O(b^40))*x + 648*b +
    O(b^40)
> SuggestedPrecision(f);
80
> Precision(L);
80
> P<y> := PolynomialRing(Integers());
> R<b> := ext<ext<pAdicRing(3, 20) | 2> |  y^2 + 3*y + 3>;
> P<x> := PolynomialRing(R);
> f := x^12 + 100*x^11 + 4050*x^10 + 83700*x^9 + 888975*x^8 + 3645000*x^7 -
> 10570500*x^6 - 107163000*x^5 + 100875375*x^4 + 1131772500*x^3 -
> 329614375*x^2 + 1328602500*x + 332150625;
> SuggestedPrecision(f);
48
> Factorization(f);
[
    <x + 153560934 + O(b^40), 1>,
    <x - 1595360367 + O(b^40), 1>,
    <x + 1273329451*$.1 - 1037496066 + O(b^40), 1>,
```

```
    <x + -1273329451*$.1 - 97370567 + O(b^40), 1>,
    <x^4 + (-1598252738*$.1 - 309919655 + O(b^40))*x^3 + (-280421715*$.1 -
        102998055 + O(b^40))*x^2 + (1263867503*$.1 + 923047935 + O(b^40))*x +
        -1252549104*$.1 - 786365260 + O(b^40), 1>,
    <x^4 + (1598252738*$.1 - 600198580 + O(b^40))*x^3 + (280421715*$.1 +
        457845375 + O(b^40))*x^2 + (-1263867503*$.1 - 1604687071 + O(b^40))*x +
        1252549104*$.1 + 1718732948 + O(b^40), 1>
]
1 + O(b^40)
> R<b> := ext<ext<pAdicRing(3, 25) | 2> |  y^2 + 3*y + 3>;
> P<x> := PolynomialRing(R);
> f := x^12 + 100*x^11 + 4050*x^10 + 83700*x^9 + 888975*x^8 + 3645000*x^7 -
> 10570500*x^6 - 107163000*x^5 + 100875375*x^4 + 1131772500*x^3 -
> 329614375*x^2 + 1328602500*x + 332150625;
> Factorization(f);
[
    <x + 143905694229 + O(b^50), 1>,
    <x - 399882754935 + O(b^50), 1>,
    <x + 46601526664*$.1 + 229090274400 + O(b^50), 1>,
    <x + -46601526664*$.1 + 135887221072 + O(b^50), 1>,
    <x^4 + (242476655332*$.1 + 187976437999 + O(b^50))*x^3 + (372805509192*$.1 -
        38457626466 + O(b^50))*x^2 + (126788105939*$.1 + 60198382752 +
        O(b^50))*x + 347425890996*$.1 + 215394267602 + O(b^50), 1>,
    <x^4 + (-242476655332*$.1 - 296976872665 + O(b^50))*x^3 + (-372805509192*$.1
        + 63219964593 + O(b^50))*x^2 + (-126788105939*$.1 - 193377829126 +
        O(b^50))*x + -347425890996*$.1 + 367831095053 + O(b^50), 1>
]
1 + O(b^50)
```

Note that the polynomial itself must have coefficients with precision at least that given by `SuggestedPrecision` (and not just the coefficient ring) for `Factorization` to succeed. Sometimes this will not be possible if the coefficients of the polynomial are not known to sufficient precision.

Example H47E21

In this example we demonstrate how factorizations of a rational polynomial over some local rings can give information on the Galois group.

```
> Zx<x> := PolynomialRing(Integers());
> g := x^5 - x + 1;
> Factorization(Discriminant(g));
[ <19, 1>, <151, 1> ]
> g2 := Factorization( PolynomialRing(pAdicRing(2, 10)) ! g );
> g2;
[
    <$.1^2 + 367*$.1 - 93, 1>,
    <$.1^3 - 367*$.1^2 - 386*$.1 + 11, 1>
]
```

```
> g3 := Factorization( PolynomialRing(pAdicRing(3, 10)) ! g );
> g3;
[
    <$.1^5 - $.1 + 1, 1>
]
> g7 := Factorization( PolynomialRing(pAdicRing(7, 10)) ! g );
> g7;
[
    <$.1^2 + 138071312*$.1 + 2963768, 1>,
    <$.1^3 - 138071312*$.1^2 + 132202817*$.1 - 84067650, 1>
]
```

This shows that the Galois group of g contains elements of orders 2, 3, 5 and 6, and therefore is isomorphic to S_5.

47.12 Automorphisms of Local Rings and Fields

The automorphisms of a local ring or field are determined by their images on the generators of the ring. All computations necessary to determine the automorphism group can be performed in the local ring.

`Automorphisms(L)`

Given a local ring or field L, returns the automorphisms of L over its p-adic sub-field $\mathbf{Q}_p$ as a sequence of maps of L into L.

`Automorphisms(K, k)`

Given a local ring or field K over k, returns the k-automorphisms of K as a sequence of maps of K into K.

`AutomorphismGroup(L)`

Return the automorphism group acting on L over its p-adic sub-field $\mathbf{Q}_p$ as a permutation group (representing the regular action). Also return the map from the permutation group to the group of automorphisms represented explicitly (i.e. like returned from the function above).

`AutomorphismGroup(K, k)`

Return the automorphism group acting on K over its p-adic k as a permutation group (representing the regular action). Also return the map from the permutation group to the group of automorphisms represented explicitly (i.e. like returned from the function above).

`IsNormal(K)`

Given a p-adic ring or field K, test if K is normal over it's prime field $\mathbf{Q}_p$, ie. if K admits exactly n automorphisms where n is the degree of K.

`IsNormal(K, k)`

Given a p-adic ring or field K, test if K is normal over the subfield k.

`IsAbelian(K, k)`

Given p-adic fields K/k, test if the automorphism group of K over k is abelian.

`Continuations(m, L)`

For an automorphism m of the p-adic ring L, compute all possible extensions of m to L.

`IsIsomorphic(E, K)`

For two p-adic rings or fields, test if they are isomorphic over $\mathbf{Q}_p$.

Example H47E22

We define an extension of $\mathbf{Z}_2$ with ramification degree 2 and inertia degree 2 and compute automorphisms.

```
> I<a> := ext<pAdicRing(2, 10) | 2>;
> R<x> := PolynomialRing(I);
> L<b> := ext<I | x^2 + 2*a*x + 2*a^2>;
> L;

47.13 Completions

Local Rings can be obtained by completing an order at a prime ideal (see Chapter 34 and Completion on page 891).

```
Completion(O, P)
Completion(K, P)
```

Precision RngIntElt *Default :* 20

The completion (as an unbounded precision local ring or field with default precision given by Precision) of the order or number field at the prime ideal P, and the embedding of the order or number field into the resulting local ring.

```
LocalRing(P, k)
```

The completion (as a local ring) of the order of the prime ideal P at P with precision k and the embedding of the order into the resulting local ring.

Example H47E23

Here we demonstrate the use of Completion.

```
> K := NumberField(x^6 - 5*x^5 + 31*x^4 - 85*x^3 + 207*x^2 - 155*x + 123);
> lp := Decomposition(K, 7);
> C, mC := Completion(K, lp[2][1]);
> C;

47.14 Class Field Theory

The class field theory of local fields classifies abelian extensions of local field in a way similar to the way global class field theory deals with extensions of number fields and global function fields.

While the origins of local class field theory are, via completions and localisations, in the global case, today it is a theory in its own. Although local class field theory can be used to obtain global results, it has very powerful generalisations that the global case (currently) does not allow.

Local class fields are classified in terms of the norm group, ie. the multiplicative group of norms of elements, rather than some ideal or divisor class group as in the global case. Since the multiplicative group of a local field is far better understood than the ideal group of a global field, the theory is much more explicit and easier in the local case.

47.14.1 Unit Group

In contrast to the case of global fields, the multiplicative group of both p-adic rings and fields has a well understood structure which can be computed by algorithms developed and implemented by S. Pauli [Pau06]. It should be noted that all the unit group related functions operate on fixed-precision rings only.

`PrincipalUnitGroupGenerators(R)`

The principal units of a p-adic ring or field R are elements of the form $1 + \pi\mathbf{Z}_R$ where π is a uniformizing element of R and $\mathbf{Z}_R$ is the ring of integers. This function returns a sequence of generators for this group.

`PrincipalUnitGroup(R)`

The principal units of a p-adic ring or field R are elements of the form $1 + \pi\mathbf{Z}_R$ where π is a uniformizing element of R and $\mathbf{Z}_R$ is the ring of integers. This function returns an abstract abelian group isomorphic to the group of principal units and an explicit isomorphism, ie. a map between the abstract group and the p-adic ring or field.

`UnitGroup(R)`

Given a p-adic ring R of fixed precision, this function computes an abstract abelian group isomorphic to the unit group as well as an explicit map between the abstract group and R.

`UnitGroup(F)`

Given a p-adic field F of fixed precision, this function computes an abstract abelian gorup isomorphic to the multiplicative group of F as well as an explicit map between the abstract group and F.

`UnitGroupGenerators(R)`

Given a p-adic ring with fixed precision, this function computes generators for its unit group.

`UnitGroupGenerators(F)`

Given a p-adic field with fixed precision, this function computes generators for its multiplicative group.

`pSelmerGroup(p,F)`

Given a l-adic field F, return the p-Selmer group, i.e., the group F^*/F^{*p}, as an abstract group, as well as the map from F^* to the abstract group.

47.14.2 Norm Group

Given two p-adic field F/k the norm group of F in k, ie. the image of the norm map from F to k is the central object of local class field theory. Since the norm map will always operate on some multiplicative group, all functions in this section will take the map returned by `UnitGroup` as an argument as this then allows the convenient way of describing the norm group as a subgroup of some explicit finitely generated abelian group.

`NormGroup(R, m)`

Given a p-adic ring or field R extending S and a description of the unit group of S encoded by a map m from some abstract abelian group to S as computed by `UnitGroup`, compute the image of the norm map as a subgroup. The map returned is the embedding map returned form the subgroup constructor.

`NormEquation(R, m, b)`

Given a p-adic ring R defined over S, the unit group of S encoded by the map m as computed by `UnitGroup(S)` and some element $b \in S$, try to compute an element $a \in R$ such that the norm of a equals b. In case such an element exists, it is returned as a second value.

`NormEquation(m1, m2, G)`

Given two p-adic rings R and S and their unit groups U_R and U_S as parameterized by the maps $m_1 : U_R \to R$ and $U_S \to S$ as well as a subgroup $G < U_S$, compute the preimage of G under the norm map operating on the unit groups.

`Norm(m1, m2, G)`

Given two p-adic rings R and S and their unit groups U_R and U_S as parameterized by the maps $m_1 : U_R \to R$ and $U_S \to S$ as well as a subgroup $G < U_R$, compute the image of G under the norm map operating on the unit groups.

`NormKernel(m1, m2)`

Given two p-adic rings R and S and their unit groups U_R and U_S as parameterized by the maps $m_1 : U_R \to R$ and $U_S \to S$ compute the kernel of the norm map from U_R to U_S as a subgroup of U_R.

47.14.3 Class Fields

Class fields, that is abelian extensions are parameterized by their norm groups. Pauli, in [Pau06] gave explicit algorithms to solve the reverse problem of class field theory: given a suitable subgroup of some (abstractly given) multiplicatively group of some p-adic field, compute explicit defining equations for the class field.

`ClassField(m, G)`

Given a p-adic field S and its multiplicative group U_S specified by the map $m : U_S \to S$ and a suitable subgroup $G < U_S$, this function computes for each cyclic factor of U_S/G an explicit defining equation for the class field corresponding to this factor.

`NormGroupDiscriminant(m, G)`

Given a p-adic field S and its multiplicative group U_S specified by the map $m : U_S \to S$ and a suitable subgroup $G < U_S$, this function computes the valuation of the discriminant of the extension parameterized by G without computing explicit equations for it.

47.15 Extensions

It is a well known classical theorem that p-adic fields admit only finitely many different extensions of bounded degree (in contrast to number fields which have an infinite number of extensions of any degree). In his thesis, Pauli [Pau01a] developed explicit methods to enumerate those extensions.

`AllExtensions(R, n)`

`E`	RngIntElt	*Default :* 0
`F`	RngIntElt	*Default :* 0
`Galois`	BoolElt	*Default :* `false`
`D`	RngIntElt	*Default :* 0
`j`	RngIntElt	*Default :* -1

Given a p-adic ring or field R and some positive integer n, compute defining equations for all extensions of R of degree n. The optional parameters can be used to limit the extensions in various ways:

`E`	specifies the ramification index. 0 implies no restriction.
`F`	specifies the inertia degree, 0 implies no restriction.
`D`	specified the valuation of the discriminant, 0 implies no restriction.
`j`	specifies the valuation of the discriminant via the formula $D := d+j-1$ where d is the degree of R.
`Galois`	when set to `true`, limits the extensions to only list normal extensions.

`NumberOfExtensions(R, n)`

`E`	RngIntElt	*Default :* 0
`F`	RngIntElt	*Default :* 0
`Galois`	BoolElt	*Default :* `false`
`D`	RngIntElt	*Default :* 0
`j`	RngIntElt	*Default :* -1

Given a p-adic ring or field R and some positive integer n, compute the number of extensions of R of degree n. Similarly to the above function, the optional parameters can be used to impose restrictions on the fields returned.

`OreConditions(R, n, j)`

Given a p-adic ring or field R and positive integers n and j, test if there exists extensions of R of degree n with valuation of the discriminant being $n + j - 1$.

48 GALOIS RINGS

Chapter 48
GALOIS RINGS

48.1 Introduction

MAGMA provides facilities for computing with Galois rings. The features are currently very basic, but advanced features will be available in the near future, including support for the creation of subrings and appropriate embeddings, allowing lattices of compatible embeddings, just as for finite fields.

A Galois ring R in MAGMA is considered as a finite algebraic extension of $\mathbf{Z}_{p^a}$ (where p is prime) by a monic polynomial $D \in \mathbf{Z}[x]$ which is irreducible modulo p. Thus R is presented as the polynomial quotient ring

$$\mathbf{Z}_{p^a}[x]/\langle D \rangle$$

and is usually written as $\mathbf{GR}(p^a, d)$, where d is the degree of D. The cardinality of R is easily seen to be p^{ad}.

R has a unique maximal ideal generated by p, and the quotient ring $R/\langle p \rangle$ is a finite field isomorphic to $\mathbf{Z}_p[x]/\langle D \rangle$, where D is here considered as a polynomial in $\mathbf{Z}_p[x]$ (the coefficients are reduced modulo p). This finite field is called the *residue field* of R. In the following, we will also call the integer residue ring $\mathbf{Z}_{p^a}$ the *base ring* of R, because this is the subring of R generated by 1 and we can think of R as an extension of $\mathbf{Z}_{p^a}$.

For an non-zero element x of R, the valuation of x is defined to be the largest power of p which divides the coefficients of x, where x is considered as a polynomial in $\mathbf{Z}_p[x]/\langle D \rangle$. x is a unit if and only if the valuation of x is zero.

Because of the valuation defined on them, Galois rings are Euclidean rings, so they may be used in MAGMA in any place where general Euclidean rings are valid. This includes many matrix and module functions, and the computation of Gröbner bases. Linear codes over Galois rings will be supported in the near future.

48.2 Creation Functions

48.2.1 Creation of Structures

`GaloisRing(q, d)`

`GR(q, d)`

Given integers q, $d \geq 1$, where $q = p^a$ for prime p and $a \geq 1$, create the default Galois ring $\mathbf{GR}(p^a, d)$. The defining polynomial used to construct the ring will be that used for $\mathbf{F}_{p^d}$, lifted to $\mathbf{Z}_{p^a}$. If p is very large, it is advised to use the next function instead, because MAGMA must first factor q completely.

The angle bracket notation can be used to assign names to the generator; e.g.: `R<w> := GaloisRing(2, 3)`.

`GaloisRing(p, a, d)`

`GR(p, a, d)`

`Check` BoolElt *Default :* `true`

Given a prime p and integers $a, d \geq 1$, create the default Galois ring $\mathbf{GR}(p^a, d)$. The defining polynomial used to construct the ring will be that used for $\mathbf{F}_{p^d}$, lifted to $\mathbf{Z}_{p^a}$.

By default p is checked to be a strong pseudoprime for 20 random bases b with $1 < b < p$; if the parameter `Check` is false, then no check is done on p at all (this is useful when p is very large and one does not wish to perform an expensive primality test on p).

`GaloisRing(q, D)`

`GR(q, D)`

Given an integer q, where $q = p^a$ for prime p and $a \geq 1$, and a monic polynomial D over $\mathbf{Z}$ such that D is irreducible mod p, create the Galois ring $R = \mathbf{GR}(p^a, D)$. The coefficients of D are reduced modulo p^a, and R is constructed to behave like the polynomial quotient ring $\mathbf{Z}_{p^a}[x]/\langle D \rangle$. If p is very large, it is advised to use the next function instead, because Magma must first factor q completely.

`GaloisRing(p, a, D)`

`GR(p, a, D)`

`Check` BoolElt *Default :* `true`

Given a prime p, an integer $a \geq 1$, and a monic polynomial D over $\mathbf{Z}$ such that D is irreducible mod p, create the Galois ring $R = \mathbf{GR}(p^a, D)$. The coefficients of D are reduced modulo p^a, and R is constructed to behave like the polynomial quotient ring $\mathbf{Z}_{p^a}[x]/\langle D \rangle$. The parameter `Check` is as above.

48.2.2 Names

`AssignNames(~R, [f])`

Procedure to change the name of the generating element in the Galois ring R to the contents of the string f. When R is created, the name will be `R.1`.

This procedure only changes the name used in printing the elements of R. It does *not* assign to an identifier called f the value of the generator in R; to do this, use an assignment statement, or use angle brackets when creating the ring.

Note that since this is a procedure that modifies R, it is necessary to have a reference `~R` to R in the call to this function.

`Name(R, 1)`

Given a Galois ring R, return the element which has the name attached to it, that is, return the element `R.1` of R.

48.2.3 Creation of Elements

`R . 1`

`Generator(R)`

The generator for R as an algebra over its base ring $\mathbf{Z}_{p^a}$. Thus, if R is viewed as $\mathbf{Z}_{p^a}[x]/\langle D\rangle$, then `R.1` corresponds to x in this presentation.

`R ! a`

Given a Galois ring R create the element specified by a; here a is allowed to be an element coercible into R, which means that a may be

(i) An element of R;

(ii) An integer, to be identified with a modulo the characteristic p^a of R;

(iii) An element of the base ring $\mathbf{Z}_{p^a}$ of R, to be identified with the corresponding element of R.

(iv) A sequence of elements of the base ring $\mathbf{Z}_{p^a}$ of R. In this case the element $a_0 + a_1 w + \cdots + a_{n-1}w^{n-1}$ is created, where $a = [a_0, \ldots a_{n-1}]$ and w is the generator `R.1` of R over $\mathbf{Z}_{p^a}$.

`One(R)` `Identity(R)`

`Zero(R)` `Representative(R)`

These generic functions create 1, 1, 0, and 0 respectively, in any Galois ring.

`Random(R)`

Create a pseudo-random element of Galois ring R.

48.2.4 Sequence Conversions

`ElementToSequence(a)`

`Eltseq(a)`

Given an element a of the Galois ring R, return the sequence of coefficients $[a_0, \ldots, a_{n-1}]$ in the base ring $\mathbf{Z}_{p^a}$ of R (where R is $\mathbf{Z}_{p^a}[x]/\langle D\rangle$), such that $a = a_0 + a_1 w + \cdots + a_{n-1}w^{d-1}$, with w the generator of R, and d the degree of D.

Example H48E1

We can define the Galois ring $\mathbf{GR}(2^3, 2)$ using the default function:

```
> R<w> := GaloisRing(2^3, 2);
> R;
GaloisRing(2, 3, 2)
```

We note that R has characteristic 8 and that $w^2 + w + 1 = 0$ in R.

```
> R!8;
```

```
0
> R!9;
1
> w;
w
> 4*w;
4*w
> 4*w + 4*w;
0
> w^2;
7*w + 7
> w^2 + w + 1;
0
```

We can list all the elements of R by simply looping over R:

```
> [x: x in R];
[ 0, 1, 2, 3, 4, 5, 6, 7, w, w + 1, w + 2, w + 3, w + 4, w + 5, w + 6,
    w + 7, 2*w, 2*w + 1, 2*w + 2, 2*w + 3, 2*w + 4, 2*w + 5, 2*w + 6, 2*w
    + 7, 3*w, 3*w + 1, 3*w + 2, 3*w + 3, 3*w + 4, 3*w + 5, 3*w + 6,
    3*w + 7, 4*w, 4*w + 1, 4*w + 2, 4*w + 3, 4*w + 4, 4*w + 5, 4*w +
    6, 4*w + 7, 5*w, 5*w + 1, 5*w + 2, 5*w + 3, 5*w + 4, 5*w + 5, 5*w
    + 6, 5*w + 7, 6*w, 6*w + 1, 6*w + 2, 6*w + 3, 6*w + 4, 6*w + 5,
    6*w + 6, 6*w + 7, 7*w, 7*w + 1, 7*w + 2, 7*w + 3, 7*w + 4, 7*w +
    5, 7*w + 6, 7*w + 7 ]
```

We see that the elements of R can be considered as polynomials of degree at most 1, with coefficients in the range $\{0 \dots 7\}$.
We can easily create elements of R also using the `!` operator, and use the `Eltseq` function to recover the corresponding sequence of coefficients.

```
> R ! [1, 2];
2*w + 1
> Eltseq(2*w + 1);
[ 1, 2 ]
> Eltseq(w);
[ 0, 1 ]
```

48.3 Structure Operations

48.3.1 Related Structures

`Category(R)` `Parent(R)` `Centre(R)`
`PrimeRing(R)` `PrimeField(R)`
`FieldOfFractions(R)`

48.3.2 Numerical Invariants

`Characteristic(R)`

The characteristic of R, which is p^a where R is considered as $\mathbf{Z}_{p^a}[x]/\langle D\rangle$.

`#R`

The cardinality of R, which is p^{ad} where R is considered as $\mathbf{Z}_{p^a}[x]/\langle D\rangle$ and d is the degree of D.

`Degree(R)`

The degree of R, which is the degree of D, where R is considered as $\mathbf{Z}_{p^a}[x]/\langle D\rangle$.

`ResidueField(R)`

The residue field of R, which is the finite field $\mathbf{Z}_p[x]/\langle D\rangle$, where R is considered as $\mathbf{Z}_{p^a}[x]/\langle D\rangle$.

48.3.3 Ring Predicates and Booleans

The following functions are described for rings in general in Section 17.4.3.

`IsCommutative(R)` `IsUnitary(R)`
`IsFinite(R)` `IsOrdered(R)`
`IsField(R)` `IsEuclideanDomain(R)`
`IsPID(R)` `IsUFD(R)`
`IsDivisionRing(R)` `IsEuclideanRing(R)`
`IsPrincipalIdealRing(R)` `IsDomain(R)`
`R eq G` `R ne G`

48.4 Element Operations

See also Section 17.5.

48.4.1 Arithmetic Operators

`+ a` `- a`
`a + b` `a - b` `a * b` `a ^ k`
`a +:= b` `a -:= b` `a *:= b`

48.4.2 Euclidean Operations

a div b | a mod b | Quotrem(a, b)
GCD(a, b) | LCM(a, b) | XGCD(a, b)

48.4.3 Equality and Membership

a eq b | a ne b
a in R | a notin R

48.4.4 Parent and Category

Parent(a) | Category(a)

48.4.5 Predicates on Ring Elements

IsZero(a) | IsOne(a) | IsMinusOne(a)
IsNilpotent(a) | IsIdempotent(a)
IsUnit(a) | IsZeroDivisor(a)

Example H48E2

This simple example shows how one can compute Gröbner bases over Galois rings. We create an ideal in 3 variables over a Galois ring and compute its Gröbner basis.

```
> R<w> := GaloisRing(3, 3, 2);
> #R;
729
> P<x,y,z> := PolynomialRing(R, 3);
> I := ideal<P | [x^2 - w*y, 3*y^3 - 3*w*x*z, 9*z^5 - 9*w]>;
> GroebnerBasis(I);
[
    x^2 + 26*w*y,
    3*x*y^3 + (6*w + 6)*y*z,
    3*x*z + (15*w + 3)*y^3,
    9*x + (9*w + 9)*y^3*z^4,
    3*y^6 + (21*w + 15)*y*z^2,
    9*z^5 + 18*w
]
```

Notice that the leading coefficients include 3 and 9, which are not units in the ring. See Chapter 105 for much more information on such Gröbner bases.

49 POWER, LAURENT AND PUISEUX SERIES

Chapter 49
POWER, LAURENT AND PUISEUX SERIES

49.1 Introduction

This chapter describes the operations on formal power, Laurent and Puiseux series available in MAGMA.

49.1.1 Kinds of Series

Internally MAGMA has only one kind of formal series, where general fractional exponents are allowed, but externally there are three kinds of series: power, Laurent and Puiseux. Power series must have a non-negative integral valuation and integral exponents, Laurent series must have an integral valuation and integral exponents (possibly negative), while Puiseux series may have a general rational valuation and general rational exponents. The main reason for the three kinds is simply to supply error checking for operations illegal to a specific kind, so the user will not move into the next kind of exponents inadvertently. Apart from these error checks, there is no difference at all between the different kinds of series, so one can simply use Puiseux series always if the restrictions on exponents are not desired, and this will cause no loss of efficiency or functionality at all even if all exponents remain integral or integral and non-negative.

In MAGMA, the set of all power series over a given base ring R is called a power series ring (denoted by $R[[x]]$) and the category names are `RngSerPow` for the ring and `RngSerPowElt` for the elements. The set of all Laurent series over a given base ring R is called a Laurent series ring (denoted by $R((x))$) and the category names are `RngSerLaur` for the ring and `RngSerLaurElt` for the elements. Finally, the set of all Puiseux series over a given base ring R is called a Puiseux series ring (denoted by $R\langle\langle x\rangle\rangle$) and the category names are `RngSerPuis` for the ring and `RngSerPuisElt` for the elements. For the rest of this chapter, the term "series ring" refers to any of the above rings and the corresponding virtual category name is `RngSer`; the term "series" refers to any of the above series kinds and the corresponding virtual category name is `RngSerElt`.

49.1.2 Puiseux Series

Puiseux series in a variable x are often mathematically defined to be Laurent series in another variable y say, where $y = x^{1/d}$, for a fixed positive integer d; this d is usually fixed for all the series under consideration. MAGMA is more general, in that although each series is internally represented in this way (i.e., its valuation, exponents and precision are thought to be divided by a single denominator associated with it), different Puiseux series may have different exponent denominators and may be freely mixed (for example, in addition, where the exponent denominator of the result will be derived from that of the arguments). Thus there is no restriction whatsoever to a fixed exponent denominator for a given Puiseux series ring.

49.1.3 Representation of Series

Formal series are stored in truncated form, unless only finitely many terms are non-zero. If a series has precision p, that means that its coefficients are unknown from exponent p onwards. This truncated form is similar to the floating point representation of real numbers except for one significant difference: because for series terms do not "carry" in arithmetic operations like they do in integer and real arithmetic, error propagation common in floating point methods does not occur. Consequently, given a result of any sequence of arithmetic operations with formal series, the coefficients of the known terms (the ones up to the given precision) will always be *exactly correct*, with no error (assuming the coefficient ring has exact arithmetic for its elements of course).

Elements

$$c_v x^v + c_{v+1} x^{v+1} + \ldots$$

(with $v \in \mathbf{Q}$ and $r_v \neq 0$) of series ring over a commutative ring R are stored in the form of approximations

$$c_v x^v + c_{v+1} x^{v+1} + \ldots + O(x^p)$$

to a certain *precision* $p \geq v$. The $O(x^p)$ notation is used to refer to terms of degree at least the precision p in x. For Laurent series v must be an integer and for power series v must be a non-negative integer. Note that for Puiseux series the above element is actually internally stored in the form

$$c_w x^{w/d} + c_{w+1} x^{(w+1)/d} + \ldots + O(x^{q/d})$$

where $v = w/d$ and $p = q/d$ and d (the exponent denominator) is minimal.

49.1.4 Precision

Associated with any series there are two types of precision: the *absolute precision* and the *relative precision*. For the element

$$c_v x^v + c_{v+1} x^{v+1} + \cdots + O(x^p)$$

(with $v \in \mathbf{Q}$ and $r_v \neq 0$), the absolute precision is p and the relative precision is $p - v$.

The absolute precision indicates the largest known term, and the relative precision indicates the size of the range over which terms are known. The two types of precision and the *valuation* of the series, which equals v in the above, are therefore always related via $p = v + r$.

49.1.5 Free and Fixed Precision

For each type of series ring, there are two sub-kinds: a *free precision* ring (the usual case), where elements of the ring have arbitrary precision, and a *fixed precision* ring, where all elements of the ring have a fixed precision. In the latter case, for power series rings the fixed precision is absolute, while for Laurent and Puiseux series ring the fixed precision is relative.

The free precision rings most closely resemble the mathematical objects $R[[x]]$ and $R((x))$; elements in these free rings and fields carry their own precision with them. Operations usually return results to a precision that is maximal given the input (and the nature of the operation). Operations which are given infinite precision series but which must return finite precision series (e.g., division) return series whose precision is the *default* precision for the series ring (this is different from the fixed precision of fixed precision rings); the default precision is 20 by default but may be set to another value at creation by a parameter (see below). Elements of free structures that have finite series expansion (i.e., polynomials) can be created and stored exactly, with infinite (absolute and relative) precision. Also note that the relative precision will be 0 for approximations to 0.

The structures with fixed precision, which we will sometimes refer to as *quotient* structures, behave differently. All elements in a *power* series ring of fixed precision have the same fixed *absolute* precision p, and the relative precision may be anything from 0 to p. This means that the ring with fixed precision p behaves like a quotient of a polynomial ring, $R[x]/x^p$. All elements in a *Laurent* or *Puiseux* series ring of fixed precision have the same fixed *relative* precision; the only exception to this rule is that 0 in the ring is stored as zero with infinite absolute precision. The absolute precision of elements in a free Laurent or Puiseux series ring can be anything.

49.1.6 Equality

Since a given series ring will contain series truncated at arbitrary precision, care has to be taken as to the meaning of equality of two elements. Two series are considered equal iff they are identical (the equality operator `eq` follows this convention). But we call two series A and B in the same ring *weakly equal* if and only if their coefficients are the same whenever both are defined, that is, if and only if for every $n \leq p$ the coefficients A_n and B_n are equal, where p is the minimum of the precisions of A and B. Thus, for example, $A = 3+x+O(x^2)$ and $B = 3+x+17x^2+O(x^4)$ are the same, but $C = 3+x+17x^2+x^3+O(x^4)$ is different from B. Note that A and C are equal under this definition, and hence weak equality is not transitive!

49.1.7 Polynomials over Series Rings

For a discussion of operations for polynomials over series rings see Chapter 46 and Section 49.7.

49.2 Creation Functions

49.2.1 Creation of Structures

`PowerSeriesRing(R)`

`PowerSeriesRing(R, p)`

`Global`	BoolElt	*Default :* `true`
`Precision`	RngIntElt	*Default :* 20

Given a commutative ring R, create the ring $R[[x]]$ of formal power series over R. If a second integer argument p is given, the resulting ring is a fixed precision series ring with fixed precision p; otherwise the resulting ring is a free precision series ring and the optional argument `Precision` may be used to set the default precision for elements of the power series ring (it will be 20 otherwise; see the section above on free and fixed precision). By default, a global series ring will be returned; if the parameter `Global` is set to `false`, a non-global series ring will be returned (to which a separate name for the indeterminate can be assigned). The angle bracket notation can be used to assign a name to the indeterminate: `S<x> := PowerSeriesRing(R)`.

`LaurentSeriesRing(R)`

`LaurentSeriesRing(R, p)`

`Global`	BoolElt	*Default :* `true`
`Precision`	RngIntElt	*Default :* 20

Given a commutative ring R, create the ring $R((x))$ of formal Laurent series over R. If a second integer argument p is given, the resulting ring is a fixed precision series ring with fixed precision p; otherwise the resulting ring is a free precision series ring and the optional argument `Precision` may be used to set the default precision for elements of the power series ring (it will be 20 otherwise; see the section above on free and fixed precision). By default, a global series ring will be returned; if the parameter `Global` is set to `false`, a non-global series ring will be returned (to which a separate name for the indeterminate can be assigned). The angle bracket notation can be used to assign a name to the indeterminate: `S<x> := LaurentSeriesRing(R)`.

`PuiseuxSeriesRing(R)`

`PuiseuxSeriesRing(R, p)`

`Global`	BoolElt	*Default :* `true`
`Precision`	RngIntElt	*Default :* 20

Given a commutative ring R, create the ring $R\langle\langle x\rangle\rangle$ of formal Puiseux series over R. If a second integer argument p is given, the resulting ring is a fixed precision series ring with fixed precision p; otherwise the resulting ring is a free precision series ring and the optional argument `Precision` may be used to set the default precision for elements of the power series ring (it will be 20 otherwise; see the section above on free and fixed precision). The optional argument `Precision` may be used to set the default precision for elements of the power series ring. By default, a global series ring will be returned; if the parameter `Global` is set to `false`, a non-global series ring will be returned (to which a separate name for the indeterminate can be assigned). The angle bracket notation can be used to assign a name to the indeterminate: `S<x> := PuiseuxSeriesRing(R)`.

Example H49E1

We demonstrate the difference between global and non-global rings. We first create the global power series ring over **Q** twice.

```
> Q := RationalField();
> P<x> := PowerSeriesRing(Q);
> PP := PowerSeriesRing(Q);
> P;
Power series ring in x over Rational Field
> PP;
Power series ring in x over Rational Field
> PP.1;
x
```

PP is identical to P. We now create non-global series rings (which are also different to the global series ring). Note that elements of all the rings are mathematically equal by automatic coercion.

```
> Pa<a> := PowerSeriesRing(Q: Global := false);
> Pb<b> := PowerSeriesRing(Q: Global := false);
> Pa;
Power series ring in a over Rational Field
> Pb;
Power series ring in b over Rational Field
> a;
a
> b;
b
> P;
Power series ring in x over Rational Field
> x;
x
> x eq a; // Automatic coercion
true
> x + a;
2*x
```

49.2.2 Special Options

`AssertAttribute(S,"DefaultPrecision", n)`

Procedure to change the default precision on a free series ring series S; the default precision will be set to n, which must be a non-negative integer.

`HasAttribute(S, "DefaultPrecision")`

Function that returns a Boolean indicating whether a default precision has been set on the free series ring S (which will always be `true`), as well as its (non-negative) integer value (which is 20 by default).

```
AssignNames(~S, ["x"])
```

Procedure to change the name of the 'indeterminate' transcendental element generating the series ring or field S; the name (used in printing elements of S) is changed to the string x. Note that no assignment to the identifier x is made (so x cannot be used for the specification of elements of S without further assignment).

```
Name(S, 1)
```

```
S . 1
```

Return the element of the series ring or field with a name attached to it, that is, return the 'indeterminate' transcendental element generating S over its coefficient ring.

49.2.3 Creation of Elements

The easiest way to create power and Laurent series in a given ring is to use the angle bracket construction to attach names to the indeterminate, and to use these names to express the series (see the examples). Below we list other options.

```
R . 1
```

```
UniformizingElement(R)
```

Return the generator (indeterminate) for the series ring R.

```
elt< R | v, [ a_1, ..., a_d], p >
```

Given a series ring R, integers v and p (where $p > 0$ or $p = \infty$), and a sequence $a = [a_1, \ldots, a_d]$ of elements of R, create the element in R with valuation v, known coefficients given by a and relative precision p. That is, this function returns the series $a_1x^v + \cdots + a_dx^{v+d-1} + O(x^{v+p})$, or, if $p = -1$, the exact series $a_1x^v + \cdots + a_dx^{v+d-1}$. If R is a power series ring, then v must be non-negative.

The integer v or the integer p or both may be omitted. If v is omitted, it will be set to zero by default; if p is omitted it will be taken to be $v + d$, where d is the length of the sequence a.

```
R ! s
```

Coerce s into the series ring R. Here s is allowed to be a sequence of elements from (or coercible into) the coefficient ring of R, or just an element from (or coercible into) R. A sequence $[a_1, \ldots, a_d]$ is converted into the series $a_1+a_2x^1+\cdots+a_dx^{d-1}+O(x^d)$.

`BigO(f)`

`O(f)`

Create the series $O(x^v)$ where x is the generator of the parent of f and v is the valuation of f. The most typical usage of this function is the expression $O(x^n)$ where x is the generator of a series ring, but a general series f is actually allowed.

`One(Q)` `Identity(Q)`

`Zero(Q)` `Representative(Q)`

49.3 Structure Operations

49.3.1 Related Structures

`Parent(R)` `Category(R)`

`BaseRing(R)`

`CoefficientRing(R)`

Return the coefficient ring of the series ring R.

`IntegerRing(R)`

`Integers(R)`

`RingOfIntegers(R)`

Return the power series ring which is the integer ring of the laurent series ring R.

`FieldOfFractions(R)`

Return the laurent series ring which is the field of fractions of the series ring R.

`ChangePrecision(R, r)`

`ChangePrecision(~R, r)`

Return a series ring identical to the series ring R but having precision r.

`ChangeRing(R, C)`

Return the series ring identical to the series ring R but having coefficient ring C.

`ResidueClassField(R)`

Return the residue class field of the series ring R (which will be the same as the coefficient ring of R) and the map from R into the residue class field.

49.3.2 Invariants

`Characteristic(R)`

`Precision(R)`
`GetPrecision(R)`

Return the precision of the fixed precision series ring R. If R is a fixed precision power series ring, then this is the fixed absolute precision for all elements of the ring. If R is a fixed precision Laurent series ring, then this is the maximum relative precision for all elements of the ring.

49.3.3 Ring Predicates and Booleans

`IsCommutative(Q)` `IsUnitary(Q)`
`IsFinite(Q)` `IsOrdered(Q)`
`IsField(Q)` `IsEuclideanDomain(Q)`
`IsPID(Q)` `IsUFD(Q)`
`IsDivisionRing(Q)` `IsEuclideanRing(Q)`
`IsPrincipalIdealRing(Q)` `IsDomain(Q)`
`R eq S` `R ne S`

49.4 Basic Element Operations

49.4.1 Parent and Category

`Parent(r)` `Category(r)`

49.4.2 Arithmetic Operators

`+ b` `- b`
`a + b` `a - b` `a * b` `a ^ k`
`a div b` `a / b`

49.4.3 Equality and Membership

`a eq b` `a ne b`
`a in R` `a notin R`

49.4.4 Predicates on Ring Elements

Note the definition of equality in the introduction to this Chapter. This not only affects the result of the application of `eq` and `ne`, but also that of `IsOne, IsZero` and `IsMinusOne`.

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`
`IsNilpotent(x)` `IsIdempotent(x)`
`IsUnit(a)` `IsZeroDivisor(x)` `IsRegular(x)`
`IsIrreducible(x)` `IsPrime(x)`

`IsWeaklyZero(f)`

Given a series f, return whether f is weakly zero, which is whether f is exactly zero or of the form $O(x^p)$ for some p.

`IsWeaklyEqual(f, g)`

Given series f and g, return whether f is weakly equal to g, which is whether $(f-g)$ is weakly zero (see `IsWeaklyZero`).

`IsIdentical(f, g)`

Given series f and g, return whether f is identical to g, which is whether f and g have exactly the same valuation, precision, and coefficients.

49.4.5 Precision

`AbsolutePrecision(f)`

Given a series f, this returns the absolute precision that is stored with f. If f is a series in x, the absolute precision of f is the exponent p such that x^p is the first term of f of which the coefficient is not known, that is, it is the least p such that $f \in O(x^p)$. If f is known exactly (in a free ring), the absolute precision is infinite and an error occurs. Note that the absolute precision may be a non-integral rational number if f is a Puiseux series.

`RelativePrecision(f)`

Given a series f, this returns the relative precision that is stored with f. The relative precision counts the number of coefficients of f that is known, starting at the first non-zero term. Hence the relative precision is the difference between the absolute precision and the valuation of f, and is therefore always non-negative; however, if f is exact, the relative precision is infinite and the value ∞ is returned. Note that the relative precision may be a non-integral rational number if f is a Puiseux series.

`ChangePrecision(f, r)`

`ChangePrecision(~f, r)`

The (non puiseux) series f with absolute precision r (which can be positive infinity).

49.4.6 Coefficients and Degree

`Coefficients(f)`

`ElementToSequence(f)`

`Eltseq(f)`

Let f be a series with coefficients in a ring R and with indeterminate x. This function returns the sequence Q of coefficients of f, the unscaled valuation v and the exponent denominator d of f (v is the true valuation of f multiplied by d). The i-th entry $Q[i]$ of Q equals the coefficient of

$$x^{\frac{v+i-1}{d}}$$

in f. Thus the first entry of Q is the 'first' (lowest order) non-zero coefficient of f, i.e., the coefficient of x^w where w is the true valuation of f.

`Coefficient(f, i)`

Given a series f with coefficients in a ring R, and a rational or integer i, return the coefficient of the i-th power of the indeterminate x of f as an element of R. If f is a Puiseux series i may be a (non-integral) rational; otherwise i must be an integer (and also must be non-negative if f is a power series). Also, i must be less than p, the precision of f.

`LeadingCoefficient(f)`

Given a series f with coefficients in a ring R, return the leading coefficient of f as an element of R, which is the first non-zero coefficient of f (i.e., the coefficient x^v in f, where x is the indeterminate of f and v is the valuation of f).

`LeadingTerm(f)`

Given a series f with coefficients in a ring R, return the leading term of f, which is the first non-zero term of f (i.e., the term of f whose monomial is x^v, where x is the indeterminate of f and v is the valuation of f).

`Truncate(f)`

Given a series f, return the exact series obtained by truncating f after the last known non-zero coefficient.

`ExponentDenominator(f)`

Given a series f, return the exponent denominator of f, i.e., the lowest common denominator of all the exponents of the non-zero terms of f (always an integer). For power series and Laurent series, this will always be 1 of course.

`Degree(f)`

Given a series f, return the degree of the truncation of f, that is, the exponent of the last known non-zero term. Note that this may be a non-integral rational number if f is a Puiseux series.

`Valuation(f)`

Given a series f, return the smallest integer v (possibly negative for Laurent series) such that the coefficient of x^v in f is not known to be zero. For the exact 0 element (in a free ring), the valuation is ∞. Note that the valuation may be a non-integral rational number if f is a Puiseux series.

`ExponentDenominator(f)`

The exponent denominator of the series f. This is the lowest common denominator of the exponents of the non-zero terms of f.

49.4.7 Evaluation and Derivative

`Derivative(f)`

Given a series $f \in R$, return the derivative of f with respect to its indeterminate, as an element of R. Note that the precision decreases by 1 (unless f has infinite precision).

`Derivative(f, n)`

Given a series $f \in R$ and an integer $n > 0$, return the n-th derivative of f with respect to its indeterminate, as an element of R. Note that the precision decreases by n (unless f has infinite precision).

`Integral(f)`

Given a series $f \in R$, return an anti-derivative F of f with respect to its indeterminate, which is an element of R which has derivative f. The coefficient of x^{-1} in f must be zero. Note that the precision of F will be exceeding that of f by 1 (unless f has infinite precision).

`Evaluate(f, s)`

Given an element f of a series ring over the coefficient ring R, and an element s of the ring S, return the value of $f(s)$ when the indeterminate x is evaluated at s. The result will be an element of the common overstructure over R and S.

`Laplace(f)`

The Laplace transform of the series f; if f has expansion $\sum_{i\geq 0} a_i x^i$, its Laplace transform has expansion $\sum_{i\geq 0}(i!a_i)x^i$. The valuation of f must be integral and non-negative.

49.4.8 Square Root

`SquareRoot(f)`

`Sqrt(f)`

Return the square root of the series f, f must have even valuation if it is a power or Laurent series.

49.4.9 Composition and Reversion

`Composition(f, g)`

Given elements f and g from the same series ring P, return their composition, defined by

$$f \circ g = \sum_{i<p} f_i(g^i),$$

where $f = \sum_{i<p} f_i x^i$.

`Reversion(f)`

`Reverse(f)`

Given a series f (in x, say), this returns the inverse of f under composition, that is, an element g of the same power series ring such that its composition with f equals x to the best possible precision. If f is a power or Laurent series, the valuation of f must be 1. If f is a Puiseux series, the valuation of f must be positive (but need not equal 1), and if the valuation of f is not 1, the leading coefficient of f must be 1.

`Convolution(f, g)`

Given elements f and g from the same series ring P, return their convolution $f * g$, defined by

$$f * g = \sum_{i<\min(p,q)} f_i g_i x^i,$$

where $f = \sum_{i<p} f_i x^i + O(x^p)$ and $g = \sum_{i<q} g_i x^i + O(x^q)$.

Example H49E2

We demonstrate the functions `Composition` and `Reversion`. First we check that `Arcsin` is the reversion of `Sin`.

```
> S<x> := PowerSeriesRing(RationalField());
> f := Sin(x);
> g := Arcsin(x);
> f;
x - 1/6*x^3 + 1/120*x^5 - 1/5040*x^7 + 1/362880*x^9 -
    1/39916800*x^11 + 1/6227020800*x^13 - 1/1307674368000*x^15 +
    1/355687428096000*x^17 - 1/121645100408832000*x^19 + O(x^21)
> g;
x + 1/6*x^3 + 3/40*x^5 + 5/112*x^7 + 35/1152*x^9 + 63/2816*x^11 +
    231/13312*x^13 + 143/10240*x^15 + 6435/557056*x^17 +
    12155/1245184*x^19 + O(x^21)
> Composition(f, g);
x + O(x^21)
> Composition(g, f);
x + O(x^21)
> Reversion(f) - g;
O(x^21)
> Reversion(g) - f;
O(x^21)
```

Next we compute the reversion of a series whose valuation is not 1.

```
> S<x> := PuiseuxSeriesRing(RationalField());
> f := x^3 - x^5 + 2*x^8;
> r := Reversion(f);
> f;
x^3 - x^5 + 2*x^8
> r;
x^(1/3) + 1/3*x + 4/9*x^(5/3) - 2/3*x^2 + 65/81*x^(7/3) -
    22/9*x^(8/3) + 5/3*x^3 - 208/27*x^(10/3) + 5005/729*x^(11/3)
    - 70/3*x^4 + 206264/6561*x^(13/3) - 50830/729*x^(14/3) +
    134*x^5 - 498674/2187*x^(16/3) + 31389020/59049*x^(17/3) +
    O(x^6)
> Composition(r, f);
x + O(x^18)
> Composition(f, r);
x + O(x^(20/3))
```

Finally we compute the reversion of a proper Puiseux series.

```
> f := x^(2/5) - x^(2/3) + x^(3/2) + O(x^2);
> r := Reversion(f);
> r;
x^(5/2) + 5/2*x^(19/6) + 145/24*x^(23/6) + 715/48*x^(9/2) +
    389795/10368*x^(31/6) - 5/2*x^(21/4) + O(x^(11/2))
> Composition(f, r);
```

```
x + O(x^4)
> Composition(r, f);
x + O(x^(11/5))
```

49.5 Transcendental Functions

In each of the functions below, the precision of the result will be approximately equal to the precision of the argument if that is finite; otherwise it will be approximately equal to the default precision of the parent of the argument. An error will result if the coefficient ring of the series is not a field. If the first argument has a non-zero constant term, an error will result unless the coefficient ring of the parent is a real or complex domain (so that the transcendental function can be evaluated in the constant term).

See also the chapter on real and complex fields for elliptic and modular functions which are also defined for formal series.

49.5.1 Exponential and Logarithmic Functions

`Exp(f)`

Given a series f defined over a field, return the exponential of f.

`Log(f)`

Given a series f defined over a field of characteristic zero, return the logarithm of f. The valuation of f must be zero.

Example H49E3

In this example we show how one can compute the Bernoulli number B_n for given n using generating functions. The function `BernoulliNumber` now actually uses this method (since V2.4). Using this method, the Bernoulli number B_{10000} has been computed, taking about 14 hours on a 250MHz Sun Ultrasparc (the computation depends on the new asymptotically fast methods for series division).

The exponential generating function for the Bernoulli numbers is:

$$E(x) = \frac{x}{e^x - 1}.$$

This means that the n-th Bernoulli number B_n is $n!$ times the coefficient of x^n in $E(x)$. The Bernoulli numbers $B_0, \ldots, B_n$ for any n can thus be calculated by computing the above power series and scaling the coefficients.

In this example we will compute B_{500}. We first set the final coefficient index n we desire to be 500. We then create the denominator $D = e^x - 1$ of the exponential generating function to precision $n+2$ (we need $n+2$ since we lose precision when we divide by the denominator and the valuation changes). For each series we create, we print the sum of it and $O(x^{20})$, which will only print the terms up to x^{19}.

```
> n := 500;
```

```
> S<x> := LaurentSeriesRing(RationalField(), n + 2);
> time D := Exp(x) - 1;
Time: 0.040
> D + O(x^20);
x + 1/2*x^2 + 1/6*x^3 + 1/24*x^4 + 1/120*x^5 + 1/720*x^6 + 1/5040*x^7 +
    1/40320*x^8 + 1/362880*x^9 + 1/3628800*x^10 + 1/39916800*x^11 +
    1/479001600*x^12 + 1/6227020800*x^13 + 1/87178291200*x^14 +
    1/1307674368000*x^15 + 1/20922789888000*x^16 + 1/355687428096000*x^17 +
    1/6402373705728000*x^18 + 1/121645100408832000*x^19 + O(x^20)
```

We then form the quotient $E = x/D$ which gives the exponential generating function.

```
> time E := x / D;
Time: 5.330
> E + O(x^20);
1 - 1/2*x + 1/12*x^2 - 1/720*x^4 + 1/30240*x^6 - 1/1209600*x^8 +
    1/47900160*x^10 - 691/1307674368000*x^12 + 1/74724249600*x^14 -
    3617/10670622842880000*x^16 + 43867/5109094217170944000*x^18 + O(x^20)
```

We finally compute the Laplace transform of E (which multiplies the coefficient of x^i by $i!$) to yield the generating function of the Bernoulli numbers up to the x^n term. Thus the coefficient of x^n here is B_n.

```
> time B := Laplace(E);
Time: 0.289
> B + O(x^20);
1 - 1/2*x + 1/6*x^2 - 1/30*x^4 + 1/42*x^6 - 1/30*x^8 + 5/66*x^10 -

49.5.2 Trigonometric Functions and their Inverses

`Sin(f)`

Given a series f defined over a field of characteristic zero, return the sine of f. The valuation of f must be zero.

`Cos(f)`

Given a series f defined over a field of characteristic zero, return the cosine of f. The valuation of f must be zero.

`Sincos(f)`

Given a series f defined over a field of characteristic zero, return both the sine and cosine of f. The valuation of f must be zero.

`Tan(f)`

Return the tangent of the series f defined over a field.

`Arcsin(f)`

Given a series f defined over a field of characteristic zero, return the inverse sine of f.

`Arccos(f)`

Given a series f defined over the real or complex field, return the inverse cosine of f.

`Arctan(f)`

Given a series f defined over a field of characteristic zero, return the inverse tangent of f.

49.5.3 Hyperbolic Functions and their Inverses

`Sinh(f)`

Given a series f defined over a field, return the hyperbolic sine of f.

`Cosh(f)`

Given a series f defined over a field, return the hyperbolic cosine of f.

`Tanh(f)`

Given a series f defined over a field, return the hyperbolic tangent of f.

`Argsinh(f)`

Given a series f defined over a field of characteristic zero, return the inverse hyperbolic sine of f.

`Argcosh(f)`

Given a series f defined over the real or complex field, return the inverse hyperbolic cosine of f.

`Argtanh(f)`

Given a series f defined over a field of characteristic zero, return the inverse hyperbolic tangent of f.

49.6 The Hypergeometric Series

For more information on the Hypergeometric Series, see [Hus87], page 176.

`HypergeometricSeries(a,b,c, z)`

Return the hypergeometric series $F(a, b, c; z)$ defined by

$$F(a, b, c; z) = \sum_{0 \leq n} \frac{(a)_n (b)_n}{n!(c)_n z^n}$$

where $(a)_n = a(a + 1) \cdots (a + n - 1)$.

49.7 Polynomials over Series Rings

Factorization is available for polynomials over series rings defined over finite fields. We recommend constructing polynomials from sequences rather than by addition of terms, especially over fields, to avoid some precision loss. For example, $x^4 + t$ will not have full precision in the constant coefficient as there will be a O term in the constant coefficient of x^4 which will reduce its precision as a field element. The equivalent polynomial `Polynomial([t, 0, 0, 0, 1])` will have more precision than that constructed as $x^4 + t$.

`HenselLift(f, L)`

Given a polynomial f over a series ring over a finite field or an extension of a series ring and a factorization L of f to precision 1 return a factorization of f known to the full precision of the coefficient ring of f.

`Factorization(f)`

`Certificates`	BoolElt	*Default :* `false`
`Ideals`	BoolElt	*Default :* `false`
`Extensions`	BoolElt	*Default :* `false`

The factorization of the polynomial f over a power series ring, laurent series field over a finite field or an extension of either into irreducibles.

If `Certificates` is set to `true`, a two-element certificate for each factor, proving its irreducibility, is returned.

If `Ideals` is set to `true`, two generators of some ideal for each factor are returned within the certificates.

If `Extensions` is set to `true`, an extension for each factor is returned within the certificates.

Example H49E4

We illustrate factorizations over series rings and the extensions which can be gained through them.

```
> P<t> := PowerSeriesRing(GF(101));
> R<x> := PolynomialRing(P);
> Factorization(x^5 + t*x^4 - t^2*x^3 + (1 + t^20)*x^2 + t*x + t^6);
[
    <(1 + O(t^20))*x + t^5 + O(t^8), 1>,
    <(1 + O(t^20))*x + t + 100*t^4 + 100*t^5 + t^7 + O(t^8), 1>,
    <(1 + O(t^20))*x + 1 + 34*t^2 + 34*t^3 + 34*t^4 + 90*t^5 + 29*t^6 + 16*t^8 +
        32*t^9 + 6*t^10 + 66*t^11 + 41*t^12 + 93*t^13 + t^14 + 69*t^15 + 8*t^16
        + 61*t^17 + 86*t^18 + 19*t^19 + O(t^20), 1>,
    <(1 + O(t^20))*x^2 + (100 + 67*t^2 + 67*t^3 + 68*t^4 + 11*t^5 + 72*t^6 +
        100*t^7 + 85*t^8 + 69*t^9 + 94*t^10 + 31*t^11 + 59*t^12 + 16*t^13 +
        14*t^14 + 35*t^15 + 77*t^16 + 28*t^17 + 33*t^18 + 72*t^19 + O(t^20))*x +
        1 + 67*t^2 + 68*t^3 + 11*t^4 + 67*t^5 + 57*t^6 + 16*t^7 + 57*t^8 +
        21*t^9 + 68*t^10 + 68*t^11 + 61*t^12 + 98*t^13 + 4*t^14 + 21*t^15 +

49.8 Extensions of Series Rings

Extensions of series rings are either unramified or totally ramified. Only series rings defined over finite fields can be extended. We recommend constructing polynomials from sequences rather than by addition of terms, especially over fields, to avoid some precision loss. For example, $x^4 + t$ will not have full precision in the constant coefficient as there will be a O term in the constant coefficient of x^4 which will reduce its precision as a field element. Extensions require full precision polynomials and some polynomials such as $x^4 + t$ may not have enough precision to be used to construct an extension whereas the equivalent `Polynomial([t, 0, 0, 0, 1])` will.

49.8.1 Constructions of Extensions

`UnramifiedExtension(R, f)`

Construct the unramified extension of R, a series ring or an extension thereof, defined by the inertial polynomial f, that is, adjoin a root of f to R.

`TotallyRamifiedExtension(R, f)`

`MaxPrecision` RngIntElt *Default :*

Construct a totally ramified extension of R, a series ring or an extension thereof, defined by the eisenstein polynomial f, that is, adjoin a root of f to R.

The parameter `MaxPrecision` defaults to the precision of R. It can be set to the maximum precision the coefficients of f are known to, which must not be less than the precision of R. This allows the precision of the result to be increased to the degree of f multiplied by this maximum precision.

The polynomial f may be given over a series ring or an extension of a series ring having a higher precision than R. This allows the precision of the result to be increased up to the precision the polynomial is known to (or `MaxPrecision` if set) without losing any of the polynomial known past the precision of R.

The precision of a ramified extension cannot be increased unless the defining polynomial is known to more precision than the coefficient ring, indicated either by providing the polynomial to greater precision or by setting `MaxPrecision`. This should be taken into account when constructing ramified extensions, especially if polynomials are to be factored over the extension.

`ChangePrecision(E, r)`

`ChangePrecision(~E, r)`

The extension of a series ring E with precision r. It is not possible to increase the precision of a ramified extension unless the parameter `MaxPrecision` was set on construction of the extension and r is less than or equal to this value multiplied by the ramification degree or the polynomial used in creating the extension was given to more precision than the coefficient ring of E.

`FieldOfFractions(E)`

The field of fractions of the extension of a series ring E.

Example H49E5

We show a simple creation of a two-step extension and change its precision.

```
> P<t> := PowerSeriesRing(GF(101), 50);
> PP<tt> := PowerSeriesRing(GF(101));
> R<x> := PolynomialRing(PP);
> U := UnramifiedExtension(P, x^2 + 2);
> T := TotallyRamifiedExtension(U, x^2 + tt*x + tt); T;
Extension of Extension of Power series ring in t over GF(101) with fixed
absolute precision 50 by x^2 + 2 + O(t^50) by x^2 + (t + O(t^50))*x + t +
    O(t^50)
> Precision($1);
100
> ChangePrecision($2, 200);
Extension of Extension of Power series ring in $.1 over GF(101) with fixed
absolute precision 100 by x^2 + 2 + O($.1^100) by x^2 + ($.1 + O($.1^100))*x +
    $.1 + O($.1^100)
> ChangePrecision($1, 1000);
Extension of Extension of Power series ring in $.1 over GF(101) with fixed
absolute precision 500 by x^2 + 2 + O($.1^500) by x^2 + ($.1 + O($.1^500))*x +
    $.1 + O($.1^500)
> ChangePrecision($1, 20);
Extension of Extension of Power series ring in $.1 over GF(101) with fixed
absolute precision 10 by x^2 + 2 + O($.1^10) by x^2 + ($.1 + O($.1^10))*x + $.1
    + O($.1^10)
```

Both U and T have a field of fractions.

```
> FieldOfFractions(U);
Extension of Laurent series field in $.1 over GF(101) with fixed relative
precision 50 by (1 + O($.1^50))*x^2 + O($.1^50)*x + 2 + O($.1^50)
> FieldOfFractions(T);
Extension of Extension of Laurent series field in $.1 over GF(101) with fixed
relative precision 50 by (1 + O($.1^50))*x^2 + O($.1^50)*x + 2 + O($.1^50) by (1
    + O($.1^50))*x^2 + ($.1 + O($.1^50))*x + $.1 + O($.1^50)
```

49.8.2 Operations on Extensions

`Precision(E)`

`GetPrecision(E)`

The maximum precision elements of the extension of a series ring E may have.

`CoefficientRing(E)`

`BaseRing(E)`

The ring the extension of a series ring E was defined over.

`DefiningPolynomial(E)`

The polynomial used to define the extension E.

`InertiaDegree(E)`

The degree of the extension E if E is an unramified extension, 1 otherwise.

`RamificationIndex(E)`
`RamificationDegree(E)`

The degree of the extension E if E is a totally ramified extension, 1 otherwise.

`ResidueClassField(E)`

The residue class field of the extension E, that is, $E/\pi * E$.

`UniformizingElement(E)`

A uniformizing element for the extension E, that is, an element of E of valuation 1.

`IntegerRing(E)`
`Integers(E)`
`RingOfIntegers(E)`

The ring of integers of the extension E of a series ring if E is a field (extension of a laurent series ring).

`E1 eq E2`

Whether extensions $E1$ and $E2$ are considered to be equal.

`E . i`

The primitive element of the extension E, that is, the root of the defining polynomial of E adjoined to the coefficient ring of E to construct E.

`AssignNames(~E, S)`

Assign the string in the sequence S to be the name of the primitive element of E, that is, the root of the defining polynomial adjoined to the coefficient ring of E to construct E.

Example H49E6

A number of the operations above are applied to a two-step extension

```
> L<t> := LaurentSeriesRing(GF(53), 30);
> P<x> := PolynomialRing(L);
> U := UnramifiedExtension(L, x^3 + 3*x^2 + x + 4);
> P<y> := PolynomialRing(U);
> T := TotallyRamifiedExtension(U, Polynomial([t, 0, 0, 0, 1]));
> Precision(U);
30
> Precision(T);
120
> CoefficientRing(U);
Laurent series field in t over GF(53) with fixed relative precision 30
> CoefficientRing(T);
Extension of Laurent series field in t over GF(53) with fixed relative precision
30 by (1 + O(t^30))*x^3 + (3 + O(t^30))*x^2 + (1 + O(t^30))*x + 4 + O(t^30)
> DefiningPolynomial(U);
(1 + O(t^30))*x^3 + (3 + O(t^30))*x^2 + (1 + O(t^30))*x + 4 + O(t^30)
> DefiningPolynomial(T);
(1 + O(t^30))*y^4 + O(t^30)*y^3 + O(t^30)*y^2 + O(t^30)*y + t + O(t^30)
> InertiaDegree(U);
3
> InertiaDegree(T);
1
> RamificationDegree(U);
1
> RamificationDegree(T);
4
> ResidueClassField(U);
Finite field of size 53^3
Mapping from: RngSerExt: U to GF(53^3)
> ResidueClassField(T);
Finite field of size 53^3
Mapping from: RngSerExt: T to GF(53^3)
> UniformizingElement(U);
t + O(t^31)
> UniformizingElement(T);
(1 + O(t^30))*$.1 + O(t^30)
> Integers(T);
Extension of Extension of Power series ring in $.1 over GF(53) with fixed
absolute precision 30 by x^3 + (3 + O($.1^30))*x^2 + x + 4 + O($.1^30) by x^4 +
    $.1 + O($.1^30)
> U.1;
(1 + O(t^30))*$.1 + O(t^30)
> T.1;
```

```
(1 + O(t^30))*$.1 + O(t^30)
```

49.8.3 Elements of Extensions

`x * y` `x + y` `x - y` `- x` `x ^ n` `x div y` `x / y`

`x eq y` `IsZero(e)` `IsOne(e)` `IsMinusOne(e)` `IsUnit(e)`

`Valuation(e)`

The valuation of the element e of an extension of a series ring. This is the index of the largest power of π which divides e.

`RelativePrecision(e)`

The relative precision of the element e of an extension of a series ring. This is the number of digits of e (in π) which are known.

`AbsolutePrecision(e)`

The absolute precision of the element e of an extension of a series ring. This is the same as the sum of the relative precision of e and the valuation of e.

`Coefficients(e)`
`Eltseq(e)`
`ElementToSequence(e)`

Given an element e of an extension of a series ring, return the coefficients of e with respect to the powers of the uniformizing element of the extension.

Example H49E7

We show some simple arithmetic with some elements of some extensions.

```
> P<t> := PowerSeriesRing(GF(101), 50);
> R<x> := PolynomialRing(P);
> U<u> := UnramifiedExtension(P, x^2 + 2*x + 3);
> UF := FieldOfFractions(U);
> R<y> := PolynomialRing(U);
> T<tt> := TotallyRamifiedExtension(U, y^2 + t*y + t);
> TF<tf> := FieldOfFractions(T);
> UF<uf> := FieldOfFractions(U);
> u + t;
u + t + O(t^50)
> uf * t;
($.1 + O($.1^50))*uf + O($.1^51)
> tf eq tt;
false
> tf - tt;
```

```
O($.1^50)*tf + O($.1^50)
> IsZero($1);
false
> Valuation($2);
100
> Valuation(tt);
1
> Valuation(U!t);
1
> Valuation(T!t);
2
> RelativePrecision(u);
50
> AbsolutePrecision(u);
50
> AbsolutePrecision(uf);
50
> RelativePrecision(uf);
50
> RelativePrecision(u - uf);
0
> AbsolutePrecision(u - uf);
50
> u^7;
(13 + O(t^50))*u + 71 + O(t^50)
> Coefficients($1);
[
    71 + O(t^50),
    13 + O(t^50)
]
> tt^8;
(4*t^4 + 91*t^5 + 6*t^6 + 100*t^7 + O(t^50))*tt + t^4 + 95*t^5 + 5*t^6 + 100*t^7
    + O(t^50)
> Coefficients($1);
[ t^4 + 95*t^5 + 5*t^6 + 100*t^7 + O(t^50), 4*t^4 + 91*t^5 + 6*t^6 + 100*t^7 +
    O(t^50) ]
```

49.8.4 Optimized Representation

OptimizedRepresentation(E)
OptimisedRepresentation(E)

An optimized representation for the unramified extension E of a series ring. The defining polynomial of E must be coercible into the residue class field. The result is a series ring over the residue class field of E and a map from E to this series ring.

Example H49E8

We give a simple example of the use of `OptimizedRepresentation`.

```
> P<t> := PowerSeriesRing(GF(101), 50);
> R<x> := PolynomialRing(P);
> U<u> := UnramifiedExtension(P, x^2 + 2*x + 3);
> U;
Extension of Power series ring in t over GF(101) with fixed absolute precision
50 by x^2 + (2 + O(t^50))*x + 3 + O(t^50)
> OptimizedRepresentation(U);
Power series ring in $.1 over GF(101^2) with fixed absolute precision 50
Mapping from: RngSerExt: U to Power series ring in s over GF(101^2) with fixed
absolute precision 50 given by a rule
```

50 LAZY POWER SERIES RINGS

Chapter 50
LAZY POWER SERIES RINGS

50.1 Introduction

The lazy series rings `RngLaz` and their elements `RngLazElt` allow the creation of infinite precision series by providing series for which all coefficients can be calculated by some given formula. Only finitely many coefficients of such a series can be known at any one time but all infinitely many of the coefficients are knowable. Any coefficient of a lazy series can be generated and once a coefficient is computed it will be stored in the series for quick retrieval.

The simplest implementation of this idea is creating a series by providing a map. This map is a formula for computing coefficients of a series. Given the exponents of the variables of a term it will give you the coefficient of that term. Series with finitely many non–zero terms can be created in special ways and several usual arithmetic operations can be applied to lazy series. Such constructions yield lazy series with more complicated formulas for their coefficients.

Consider the series $\sum_{i=0}^{n} i * x^i$. A formula for the coefficients is given by $i \mapsto i$. This series can be created as a lazy series as follows:

```
> L<x> := LazyPowerSeriesRing(Integers(), 1);
> m := map<Integers() -> Integers() | i :-> i>;
> s := elt<L | m>;
> s;
Lazy power series
```

Currently s does not know what any of its coefficients are yet it is possible to calculate any coefficient of s.

```
> Coefficient(s, 0);
0
> Coefficient(s, 100);
100
> Coefficient(s, 100000000000000000000000);
100000000000000000000000
```

50.2 Creation of Lazy Series Rings

Both univariate and multivariate lazy series rings can be created.

`LazyPowerSeriesRing(C, n)`

The lazy power series ring with coefficient ring C and n variables. Any ring is valid input for C and n can be any positive integer.

`ChangeRing(L, C)`

Given a lazy series ring L defined over a ring R and some ring C, return the lazy series ring with coefficient ring C but the same number of variables as L. A map from L to the new lazy series ring is also returned which takes an series s in L to a series whose coefficients are those of s coerced into C.

Example H50E1

Here we illustrate the creation and printing of lazy power series rings.

```
> L := LazyPowerSeriesRing(Rationals(), 5);
> L;
Lazy power series ring in 5 variables over Rational Field
> ChangeRing(L, MaximalOrder(CyclotomicField(7)));
Lazy power series ring in 5 variables over Maximal Equation Order with defining
polynomial x^6 + x^5 + x^4 + x^3 + x^2 + x + 1 over Z
```

50.3 Functions on Lazy Series Rings

Lazy series rings have variables, names for their variables and a coefficient ring.

`R . i`

The ith variable of the lazy power series ring R, where i is between 1 and the rank of R.

`AssignNames(~R, S)`

Given a lazy series ring R with n indeterminates and a sequence S of n strings, assign the elements of S to the names of the variables of R.

`BaseRing(R)`

`CoefficientRing(R)`

The coefficient ring of the lazy power series ring R. The coefficients of all the series in R will lie in this ring.

`Rank(R)`

The number of variables associated with the lazy power series ring R.

`R1 eq R2`

Return `true` if the lazy series rings $R1$ and $R2$ are the same ring, that is, they have the same coefficient ring and rank.

Example H50E2

The functions on lazy power series rings are illustrated here.

```
> L := LazyPowerSeriesRing(FiniteField(73), 7);
> L.4;
Lazy power series
> AssignNames(~L, ["a", "b", "c", "d", "fifth", "sixth", "seventh"]);
> L.4;
Lazy power series
```

The names for the variables of L are not used in default series printing. However they are used when printing an element to a given precision using PrintToPrecision.

```
> CoefficientRing(L);
Finite field of size 73
> Rank(L);
7
> L eq LazyPowerSeriesRing(CoefficientRing(L), Rank(L));
true
```

50.4 Elements

Lazy series may be created in a number of ways. Arithmetic for ring elements is available as well as a few predicates. Coefficients of the monomials in the series can be calculated.

50.4.1 Creation of Finite Lazy Series

`R ! c`

Return the series in the lazy series ring R with constant term c and every other coefficient 0 where c is any ring element coercible into the coefficient ring of R.

`R ! s`

Return the lazy series in the lazy series ring R whose coefficients are those of the lazy series s coerced into the coefficient ring of R.

`R ! S`

Return the series in the lazy series ring R whose coefficients are the elements of S where S is a sequence of elements each coercible into the coefficient ring of R. The coefficients are taken to be given in the order which Coefficients will return them and PrintToPrecision will print the terms of the series. Any coefficient not given is assumed to be zero so that all coefficients are calculable. The resulting series can only have finitely many non zero terms and all such non zero coefficients must be given in S.

`LazySeries(R, f)`

Create the lazy series in the lazy series ring R with finitely many non zero terms which are the terms of the polynomial f. The number of variables of the parent ring of f must be the same as the number of variables of R. The coefficients of f must be coercible into the coefficient ring of R.

It is also possible for f to be a rational function, p/q. The series created from f will be `LazySeries(R, p)*LazySeries(R, q)`$^{-1}$.

Example H50E3

Creation of series using the above functions is shown here.

```
> L := LazyPowerSeriesRing(AlgebraicClosure(), 3);
> LR := LazyPowerSeriesRing(Rationals(), 3);
> s := L!1;
> s;
Lazy power series
> LR!s;
Lazy power series
> P<x, y, z> := RationalFunctionField(Rationals(), 3);
> LazySeries(L, (x + y + 8*z)^7/(1 + 5*x*y*z + x^8)^3);
Lazy power series
```

50.4.1.1 Creation of Lazy Series from Maps

Creating a lazy series from a map simulates the existence of lazy series as series for which coefficients are not known on creation of the series but calculated by some rule given when creating the series.

This rule can be coded in a map where the input to the map is the exponents of the variables in a term and the output is the coefficient of the term described by the input. So for a lazy series ring with variables x, y and z, a general term of a series will look like $c_{ijk} * x_i^r * y_j^s * z_k^t$. The coefficient of this term, c_{ijk}, in a series defined by a map m is the result of $m(\langle i, j, k\rangle)$.

`elt< R | m >`

Creates a series in the lazy series ring R from the map m. The map m must take as input either an integer (when R is univariate only) or a tuple of integers (of length the number of variables of R) and return an element of the coefficient ring of R. This element will be taken as the coefficient of the term of the series whose variables have the exponents given in the input tuple, as described above.

Example H50E4

We first illustrate the univariate case.

```
> L<x> := LazyPowerSeriesRing(MaximalOrder(QuadraticField(5)), 1);
> Z := Integers();
> m := map<Z -> CoefficientRing(L) | t :-> 2*t>;
> s := elt<L | m>;
> PrintToPrecision(s, 10);
2*x + 4*x^2 + 6*x^3 + 8*x^4 + 10*x^5 + 12*x^6 + 14*x^7 + 16*x^8 + 18*x^9 +
    20*x^10
> Coefficient(s, 34);
68
> m(34);
68
> Coefficient(s, 2^30 + 10);
2147483668
> m(2^30 + 10);
2147483668
```

Example H50E5

And now for the multivariate case.

```
> L<x, y, z> := LazyPowerSeriesRing(AlgebraicClosure(), 3);
> Z := Integers();
> m := map<car<Z, Z, Z> -> CoefficientRing(L) | t :-> t[1]*t[2]*t[3]>;
> s := elt<L | m>;
> PrintToPrecision(s, 5);
x*y*z + 2*x^2*y*z + 2*x*y^2*z + 2*x*y*z^2 + 3*x^3*y*z + 4*x^2*y^2*z +
    4*x^2*y*z^2 + 3*x*y^3*z + 4*x*y^2*z^2 + 3*x*y*z^3
> Coefficient(s, [1, 1, 1]);
1
> m(<1, 1, 1>);
1
> Coefficient(s, [3, 1, 2]);
6
> m(<3, 1, 2>);
6
```

50.4.2 Arithmetic with Lazy Series

All the usual arithmetic operations are possible for lazy series.

`s + t`

The sum of the two lazy series s and t.

`-s`

The negation of the lazy series s.

`s - t`

The difference between lazy series s and t.

`s * t`

The product of the lazy series s and t.

`s + r`
`r + s`

The sum of the lazy series s and the element r of the coefficient ring of the parent ring of s.

`c * s`
`s * c`

The product of the lazy series s and the element c of the coefficient ring of the parent ring of s.

`s * n`

The product of the lazy series s and the monomial x^n, where x^n is $x_1^{n_1} \times \ldots \times x_r^{n_r}$ where r is the number of variables of the parent ring of s, n is the sequence $[n_1, \ldots, n_r]$ and $x = x_1, \ldots, x_r$ are the series variables of the parent ring of s.

`s ^ n`

Given a lazy series s and an integer n, return the nth power of s. It is allowed for n to be negative and inverses will be taken where possible.

Example H50E6

Here we demonstrate the above arithmetic operations.

```
> L<a, b, c, d> := LazyPowerSeriesRing(Rationals(), 4);
> (a + 4*b + (-c)*[8, 9, 2^30 + 10, 2] - d*b + 5)^-8;
Lazy power series
```

50.4.3 Finding Coefficients of Lazy Series

In theory, all the coefficients of most series can be calculated. In practice it is not possible to compute infinitely many. Some problems arise however when a series has been created using multiplication, inversion, evaluation or by taking square roots. For such series the jth coefficient for all $j < i$ must be known for the ith coefficient to be calculated. In such cases the exponents specified for each variable in the monomial whose coefficient is required must be small integers ($< 2^{30}$).

The default ordering of coefficients is by total degree of the corresponding monomials. This is the same order on multivariate polynomials by default. When drawn on paper or imagined in 3 or more dimensions this looks like a spiral if the coordinates representing the monomial exponents are joined. This is the same ordering which is used to compute the valuation of a series.

Once computed, coefficients are stored with the series so any subsequent call to these functions will be faster in non–trivial cases than the first call. It is possible to interrupt any of these functions and return to the prompt.

`Coefficient(s, i)`

Returns the coefficient in the univariate lazy series s of x^i where x is the series variable of the parent of s and i is a non negative integer.

`Coefficient(s, T)`

Returns the coefficient in the multivariate lazy series s of the monomial $x_1^{T_1} * \ldots * x_r^{T_r}$ where T is the sequence $[T_1, \ldots, T_r]$, $x_1, \ldots, x_r$ are the variables of the parent ring of s and r is the rank of the parent of s.

`Coefficients(s, n)`

`Coefficients(s, l, n)`

The coefficients of the lazy series s whose monomials have total degree at least l (0 if not given) and at most n where the monomials are ordered using the default "spiral" degree order. The bounds l and n must be non negative integers.

`Valuation(s)`

The valuation of the lazy series s. This is the exponent of the monomial with the first non–zero coefficient as returned by `Coefficients` above. The return value will be either `Infty`, an integer (univariate case) or a sequence (multivariate case).

`PrintToPrecision(s, n)`

Print the sum of all terms of the lazy series s whose degree is no more than n where n is a non negative integer. The series is printed using the "spiral" ordering.

`PrintTermsOfDegree(s, l, n)`

Print the sum of the terms of the lazy series s whose degree is at least l and at most n. The terms are printed using the spiral ordering. The bounds l and n must be non negative integers.

`LeadingCoefficient(s)`

The coefficient in the lazy series s whose monomial exponent is the valuation of s. That is, the first non–zero coefficient of s where the ordering which determines "first" is the "spiral" ordering used by `Coefficients` and `Valuation`.

`LeadingTerm(s)`

The term in the lazy series s whose monomial exponent is the valuation of s. That is, the first non–zero term of s where the ordering which determines "first" is the "spiral" ordering used by `Coefficients` and `Valuation`.

Example H50E7

In this example we look at some coefficients of an infinite series.

```
> L<a, b, c, d> := LazyPowerSeriesRing(Rationals(), 4);
> s := (1 + 2*a + 3*b + 4*d)^-5;
```

Find the coefficient of $a * b * c * d$.

```
> Coefficient(s, [1, 1, 1, 1]);
0
```

Find the coefficients of all monomials with total degree at most 6.

```
> time Coefficients(s, 6);
[ 1, -10, -15, 0, -20, 60, 180, 0, 240, 135, 0, 360, 0, 0, 240, -280, -1260, 0,

Time: 0.010
```

The valuation of s can be obtained as follows. The valuation of zero is a special case.

```
> Valuation(s);
[ 0, 0, 0, 0 ]
> Valuation(s*0);
Infinity
```

`CoefficientsNonSpiral(s, n)`

Returns the coefficients of the monomials in the lazy series s whose exponents are given by $[i_1, ..., i_r]$ where each $i_j \leq n_j$. The argument n may either be a non negative integer (univariate case) or a sequence of non negative integers of length r where r is the rank of the parent ring of s. The index of the $[i_1, ..., i_r]$-th coefficient in the return sequence is given by

$$\sum_{j=1}^{r} i_j * (\prod_{k=j+1}^{r} (n_k + 1)).$$

`Index(s, i, n)`

Return the index in the return value of `CoefficientsNonSpiral(s, n)` of the monomial in the lazy series s whose exponents are given by the (trivial in the univariate case) sequence i.

Example H50E8

We find the coefficients of the series used in the last example using the alternative algorithm.

```
> L<a, b, c, d> := LazyPowerSeriesRing(Rationals(), 4);
> s := (1 + 2*a + 3*b + 4*d)^-5;
> time CoefficientsNonSpiral(s, [3, 3, 3, 2]);

It appears that the "spiral" algorithm may be faster since it computed more coefficients in less time. This may be because of the operations (inversion) involved in calculating s and that `CoefficientsNonSpiral` computed coefficients of larger degree monomials than `Coefficients`. In calculating these coefficients for larger degrees, coefficients which were not asked for may have been calculated. `Coefficients` will only need to calculate the coefficients which have been asked for — all intermediate calculations would have been asked for.

50.4.4 Predicates on Lazy Series

`s eq t`

Return `true` if the lazy series s and t are exactly the same series.

`IsZero(s)`

Return `true` if the lazy series s was created as the zero series.

`IsOne(s)`

Return `true` if the lazy series s was created as the one series.

`IsMinusOne(s)`

Return `true` if the lazy series s was created as the minus one series.

`IsUnit(s)`

Return `true` if the lazy series s is a unit.

`IsWeaklyZero(s, n)`

Return `true` if all the terms of the lazy series s with degree at most n are zero. Calling this function without the second argument returns `IsZero(s)`.

`IsWeaklyEqual(s, t, n)`

Return `true` if the terms of the lazy series s and t with degree at most n are the same. Calling this function without the third argument returns `s eq t`.

50.4.5 Other Functions on Lazy Series

`Derivative(s)`

`Derivative(s, v)`

`Derivative(s, v, n)`

Return the (nth) derivative of the lazy series s with respect to the vth variable of the parent ring of s. If v is not given, the parent ring of s must be univariate and the derivative with respect to the unique variable is returned. It is only allowed to give values of v from 1 to the rank of the parent of s and for n to be a positive integer.

`Integral(s)`

`Integral(s, v)`

Return the integral of the lazy series s with respect to the vth variable of the parent ring of s. If v is not given, the parent ring of s must be univariate and the integral with respect to the unique variable is returned. It is only allowed to give values of v from 1 to the rank of the parent of s.

`Evaluate(s, t)`

`Evaluate(s, T)`

Return the lazy series s evaluated at the lazy series t or the sequence T of lazy series. The series t or the series in T must have zero constant term so that every coefficient of the result can be finitely calculated.

Example H50E9

Some usage of `Evaluate` is shown below.

```
> R := LazyPowerSeriesRing(Rationals(), 2);
> AssignNames(~R, ["x","y"]);
> m := map<car<Integers(), Integers()> -> Rationals() | t :-> 1>;
> s := elt<R | m>;
> PrintToPrecision(s, 3);
1 + x + y + x^2 + x*y + y^2 + x^3 + x^2*y + x*y^2 + y^3
> R1 := LazyPowerSeriesRing(Rationals(), 1);
> AssignNames(~R1, ["z"]);
```

```
> m1 := map<car<Integers()> -> Rationals() | t :-> t[1]>;
> s1 := elt<R1 | m1>;
> PrintToPrecision(s1, 3);
z + 2*z^2 + 3*z^3
> e := Evaluate(s, [s1,s1]);
> PrintToPrecision(e, 10);
1 + 2*z + 7*z^2 + 22*z^3 + 67*z^4 + 200*z^5 + 588*z^6 + 1708*z^7 + 4913*z^8 +
    14018*z^9 + 39725*z^10
> Parent(e);
Lazy power series ring in 1 variable over Rational Field
> f := Evaluate(s1, s - 1);
> PrintToPrecision(f, 10);
x + y + 3*x^2 + 5*x*y + 3*y^2 + 8*x^3 + 18*x^2*y + 18*x*y^2 + 8*y^3 + 20*x^4 +
    56*x^3*y + 75*x^2*y^2 + 56*x*y^3 + 20*y^4 + 48*x^5 + 160*x^4*y + 264*x^3*y^2
    + 264*x^2*y^3 + 160*x*y^4 + 48*y^5 + 112*x^6 + 432*x^5*y + 840*x^4*y^2 +
    1032*x^3*y^3 + 840*x^2*y^4 + 432*x*y^5 + 112*y^6 + 256*x^7 + 1120*x^6*y +
    2496*x^5*y^2 + 3600*x^4*y^3 + 3600*x^3*y^4 + 2496*x^2*y^5 + 1120*x*y^6 +
    256*y^7 + 576*x^8 + 2816*x^7*y + 7056*x^6*y^2 + 11616*x^5*y^3 +
    13620*x^4*y^4 + 11616*x^3*y^5 + 7056*x^2*y^6 + 2816*x*y^7 + 576*y^8 +
    1280*x^9 + 6912*x^8*y + 19200*x^7*y^2 + 35392*x^6*y^3 + 47280*x^5*y^4 +
    47280*x^4*y^5 + 35392*x^3*y^6 + 19200*x^2*y^7 + 6912*x*y^8 + 1280*y^9 +
    2816*x^10 + 16640*x^9*y + 50688*x^8*y^2 + 103168*x^7*y^3 + 154000*x^6*y^4 +
    175344*x^5*y^5 + 154000*x^4*y^6 + 103168*x^3*y^7 + 50688*x^2*y^8 +
    16640*x*y^9 + 2816*y^10
> f := Evaluate(s1 + 1, s - 1);
> PrintToPrecision(f, 10);
1 + x + y + 3*x^2 + 5*x*y + 3*y^2 + 8*x^3 + 18*x^2*y + 18*x*y^2 + 8*y^3 + 20*x^4
    + 56*x^3*y + 75*x^2*y^2 + 56*x*y^3 + 20*y^4 + 48*x^5 + 160*x^4*y +
    264*x^3*y^2 + 264*x^2*y^3 + 160*x*y^4 + 48*y^5 + 112*x^6 + 432*x^5*y +
    840*x^4*y^2 + 1032*x^3*y^3 + 840*x^2*y^4 + 432*x*y^5 + 112*y^6 + 256*x^7 +
    1120*x^6*y + 2496*x^5*y^2 + 3600*x^4*y^3 + 3600*x^3*y^4 + 2496*x^2*y^5 +
    1120*x*y^6 + 256*y^7 + 576*x^8 + 2816*x^7*y + 7056*x^6*y^2 + 11616*x^5*y^3 +
    13620*x^4*y^4 + 11616*x^3*y^5 + 7056*x^2*y^6 + 2816*x*y^7 + 576*y^8 +
    1280*x^9 + 6912*x^8*y + 19200*x^7*y^2 + 35392*x^6*y^3 + 47280*x^5*y^4 +
    47280*x^4*y^5 + 35392*x^3*y^6 + 19200*x^2*y^7 + 6912*x*y^8 + 1280*y^9 +
    2816*x^10 + 16640*x^9*y + 50688*x^8*y^2 + 103168*x^7*y^3 + 154000*x^6*y^4 +
    175344*x^5*y^5 + 154000*x^4*y^6 + 103168*x^3*y^7 + 50688*x^2*y^8 +
    16640*x*y^9 + 2816*y^10
```

`SquareRoot(s)`

`Sqrt(s)`

The square root of the lazy series s.

`IsSquare(s)`

Return `true` if the lazy series s is a square and the square root if so.

`PolynomialCoefficient(s, i)`

Given a series s in a lazy series ring whose coefficient ring is a polynomial ring (either univariate or multivariate), consider the polynomial which would be formed if this series was written as a polynomial with series as the coefficients. For i a non negative integer and the coefficient ring of the series ring a univariate polynomial ring this function returns the series which is the ith coefficient of the polynomial resulting from the rewriting of the series.

When the coefficient ring of the parent of s is a multivariate polynomial ring i should be a sequence of non negative integers of length the rank of the coefficient ring. The series returned will be the series which is the coefficient of $x_1^{i_1} * \ldots * x_r^{i_r}$ in the rewritten series where r is the rank of the coefficient ring and x_j are the indeterminates of the coefficient ring.

51 GENERAL LOCAL FIELDS

Chapter 51
GENERAL LOCAL FIELDS

51.1 Introduction

The local fields described in this chapter are extensions of any local field in MAGMA by any irreducible polynomial over that field. They are not constrained by requirements that the polynomial defining the extension be inertial or eisenstein. These local fields allow for ramified and inertial extensions to be made in one step rather than forcing such an extension to be split into two – being a ramified extension and an unramified extension. They are typed `RngLocA` with elements of type `RngLocAElt`. To compare these fields to the local fields where extensions are either totally ramified or unramified, see Chapter 47.

The fields are represented as a polynomial quotient ring. A map into an isomorphic `FldPad` can be constructed and the isomorphic field used for various calculations.

51.2 Constructions

Local fields can be constructed as extensions of other local fields and as subfields of other local fields.

`LocalField(L, f)`

Construct a local field F as an extension of the local field L by the polynomial f over L.

Example H51E1

We can use the 2 step local fields to help us find an irreducible polynomial over a p-adic field which can be used to extend that p-adic field in 1 step.

```
> P<x> := PolynomialRing(Integers());
> Zp := pAdicRing(7, 50);
> U := UnramifiedExtension(Zp, x^2 + 6*x + 3);
> R := TotallyRamifiedExtension(U, x^3 + 7*x^2 + 7*x + 7);
> L<a> := LocalField(pAdicField(7, 50), MinimalPolynomial(R.1 + U.1, Zp));
> L;
Extension of 7-adic field mod 7^50 by x^6 + (32 + O(7^50))*x^5 + (390 +
    O(7^50))*x^4 + (2284 + O(7^50))*x^3 + (6588 + O(7^50))*x^2 + (8744 +
    O(7^50))*x + 5452 + O(7^50)
```

We can also use any irreducible polynomial we can find to define a 1 step extension.

```
> LocalField(pAdicField(7, 50), x^6 - 49*x^2 + 686);
Extension of 7-adic field mod 7^50 by x^6 + O(7^50)*x^5 + O(7^50)*x^4 +
    O(7^50)*x^3 - (7^2 + O(7^52))*x^2 + O(7^50)*x + 2*7^3 + O(7^53)
```

`sub< L | $a_1, ..., a_n$ >`

`sub< L | S >`

Construct the local field F as a subfield of the local field L containing the elements a_i of L or the elements of the sequence S.

Example H51E2

```
> Qp := pAdicField(5, 20);
> P<x> := PolynomialRing(Qp);
> L<a> := LocalField(Qp, x^4 + 4*x^2 + 2);
> P<x> := PolynomialRing(L);
> LL<aa> := LocalField(L, x^4 + 4*L.1);
> r := (10236563738184*a^3 - 331496727861*a^2 + 10714284669258*a +
> 8590525712453*5)*aa^2
> -12574685904653*a^3 + 19786544763736*a^2 + 4956446023134*a + 37611818678747;
> S, m := sub< LL | r >;
> S;
Extension of Extension of 5-adic field mod 5^20 by x^4 + O(5^20)*x^3 + (4 +
    O(5^20))*x^2 + (4 + O(5^20))*x + 2 + O(5^20) by (O(5^20)*a^3 + O(5^20)*a^2 +
    O(5^20)*a + (1 + O(5^20)))*x^2 + (O(5^20)*a^3 + O(5^20)*a^2 + O(5^20)*a +
    O(5^20))*x + O(5^20)*a^3 + O(5^20)*a^2 + (4 + O(5^20))*a + O(5^20)
> m(S.1);
(O(5^20)*a^3 + O(5^20)*a^2 + O(5^20)*a + O(5^20))*aa^3 + (O(5^20)*a^3 +
    O(5^20)*a^2 + O(5^20)*a + (1 + O(5^20)))*aa^2 + (O(5^20)*a^3 + O(5^20)*a^2 +
    O(5^20)*a + O(5^20))*aa + O(5^20)*a^3 + O(5^20)*a^2 + O(5^20)*a + O(5^20)
```

51.3 Operations with Fields

`BaseRing(L)`

`CoefficientRing(L)`

Return the coefficient field of the local field L. This is the field which was extended to construct L.

`DefiningPolynomial(L)`

Return the polynomial used to define the local field L as an extension of its coefficient field.

`Degree(L)`

Return the degree of the local field L, that is, the degree of its defining polynomial.

`Degree(L, R)`

Return the degree of L as an extension of R where R is some coefficient ring of L.

`InertiaDegree(L)`

`RamificationDegree(L)`

`RamificationIndex(L)`

Return the degree of the inertial or totally ramified subfield of the local field L as an extension of the coefficient field of L.

`Precision(L)`

Return the precision of the local field L. This is the maximum number of digits which can occur in an element of L, the difference between the valuation of an element of L and the valuation of the term of highest valuation occurring in that element.

`Prime(L)`

Return the prime of the local field L. This is the same as the prime of the coefficient field of L.

Example H51E3

Continuing from the first example we have :

```
> CoefficientRing(L);
7-adic field mod 7^50
> DefiningPolynomial(L);
$.1^6 + (32 + O(7^50))*$.1^5 + (390 + O(7^50))*$.1^4 + (2284 + O(7^50))*$.1^3 +
    (6588 + O(7^50))*$.1^2 + (8744 + O(7^50))*$.1 + 5452 + O(7^50)
> Precision(L);
150
> Prime(L);
7
> Degree(L); RamificationDegree(L); InertiaDegree(L);
6
3
2
```

`QuotientRepresentation(L)`

Return the polynomial quotient ring which is isomorphic to the local field L and is used to represent L.

`RamifiedRepresentation(L)`

Return the local field isomorphic to the local field L constructed as an unramified then a ramified extension and the map from L into the isomorphic field.

Example H51E4

We create a 1 step local field and compute its representation as a 2 step local field.

```
> P<x> := PolynomialRing(Integers());
> L<a> := LocalField(pAdicField(7, 50), x^6 - 49*x^2 + 686);
> L;
Extension of 7-adic field mod 7^50 by x^6 + O(7^50)*x^5 + O(7^50)*x^4 +
    O(7^50)*x^3 - (7^2 + O(7^52))*x^2 + O(7^50)*x + 2*7^3 + O(7^53)
> QuotientRepresentation(L);

    O(7^37)*$.1 + 13128487736606729510635017356 8*7 + O(7^36)
```

`AssignNames(~L, S)`

Assign the name in the sequence S to the generator of the extension defining the local field L.

`Name(L, i)`

Return the generator of the local field L which has assigned to it the name in the sequence S which was input to `AssignNames`. The only valid input for i is 1.

`Discriminant(L)`

Return the discriminant of the local field L.

`ResidueClassField(L)`

Return the residue class field of the maximal order of the local field L and the map between L and its residue class field.

`RelativeField(L, m)`

Return L as an extension of the domain of the map m which should be a map from a subfield of L (having the same coefficient ring as L) into L.

51.3.1 Predicates on Fields

`IsRamified(L)`

Return whether the local field L has an non trivial ramified subfield, that is, the ramification degree of L is greater than 1.

`IsTamelyRamified(L)`

`IsWildlyRamified(L)`

Return whether the local field L is tamely or wildly ramified.

`IsTotallyRamified(L)`

Return whether the local field L is a totally ramified extension, that is, L has a trivial inertial subfield.

`IsUnramified(L)`

Return whether the local field L is equal to its inertial subfield.

51.4 Maximal Order

`IntegralBasis(L)`

Return a basis for the maximal order of the local field L.

`IsIntegral(a)`

Return whether the local field element a lies in the maximal order of its parent L and a sequence giving the coordinates of a with respect to the integral basis of L if so.

Example H51E5

We construct a local field and compute an integral basis for it.

```
> P<x> := PolynomialRing(Integers());
> L := LocalField(pAdicField(7, 50), x^6 - 49*x^2 + 686);
> IntegralBasis(L);
[ 1 + O(7^50), (7^-1 + O(7^49))*$.1^2 + O(7^49)*$.1 + O(7^49), (7^-2 +
    O(7^48))*$.1^4 + O(7^48)*$.1^3 + O(7^48)*$.1^2 + O(7^50)*$.1 + O(7^50), $.1
    + O(7^50), (7^-1 + O(7^49))*$.1^3 + O(7^49)*$.1^2 + O(7^49)*$.1 + O(7^99),
    (7^-2 + O(7^48))*$.1^5 + O(7^48)*$.1^4 + O(7^48)*$.1^3 + O(7^50)*$.1^2 +
    O(7^50)*$.1 + O(7^50) ]
```

51.5 Homomorphisms from Fields

`hom< L → R | a >`

`hom< L → R | cfm, a >`

Return the homomorphism from the local field L into the ring R whose image of the generator of L is a and whose action on the coefficient field of L is given by cfm if given.

51.6 Automorphisms and Galois Theory

`FrobeniusAutomorphism(L)`

Return the automorphism of the unramified extension L which is the lift of the frobenius automorphism on the residue class field of L.

`AutomorphismGroup(L)`

Return the automorphism group of the local field L and a map from the group to the parent of automorphisms of L.

`DecompositionGroup(L)`

`InertiaGroup(L)`

`RamificationGroup(L, i)`

Return the subgroup of the automorphism group of the local field L whose elements are the automorphisms (represented as group elements) σ such that $v(\sigma(z) - z) \geq i+1$. The decomposition group is the -1th ramification group and the inertia group is the 0th ramification group.

`FixedField(L, G)`

Return the subfield of the local field L which is fixed by the automorphisms (represented as group elements) in the subgroup G of the automorphism group of L.

Example H51E6

The automorphism and inertia groups of a local field are computed and their fixed fields examined.

```
> P<x> := PolynomialRing(Integers());
> L := LocalField(pAdicField(7, 50), x^6 - 49*x^2 + 686);
> A, am := AutomorphismGroup(L);
> am(Random(A));
Mapping from: RngLocA: L to RngLocA: L
> $1(L.1);
-(279674609046925265141076018485*7^-2 + O(7^34))*$.1^5 + O(7^35)*$.1^4 +
    (10359052517489881294588814641 23*7^-1 + O(7^35))*$.1^3 + O(7^36)*$.1^2 -
    (10094439077108649085019837355 01 + O(7^36))*$.1 + O(7^37)
> FixedField(L, A);
Extension of 7-adic field mod 7^50 by (1 + O(7^33))*x + O(7^33)
```

```
> InertiaGroup(L);
Permutation group acting on a set of cardinality 6
    Id($)
    (1, 2)(3, 5)(4, 6)
> FixedField(L, InertiaGroup(L));
Extension of 7-adic field mod 7^50 by (1 + O(7^37))*x^3 - (2*7^2 + O(7^37))*x^2
    + (7^4 + O(7^37))*x - 4*7^6 + O(7^37)
```

51.7 Local Field Elements

`L ! r`

Return the element of the local field L described by r where r may be anything which is coercible into the quotient representation of L.

`L . i`

Return the generator of the local field L. The only valid input for i is 1.

`InertialElement(L)`

Return a generator for the inertial subfield of the local field L.

`UniformizingElement(L)`

Return an element of the local field L of valuation 1.

51.7.1 Arithmetic

`a * b` `a + b` `a - b` `- a` `a ^ n` `a / b`

51.7.2 Predicates on Elements

`a eq b`

Return whether the local field elements a and b are considered equal.

`IsOne(a)`
`IsMinusOne(a)`

Return whether the local field element a is known to be 1 or -1 to the precision of the field.

`IsWeaklyZero(a)`

Return whether the local field element a is not known to be non zero.

`IsZero(a)`

Return whether the local field element a is known to be zero.

51.7.3 Other Operations on Elements

`Valuation(a)`

The valuation of the element a in a local field.

`RelativePrecision(a)`

The relative precision of the element a in a local field.

`Eltseq(a)`

Return the coefficients of powers of the generator of the parent of a in a.

`RepresentationMatrix(a)`

The representation matrix of the element a of a local field.

Example H51E7

Continuing from the first example we have :

```
> UniformizingElement(L);
a^2 + (6 + O(7^50))*a + 3 + O(7^50)
> InertialElement(L);
a + O(7^50)
> Valuation(UniformizingElement(L));
1
> Valuation(InertialElement(L));
0
> Eltseq(UniformizingElement(L));
[ 3 + O(7^50), 6 + O(7^50), 1 + O(7^50) ]
```

51.8 Polynomials over General Local Fields

Polynomials over local fields can be factored and their roots computed.

`Factorization(f)`

`Certificates` BoolElt *Default :* `false`

The factorization of the polynomial f over a local field defined by an arbitrary polynomial. The factorization is returned as a sequence of tuples of prime polynomials and exponents along with a scalar factor. If the parameter `Certificates` is `true` then certificates proving the primality of each prime are also returned.

`SuggestedPrecision(f)`

For a polynomial f over a general local field, return a precision at which the factorization of f as given by `Factorization(f)` will be Hensel liftable to the correct factorization.

The precision returned is not guaranteed to be enough to obtain a factorization of the polynomial. It may be that a correct factorization cannot be found at that precision but may be possible with a little more precision.

`Roots(f)`

`Roots(f, R)`

The roots of the polynomial f over the general local field R where R is taken to be the coefficient ring of f if it is not given.

Example H51E8

```
> Q3:=pAdicField(3,40);
> Q3X<x>:=PolynomialRing(Q3);
> L<a>:=LocalField(Q3,x^6-6*x^4+9*x^2-27);
> Factorization(Polynomial(L,x^6-6*x^4+9*x^2-27));
[
    <(O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + (1 +
        O(3^40)))*$.1 + (5*3^35 + O(3^38))*a^5 + O(3^38)*a^4 - (10*3^36 +
        O(3^39))*a^3 + O(3^39)*a^2 + (2701703435345984179 + O(3^40))*a +
        O(3^40), 1>,
    <(O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + (1 +
        O(3^40)))*$.1 + -(29642867960*3^-1 + O(3^23))*a^5 + O(3^24)*a^4 +
        (148214339800*3^-1 + O(3^24))*a^3 + O(3^25)*a^2 - (116512378274*3 +
        O(3^25))*a + O(3^26), 1>,
    <(O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + (1 +
        O(3^40)))*$.1 + -(29642867960*3^-1 + O(3^23))*a^5 + O(3^24)*a^4 +
        (148214339800*3^-1 + O(3^24))*a^3 + O(3^25)*a^2 - (349537134821 +
        O(3^25))*a + O(3^26), 1>,
    <(O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + (1 +
        O(3^40)))*$.1 + -(5*3^35 + O(3^38))*a^5 + O(3^38)*a^4 + (10*3^36 +

    <(O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + (1 +
        O(3^40)))*$.1 + (29642867960*3^-1 + O(3^23))*a^5 + O(3^24)*a^4 -
        (148214339800*3^-1 + O(3^24))*a^3 + O(3^25)*a^2 + (349537134821 +
        O(3^25))*a + O(3^26), 1>
]
O(3^38)*a^5 + O(3^38)*a^4 + O(3^39)*a^3 + O(3^39)*a^2 + O(3^40)*a + 1 + O(3^40)
```

52 ALGEBRAIC POWER SERIES RINGS

Chapter 52
ALGEBRAIC POWER SERIES RINGS

52.1 Introduction

Algebraic Power Series are a lazy representation of multivariate power series with fractional exponents, which are roots of univariate polynomials with coefficients in multivariate polynomial rings. The functionality allows the "lazy" computation of the power series expansion to any finite degree, this being well-determined by the defining algebraic equation.

The package was designed with the computation of formal resolutions of singularities of surfaces in mind but should provide a useful general tool for users. As well as allowing definition directly from a polynomial equation, the user can compose algebraic power series and recursively define series which are roots of polynomials whose coefficients are polynomial functions in other algebraic power series. There are also functions for basic arithmetic operations and tests for exact equality and the like.

The defined series must be expandable in fractional (positive) powers of the base variables. This is true for all roots of a *quasi-ordinary* polynomial possibly after a finite extension of the base field.

The package was designed and implemented by Tobias Beck at the RICAM institute in Linz, Austria. Some low-level adaptations for added efficiency and integration were carried out by the MAGMA group. The algorithms are described in [Bec07, Sec. 4].

52.2 Basics

In MAGMA, algebraic power series are represented in a hybrid lazy-exact way. Eventually every power series is given by a defining polynomial and a sufficiently large initial segment. Intermediate operations are represented in a lazy way. This makes it possible to compute both quickly and to high precision if necessary.

Note, however, that decision procedures may be very time intensive. In the sequel we have indicated in each function whether it is fast or whether it has to be used with care.

52.2.1 Data Structures

Algebraic power series are of type `RngPowAlgElt`.

There are two types of algebraic series: `Atomic` and `Substitution` which we sometimes refer to briefly as type A or type B. There is no difference in the functionality available but they are structurally different. The user can determine the type of a series, if (s)he desires, from the attribute `type` which is 0 for type A and 1 for type B.

`Atomic` series are the basic type that are given directly as the root of a univariate polynomial $p(z)$ with given initial expansion. $p(z)$ comes from a polynomial $f(z)$ with coefficients in a multivariate polynomial ring. Either $p = f$ or p is determined from f by

evaluating the coefficients of f at a given array, *subs*, of algebraic power series. This allows the construction of algebraic power series as roots of polynomials over finitely-generated fields of already-constructed series. Most of the constructors return a series of this type.

`Substitution` series allow the composition of algebraic power series. The principal defining data is an algebraic power series s in n variables and an array of n algebraic series that are substituted into this. In fact, the substitution is not necessarily direct, but through n given elements in the dual lattice of the exponent lattice of s as explained in the constructor `EvaluationPowerSeries`.

Both types of series have an associated exponent lattice specified by two components: Γ, a sublattice of a standard integral lattice, and e, a positive integer. The expansion of the series will in general have fractional exponents and e is the LCM of the denominators of these (e may be 1). The finite expansions that are returned are always integral-exponent multivariate polynomials. The *actual* mathematical expansion is derived from this return value by dividing all exponents by e. With this scaling up of fractional exponents by e to get integral exponents, all exponent vectors for monomials occurring in the expansion (up to any degree) will lie in the lattice Γ. So the actual exponent lattice for the series is $(1/e)\Gamma$.

The user doesn't have to worry too much about the lattice Γ. It is automatically computed by most of the constructors for algebraic power series and the default of the standard integral lattice can always be used (assuming e is correct!). It's utility is that, in computing the exponent lattice for composite constructions on series, factors of e may be cancelled out from the resulting lattice. So an algebraic construction involving series with non-integral exponents may produce a result with only integral exponents. Such lattice computations are carried out automatically.

Important note: To speed up some of the basic internal polynomial operations, it is assumed that the domain of an algebraic power series is a multivariate polynomial ring with a *degree* ordering (`glex` or `grevlex`). Attempts to create series using polynomial rings with a non-degree ordering will result in a user error.

52.2.2 Verbose Output

A verbose flag `AlgSeries` exists which can take values `true`, `false`, 0 or 1. Setting to `true` (or 1) will output information on the progress of some of the potentially more time-consuming intrinsics.

52.3 Constructors

Using constructors one can construct power series starting from polynomial data or using other power series recursively.

`PolyToSeries(s)`

Given a multivariate polynomial s, returns the series representation of s.

`AlgebraicPowerSeries(dp, ip, L, e)`

`subs` SeqEnum *Default :* []

Define a power series root of a polynomial p using an initial expansion ip and its exponent lattice $1/\texttt{e}\ \texttt{L}$. The defining polynomial p is either dp when $subs$ is empty or obtained by substituting the elements of $subs$ into the variables of dp. The initial expansion has to be sufficiently long in order to uniquely identify a root, see [Bec07, Cond. 4.3]. In this initial finite expansion and in subsequent ones, the variables occurring actually represent e-th roots, *ie* $x_1x_2^2$ is really $x_1^{1/e}x_2^{2/e}$. All exponents of monomials occurring in these expansions and the coefficients of p should lie in L (although this is not checked in many places), monomials of p giving true values rather than e-th roots.

There are simpler constructors where L is omitted (when it is assumed to be the standard integral lattice) or e is (when it is taken as 1).

As noted earlier, no strong checks are performed at construction time on the correctness of L or e or whether ip is indeed the initial expansion of a unique root in this "raw data" constructor. Incorrect initial data will only be revealed when failure occurs in further expansion of the series. The preferred methods of series creation are `ImplicitFunction`, `EvaluationPowerSeries` and `RationalPuiseux` because in these cases the sanity checks are more easily verified.

`EvaluationPowerSeries(s, nu, v)`

Given a series s, a sequence nu of vectors in the dual of its exponent lattice of s and a sequence v (of the same length) of power series in some other common domain (with compatible coefficient field). Returns the series obtained by substituting $\underline{x}^{\mu} \mapsto \prod_i \texttt{v[i]}^{\langle \texttt{nu[i]},\mu\rangle}$. This requires that nu and v fulfill a certain condition on the orders to guarantee convergence of the resulting series, see [Bec07, Cond. 4.6].

`ImplicitFunction(dp)`

`subs` SeqEnum *Default :* []

The unique series with zero constant term defined by a polynomial $p \in k[x_1, .., x_n][z]$ or $k[[x_1, \ldots, x_n]][z]$, fulfilling the conditions of the implicit function theorem, *i.e.*, $p(0, \ldots, 0) = 0$ and $\partial p/\partial z(0, \ldots, 0) \neq 0$. The polynomial p is equal to dp possibly substituted with the series in $subs$ as in `AlgebraicPowerSeries`. dp should have coefficients in a multivariate polynomial ring.

52.3.1 Rational Puiseux Expansions

Let $p \in k[[x_1, \ldots, x_n]][z]$ be a quasi-ordinary polynomial over a field k of characteristic zero. This means that p is non-zero, squarefree and monic (i.e., its leading coefficient in z is a unit in the power series ring) and if $d \in k[[x_1, \ldots, x_n]]$ denotes its discriminant then $d = x_1^{e_1} \cdots x_n^{e_n} u(x_1, \ldots, x_n)$ where u is a unit in the power series ring.

In this case the Theorem of Jung-Abhyankar states that p has $\deg(p)$ distinct Puiseux series roots, i.e., power series roots with fractionary exponents and coefficients in the algebraic closure of k.

These roots are computed by a generalization of the so called Newton-Puiseux algorithm. Also Duval's extension for computing rational parametrization has been implemented.

`RationalPuiseux(p)`

`Gamma`	LATTICE	*Default :* `StandardLattice`
`subs`	SEQENUM	*Default :* []
`Duval`	BOOLELT	*Default :* `false`
`OnlySingular`	BOOLELT	*Default :* `false`
`ExtName`	MONSTGELT	*Default :* "*gamma*"
`ExtCount`	RNGINTELT	*Default :* 0

We first specify the behavior of this function in the case that no special value of *subs* has been given. This function assumes that p is a univariate polynomial over a multivariate polynomial ring $S = k[x_1, ..., x_r]$ and that p is quasi-ordinary. In this case it will compute a set of rational parametrizations of p. Note that for reasons of efficiency the user has to make sure that p is actually quasi-ordinary! (Otherwise, further processing of the output may result in runtime errors.)

The first return value will be the exponent lattice of the input polynomial in the usual format $< \Gamma_0, e_0 >$. If the parameter `Gamma` has been specified, then Γ_0 = `Gamma` and $e_0 = 1$. In this case `Gamma` has to be an integral 'r'-dimensional lattice of full rank containing all the exponents of p. Otherwise Γ_0 will be set to the r-dimensional standard lattice and again $e_0 = 1$.

As a second value a complete list of rational parametrizations in the format $< \lambda, s, N, E >$ is returned. Here λ is a sequence of r field elements and s is a fractionary algebraic power series of type `RngPowAlgElt`. Let p_1 denote the image of p under the transformation $x^{\mu_i} \mapsto \lambda_i x^{\mu_i}$ where $(\mu_i)_i$ is the basis of the exponent lattice $e_0^{-1}\Gamma_0$ then s is a solution of p_1, i.e., we have $p_1(s) = 0$. Note that if neither `Gamma` nor `subs` have been supplied this just means that x_i is substituted by $\lambda_i x_i$. Finally N is the index of $e_0^{-1}\Gamma_0$ in the exponent lattice of s and E is the degree of the extension of the coefficient field needed for defining s.

The behavior described above corresponds to the Newton-Puiseux algorithm with Duval's trick. The field extensions that are used for expressing the series fulfill a certain minimality condition. If `Duval` is set to `false` then the function returns a complete set of representatives (up to conjugacy) of Puiseux series roots of the original polynomial p, in other words, the λ-vectors will always be vectors of ones.

If `OnlySingular` is set to `true` then only those parametrizations that correspond to singular branches are returned.

If the ground field has to be extended, the algebraic elements will be assigned the name `ExtName_`i where i starts from `ExtCount`. The last return value is the value of `ExtCount` plus the number of field extensions that have been introduced during the computation.

Finally, if the parameter `subs` is passed, then it has to be a sequence of r power series in a common domain and internally the variables in p will be substituted by

the corresponding series. Again the resulting polynomial has to be quasi-ordinary. In this case Γ_0 and e_0 are determined by building the sum of the exponent lattices of all series in `subs`. The parameter `Gamma` then has no effect.

For further details on the algorithm and other references see [Bec07, Sec. 4.3]

Example H52E1

We illustrate the constructors by examples. For displaying results we already use the command `Expand` that will be explained later.

```
> Q := Rationals(); Qs<s> := FunctionField(Q);
> Qxy<x,y> := PolynomialRing(Q, 2, "glex");
> Qxyz<z> := PolynomialRing(Qxy);
> Qst<t> := PolynomialRing(Qs, 1, "glex");
> Qstu<u> := PolynomialRing(Qst);
```

One can consider polynomials as series.

```
> s0 := PolyToSeries(1 - 3*x + x^2*y + y^20);
> Expand(s0, 10);
true x^2*y - 3*x + 1
```

One can define series by the implicit function theorem at the origin.

```
> s1 := ImplicitFunction(z*(1 - x - y) - x - y);
> Expand(s1, 4);
true x^3 + 3*x^2*y + 3*x*y^2 + y^3 + x^2 + 2*x*y + y^2 + x + y
```

One can define a power series if an initial expansion is known. Note that the following power series has exponent lattice $\mathbf{Z}(\frac{1}{5}, -\frac{2}{5}) + \mathbf{Z}(\frac{2}{5}, \frac{1}{5})$ but its "expansions" are polynomials supported on $\mathbf{Z}(1, -2) + \mathbf{Z}(2, 1)$.

```
> defpol := (1+5*y+10*y^3+10*y^2+5*y^4+y^5)*z^5+(-20*y^3*x-
>   30*y^2*x-5*y^4*x-5*x-20*y*x)*z^4+(10*x^2+30*y^2*x^2+10*y^3*x^2+
>   30*x^2*y)*z^3+(-20*y*x^3-10*x^3-10*y^2*x^3)*z^2+
>   (5*y*x^4+5*x^4)*z-x^5-x^2*y;
> Gamma := Lattice(RMatrixSpace(Integers(), 2, 2) ! [1,-2, 2,1]);
> init := x^2*y;
> s2 := AlgebraicPowerSeries(defpol, init, Gamma, 5);
> Expand(s2, 20);
true
-x^2*y^16 + x^5*y^10 + x^2*y^11 - x^5*y^5 - x^2*y^6 + x^5 + x^2*y
```

We can "substitute" series into each other.

```
> X := AlgebraicPowerSeries(u^3-t+s*t^2, t, StandardLattice(1), 3);
> Y := PolyToSeries(t);
> duals := [RSpace(Integers(), 2) | [1, 3], [2, 1]];
> s3 := EvaluationPowerSeries(s2, duals, [X, Y]);
> Expand(s3, 13);
```

```
true (-1/9*s^2 - 1/3*s - 1)*t^10 + (-1/3*s + 1)*t^7 + t^4
```

We can compute all the Puiseux series roots of a quasi-ordinary polynomial up to conjugacy over $\mathbf{Q}$.

```
> qopol := z^6 + 3*x*y^2*z^4 + x*y*z^3 + 3*x^2*y^4*z^2 + x^3*y^6;
> _, prms := RationalPuiseux(qopol : Duval := false); prms;
[*
    <[ 1, 1 ], Algebraic power series -x*y, 3, 1>,
    <[ 1, 1 ], Algebraic power series gamma_0*x*y, 3, 2>,
    <[ 1, 1 ], Algebraic power series -x^2*y^5, 3, 1>,
    <[ 1, 1 ], Algebraic power series gamma_1*x^2*y^5, 3, 2>
*]
> Domain(prms[2][2]); ExponentLattice(prms[2][2]);
Polynomial ring of rank 2 over Number Field with defining
polynomial $.1^2 - $.1 + 1 over the Rational Field
Graded Lexicographical Order
Variables: x, y
<
    Lattice of rank 2 and degree 2
    Basis:
    ( 1  1)
    ( 1 -2),
    3
>
> Expand(prms[2][2], 15);
true x^3*y^9 + (gamma_0 - 1)*x^2*y^5 + gamma_0*x*y
```

We find that the sum over all field extensions $1 + 2 + 1 + 2 = 6$ is equal to the degree of the defining polynomial `qopol`. The third parametrization involves a field extension of $\mathbf{Q}$ by `gamma_0` s.t. $\texttt{gamma\_0}^2 - \texttt{gamma\_0} + 1 = 0$ and an extension of the exponent lattice to $\mathbf{Z}(\frac{1}{3}, \frac{1}{3}) + \mathbf{Z}(\frac{1}{3}, -\frac{2}{3})$. It turns out that the field extension is not necessary if we are only interested in parametrizations.

```
> _, prms := RationalPuiseux(qopol : Duval := true); prms;
[*
    <[ -1, -1 ], Algebraic power series -x*y, 3, 1>,
    <[ -1, 1 ], Algebraic power series -x^2*y^5, 3, 1>
*]
```

No field extensions have been introduced, but this required the application of automorphisms $\mathbf{Q}[[x, y]] \to \mathbf{Q}[[x, y]]$ in advance (more precisely $x \mapsto -x, y \mapsto -y$ resp. $x \mapsto -x, y \mapsto y$). This time we can sum up the overall extension degrees (*i.e.*, for fields and lattices) $3 \cdot 1 + 3 \cdot 1 = 6$ to the degree of `qopol`.

52.4 Accessors and Expansion

The following functions provide an interface to conveniently extract information from a power series defined as above.

`Domain(s)`

Return the multivariate polynomial ring that is used for approximating the series s by its truncations.

`ExponentLattice(s)`

Return the exponent lattice $(1/e)\Gamma$ of the series as tuple (Γ, e) where Γ is an integral lattice and e is an integer.

`DefiningPolynomial(s)`

Return a defining polynomial of the series which is a squarefree univariate polynomial over the multivariate polynomial domain `Domain(s)`. In the case of series defined with substitutions, the computation may be expensive and can involve recursive resultant computations.

`Order(s)`

`TestZero` BoolElt *Default :* `false`

Given a series s, return the integral order (total degree of smallest non-zero term occurring) of its expansion as returned by `Expand`, *i.e.*, its fractionary order times the exponent denominator. If s is zero, this function will **not terminate**. Set `TestZero` to `true` to get a return value -1 in this case, but note that this involves the computationally complex call `IsZero`.

`Expand(s,ord)`

Given the power series β which is represented by s, let α be the result of substituting variables $x_i \mapsto x_i^e$ where e is taken from the output of `ExponentLattice(s)` (*i.e.*, α is β without exponent denominators). Returns `true` and the truncation of α modulo terms of order greater or equal `ord`. A return of `false` indicates that the representation is inconsistent (which should only happen when `RationalPuiseux` is called with non quasi-ordinary input or `AlgebraicPowerSeries` is used inconsistently).

Example H52E2

We can study the series `s3`.

```
> Domain(s3);
Polynomial ring of rank 1 over Univariate rational function
field over Rational Field
Graded Lexicographical Order
Variables: t
> ExponentLattice(s3);
<
    Standard Lattice of rank 1 and degree 1,
```

```
    3
>
> DefiningPolynomial(s3);
(s^45*t^45 - ... - 15*s^30*t^2 - s^30)*u^15 + ... +
(5*s^37*t^41 - ... + 120*s^31*t^19 - 30*s^30*t^18)*u^3 -
s^35*t^40 + ... - 5*s^31*t^21 + s^30*t^20
> Order(s3);
4
```

These commands reveal the following about `s3`: It is a power series in $\mathbf{Q}(s)[[t^{1/3}]]$, because it is approximated in $\mathbf{Q}(s)[t]$ and has exponent lattice $\frac{1}{3}\mathbf{Z}$. A defining polynomial in $\mathbf{Q}(s)[t][u]$ was also computed. (Recall that `s3` has been defined recursively.) The order is $\frac{4}{3}$ which we know already from a previous expansion.

52.5 Arithmetic

There are functions to perform basic arithmetic operations (addition, subtraction etc.) on power series.

`AlgComb(c,ss)`

Given a polynomial c in r variables and a sequence ss of r power series (in a common domain with compatible coefficient field) return the series obtained by substituting the elements of ss for the variables of c. This allows the construction of completely arbitrary algebraic combinations.

`s + t`
`s - t`
`s * t`

Add, subtract or multiply two power series.

Example H52E3

One can easily substitute power series into polynomials.

```
> // construct the series s0^2+s1^2
> h0 := AlgComb(x^2 + y^2, [s0,s1]);
> Expand(h0, 3);
true 10*x^2 + 2*x*y + y^2 - 6*x + 1
```

This includes of course the ring operations.

```
> h1 := Add(s1, PolyToSeries(One(Qxy)));
> Expand(h1, 4);
true
x^3 + 3*x^2*y + 3*x*y^2 + y^3 + x^2 + 2*x*y + y^2 + x + y + 1
> h2 := Mult(h1, PolyToSeries(1 - x - y));
> Expand(h2, 4);
true 1
```

```
> h3 := Add(h2, PolyToSeries(-One(Qxy)));
> Expand(h3, 4);
true 0
```

52.6 Predicates

The following functions provide decision algorithms for algebraic power series. They may involve **recursive resultant computations**, hence, have a high complexity and should be used with care.

`IsZero(s)`

Decides if the series is zero.

`s eq t`

Decides if two series are equal.

`IsPolynomial(s)`

Decides whether the series is actually a polynomial (with integral exponents) in the multivariate polynomial domain as returned by `Domain(s)`. In the positive case also returns that polynomial. This function relies on `SimplifyRep`.

Example H52E4

The previous computations suggest that `h2` is 1, in particular it is polynomial (in contrast to `h1`). In this case `h3` would be zero.

```
> IsPolynomial(h1);
false
> IsPolynomial(h2);
true 1
> IsEqual(h2, PolyToSeries(One(Qxy)));
true
> IsZero(h3);
true
```

52.7 Modifiers

The following functions modify the representation of the power series or apply a simple automorphism.

`ScaleGenerators(s,ls)`

Let $\{\gamma_i\}_i$ be the basis (determined from the representation chosen by MAGMA) of the exponent lattice of the series s, and let $\sigma : \underline{x}^{\gamma_i} \mapsto ls[i]\underline{x}^{\gamma_i}$. Return the series $\sigma(s)$.

`ChangeRing(s,R)`

If R is a multivariate polynomial domain compatible with the approximation domain `Domain(s)`, return the same power series with new approximation domain R. This is sort of a "coercion between power series rings".

`SimplifyRep(s)`

`Factorizing` BoolElt *Default :* `true`

"Simplifies" the internal representation of a series. The result will be a series of atomic type without recursive (substitution) dependencies on other power series. The defining polynomial of the simplified series will be irreducible and therefore a minimal polynomial over `Domain(s)` (unless `Factorizing` is `false` when it will only be guaranteed to be squarefree). After the simplification, `DefiningPolynomial` returns this polynomial, which can be useful (*e.g.*, for `IsPolynomial`). However, experience shows that the resulting representation is in general neither simple nor more efficient for subsequent computations.

There is a **dangerous pitfall:**

Assume we have a series represented by a tree with nodes of type A and B. Assume further that the leaves have been constructed by `RationalPuiseux` with parameter `Gamma` set to some value. Then the intention was probably to work over the subring of a polynomial ring with restricted support. If now `SimplifyRep`, with `Factorizing` as `true`, is called, then a minimal polynomial over the whole polynomial ground ring is computed which is maybe not what one wants.

Example H52E5

We can modify `s2` by mapping generators (of Laurent polynomials) $x^{1/5}y^{-2/5} \mapsto 3x^{1/5}y^{-2/5}$ and $x^{2/5}y^{1/5} \mapsto 4x^{2/5}y^{1/5}$.

```
> Expand(ScaleGenerators(s2, [3,4]), 15);
true
64/81*x^2*y^11 - 64/3*x^5*y^5 - 16/9*x^2*y^6 + 48*x^5 + 4*x^2*y
```

One can naturally view `h1` as a series in $\mathbf{Q}(i)[[u, v]]$.

```
> Qi<i> := NumberField(R.1^2 + 1) where R is PolynomialRing(Q);
> Qiuv<u,v> := PolynomialRing(Qi, 2, "glex");
> h4 := ChangeRing(s1, Qiuv);
> Expand(h4, 4); Domain(h4);
true u^3 + 3*u^2*v + 3*u*v^2 + v^3 + u^2 + 2*u*v + v^2 + u + v
```

```
Polynomial ring of rank 2 over Qi
Graded Lexicographical Order
Variables: u, v
```

We have seen that the power series `h3` is zero, but its representation does not show this immediately. We can "explicitize" its representation.

```
> SimplifyRep(h3 : Factorizing := true);
Algebraic power series
0
> DefiningPolynomial($1);
z
```

PART VIII
MODULES

53 INTRODUCTION TO MODULES

Chapter 53
INTRODUCTION TO MODULES

53.1 Overview

This section of the Handbook describes the Magma facilities for linear algebra and module theory. Since this topic is absolutely fundamental for much of algebra, it is important that the reader understand how linear algebra is presented in Magma. The structures covered under this heading include:

(i) Vector spaces;

(ii) Inner product spaces;

(iii) Modules defined over any ring or algebra

(iv) $R[G]$-modules, where R is a ring and G is a group;

(v) Linear transformations and R-module homomorphisms.

Although vector spaces are, of course, subsumed under general modules, we present a separate treatment of them, firstly because of their importance and secondly because their theory is somewhat cleaner than that of a general module. Magma users who are unfamiliar with the language of module theory will find a self-contained treatment of the vector space machinery in Chapter 28.

In the Magma universe, rectangular matrices are regarded as forming a module (actually a bimodule). We shall regard a rectangular matrix as the concrete realization of a linear transformation or R-module homomorphism. Thus, an $m \times n$ matrix over a ring R is considered to be an element of the module $\mathrm{Hom}_R(M, N)$. Reflecting the dual nature of matrices, the $\mathrm{Hom}_R(M, N)$ operations include the standard module-theoretic operations as well as operations that interpret an element of $\mathrm{Hom}_R(M, N)$ as a homomorphism.

53.2 General Modules

A module M is always regarded as a submodule or quotient module of the free module $S^{(n)}$, for some ring or algebra S. The types of module that are definable in the system fall into three classes:

(a) **Abstract Modules**: Given a ring R, a set M and a mapping $\phi : R \times M \to M$, the pair (M, ϕ) will be referred to as an *abstract* R-module. Because of the very general nature of this construction, only the basic arithmetic operations may be applied to modules of this type.

(b) **Modules with Scalar Action**: Given a general ring R, an R-module with *scalar action* is a submodule or quotient module of the free R-module $R^{(n)}$, where the action is that of ring multiplication in R.

(c) **Modules with Matrix Action**: Let R be a PIR and suppose S is a R-algebra. Thus there exists a ring homomorphism $\phi : R \to S$, and so S is a (left) R-module with the

R-action defined by $r * s = \phi(r) * s$. Indeed, any S-module M is a (left) S-module with action defined by $r * m = \phi(r) * m$. Furthermore, if $\phi(R)$ lies in the centre of S, then S acts on M as a ring of R-module endomorphisms. Consequently, M is an S-module. We take M to be the free R-module $R^{(n)}$, and so the action of S on M is given by the action of a subring of $M_n(R)$ on M. Thus, given an R-algebra S, an S-module of the form $M = R^{(n)}$ may be specified by giving M together with a homomorphism of S into $M_n(R)$.

53.3 The Presentation of Submodules

Let N be a submodule of the module $M = R^{(m)}$. For simplicity, assume that N is free, and has dimension n where $n < m$. There are two ways in which N may be viewed:

(a) As a submodule embedded in M. Thus, though N is a module of dimension n, its elements are regarded as elements of M.

(b) As the module $R^{(n)}$ represented on a reduced basis, together with a morphism ϕ defining the inclusion of N into M.

The presentation (a) is the usual way submodules are regarded in elementary linear algebra. However, this presentation is inconvenient for more advanced applications. For example, many of the major functions available for studying an $R[G]$-module N expect that N is given relative to a reduced basis. We shall refer to a submodule presentation (a) as the *embedded presentation*, and (b) as the *reduced presentation*.

To provide the user with the maximum flexibility, Magma supports both forms of submodule presentation for the important classes of modules. Usually, a module calculation commences with the definition of one or two modules from which further modules are created by the operations of forming submodules, quotient modules and extensions. Let us call these latter modules *descendants* of the original module. Magma provides parallel creation functions which allow the user to choose the form of submodule presentation. Once that choice has been made, all descendants of the initial module(s) will follow the same presentation convention.

The module creation functions that select the embedded form are usually of the form *Qualifier*`Space`, while those that adopt the standard form are usually of the form *Qualifier*`Module`. Thus in the case of vector spaces the function `KSpace(K, n)` constructs the n-dimensional vector space over the field K, where submodules are to be presented in embedded form. On the other hand, `RModule(K, n)` constructs the n-dimensional vector space over the field K, where submodules are to be presented in reduced form.

54 FREE MODULES

Chapter 54
FREE MODULES

54.1 Introduction

54.1.1 Free Modules

This chapter describes the facilities provided for modules in the following representations:

Tuple Modules: Modules whose elements are n-tuples over a fixed ring R, i.e., modules $R^{(n)}$;

Matrix Modules: Modules whose elements are homomorphisms of modules, i.e., $Hom_R(M, N)$. The elements of these modules are $m \times n$ matrices over the ring R;

The ring R acts on the right of the module element by scalar multiplication. If R is not an Euclidean Domain then, currently, only arithmetic with vectors is supported. In particular, the ability to work with submodules and quotient modules is restricted to situations where R is either a field or Euclidean Domain.

In the first part of the chapter we describe the operations that apply to modules generally, while in the second half we describe the creation of modules $Hom_R(M, N)$ together with the operations that are specific to them. Insofar as elementary module-theoretic operations are concerned, there is no real difference between tuple modules and matrix modules except for the input and display of elements. Many special operations provided for matrices are described in the chapter on matrices.

The reader is referred to the chapter on vector spaces for descriptions of the extensive functionality provided for modules over fields.

54.1.2 Module Categories

The family of all finitely generated modules over a given ring R forms a category, while the set of all finitely generated modules forms a family of categories indexed by the ring R. In this family of categories, objects are modules and the morphisms are module homomorphisms. The category name for modules is `ModRng`. We distinguish the following subcategories of `ModRng`:

`ModTupFld` - the category of modules of n-tuples over a field;

`ModMatFld` - the category of modules of $m \times n$ matrices over a field;

`ModTupEd` - the category of modules of n-tuples over an euclidean domain.

`ModTupRng` - the category of modules of n-tuples over a ring;

`ModMatRng` - the category of modules of $m \times n$ matrices over a ring;

54.1.3 Presentation of Submodules

Let N be a free submodule of the R-module M. We have two alternative ways of presenting N. Firstly, we can present it on a set of generators that are elements of M; we call such a presentation an *embedded presentation*. Alternatively, given that N has rank r, we can present it as the module $S^{(r)}$, with appropriate action induced from the action of R on M. We call this presentation of N a *reduced presentation*.

The user can control the method of submodule presentation at the time of creation of an initial module through selection of the appropriate creation function. Thus, the function `RModule` will create a module with the convention that it and all its submodules and quotient modules will have their submodules presented in reduced form. The use of `RSpace`, on the other hand, signifies that submodules are to be presented in embedded form.

54.1.4 Notation

Throughout this chapter, R will denote a ring (possibly a field) while K will denote a field. The letters M and N will denote modules, while U and V will denote vector spaces.

54.2 Definition of a Module

54.2.1 Construction of Modules of n-tuples

`RSpace(R, n)`

`RModule(R, n)`

Given a ring R and a non-negative integer n, create the free right R-module $R^{(n)}$, consisting of all n-tuples over R. The module is created with the standard basis, $e_1, \ldots, e_n$, where e_i $(i = 1, \ldots, n)$ is the vector containing a 1 in the i-th position and zeros elsewhere.

The function `RModule` creates a module in reduced mode while `RSpace` creates a module in embedded mode.

`RSpace(R, n, F)`

Given a ring R, a non-negative integer n and a square $n \times n$ symmetric matrix F, create the free right R-module $R^{(n)}$ (in embedded form), with inner product matrix F. This is the same as `RSpace(R, n)`, except that the functions `Norm` and `InnerProduct` (see below) will be with respect to the inner product matrix F.

Example H54E1

We construct the module consisting of 6-tuples over the integers.

```
> Z := IntegerRing();
> M := RModule(Z, 6);
> M;
RModule M of dimension 6 with base ring Integer Ring
```

54.2.2 Construction of Modules of $m \times n$ Matrices

`RMatrixSpace(R, m, n)`

The module comprising all $m \times n$ matrices over the ring R.

54.2.3 Construction of a Module with Specified Basis

`RModuleWithBasis(Q)`

`RSpaceWithBasis(Q)`

`RSpaceWithBasis(a)`

Given a sequence Q (or matrix a) of k independent vectors each lying in a module M, construct the submodule of M of dimension k whose basis is Q (or the rows of a). The basis is echelonized internally but all functions which depend on the basis of the space (e.g. `Coordinates`) will use the given basis.

`RMatrixSpaceWithBasis(Q)`

The module of $m \times n$ matrices whose basis is given by the linearly independent matrices of the sequence Q.

54.3 Accessing Module Information

`M . i`

Given an R-module M and a positive integer i, return the i-th generator of M. The integer i must lie in the range $[1, r]$, where r is the number of generators for M.

`CoefficientRing(M)`

`BaseRing(M)`

`CoefficientRing(M)`

`BaseRing(M)`

`CoefficientField(M)`

`BaseField(M)`

Given an R-module M which is defined as a submodule of $S^{(n)}$, return the ring S.

`Generators(M)`

The generators for the R-module M, returned as a set.

`OverDimension(M)`

Given an R-module M which is an embedded submodule of the module $S^{(n)}$, return n.

`OverDimension(u)`

Given an element u of an embedded submodule of the module $S^{(n)}$, return n.

`Moduli(M)`

The column moduli of the module M over a euclidean domain.

`Parent(u)`

Given an element u belonging to the R-module M, return M.

`Generic(M)`

Given an R-module M which is a submodule of the module $R^{(n)}$, return the module $R^{(n)}$ as an R-module.

54.4 Standard Constructions

Given one or more existing modules, various standard constructions are available to construct new modules.

54.4.1 Changing the Coefficient Ring

`ChangeRing(M, S)`

Given a module M with base ring R, together with a ring S, construct the module N with base ring S obtained by coercing the components of elements of M into N, together with the homomorphism from M to N.

`ChangeRing(M, S, f)`

Given a module M with base ring R, together with a ring S, and a homomorphism $f : R \to S$, construct the module N with base ring S obtained by mapping the components of elements of M into N by f, together with the homomorphism from M to N.

`ChangeUniverse(~x, R)`

Change the coefficient ring of x to be R.

54.4.2 Direct Sums

`DirectSum(M, N)`

Given R-modules M and N, construct the direct sum D of M and N as an R-module. The embedding maps from M into D and from N into D respectively, and the projection maps from D onto M and from D onto N respectively are also returned.

`DirectSum(Q)`

Given a sequence Q of R-modules, construct the direct sum D of these modules. The embedding maps from each of the elements of Q into D and the projection maps from D onto each of the elements of Q are also returned.

54.5 Elements

54.6 Construction of Elements

`elt< M | a1, ..., an >`

Given a module M with base module $S^{(n)}$, and elements $a_1, \ldots, a_n$ belonging to S, construct the element $m = (a_1, \ldots, a_n)$ of M. Note that if m is not an element of M, an error will result.

`M ! Q`

Given the module M with base module $S^{(n)}$, and elements $a_1, \ldots, a_n$ belonging to S, construct the element $m = (a_1, \ldots, a_n)$ of M. Note that if m is not an element of M, an error will result.

`CharacteristicVector(M, S)`

Given a submodule M of the module $R^{(n)}$ together with a set S of integers lying in the interval $[1, n]$, return the characteristic number of S as a vector of R.

`Zero(M)`
`M ! 0`

The zero element for the R-module M.

`Random(M)`

Given a module M defined over a finite ring or field, return a random vector.

Example H54E2

We create the module of 4-tuples over the polynomial ring $\mathbf{Z}[x]$ and define various elements.

```
> P<x> := PolynomialRing(IntegerRing());
> M := RModule(P, 4);
> a := elt< M | 1+x, -x, 2+x, 0 >;
> a;
(x + 1    -x x + 2     0)
> b := M ! [ 1+x+x^2, 0, 1-x^7, 2*x ];
> b;
(x^2 + x + 1           0    -x^7 + 1         2*x)
> zero := M ! 0;
> zero;
(0 0 0 0)
```

54.6.1 Deconstruction of Elements

`ElementToSequence(u)`

`Eltseq(u)`

Given an element u belonging to the R-module M, return u in the form of a sequence Q of elements of R. Thus, if u is an element of $R^{(n)}$, then $Q[i] = u[i], 1 \leq i \leq n$, while if u is an element of $R^{(m \times n)}$, then $Q[(i-1)n+j] = u[i,j], 1 \leq i \leq m, 1 \leq j \leq n$.

54.6.2 Operations on Module Elements

54.6.2.1 Arithmetic

`u + v`

Sum of the elements u and v, where u and v lie in the same R-module M.

`-u`

Additive inverse of the element u.

`u - v`

Difference of the elements u and v, where u and v lie in the same R-module M.

`x * u`

Given an element x belonging to a ring R, and an element u belonging to the left R-module M, return the (left) scalar product $x * u$ as an element of M.

`u * x`

Given an element x belonging to a ring R, and an element u belonging to the right R-module M, return the (right) scalar product $u * x$ as an element of M.

`u / x`

Given a non-zero element x belonging to a field K, and an element u belonging to the right K-module M, return the scalar product $u * (1/x)$ as an element of M.

54.6.2.2 Indexing

`u[i]`

Given an element u belonging to a submodule M of the R-module $R^{(n)}$ and a positive integer i, $1 \leq i \leq n$, return the i-th component of u (as an element of the ring R).

`u[i] := x`

Given an element u belonging to a submodule M of the R-module $T = R^{(n)}$, a positive integer i, $1 \leq i \leq n$, and an element x of the ring R, redefine the i-th component of u to be x. The parent of u is changed to T (since the modified element u need not lie in M).

54.6.2.3 Normalization

`Normalize(u)`

`Normalise(u)`

The element u must belong to an R-module, where R is either a field, the ring of integers or a univariate polynomial ring over a field. Assume that the vector u is non-zero. If R is a field then `Normalize` returns $\frac{1}{a} * u$, where a is the first non-zero component of u. If R is the ring of integers, `Normalize` returns $\epsilon * u$, where ϵ is $+1$ if the first non-zero component of u is positive, and -1 otherwise. If R is the polynomial ring $K[x]$, K a field, then `Normalize` returns $\frac{1}{a} * u$, where a is the leading coefficient of the first non-zero (polynomial) component of u. If u is the zero vector, it is returned as the value of this function.

`Rotate(u, k)`

Given a vector u, return the vector obtained from u by rotating by k coordinate positions.

`Rotate(~u, k)`

Given a vector u, destructively rotate u by k coordinate positions.

Example H54E3

We illustrate the use of the arithmetic operators for module elements by applying them to elements of the module of 4-tuples over the polynomial ring $\mathbf{Z}[x]$.

```
> P<x> := PolynomialRing(IntegerRing());
> M := RModule(P, 4);
> a :=  M ! [ 1+x, -x, 2+x, 0 ];
> b := M ! [ 1+x+x^2, 0, 1-x^7, 2*x ];
> a + b;
(x^2 + 2*x + 2    -x    -x^7 + x + 3    2*x)
> -a;
(-x - 1      x -x - 2      0)
> a - b;
(       -x^2          -x x^7 + x + 1        -2*x)
> (1-x + x^2)*a;
(x^3 + 1    -x^3 + x^2 - x    x^3 + x^2 - x + 2    0)
> a*(1-x);
(    -x^2 + 1      x^2 - x -x^2 - x + 2            0)
> a[3];
x + 2
> a[3] := x - 2;
> a;
(x + 1    -x x - 2     0)
> ElementToSequence(a - b);
[
    -x^2,
```

```
    -x,
    x^7 + x - 3,
    -2*x
]
> Support(a);
{ 1, 2, 3 }
```

54.6.3 Properties of Vectors

`IsZero(u)`

Returns `true` if the element u of the R-module M is the zero element.

`Depth(v)`

The index of the first non-zero entry of the vector v (0 if none such).

`Support(u)`

A set of integers giving the positions of the non-zero components of the vector u.

`Weight(u)`

The number of non-zero components of the vector u.

54.6.4 Inner Products

`(u, v)`

`InnerProduct(u, v)`

Return the inner product of the vectors u and v with respect to the inner product defined on the space. If an inner product matrix F is given when the space is created, then this is defined to be $u \cdot F \cdot v^{tr}$. Otherwise, this is simply $u \cdot v^{tr}$.

`Norm(u)`

Return the norm product of the vector u with respect to the inner product defined on the space. If an inner product matrix F is given when the space is created, then this is defined to be $u \cdot F \cdot u^{tr}$. Otherwise, this is simply $u \cdot u^{tr}$.

54.7 Bases

The application of the functions in this section is restricted either to vector spaces or to torsion-free modules over a Euclidean Domain.

For a full description of the basis functions for a module defined over a field, the reader is referred to the chapter on vector spaces.

`Basis(M)`

The current basis for the free R-module M, R an ED, returned as a sequence of module elements.

`Rank(M)`

The rank of the free R-module M.

`Coordinates(M, u)`

Given a vector u belonging to the rank r free R-module M, R an Euclidean Domain, with basis $u_1, \ldots, u_r$, return a sequence $[a_1, \ldots, a_r]$ giving the coordinates of u relative to the M-basis: $u = a_1 * u_1 + \cdots + a_r * u_r$.

54.8 Submodules

54.8.1 Construction of Submodules

Submodules may be defined for any type of module. However, functions that depend upon membership testing are only implemented for modules over Euclidean Domains (EDs). The conventions defining the presentations of submodules are as follows:

If M has been created using the function `RSpace`, then every submodule of M is given in terms of a generating set consisting of elements of M, i.e. by means of an embedded generating set.

If M has been created using the function `RModule`, then every submodule of M is given in terms of a reduced basis.

`sub< M | L >`

Given an R-module M, construct the submodule N generated by the elements of M specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of R defining an element of M;

(b) A set or sequence whose terms are elements of M;

(c) A submodule of M;

(d) A set or sequence whose terms are submodules of M.

The generators stored for N consist of the elements specified by terms L_i together with the stored generators for submodules specified by terms of L_i. Repetitions of an element and occurrences of the zero element are removed (unless N is trivial).

The constructor returns the submodule N and the inclusion homomorphism $f : N \to M$.

Example H54E4

We construct a submodule of the 4-dimensional vector space over the field of rational function $F[x]$, where F is $\mathbf{F}_5$.

```
> P := PolynomialRing(GF(5));
> R<x> := FieldOfFractions(P);
> M := RSpace(R, 4);
> N := sub< M | [1, x, 1-x, 0], [1+2*x-x^2, 2*x, 0, 1-x^4 ] >;
> N;
Vector space of degree 4, dimension 2 over Field of Fractions in x over
Univariate Polynomial Algebra over GF(5)
Generators:
(1    x    4*x + 1    0)
(4*x^2 + 2*x + 1    2*x    0    4*x^4 + 1)
Echelonized basis:
(1  0  3/(x + 4)  (x^3 + x^2 + x + 1) / (x + 4))
(0  1  (4*x^2 + 2*x + 1) / (x^2 + 4*x)  (4*x^3 + 4*x^2 + 4*x + 4) / (x^2 + 4*x))
```

54.8.2 Operations on Submodules

54.8.3 Membership and Equality

The following operations are only available for submodules of $R^{(n)}$, $\mathrm{Hom}_R(M, N)$ and $R[G]$, where R is a Euclidean Domain. If the modules involved are $R[G]$-modules, the operators refer to the underlying R-module.

`u in M`

Returns `true` if the element u lies in the R-module M, where u and M belong to the same R-module.

`u notin M`

Returns `true` if the element u does not lie in the R-module M, where u and M belong to the same R-module.

`N subset M`

Returns `true` if the R-module N is contained in the R-module M, where M and N belong to a common R-module.

`N notsubset M`

Returns `true` if the R-module N is not contained in the R-module M, where M and N belong to a common R-module.

`M eq N`

Returns `true` if the R-modules N and M are equal, where N and M belong to a common R-module.

`M ne N`

Returns `true` if the R-modules N and M are not equal, where N and M belong to a common R-module.

54.8.4 Operations on Submodules

The following operations are only available for submodules of $R^{(n)}$, $\mathrm{Hom}_R(M, N)$ and $R[G]$, where R is a Euclidean Domain. If the modules involved are $R[G]$-modules, the operators refer to the underlying R-module.

`M + N`

Sum of the submodules M and N, where M and N belong to a a common R-module.

`M meet N`

Intersection of the submodules M and N, where M and N belong to a common R-module.

54.9 Quotient Modules

54.9.1 Construction of Quotient Modules

`quo< M | L >`

Given an R-module M, construct the quotient module $P = M/N$, where N is the submodule generated by the elements of M specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of R defining an element of M;

(b) A set or sequence whose terms are elements of M;

(c) A submodule of M;

(d) A set or sequence whose terms are submodules of M.

The generators constructed for N consist of the elements specified by terms L_i together with the stored generators for submodules specified by terms of L_i.

The constructor returns the quotient module P and the natural homomorphism $f : M \to P$.

54.10 Homomorphisms

Throughout this part of the chapter, when discussing the set of all R-homomorphisms from the R-module M into the R-module N, it will be assumed that R is a **commutative** ring. We further assume that M and N are free R-modules and that bases for these modules are present. The module $\mathrm{Hom}_R(M, N)$ will be identified with the module of $m \times n$ matrices over R. Thus, an element of $\mathrm{Hom}_R(M, N)$ is represented as a matrix relative to the bases of the generic modules corresponding to M and N. For this reason, we will refer to these modules as *matrix modules*.

We remind the reader that submodules of $\mathrm{Hom}_R(M, N)$ are always presented in embedded form. If the user wishes to have submodules presented in reduced form then he/she should use the natural isomorphism between $R^{(m\times n)}$ and $R^{(mn)}$.

It should be noted that essentially operation defined for tuple modules, their elements and submodules applies to matrix modules. Thus, all of the operations discussed earlier in this chapter apply to matrix modules.

The modules M and N may themselves be matrix modules. In this case, the resulting matrix module has either a right or left action and an element belonging to it transforms a (homomorphism) element of M into a (homomorphism) element of N.

The function `Reduce` may be used to construct for a matrix module H the matrix module H' equivalent to H whose elements are with respect to the actual bases of the domain and codomain of elements of H (not the generic bases of the domain and codomain).

54.10.1 $\mathrm{Hom}_R(M, N)$ for R-modules

`Hom(M, N)`

If M is the tuple module $R^{(m)}$ and N is the tuple module $R^{(n)}$, create the module $\mathrm{Hom}_R(M, N)$ as the (R, R)-bimodule $R^{(m\times n)}$, represented as the set of all $m \times n$ matrices over R. The module is created with the standard basis, $\{E_{ij} \mid i = 1\ldots, m, j = 1\ldots, n\}$, where E_{ij} is the matrix having a 1 in the (i, j)-th position and zeros elsewhere.

`RMatrixSpace(R, m, n)`

Given a ring R and positive integers m and n, construct $H = \mathrm{Hom}(M, N)$, where $M = R^{(m)}$ and $N = R^{(n)}$, as the free (R, R)-bimodule $R^{(m\times n)}$, consisting of all $m \times n$ matrices over R. The module is created with the standard basis, $\{E_{ij} \mid i = 1\ldots, m, j = 1\ldots, m\}$. Note that the modules M and N are created by this function and may be accessed as `Domain(H)` and `Codomain(H)`, respectively.

Example H54E5

We construct the vector spaces V and W of dimensions 3 and 4, respectively, over the field of two elements and then define M to be the module of homomorphisms from V into W.

```
> F2 := GaloisField(2);
> V  := VectorSpace(F2, 3);
> W  := VectorSpace(F2, 4);
```

```
> M  := Hom(V, W);
> M;
Full KMatrixSpace of 3 by 4 matrices over GF(2)
```

54.10.2 $\mathrm{Hom}_R(M, N)$ for Matrix Modules

`Hom(M, N, "right")`

Suppose M is a matrix module over the coefficient ring R whose elements are a by b matrices and have domain D and codomain C. Suppose also that N is a matrix module over the coefficient ring R whose elements are a by c matrices and have domain D and codomain C'. Then the homomorphism module $H = \mathrm{Hom}(M, N)$ with right multiplication action exists and consists of all b by c matrices over R which multiply an element of M on the right to yield an element of N. This function constructs H explicitly. The domain of elements of H is then M and the codomain of elements of H is N and the elements are b by c matrices over R which multiply an element of M on the right to yield an element of N. Note that if M and N are proper submodules of their respective generic modules, then H may be a proper submodule of its generic module, and the correct basis of H will be explicitly constructed.

`Hom(M, N, "left")`

Suppose M is a matrix module over the coefficient ring R whose elements are a by c matrices and have domain D and codomain C. Suppose also that N is a matrix module over the coefficient ring R whose elements are b by c and have domain D' and codomain C. Then the homomorphism module $H = \mathrm{Hom}(M, N)$ with left multiplication action exists and consists of all b by a matrices over R which multiply an element of M on the left to yield an element of N. This function constructs H explicitly. The domain of elements of H is then M and the codomain of elements of H is N and the elements are b by a matrices over R which multiply an element of M on the right to yield an element of N. Note that if M and N are proper submodules of their respective generic modules, then H may be a proper submodule of its generic module, and the correct basis of H will be explicitly constructed.

Example H54E6

We construct two homomorphism modules H_1 and H_2 over $\mathbf{Q}$ and then the homomorphism module $H = \mathrm{Hom}(H_1, H_2)$ with right matrix action.

```
> Q := RationalField();
> H1 := sub<RMatrixSpace(Q, 2, 3) | [1,2,3, 4,5,6], [0,0,1, 1,3,3]>;
> H2 := sub<RMatrixSpace(Q, 2, 4) | [6,5,7,1, 15,14,16,4], [0,0,0,0, 1,2,3,4]>;
> H := Hom(H1, H2, "right");
> H: Maximal;
KMatrixSpace of 3 by 4 matrices and dimension 1 over Rational Field
```

```
Echelonized basis:

[   1    2    3    4]
[-1/2   -1 -3/2   -2]
[   0    0    0    0]

> H1.1 * H.1;
[  0   0   0   0]
[3/2   3 9/2   6]
> H1.1 * H.1 in H2;
true
> Image(H.1): Maximal;
KMatrixSpace of 2 by 4 matrices and dimension 1 over Rational Field
Echelonized basis:

[0 0 0 0]
[1 2 3 4]

> Kernel(H.1): Maximal;
KMatrixSpace of 2 by 3 matrices and dimension 1 over Rational Field
Echelonized basis:

[ 1  2  6]
[ 7 14 15]

> H1 := sub<RMatrixSpace(Q,2,3) | [1,2,3, 4,5,6]>;
> H2 := sub<RMatrixSpace(Q,3,3) | [1,2,3, 5,7,9, 4,5,6]>;
> H := Hom(H1, H2, "left");
> H: Maximal;
KMatrixSpace of 3 by 2 matrices and dimension 1 over Rational Field
Echelonized basis:

[1 0]
[1 1]
[0 1]
> Image(H.1);
KMatrixSpace of 3 by 3 matrices and dimension 1 over Rational Field
> Kernel(H.1);
KMatrixSpace of 2 by 3 matrices and dimension 0 over Rational Field
```

54.10.3 Modules $\mathrm{Hom}_R(M, N)$ with Given Basis

`RMatrixSpaceWithBasis(Q)`

Given a sequence Q of k independent matrices each lying in a matrix space $H = \mathrm{Hom}(M, N)$, where $M = R^{(m)}$ and $N = R^{(n)}$, construct the subspace of H of dimension k whose basis is Q. The basis is echelonized internally but all functions which depend on the basis of the matrix space (e.g. `Coordinates`) will use the given basis Q.

`KMatrixSpaceWithBasis(Q)`

Given a sequence Q of k independent matrices each lying in a matrix space $H = \mathrm{Hom}(M, N)$, where $M = K^{(m)}$ and $N = K^{(n)}$, with K a field, construct the subspace of H of dimension k whose basis is Q. The basis is echelonized internally but all functions which depend on the basis of the matrix space (e.g. `Coordinates`) will use the given basis Q.

54.10.4 The Endomorphsim Ring

`EndomorphismAlgebra(M)`

If M is the free R-module $R^{(m)}$, create the matrix algebra $\mathrm{Mat}_m(R)$. The algebra is created with the standard basis, $\{E_{ij} \mid i = 1 \ldots, m, j = 1 \ldots, m\}$, where E_{ij} is the matrix having a 1 in the (i, j)-th position and zeros elsewhere.

Example H54E7

We construct the endomorphism ring of the 4-dimensional vector space over the rational field.

```
> Q  := RationalField();
> R4 := RModule(Q, 4);
> M  := EndomorphismAlgebra(R4);
> M;
Full Matrix Algebra of degree 4 over Rational Field
```

54.10.5 The Reduced Form of a Matrix Module

`Reduce(H)`

Suppose H is a matrix module whose elements have domain A and codomain B. Suppose first that A and B are tuple modules (R-spaces, R-modules, or RG-modules) and that A has degree a and dimension d while B has degree b and dimension e. (For the reduced cases (R-modules or RG-modules), a equals d and b equals e). The elements of H have the natural representation with respect to the standard embedded basis of the generic modules of A and B. Thus H has degree a by b. So one can multiply a 1 by a vector of A directly by an element h of H (in the natural matrix way) to get a 1 by b vector of B. Now suppose A and B are in the embedded form (R-space) and h is in H. Then h is an a by b matrix but there is a corresponding d by e matrix h' which gives the same transformation of h from A to B but is *with respect to the bases of A and B*. We call h' the *reduced* form of h. Also, there is the *reduced module* H' corresponding to H. This function constructs the reduced module H' corresponding to H, together with the epimorphism f from H onto H'. Note that if A and B are in reduced form, then H' is the same as H.

Suppose secondly that A and B are matrix modules themselves. Suppose $A = \mathrm{Hom}(D_1, C_1)$, $B = \mathrm{Hom}(D_1, C_2)$, and $H = \mathrm{Hom}(A, B)$ with the right multiplication action. Suppose also that A has degree r by s and dimension d while B has degree r by t, and dimension e. Then H would have degree s by t so an element h of H would be s by t and would multiply a r by s element of A on the right to yield an r by t element of B. Then the reduced matrix h' corresponding to a matrix h of H would be a d by e matrix corresponding to the bases of A and B. This function similarly constructs the reduced module H' corresponding to H, together with the epimorphism f from H onto H'. Note also that in this case the domain and codomains of H' are the generic R-spaces (tuple modules) corresponding to A (of dimension d) and B (of dimension e). Similarly, for the left multiplication action there is the corresponding reduced module constructed in the obvious way.

Note also that the kernel of the epimorphism f is the submodule of H which consists of all matrices which transform all elements of A to the zero element of B.

Example H54E8

We demonstrate the function `Reduce` for a homomorphism module from one vector space to another.

```
> V1 := sub<VectorSpace(GF(3), 3) | [1,0,1], [0,1,2]>;
> V2 := sub<VectorSpace(GF(3), 4) | [1,1,0,2], [0,0,1,2]>;
> H := Hom(V1, V2);
> H;
KMatrixSpace of 3 by 4 matrices and dimension 8 over GF(3)
> R, f := Reduce(H);
> R;
Full KMatrixSpace of 2 by 2 matrices over GF(3)
> H.1;
```

```
[1 0 0 0]
[0 1 0 2]
[0 1 0 2]
> f(H.1);
[1 0]
[0 0]
> V1.1;
(1 0 1)
> V1.1 * H.1;
(1 1 0 2)
> Coordinates(V2, V1.1 * H.1);
[ 1, 0 ]
> Coordinates(V2, V1.2 * H.1);
[ 0, 0 ]
> Kernel(f): Maximal;

```

54.10.6 Construction of a Matrix

`M ! Q`

Given the matrix bimodule M over the ring R, and the sequence $Q = [a_{11}, \ldots, a_{1n}, a_{21}, \ldots, a_{2n}, \ldots, a_{m1}, \ldots, a_{mn}]$ whose terms are elements of the ring R, construct the $m \times n$ matrix

$$\begin{pmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ a_{21} & a_{22} & \ldots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \ldots & a_{mn} \end{pmatrix}$$

as an element of M. In the context of the `sub` or `quo` constructors the coercion clause `M !` may be omitted.

Example H54E10

We create the 4×4 Hilbert matrix $h4$ as an element of the endomorphism ring of the 4-dimensional vector space over the rational field.

```
> Q  := RationalField();
> R4 := RModule(Q, 4);
> M  := EndomorphismAlgebra(R4);
> h4 := M ! [ 1/i :  i in [1 .. 16 ] ];
> h4;
[   1  1/2  1/3  1/4]
[ 1/5  1/6  1/7  1/8]
[ 1/9 1/10 1/11 1/12]
[1/13 1/14 1/15 1/16]
```

54.10.7 Element Operations

All operations that apply to elements of tuple modules also apply to elements of matrix modules. Here, we confine our discussion to those operations which are special to matrix modules.

Throughout this section, M is a submodule of $R^{(m)}$, N is a submodule of $R^{(n)}$ and a is a homomorphism belonging to $\mathrm{Hom}_R(M, N)$, where R is a Euclidean Domain.

See also the chapter on general matrices for many other functions applicable to matrices (e.g., `EchelonForm`).

`u * a`
`a(u)`

Given an element u belonging to the module M, return the image of u under the homomorphism a as an element of the module N.

`a * b`

Given a homomorphism a belonging to a submodule of $\mathrm{Hom}(M, N)$, and a homomorphism b belonging to a submodule of $\mathrm{Hom}(N, P)$, return the composition of the homomorphisms a and b as an element of $\mathrm{Hom}(M, P)$. Note that if $\mathrm{Hom}(M, P)$ does not already exist, it will be created.

`a ^ -1`

Given a homomorphism a belonging to a submodule of $\mathrm{Hom}(M, N)$ with M and N having the same dimension, return the inverse of a as an element of $\mathrm{Hom}(N, M)$.

`Codomain(S)`

Given a submodule S of the module $\mathrm{Hom}(M, N)$, return the module N.

`Codomain(a)`

The codomain N of the homomorphism a belonging to $\mathrm{Hom}(M, N)$.

`Cokernel(a)`

The cokernel for the homomorphism a belonging to the module $\mathrm{Hom}(M, N)$.

`Domain(S)`

The domain M of the submodule S belonging to the module $\mathrm{Hom}(M, N)$.

`Domain(a)`

The domain M of the homomorphism a belonging to the module $\mathrm{Hom}(M, N)$.

`Image(a)`

The image of the homomorphism a belonging to the module $H = \mathrm{Hom}(M, N)$, returned as a submodule of N. Note that if the domain and codomain of a are matrix modules themselves, the image will be with respect to the appropriate action (right or left).

`Kernel(a)`

`NullSpace(a)`

The kernel of the homomorphism a belonging to the module $\mathrm{Hom}(M, N)$, returned as a submodule of M. Note that if the domain and codomain of a are matrix modules themselves, the kernel will be with respect to the appropriate action (right or left).

`Morphism(M, N)`

Assuming the R-module M was created as a submodule of the module N, return the matrix defining the inclusion homomorphism $\phi : M \to N$ as an element of $\mathrm{Hom}_R(M, N)$. Thus ϕ gives the correspondence between elements of M (represented with respect to the standard basis of M) and elements for N.

`Rank(a)`

The dimension of the image of the homomorphism a, i.e. the rank of a.

`IsBijective(a)`

Returns `true` if the homomorphism a belonging to the module $\mathrm{Hom}(M, N)$ is a bijective mapping.

`IsInjective(a)`

Returns `true` if the homomorphism a belonging to the module $\mathrm{Hom}(M, N)$ is an injective mapping.

`IsSurjective(a)`

Returns `true` if the homomorphism a belonging to the module $\mathrm{Hom}_R(M, N)$ is a surjective mapping.

Example H54E11

We illustrate some of these operations in the context of the module $\mathrm{Hom}_R(M, N)$, where M and N are, respectively, the 4-dimensional and 3-dimensional vector spaces over $GF(8)$.

```
> K<w> := GaloisField(8);
> V3 := VectorSpace(K, 3);
> V4 := VectorSpace(K, 4);
> M := Hom(V4, V3);
> A := M ! [1, w, w^5, 0,  w^3, w^4, w, 1,  w^6, w^3, 1, w^4 ];
> A;
[  1   w w^5]
[  0 w^3 w^4]
[  w   1 w^6]
[w^3   1 w^4]
> Rank(A);
3
> Image(A);
```

```
Full Vector space of degree 3 over GF(2^3)
> Kernel(A);
Vector space of degree 4, dimension 1 over GF(2^3)
Echelonized basis:
(  1 w^5   1   1)
> Cokernel(A);
Vector space of degree 3, dimension 0 over GF(2^3)
```

55 MODULES OVER DEDEKIND DOMAINS

Chapter 55
MODULES OVER DEDEKIND DOMAINS

55.1 Introduction

Since the structure theory for modules over arbitrary orders (which are in general not Dedekind domains) is very unsatisfactory, modules over orders in MAGMA are always modules over some maximal order of a number field or function field, they form a magma of type `ModDed`.

Let k be a number field or function field and $\mathcal{O}_k$ its ring of integers. Since $\mathcal{O}_k$ is a Dedekind domain, every finitely generated torsion free module M over $\mathcal{O}_k$ has a representation as a direct sum

$$M = \sum_{i=1}^{m} \mathcal{A}_i \alpha_i = \{ \sum_{i=1}^{m} a_i \alpha_i \mid a_i \in \mathcal{A}_i \}$$

with (fractional) ideals $\mathcal{A}_i$ and elements $\alpha_i \in kM \cong k^r$.

A (not necessarily direct) sum $\sum_{i=1}^{m} \mathcal{A}_i \alpha_i$ will be represented as a pseudo–matrix $(\mathcal{A}|A)$ where $\mathcal{A} = (\mathcal{A}_1, \ldots, \mathcal{A}_m)^t$ is a column vector of ideals and $A = (\alpha_1, \ldots, \alpha_m)^t \in k^{m \times r}$ is a matrix. The ideals $\mathcal{A}_i$ are called coefficient ideals.

This pseudo–matrix is called a pseudo–basis iff the sum is direct. A pseudo–matrix $(\mathcal{A}|A)$ is in Hermite normal form iff there are $s \leq m$, $1 \leq i_1 < i_2 < \cdots < i_s$ such that $A_{j,l} = 0$ $(1 \leq l < i_j)$, $A_{j,i_j} = 1$ and $A_{j,l}$ is reduced modulo $\mathcal{A}_j {\mathcal{A}_l}^{-1}$. For $j > s$ we have $A_{j,l} = 0$.

This normal form is unique if a suitable reduction is used.

As a consequence of this normalisation, usually $\alpha_i \notin M$. To be precise: $\alpha_i \in M$ iff $1 \in \mathcal{A}_i$.

All modules are in Hermite normal form, i.e. every module is represented by a pseudo–basis in Hermite normal form.

General (non torsion free) modules are represented as quotients of a torsion free module M and a submodule S. Elements of $Q := M/S$ are represented as elements of M, arithmetic in Q is reduced to arithmetic in M followed by a reduction modulo the pseudo–basis of S.

55.2 Creation of Modules

Modules over dedekind domains can be created from orders of number fields and function fields and combinations of ideals and vector space elements. Submodules and quotient modules by submodules can also be created.

`Module(O, n)`

Create the free module O^n where O is a dedekind domain.

`Module(O)`

Create the relative order O as a module over its coefficient ring. Also returns the map from the resulting module into O.

`Module(I)`

Create the ideal I of a relative order O as a module over the coefficient ring of the order. Also returns the map from the module into O.

`Module(S)`

Create a module from the sequence of tuples of ideals of a dedekind domain and `ModElt`s with entries in the dedekind domain or its field of fractions. The elements of the resulting module will be the sum of products of an element of an ideal and the corresponding `ModElt`. Also returns the map from the vector space into the module.

`Module(S)`

Create the module which is equal to the direct sum of the ideals in the sequence.

`Module(S)`

Create the module which is freely generated by the elements of the sequence S. The elements of the sequence must be `ModElt`s with entries in a dedekind domain or field of fractions of a dedekind domain. Also returns the map from the vector space into the module.

Example H55E1

The creation of some simple modules is shown.

```
> x := ext<Integers()|>.1;
> M := MaximalOrder(x^2 + 5);
> Module(M, 5);
Module over Maximal Equation Order with defining polynomial x^2 + 5 over Z
 generated by: (in echelon form)
Principal Ideal of M
Generator:

Generator:
1/5 car Ideal of M
Generator:
1/125
```

`sub< M | m >`

`sub< M | m1, .., mn >`

Construct the submodule of the module M generated by the elements in the sequence or list of elements m. Also returns the inclusion map of the submodule into M.

`quo< M | S >`

`quo< M | m >`

`quo< M | m1, .., mn >`

Construct the quotient of the module M by the submodule S or the submodule generated by the elements of the sequence or list of elements m. Also returns the inclusion map of the quotient module into M.

Example H55E2

Use of the sub and quo constructors is illustrated below. Let M and V be as above when they were referring to number fields.

```
> Mod := Module([V|[0,1,0], [4,4,0]]);
> S1 := sub<Mod | >;
> S1;

55.3 Elementary Functions

Various simple properties of a module can be retrieved using the following functions.

`BaseRing(M)`

`CoefficientRing(M)`

The dedekind domain which M is a module over.

`Degree(M)`

The dimension of the vector space the module M embeds into.

`Ngens(M)`

`NumberOfGenerators(M)`

The minimum number of vectors and ideals which generate the module M.

`M . i`

The vector of the *ith* vector and ideal pair generating the module M.

`Determinant(M)`

The determinant of the module M.

`Dimension(M)`

The dimension of the vector space spanned by the module M over its coefficient ring. This is the same as the number of generators of a pseudo basis of M.

`Contents(M)`

`UseBasis` BoolElt *Default :* `false`

The contents of the module M, ie. the gcd of the ideals obtained by multiplying the coefficient ideals by the ideal generated by the coefficients in the corresponding generators. The parameter `UseBasis` decides whether a pseudo basis or pseudo generators are used.

`Simplify(M)`

`UseBasis` BoolElt *Default :* `false`

Computes a module of contents 1 by scaling each coefficient ideal by the inverse of the contents of the module M. The parameter `UseBasis` determines if the operations are performed on the pseudo generators or the pseudo basis of M.

`EmbeddingSpace(M)`

The canonical vector space containing the module M, ie.. M tensored with the field of fractions of the coefficient ring.

Example H55E3

The use of some elementary functions on a module is shown below.

```
> P<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(P);
> F<c> := FunctionField(x^2 - y);
> M := MaximalOrderFinite(F);
> Vs := RModule(M, 2);
> s := [Vs | [1, 3], [2, 3]];
> Mods := Module(s);
> CoefficientRing(Mods);
Maximal Equation Order of F over Univariate Polynomial Ring in x over Rational
Field
> Mods.1;
(1 0)
> Determinant(Mods);
Ideal of M
Generator:
```

```
-3
> Vs := RSpace(M, 2);
> s := [Vs | [1, 3], [2, 3]];
> Mods := Module(s);
> sMods := sub<Mods | Mods!Vs![1, 3]>;
> qMods := quo<Mods | sMods>;
> Degree(Mods);
2
> Ngens(Mods);
2
> Ngens(sMods);
1
> Degree(sMods);
2
> Degree(qMods);
2
> Ngens(qMods);
2
> Determinant(Mods);

>  Determinant(sMods);
>>   Determinant(sMods);
               ^
Runtime error in 'Determinant': Module must be square
> Determinant(qMods);
Ideal of M
Basis:
[1]
```

55.4 Predicates on Modules

Modules and potential elements can be tested against each other for a few properties.

`M eq N`

Return `true` if M and N are equal as modules.

`x in M`

Return `true` if x can be coerced into the module M.

`M subset N`

Return `true` if M is a submodule of N. An embedding map of M in N can be returned by `IsSubmodule(M, N)`.

55.5 Arithmetic with Modules

Some arithmetic operations can be carried out involving modules and their elements and compatible ideals to gain more modules.

```
I * M
M * I
```

The module generated by the products of the ideals of the module M with I.

```
M1 + M2
```

The union of the modules $M1$ and $M2$.

```
u * I
I * u
```

The module containing elements which are products of the dedekind module element u and an element lying in the ideal I.

Example H55E4

Some module predicates and arithmetic are shown below.

```
> P<x> := PolynomialRing(Integers());
> K :=  NumberField([x^5 + 3, x^2 + 2]);
> M := MaximalOrder(K);
> Vs := RModule(M, 2);
> s := [Vs | [1, 3], [2, 3]];
> Mods := Module(s);

```

55.6 Basis of a Module

The basis of a module is given by vectors. However, more complete information can be supplied which includes the ideals.

`Basis(M)`

A sequence of vectors which correspond to a pseudo basis of the module M.

`PseudoBasis(M)`

A sequence of tuples containing ideals and vectors which generate the module M. The vectors are guaranteed to be linearly independent.

`PSeudoGenerators(M)`

A sequence of tuples containing ideals and vectors which generate the module M. This will return the data used to define the module, so that in contrast to `PseudoBasis` the vectors will in general not be independent.

55.7 Other Functions on Modules

Intersections of modules can taken. Several other functions are also available.

`M1 meet M2`

Return the intersection of the modules $M1$ and $M2$.

`Dual(M)`

The module dual to M.

`ElementaryDivisors(M, N)`

The elementary divisors (ideals) of the torsion part of the quotient R-module M/N: For $N \subseteq M$ we get

$$T(M/N) \cong \oplus_{i=1}^{n} R/\mathcal{A}_i$$

The $\mathcal{A}_i$ are unique if we require $R \subseteq \mathcal{A}_1 \subseteq \cdots \subseteq \mathcal{A}_n$. The $\mathcal{A}_i$ are called the elementary divisors (or elementary ideals) of M/N. This corresponds to the Smith normal form for integral matrices.

`SteinitzClass(M)`

The Steinitz class of the module M.

`SteinitzForm(M)`

The Steinitz (almost–free) form of the module M.

Example H55E5

Some bases and other functions are demonstrated below.

```
> P<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(P);
> F<c> := FunctionField(y^3 - x^3*y^2 + y - x^7);
> M := MaximalOrderFinite(F);
> Vs := RSpace(M, 2);
> s := [Vs | [1, Random(M, 3)], [Random(M, 3), 3]];

55.8 Homomorphisms between Modules

It is possible to create a homomorphism between two modules, take the image and kernel of such and verify that these are submodules of the codomain and domain respectively. The Hom–module can also be created as a module of a dedekind domain.

`hom< M -> N | T >`

`ModuleBasis` BoolElt *Default :* `true`

Return a homomorphism from the module M into the module N as specified by T from which the images of the generators can be inferred. T may be a map between the vector spaces of same degree as M and N, a matrix over the field of fractions or a sequence of vectors. If `ModuleBasis` is `true` then the matrix will be taken to be a transformation between the modules and as such will be expected to have size `Dimension(M)*Dimension(N)` otherwise it will be interpreted as a transformation between the corresponding vector spaces and will be expected to have size `Degree(M)*Degree(N)`.

`Hom(M, N)`

The module of homomorphisms between the module M and the module N and the map from the hom–module to the collection of maps from M to N, (such that given an element of the hom–module a homomorphism from M to N is returned). The module is over the same dedekind domain as M and N.

`IsSubmodule(M, N)`

Return `true` if M is a submodule of N and the map embedding M into N.

`Morphism(M, N)`

The map giving the morphism from the module M to the module N. Either M is a submodule of N, in which case the embedding of M into N is returned, or N is a quotient module of M, in which case the natural epimorphism from M onto N is returned.

Example H55E6

This example demonstrates the use of homomorphisms between modules over dedekind domains. Let `M` and `V` be as above referring to function fields.

```
> S := [V|[0,1,0], [4,4,0]];
> Mod := Module(S);
> W := KModule(FieldOfFractions(M), 4);
> S := [W|[3, 2, 1, 0]];
> N := Module(S);

55.9 Elements of Modules

55.9.1 Creation of Elements

`M ! v`

Coerce v into an element of M. v can be a sequence of length dimension of M, a module element or vector or an element of another module over a dedekind domain which is compatible with M.

Example H55E7

Let `Mod` and its submodules and quotient modules be as in the sub and quotient module example above.

```
> m := 4*Mod.1;
> m;
(4/1*M.1 0)
> Q1!m;
( 4/1*M.1 0 )
> Q2!m;
( 4/1*M.1 0 )
> m := Mod!m;
> Q3!m;
( 4/1*M.1 0 )
> Q4!m;
( 4/1*M.1 0 )
>  S1!m;
>> S1!m;
     ^
Runtime error in '!': Illegal coercion
LHS: ModDed
RHS: ModDedElt
> S1!Mod!V!0;
(  )
> S2!Mod!Mod.2;
( M.1 )
> S3!Mod!(4*Mod.1);
( 4/1*M.1 0 )
```

55.9.2 Arithmetic with Elements

Basic arithmetic can be performed with elements of a module over a dedekind domain.

```
x + y
```

The sum of the module elements.

```
x - y
```

The difference of the module elements.

```
u * c
c * u
```

The product of the module element u and the ring element c.

```
u / c
```

The product of u and $1/c$ if it lies in the parent module of u.

```
I * u
u * I
```

The module containing elements which are products of u and an element lying in I.

55.9.3 Other Functions on Elements

Elements of modules over a dedekind domain can be tested for equality and represented as a sequence.

```
x eq y
```

Return `true` if x and y are the same element of a module.

```
ElementToSequence(a)
Eltseq(a)
```

The module element a expressed as a sequence.

55.10 Pseudo Matrices

A pseudo matrix, ie. an object of type `PMat`, is a sequence of ideals together with a matrix. Pseudo matrices arise naturally in the (computational) theory of finitely generated torsion free modules over Dedekind domains, they are a natural extension of ordinary matrices which should be thought of as pseudo matrices where all the ideals are generated by 1. Pseudo matrices are generally used to represent the module that is generated by the rows of the matrix scaled by the elements of the corresponding ideal. Thus, if the matrix is regular, a linear combination of the rows lies in the module if and only if the coefficient of the ith row is a member of the ith ideal. The ideals are therefore called coefficient ideals.

55.10.1 Construction of a Pseudo Matrix

`PseudoMatrix(I, m)`

Construct the pseudo matrix with coefficient ideals the elements of the sequence I and matrix m.

`PseudoMatrix(m)`

Construct the pseudo matrix with trivial coefficient ideals and the matrix m.

`PseudoMatrix(M)`

`Generators` BoolElt *Default :* `false`

Construct the pseudo matrix described by the pseudo basis of the module M. If `Generators` is `true` the pseudo matrix described by the pseudo generators of M is returned.

55.10.2 Elementary Functions

`CoefficientIdeals(P)`

Return the coeffficient ideals of the pseudo matrix P.

`Matrix(P)`

Return the matrix of the pseudo matrix P.

`Order(pm)`

Return the order the pseudo matrix pm is over.

`Dimension(pm)`

The dimension of the pseudo matrix pm. This is the numer of columns of the matrix.

`Length(pm)`

The length or dimension of the pseudo matrix pm. This is the number of coefficient ideals of pm.

55.10.3 Basis of a Pseudo Matrix

`Basis(P)`

Return a list of sequences of ring elements corresponding to the entries of each row of the matrix of the pseudo matrix P.

55.10.4 Predicates

`p1 eq p2`

Return whether the pseudo matrices $p1$ and $p2$ are equal, that is, whether they have the same matrix and the same sequence of coefficient ideals.

55.10.5 Operations with Pseudo Matrices

`Transpose(P)`

Return the pseudo matrix whose coefficient ideals are the same as those of P but whose matrix is the transpose of the matrix of P. This function requires the matrix to be square.

`HermiteForm(X)`

Return the Hermite normal form H of the pseudo matrix X together with a regular transformation matrix such that the module generated by X is the same as the one generated by H and such that (for the matrix parts) $H = TX$ holds.

`VerticalJoin(X, Y)`

Return the pseudo matrix whose matrix is the vertical join of the matrices of the pseudo matrices X and Y with coefficient ideals the concatenation of those of X and Y.

`X meet Y`

Return the intersection of the pseudo matrices X and Y.

`Module(X)`

Return the module $\sum C_i * m_i$ where C_i are the coefficient ideals of the pseudo matrix X and m_i are the rows of the matrix of X.

`I * X`
`X * I`

The pseudo matrix whose coefficient ideals are those of the pseudo matrix X multiplied by I and whose matrix is the matrix of X.

56 CHAIN COMPLEXES

Chapter 56
CHAIN COMPLEXES

56.1 Complexes of Modules

Complexes of modules are a fundamental object in homological algebra. MAGMA supports the type `ModCpx` representing a complex of modules. Conceptually, a complex is an infinite sequence of modules, indexed by integers, with maps between successive modules such that the composition of any two maps is zero. Complexes are often written

$$\ldots \xrightarrow{f_{n+1}} M_n \xrightarrow{f_n} M_{n-1} \xrightarrow{f_{n-1}} M_{n-2} \xrightarrow{f_{n-2}} \ldots$$

where the map f_n has domain M_n and codomain M_{n-1}. The indices on the modules and maps decrease to the right. In practice, MAGMA requires all but a finite number of the modules and maps to be zero.

The homomorphism from M_n to M_{n-1} in the complex is the n^{th} boundary map of the complex. The homology of the complex in degree n is the quotient of the kernel of the n^{th} boundary map by the cokernel of the boundary map of degree $n-1$. MAGMA computes the homology only if both boundary maps are defined. A complex is said to be *exact* if the image of each map is equal to the kernel of the next.

Currently, there are two types of modules over which complexes are supported:

(a) Modules over a basic algebra A (see Chapter 85);

(b) Modules over a multivariate polynomial ring over a field (see Chapter 109 and in particular the function `FreeResolution`).

Most of the functions in this chapter work for either type of module but exceptions are noted.

56.1.1 Creation

`Complex(L, d)`

Given a list L of maps between successive A-modules create the corresponding complex. The last term of the complex has degree d. This function returns an error if the maps don't actually form a complex.

`Complex(f, d)`

Given a map f between A-modules M and N, form the complex consisting of the two term complex whose only map is f. The term N is in degree d.

`ZeroComplex(A, m, n)`

Given a basic algebra A and integers m and n such that $m > n$, create a complex of modules over the basic algebra A, starting with a term of degree m and ending with a term of degree n, where all the modules and maps are zero.

```
Dual(C)
```
```
Dual(C, n)
```

The dual of the complex C over a basic algebra A as a complex over the opposite algebra of A. If an integer n is supplied then the last term of the dual complex is in degree n. Otherwise, the last term of the dual complex is in degree 0.

56.1.2 Subcomplexes and Quotient Complexes

Let C be a complex of A-modules, $M_m, \ldots, M_n$. A subcomplex S of C is a complex whose terms are submodules of the terms of C and whose maps are the restrictions of the maps of C to the terms of S.

```
sub< C | Q >
```
```
sub< C | L >
```

Given a complex C and a sequence Q of submodules of the terms of C, returns the smallest subcomplex whose terms contain the modules in Q. The input can also be a list L of sequences of elements of the successive terms of C. In this case the submodules generated by the elements is computed. The function also returns the chain map giving the inclusion of the subcomplex in C.

```
RandomSubcomplex(C, Q)
```

Given a chain complex C over a basic algebra in degrees a to $a-t+1$ and a sequence $Q = [q_1, \ldots, q_t]$ of natural numbers, the function creates the minimal chain complex whose term in degree $a - i + 1$ is a submodule generated by q_i random elements of the term in degree $a - i + 1$ of C. The function also returns the chain map that is the inclusion of the subcomplex into C.

```
quo< C | D >
```
```
quo< C | S >
```
```
quo< C | L >
```

Given a complex C and a subcomplex D of C, returns the quotient complex C/D together with the natural quotient map. If given as a sequence S of submodules of the terms of C or a list L of sequences of elements of the terms of C, then the submodule generated by S or L is created and the quotient computed. The function also returns the chain map of C on the quotient.

56.1.3 Access Functions

```
Degrees(C)
```

Returns the first and last degrees of the defined terms of the complex C.

```
Algebra(C)
```

Given a complex C over a basic algebra A, this function returns the algebra A.

`BoundaryMap(C, n)`

Returns the boundary map of the complex C from the term of degree n to the term of degree $n-1$.

`BoundaryMaps(C)`

The list of boundary maps of the complex C.

`DimensionsOfHomology(C)`

Returns the list of the dimensions of the homology groups of the complex C.

`DimensionOfHomology(C, n)`

Returns the dimension of the homology group of the complex C in degree n.

`DimensionsOfTerms(C)`

Returns the list of the dimensions of the terms of the complex C.

`Term(C, n)`

The module in the complex C in degree n.

`Terms(C)`

The sequence of terms of the complex C.

56.1.4 Elementary Operations

`DirectSum(C, D)`

Returns the direct sum of the complex C and the complex D.

`Homology(C)`

`HomologyOfChainComplex(C)`

The sequence of homology groups of the complex C as a sequence of modules.

`Homology(C, n)`

Returns the homology group in degree n of the complex C, as an A-module.

`Prune(C)`

Returns the complex that consists of the terms of C with the right end term (term of lowest degree) removed.

`Prune(C,n)`

Returns the complex that consists of the terms of C with n terms removed from the right end.

`Preprune(C)`

Returns the complex that consists of the terms of C with the left end term (term of highest degree) removed.

`Preprune(C,n)`

Returns the complex that consists of the terms of C with n terms removed from the left end.

`Shift(C, n)`

Given the complex C in degrees r to s, returns the complex in shifted degrees $r+n$ to $s+n$. The integer n may be either positive or negative. The maps in the complex are all multiplied by the scalar $(-1)^n$.

`ShiftToDegreeZero(C)`

Given the complex C, returns the shift of C so that the last term, the term of lowest degree, is in degree 0.

`Splice(C, D)`

Given two complexes C and D over the same basic algebra, such that the end term of C coincides with the initial term of D, form the complex that corresponds to the concatenation of C and D (as sequences of maps) This function checks that the resulting sequence of maps forms a complex. The degrees of complex D remain unchanged while the degrees of the terms in complex C are changed to fit.

`Splice(C, D, f)`

The splice of the complex C with the complex D along the map f from the last term of C to the first term of D. The degree of the last term of the splice is the same as the degree of the last term of the complex D.

56.1.5 Extensions

The following are elementary operations related to extending complexes

`LeftExactExtension(C)`

Given a complex C of modules over a basic algebra, returns the complex of length one greater that is obtained by adjoining the inclusion map from the kernel of the boundary map in highest degree to the term of highest degree in C.

`RightExactExtension(C)`

Given a complex C of modules over a basic algebra, returns the complex of length one greater that is obtained by adjoining the quotient map to the cokernel of the boundary map of lowest degree from the term of lowest degree in C.

`ExactExtension(C)`

Returns the left and right exact extensions of the complex C.

`LeftZeroExtension(C)`

`LeftZeroExtension(C, n)`

Given a complex C of modules over a basic algebra, returns the complex of length one greater that is obtained by adjoining the zero map from the zero module to the term of highest degree in the complex. If a natural number n is included in the input then the operation is performed n times.

`RightZeroExtension(C)`

`RightZeroExtension(C, n)`

Given a complex C of modules over a basic algebra, returns the complex of length one greater that is obtained by adjoining the zero map to the zero module from the term of lowest degree in the complex. If a natural number n is included in the input then the operation is performed n times.

`ZeroExtension(C)`

Returns the left and right zero extensions of the complex C.

`EqualizeDegrees(C, D)`

`EqualizeDegrees(Q)`

Given complexes C and D over the same algebra, the function returns the complexes obtained by taking zero extensions of C and D, if necessary, so that both complexes have the same degrees. The input can also be given as a sequence Q of complexes, in which case the function returns the sequence of complexes obtained by taking zero extensions of the elements of Q, if necessary, until all of the elements of the sequence have the same degrees.

`EqualizeDegrees(C, D, n)`

The two complexes, C and D, with zero extension sufficient that the first and the shift by degree n of the second have the same degrees.

56.1.6 Predicates

The following functions return a Boolean value.

`IsExact(C)`

Returns `true` if and only if the complex C is an exact sequence, i.e. the image of each map in C is equal to the kernel of the succeeding map (with the obvious exceptions of the first and last maps of the complex). If the complex has only two terms then this is true trivially.

`IsShortExactSequence(C)`

Returns `true` if the complex C consists of a short exact sequence together with other terms that are zero. The function returns also the degrees of the complex of nonzero terms.

`IsExact(C, n)`

Returns `true` if and only if the complex C is an exact sequence in degree n, i.e. the image of the map in C into the term of degree n is equal to the kernel of the succeeding map.

`IsZeroComplex(C)`

Returns `true` if and only if the complex C is composed entirely of zero modules and maps.

`IsZeroMap(C, n)`

Returns `true` if and only if the boundary map in degree n of the complex C is the zero map.

`IsZeroTerm(C, n)`

Returns `true` if and only if the term in degree n of the complex C is the zero object.

Example H56E1

We construct the quiver algebra of a quiver with three nodes and three arrows going from node 1 to node 2, from 2 to 1 and 2 to 3. The relation is that $(ab)^3a = 0$ where a is the first arrow and b is the second. Then we construct projective and injective resolutions of the first simple module.

```
> ff := GF(8);
> FA<e1,e2,e3,a,b,c> := FreeAlgebra(ff,6);
> rrr := [a*b*a*b*a*b*a];
> D := BasicAlgebra(FA,rrr,3,[<1,2>,<2,1>,<2,3>]);
> D;
Basic algebra of dimension 23 over GF(2^3)
Number of projective modules: 3
Number of generators: 6
> DimensionsOfProjectiveModules(D);
[ 10, 12, 1 ]
> DimensionsOfInjectiveModules(D);
[ 8, 7, 8 ]
```

Here is the opposite algebra:

```
> OD := OppositeAlgebra(D);
reverse trees
> OD;
Basic algebra of dimension 23 over GF(2^3)
Number of projective modules: 3
Number of generators: 6
```

```
> s1 := SimpleModule(D,1);
> P,mu := ProjectiveResolution(s1,7);
> P;
Basic algebra complex with terms of degree 7 down to 0
Dimensions of terms: 12 12 12 12 12 12 12 10
> Q,nu := InjectiveResolution(s1,7);
> Q;
Basic algebra complex with terms of degree 0 down to -7
Dimensions of terms: 8 7 0 0 0 0 0 0
```

Note that the projective and injective resolutions are complexes with the appropriate augmentation and coaugmentation maps. First we form the two term complex whose boundary map is the composition of the augmentation and coaugmentation maps.

```
> theta := MapToMatrix(hom<Term(P,0)-> Term(Q,0)|mu*nu>);
> E := Complex(theta,0);
```

Then we splice all of this together.

```
> R := Splice(P,E);
> S := Splice(R,Q);
> S;
Basic algebra complex with terms of degree 8 down to -7
Dimensions of terms: 12 12 12 12 12 12 12 10 8 7 0 0 0 0 0 0
```

56.2 Chain Maps

A chain map from complex C to complex D is a sequence of homomorphisms between the terms of C and the terms of D such that the maps commute with the boundary homomorphisms on the two complexes. The chain map has degree zero if the map on C_n has it's image in D_n. Otherwise the degree of the chain map expresses the extent to which the degrees of the terms are raised or lowered by the chain map.

Chain maps do not have to be defined in every degree for which either its domain or codomain is defined. On the other hand it must be defined wherever possible, i.e. for any degree i for which the term of the domain is defined and for which the term of the codomain is defined in degree $i + n$ where n is the degree of the chain map.

The freedom of definition can cause problems with constructions such as the kernel or cokernel. That is, the kernel of a chain complex may not be a complex. For this reason we allow the Kernel and Cokernel functions to work only for proper chain maps where "proper" is defined as follows. Suppose C is a chain complex in degrees a to b and D is a complex in degrees u to v. A chain map in degree n from C to D is proper provided $u \geq a + n$ and $v \geq b + n$.

56.2.1 Creation

`ChainMap(Q, C, D, n)`

Returns the chain map given by the sequence of maps in Q. Each element in Q is a map from a term of the complex C to a corresponding term of the complex D. The integer n is the degree of the chain map. This means that for any i the term in degree i of C is mapped to the term of degree $n + i$ of D. There should be a map defined for any degree i in the range of degrees of C such that there is a corresponding term in degree $n + i$ for the complex D.

`ZeroChainMap(C, D)`

Given chain complexes C and D, construct the chain map from C to D all of whose terms are zero.

56.2.2 Access Functions

`Degree(f)`

Given a chain map f, returns the degree of f. Note that $f : C \to D$ has degree n if it takes the term in degree i of the complex C to the term in degree $i + n$ of the complex D.

`ModuleMap(f, n)`

Given a chain map $f : C \to D$ and an integer n, this function returns the map from the term in degree n of the complex C to the term in degree $n + Degree(f)$ of the complex D.

`Kernel(f)`

Returns the kernel complex of f and the inclusion of the kernel in the domain of f. The function is only defined for proper chain maps. If the chain map is not defined for a certain term of the domain then that term is equal to the term of the kernel complex. That is, if f is not defined on a term then the functions acts as if f were the zero map on that term.

`Cokernel(f)`

Returns the cokernel complex of f and the projection of the cokernel onto the codomain of f. The function is only defined for proper chain maps. If the chain map is not defined for a certain term of the codomain then that term is equal to the term of the cokernel complex. That is, if f is not defined on a term then the function acts as if f were the zero map on that term.

`Image(f)`

Returns the image complex of f and the inclusion of the image in the codomain of f and the projection of the domain of f on to the image. The function is only defined for proper chain maps.

56.2.3 Elementary Operations

`f + g`

The sum of two chain maps with the same domain and codomain.

`a * g`

The product of the chain map g by the scalar a in the base ring of the algebra.

`f * g`

The composition of the two chain maps f and g.

56.2.4 Predicates

The following functions return a Boolean value.

`IsSurjective(f)`

Returns `true` if the chain map f is a surjection in every degree, `false` otherwise.

`IsInjective(f)`

Returns `true` if the chain map f is an injection in every degree, `false` otherwise.

`IsZero(f)`

Returns `true` if the chain map f is zero in every degree, `false` otherwise.

`IsIsomorphism(f)`

Returns `true` if the chain map f is an isomorphism of chain complexes, `false` otherwise.

`IsShortExactSequence(f, g)`

Returns `true` if the sequence of chain complexes, $0 \to Domain(f) \to Domain(g) \to Codomain(g) \to 0$, where the internal maps are f and g, is exact.

`IsChainMap(L, C, D, n)`

Returns `true` if the list of maps L from the terms of complex C to the terms of the complex D is a chain map of degree n, i. e. it has the right length and the diagram commutes.

`IsChainMap(f)`

Returns `true` if the supposed chain map f really is a chain map, i. e. the diagrams commute.

`IsProperChainMap(f)`

Returns `true` if the chain map f is a proper chain map, a necessary condition for taking kernel and cokernel.

`HasDefinedModuleMap(C,n)`

Returns `true` if the module map in degree n of the complex C is defined.

Example H56E2

We from the basic algebra of the direct product of a cyclic group of order 3 with symmetric group on three letters over the field with three elements.

```
> FA<e1,e2,a,b> := FreeAlgebra(GF(3),4);
> MM:= [e1 +e2 - FA!1, a*b*a, b*a*b];
> BS3 := BasicAlgebra(FA, MM, 2, [<1,2>,<2,1>]);
> gg := CyclicGroup(3);
> BC3 := BasicAlgebra(gg,GF(3));
> A := TensorProduct(BS3,BC3);
> A;
Basic algebra of dimension 18 over GF(3)
Number of projective modules: 2
Number of generators: 6
```

Now we want the projective resolution of the second simple module as a complex. This we will manipulate and take a somewhat random complex.

```
> PR := ProjectiveResolution(SimpleModule(A,2),12);
> PR;
Basic algebra complex with terms of degree 12 down to 0
Dimensions of terms: 117 108 99 90 81 72 63 54 45 36 27 18 9
> PR := Prune(PR);
> PR := Prune(PR);
> PR := Prune(PR);
> PR;
Basic algebra complex with terms of degree 12 down to 3
Dimensions of terms: 117 108 99 90 81 72 63 54 45 36
> PR := Prune(PR);
> PR := Prune(PR);
> PR;
Basic algebra complex with terms of degree 12 down to 5
Dimensions of terms: 117 108 99 90 81 72 63 54
> PR := ZeroExtension(PR);
> PR;
Basic algebra complex with terms of degree 13 down to 4
Dimensions of terms: 0 117 108 99 90 81 72 63 54 0
> PR := Shift(PR,-4);
> PR;
Basic algebra complex with terms of degree 9 down to 0
Dimensions of terms: 0 117 108 99 90 81 72 63 54 0
> S := [* *];
> for i := 1 to 10 do
>    S[i] := [Random(Term(PR,10-i)),Random(Term(PR,10-i))];
> end for;
> C,mu := Subcomplex(PR,S);
> C;
Basic algebra complex with terms of degree 9 down to 0
Dimensions of terms: 0 36 67 64 62 63 58 54 51 0
```

```
> Homology(C);

]
```

56.2.5 Maps on Homology

`InducedMapOnHomology(f, n)`

The homomorphism induced on homology by the chain map f in degree n.

`ConnectingHomomorphism(f, g, n)`

The connecting homomorphism in degree n of the short exact sequence of chain complexes given by the chain maps f and g.

`LongExactSequenceOnHomology(f, g)`

The long exact sequence on homology for the exact sequence of complexes given by the chain maps f and g as a chain complex with the homology group in degree i for the Cokernel of the complex C appearing in degree $3i$.

Example H56E3

We create a basic algebra with two simple modules and four nonidempotent generators. The relations are given in the sequence `rrr`.

```
> ff := GF(3);
> p := Characteristic(ff);
> FA<e1, e2, y, x, a, b> := FreeAlgebra(ff,6);
> rrr := [y^p,x^p,x*y+y*x,x*a*b-a*b*x,y*a*b-a*b*y,(b*a)^2,(b*a)^2];
> A := BasicAlgebra(FA,rrr,2,[<1,1>,<1,1>,<1,2>,<2,1>]);
> A;
Basic algebra of dimension 81 over GF(3)
Number of projective modules: 2
Number of generators: 6
> DimensionsOfProjectiveModules(A);
```

```
[ 45, 36 ]
```

Now we generate the simple modules and their projective covers. We want a module PP that is the direct sum of two copies of each of the projective indecomposable module.

```
> S1 := SimpleModule(A,1);
> PP := ProjectiveModule(A,[2,2]);
```

Now we are going to create a complex all of whose terms are isomorphic to PP. To make it interesting we will insist that the first homomorphism have its image in the second radical layer of PP.

```
> J1 := JacobsonRadical(PP);
> theta1 := Morphism(J1,PP);
> J2 := JacobsonRadical(J1);
> theta2 := Morphism(J2,J1);
> theta := theta2*theta1;
> HomPJ := AHom(PP, J2);
> HomPJ;
KMatrixSpace of 162 by 150 matrices and dimension 300 over GF(3)
> gamma := Random(HomPJ)*theta;
> LL := [* gamma *];
```

So we now have the first boundary map of the complex. The other boundary maps are generated randomly.

```
> for i := 1 to 15 do
>     K, phi := Kernel(gamma);
>     HomPK := AHom(PP,K);
>     gamma := Random(HomPK)*MapToMatrix(phi);
>     LL := [* gamma *] cat LL;
> end for;
```

Now we make the list into a chain complex.

```
> C := Complex(LL,0);
> C;
Basic algebra complex with terms of degree 16 down to 0
Dimensions of terms: 162 162 162 162 162 162 162 162 162 162 162 162 162 162
162 162 162
> DimensionsOfHomology(C);
[ 30, 23, 34, 32, 35, 32, 35, 42, 30, 34, 32, 33, 29, 42, 21 ]
Now we will get a random subcomplex.
> a,b := Degrees(C);
> S, mu := RandomSubcomplex(C,[2: i in [1 .. a-b+1]]);
> S;
Basic algebra complex with terms of degree 16 down to 0
Dimensions of terms: 162 155 162 162 162 154 142 162 162 148 154 162 162 152
155 152 162
> DimensionsOfHomology(S);
```

```
[ 27, 27, 34, 32, 35, 33, 48, 42, 28, 44, 38, 33, 29, 48, 24 ]
```

Now take the quotient.

```
> Q,nu := quo<C|S>;
> Q;
Basic algebra complex with terms of degree 16 down to 0
Dimensions of terms: 0 7 0 0 0 8 20 0 0 14 8 0 0 10 7 10 0
> DimensionsOfHomology(Q);
[ 7, 0, 0, 0, 6, 18, 0, 0, 12, 6, 0, 0, 8, 5, 10 ]
```

Now we check to see if this is a short exact sequence of chain maps.

```
> IsShortExactSequence(mu,nu);
true
> lll := LongExactSequenceOnHomology(mu,nu);
Basic algebra complex with terms of degree 47 down to 3
Dimensions of terms: 27 30 7 27 23 0 34 34 0 32 32 0 35 35 6 33 32 18 48 35 0
42 42 0 28 30 12 44 34 6 38 32 0 33 33 0 29 29 8 48 42 5 24 21 10
> IsExact(lll);
true
```

PART IX
FINITE GROUPS

57 GROUPS

Chapter 57
GROUPS

57.1 Introduction

Groups arise in several different categories in MAGMA. In the case of the category of permutation groups and the category of soluble groups defined by a power-conjugate presentation, all groups in the category are finite. However, the finitely-presented group category, the polycyclic group category, the abelian group category and the matrix group category contain both finite and infinite groups. In the case of the abelian group category and the matrix group category, a large number of functions are available for finite groups only. In the near future, these functions will be extended to finite finitely-presented groups of moderate order.

In this chapter, we discuss the functions that are provided for groups collectively, noting especially those functions that are available only for finite groups. Descriptions of functions that depend upon the particular category may be found in the chapter devoted to that category.

57.1.1 The Categories of Finite Groups

At present MAGMA contains five main categories of finite groups:

(i) Permutation groups: category GrpPerm;

(ii) Finite matrix groups: category GrpMat;

(iii) Finite solvable groups given by a power-conjugate presentation: category GrpPC;

(iv) Finite abelian groups: category GrpAb;

(v) Finite polycyclic groups: category GrpGPC.

Note that the categories GrpMat, GrpAb and GrpGPC contain both finite and infinite groups; most of the operations described in this chapter apply only to finite groups belonging to these categories. In this chapter we will use the category name `GrpFin` to collectively refer to categories GrpPerm and GrpPC and the subcategories of GrpMat, GrpAb and GrpGPC consisting of finite groups. The category name `Grp` will be used when the operation does not depend upon the finiteness of the group.

57.2 Construction of Elements

57.2.1 Construction of an Element

Throughout this subsection we shall assume that the carrier set for the group G is a subset of the set S. Thus, if G is a permutation group on the set X, its carrier set will be a subset of $\mathrm{Sym}(X)$.

```
elt< G | L >
```

Given a group G whose elements are a subset of the set S, and a list L of objects $a_1, a_2, \ldots, a_n$ defining an element of S, construct this element g of S. Then, the element g will be tested for membership of G, and if g is not an element of G, the function will fail. If g does lie in G, g will be returned with G as its parent.

```
G ! Q
```

Given a group G whose elements are a subset of the set S, and a sequence $Q = [a_1, a_2, \ldots, a_n]$ defining an element of S, construct this element g of S. Then, the element g will be tested for membership of G, and if g is not an element of G, the function will fail. If g does lie in G, g will be returned with G as its parent.

```
Identity(G)
```

```
Id(G)
```

Construct the identity element in the group G.

57.2.2 Coercion

```
G ! g
```

Given a group G and an element g of H, where G and H are subgroups of some common over-group and g is contained in G, embed g in G. Thus this operator changes the parent of g into G. The coercion may fail for groups in the category GrpFP.

57.2.3 Homomorphisms

```
hom< G -> H | L >
```

Return the group homomorphism $\phi : G \to H$ defined by extending the map of the generators of G, as given by the list L on the right side of the constructor. Suppose that the generators of G are $g_1, \ldots, g_n$, and that $\phi(g_i) = h_i$ for each i. Then L must be one of the following:

(a) a list of the n 2-tuples $< g_i, h_i >$ (order not important);

(b) a list of the n arrow-pairs g_i `->` h_i (order not important);

(c) $h_1, \ldots, h_n$ (order is important).

For its computations, MAGMA often assumes that the mapping so defined is a homomorphism without attempting to verify this.

For certain categories of groups, e.g. GrpGPC, the homomorphism constructor provides some additional functionality. See the chapter on the appropriate category for further information.

`hom< G -> H | x :-> e(x) >`

Return the group homomorphism $\phi : G \to H$ defined by the rule $\phi(x) = e(x)$, where x is a general element of G and $e(x)$ is an expression in x. The symbol x may be any identifier name, and has local scope. For its computations, MAGMA assumes the expression defines a homomorphism, but does not verify this.

`IdentityHomomorphism(G)`

Return the identity homomorphism $\phi : G \to G : x \mapsto x$.

Example H57E1

Construction of an isomorphism from the cyclic group of order 15 to the abelian group isomorphic to $\mathbf{Z}/15\mathbf{Z}$, by giving the image of the generator:

```
> C15 := CyclicGroup(15);
> C15;
Permutation group C15 acting on a set of cardinality 15
Order = 15 = 3 * 5
    (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15)
> A15 := AbelianGroup([15]);
> A15;
Abelian Group isomorphic to Z/15
Defined on 1 generator
Relations:
    15*A15.1 = 0
> iso11 := hom< C15 -> A15 | C15.1 -> 11*A15.1 >;
> A15 eq iso11(C15);
true
> forall{ <c, d> : c, d in C15 | iso11(c * d) eq iso11(c) * iso11(d) };
true
```

Example H57E2

An endomorphism of the same cyclic group, defined using an expression. The image is cyclic of order 5.

```
> C15 := CyclicGroup(15);
> h := hom< C15 -> C15 | g :-> g^3 >;
> forall{ <c, d> : c, d in C15 | h(c * d) eq h(c) * h(d) };
true
> im := h(C15);
> im;
Permutation group im acting on a set of cardinality 15
Order = 5
```

```
    (1, 4, 7, 10, 13)(2, 5, 8, 11, 14)(3, 6, 9, 12, 15)
> IsCyclic(im);
true
```

57.2.4 Arithmetic with Elements

`g * h`

Product of element g and element h, where g and h belong to the same generic group U. If g and h both belong to the same proper subgroup G of U, then the result will be returned as an element of G; if g and h belong to subgroups H and K of a subgroup G of U, then the product is returned as an element of G. Otherwise, the product is returned as an element of U. The product in abelian groups is called the sum and is written `g + h` instead.

`g ^ n`

The n-th power of the group element g, where n is a positive, negative or zero integer. In abelian groups, this is written as a scalar product `n * g` instead.

`g / h`

Product of the group element g by the inverse of the group element h, i.e., the element gh^{-1}. Here g and h must belong to the same generic group U. The rules for determining the parent group of g/h are the same as for gh. In abelian groups, this is written additively as `g - h`.

`g ^ h`

Conjugate of the group element g by the group element h, i.e., the element $h^{-1}gh$. Here g and h must belong to the same generic group U. The rules for determining the parent group of g^h are the same as for gh. In abelian groups, this operation does not exist.

`(g, h)`

Commutator of the group elements g and h, i.e., the element $g^{-1}h^{-1}gh$. Here g and h must belong to the same generic group U. The rules for determining the parent group of (g, h) are the same as those for gh.

`(g1, ..., gr)`

Given r elements $g_1, \ldots, g_r$ belonging to a common group, return their commutator. Commutators are *left-normed*, so they are evaluated from left to right.

`g eq h`

Given elements g and h belonging to the same generic group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given elements g and h belonging to the same generic group, return `true` if g and h are distinct elements, `false` otherwise.

`IsId(g)`

`IsIdentity(g)`

Returns `true` if the group element g is the identity element.

`Order(g)`

The order of the group element g.

Example H57E3

We illustrate the arithmetic operations by applying them to some elements of Sym(9).

```
> G := Sym(9);
> x := G ! (1,2,4)(5,6,8)(3,9,7);
> y := G ! (4,5,6)(7,9,8);
> x*y;
(1, 2, 5, 4)(3, 8, 6, 7)
> x^-1;
(1, 4, 2)(3, 7, 9)(5, 8, 6)
> x^2;
(1, 4, 2)(3, 7, 9)(5, 8, 6)
> x / y;
(1, 2, 6, 9, 8, 4)(3, 7)
> x^y;
(1, 2, 5)(3, 8, 9)(4, 7, 6)
> (x, y);
(1, 7, 3, 6)(4, 5, 9, 8)
> x^y eq y^x;
false
> CycleStructure(x^2*y);
[ <6, 1>, <2, 1>, <1, 1> ]
> Degree(y);
6
> Order(x^2*y);
6
```

57.3 Construction of a General Group

57.3.1 The General Group Constructors

The chapters on the individual group categories describe several methods for constructing groups; this section indicates one approach only.

```
PermutationGroup< X | L >
```

```
PermutationGroup< n | L >
```

```
MatrixGroup< n, R | L >
```

These expressions construct, respectively: a permutation group G acting on the set X; a permutation group G acting on the set $X = \{1, \ldots, n\}$; or a matrix group G of degree n over the ring R. The generic group U of which G is a subgroup will be $\mathrm{Sym}(X)$ in the permutation case or $\mathrm{GL}(n, R)$ in the matrix case. There are two return values: G, and the inclusion homomorphism from G to U.

The generators of G are defined by the list L. Each term of L must be an object of one of the following types:

(a) Either (permutation case) a sequence of n elements of X, or (matrix case) a sequence of n^2 elements of R, defining an element of U;

(b) A set or sequence of sequences of type (a);

(c) An element of U;

(d) A set or sequence of elements of U;

(e) A subgroup of U;

(f) A set or sequence of subgroups of U.

Each element or group specified by the list must belong to the *same* generic group. The group G will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of G consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list. Repetitions of an element and occurrences of the identity element are removed (unless G is trivial).

The `PermutationGroup` constructor is shorthand for the two statements:

```
U := SymmetricGroup(X);
G := sub< U | L >;
```

and the `MatrixGroup` constructor is shorthand for the two statements:

```
U := GeneralLinearGroup(n, R);
G := sub< U | L >;
```

where `sub< ... >` is the subgroup constructor described in the next subsection.

```
Group< X | R >
```

```
PolycyclicGroup< X | R >
```

```
AbelianGroup< X | R >
```

These expressions construct, respectively, a finitely presented group, a finite soluble group given by a power-conjugate presentation or a polycyclic group, and an abelian group, in the categories GrpFP, GrpPC or GrpGPC, and GrpAb. Given a list X of identifier names $x_1, \ldots, x_r$, and a list of relations R over them, first construct the free group F (in GrpFP or GrpAb) on the generators $x_1, \cdots, x_r$, and then construct the quotient G of F corresponding to the normal subgroup of F defined by the relations R. There are two return values: G, and the natural homomorphism from F to G.

The relations of G are defined by the list R. Each term of R must be an object of one of the following types:

(a) A word w of F, interpreted as the relator $w =$ identity of F;

(b) A relation $w_1 = w_2$, where w_1 and w_2 are words of F;

(c) A relation list $w_1 = w_2 = \cdots = w_r$, where the w_i are words of F, interpreted as the set of relations $w_1 = w_r, \ldots, w_{r-1} = w_r$.

Within R, the identity element of F may be represented by the digit `1` for `Group` or `PolycyclicGroup`, and `0` for `AbelianGroup`.

The construct $x_1, \ldots, x_n$ defines names for the generators of G that are local to the constructor, i.e., they are used when writing down the relations to the right of the bar. However, no assignment of *values* to these identifiers is made. If the user wants to refer to the generators by these (or other) names, then the *generators assignment* construct must be used on the left hand side of an assignment statement.

The constructor `PolycyclicGroup` returns either a finite soluble group given by a power-conjugate presentation (category GrpPC) or a general polycyclic group (category GrpGPC), depending on the arguments. R must be either a valid power-conjugate presentation for a finite soluble group or a consistent polycyclic presentation. If R is a valid power-conjugate presentation for a finite soluble group, a group in the category GrpPC is returned, unless the parameter `Class` is set to `"GrpGPC"`. If the parameter `Class` is set to `"GrpGPC"` or if R is not a valid power-conjugate presentation for a finite soluble group and the parameter `Class` is not set to `"GrpPC"`, a general polycyclic group in the category GrpGPC is returned. In any case, the free group F is in the category GrpFP. If R is neither a valid power-conjugate presentation for a finite soluble group nor a consistent polycyclic presentation, or if R does not match the value of the parameter `Class`, a runtime error is caused.

For a detailed description of this constructor and in particular for a description of power-conjugate presentations and consistent polycyclic presentations, we refer to Chapter 63 and Chapter 72, respectively.

Example H57E4

(1) The permutation group of degree 8 generated by the permutations $(1,7,2,8)(3,6,4,5)$ and $(1,4,2,3)(5,7,6,8)$:

```
> G := PermutationGroup< 8 |
>     (1, 7, 2, 8)(3, 6, 4, 5), (1, 4, 2, 3)(5, 7, 6, 8) >;
> G;
Permutation group G acting on a set of cardinality 8
    (1, 7, 2, 8)(3, 6, 4, 5)
    (1, 4, 2, 3)(5, 7, 6, 8)
```

(2) A matrix group of degree 2 over $\mathbf{F}_9$:

```
> K<w> := GF(9);
> M := MatrixGroup< 2, K | [w,w,1,2*w], [0,2*w,1,1], [1,0,1,2] >;
> M;
MatrixGroup(2, GF(3^2))
Generators:
    [  w   w]
    [  1 w^5]

    [  0 w^5]
    [  1   1]

    [  1   0]
    [  1   2]
> Order(M);
5760
```

(3) The finitely presented group Q defined by the presentation

$$< s,t,u \mid t^2, u^{17}, s^2 = t^s = t, u^s = u^{16}, u^t = u >,$$

together with the natural homomorphism from the free group to Q:

```
> Q<s,t,u>, h := Group< s, t, u |
>     t^2, u^17, s^2 = t^s = t, u^s = u^16, u^t = u >;
> Q;
Finitely presented group Q on 3 generators
Relations
    t^2 = Id(Q)
    u^17 = Id(Q)
    s^2 = t
    t^s = t
    u^s = u^16
    u^t = u
> Domain(h);
Finitely presented group on 3 generators (free)
```

(4) The soluble group of order 70 defined by the presentation $< a,b,c \mid a^2 = b, b^5 = c, c^7 >$:

```
> G<a,b,c> := PolycyclicGroup< a, b, c | a^2 = b, b^5 = c, c^7 >;
```

```
> G;
GrpPC : G of order 70 = 2 * 5 * 7
PC-Relations:
a^2 = b,
b^5 = c,
c^7 = Id(G)
```

(5) A finite abelian group on 4 generators:

```
> G := AbelianGroup< h, i, j, k | 5*h, 4*i, 7*j, 2*k - h >;
> G;
Abelian Group isomorphic to Z/2 + Z/140
Defined on 4 generators
Relations:
    G.1 + 8*G.4 = 0
    4*G.2 = 0
    7*G.3 = 0
    10*G.4 = 0
> Order(G);
280
```

Example H57E5

Using the constructor `PolycyclicGroup` with different values of the parameter `Class`, we construct the dihedral group of order 10 first as a finite soluble group given by a power-conjugate presentation (GrpPC) and next as a general polycyclic group (GrpGPC). Note that the presentation $\langle a, b \,|\, a^2, b^5, b^a = b^4 \rangle$ is both a valid power-conjugate presentation and a consistent polycyclic presentation, so we have to set the parameter `Class` to `"GrpGPC"` if we want to construct a group in the category GrpGPC.

```
> G1<a,b> := PolycyclicGroup< a,b | a^2, b^5, b^a=b^4 >;
> G1;
GrpPC : G1 of order 10 = 2 * 5
PC-Relations:
    a^2 = Id(G1),
    b^5 = Id(G1),
    b^a = b^4
> G2<a,b> := PolycyclicGroup< a,b | a^2, b^5, b^a=b^4 : Class := "GrpGPC">;
> G2;
GrpGPC : G2 of order 10 = 2 * 5 on 2 PC-generators
PC-Relations:
    a^2 = Id(G2),
    b^5 = Id(G2),
    b^a = b^4
```

We construct the infinite dihedral group as a group in the category GrpGPC from a consistent polycyclic presentation. We do not have to use the parameter `Class` in this case.

```
> G3<a,b> := PolycyclicGroup< a,b | a^2, b^a=b^-1>;
> G3;
```

```
GrpGPC : G3 of infinite order on 2 PC-generators
PC-Relations:
    a^2 = Id(G3),
    b^a = b^-1
```

The presentation $\langle a, b \,|\, a^2, b^4, b^a = b^3 \rangle$ is not a valid power-conjugate presentation for the dihedral group of order 8, since the exponent of b is not prime. However, it is a consistent polycyclic presentation. Consequently, the constructor `PolycyclicGroup` without specifying a value for the parameter `Class` returns a group in the category GrpGPC.

```
> G4<a,b> := PolycyclicGroup< a,b | a^2, b^4, b^a=b^3 >;
> G4;
GrpGPC : G4 of order 2^3 on 2 PC-generators
PC-Relations:
    a^2 = Id(G3),
    b^4 = Id(G3),
    b^a = b^3
```

57.3.2 Construction of Subgroups

`sub< G | L >`

Given the group G, construct the subgroup H of G, generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) A MAGMA object which may be coerced into G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic group. The subgroup H will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of H consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list. Repetitions of an element and occurrences of the identity element are removed (unless H is trivial).

`ncl< G | L >`

Given the group G, construct the subgroup H of G that is the *normal closure* of the subgroup H generated by the elements specified by the list L, where the possibilities for L are the same as for the `sub`-constructor.

Example H57E6

Let Q be the finitely presented group in generators s, t, u constructed in an earlier example. We construct the subgroup S of Q generated by ts^2 and u^4:

```
> Q<s,t,u>, h := Group< s, t, u |
>     t^2, u^17, s^2 = t^s = t, u^s = u^16, u^t = u >;
> S := sub< Q | t*s^2, u^4 >;
> S;
Finitely presented group S on 2 generators
Generators as words
    S.1 = $.2 * $.1^2
    S.2 = $.3^4
```

57.3.3 Construction of Quotient Groups

`quo< G | L >`

Given the group G, construct the quotient group $Q = G/N$, where N is the normal closure of the subgroup of G generated by the elements specified by L. The clause L is a list of one or more items of the following types:

(a) A MAGMA object which can be coerced into G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic group. The function returns

(a) the quotient group Q, and

(b) the natural homomorphism $f : G \to Q$.

Arbitrary quotients may be readily constructed in the case of the categories GrpFP, GrpGPC, GrpPC and GrpAb. However, in the case of permutation and matrix groups, currently the quotient group is constructed via its regular representation, so that the application of this operator is restricted to the case where the index of N in G is less than 2^{30}.

The second return value is the epimorphism from G to the resulting quotient group.

`G / N`

Given a (normal) subgroup N of the group G, construct the quotient of G by N.

If G is in category GrpFP, N is not checked to be normal in G. In fact, the returned group is the quotient of G by the normal closure of N in G. For all other categories of groups, passing a subgroup which fails to be normal causes a runtime error.

If G is a permutation or matrix group, the quotient group is constructed via its regular representation, so that the application of this operator is restricted to the case where the index of N in G is at most a million. The result returned need not be regular, as an attempt is made to reduce the degree of the result.

Example H57E7

Construction of the quotient of an abelian group, with a demonstration of the use of the natural homomorphism:

```
> G<[x]>, f := AbelianGroup< h, i, j, k | 8*h, 4*i, 6*j, 2*k - h >;
> T, n := quo< G | x[1] + 2*x[2] + 24*x[3], 16*x[3] >;
> T;
Abelian Group isomorphic to Z/2 + Z/16
Defined on 2 generators
Relations:
    4*T.1 = 0
    16*T.2 = 0
> n(x);
[
    2*T.1,
    T.1 + 12*T.2,
    T.2
]
> n(sub< G | x[1] + x[2] + x[3] >);
Abelian Group isomorphic to Z/16
Defined on 1 generator in supergroup T:
    $.1 = 3*T.1 + T.2
Relations:
    16*$.1 = 0
```

57.4 Standard Groups and Extensions

57.4.1 Construction of a Standard Group

A number of functions are provided which construct various standard groups. The effect of these functions is to construct the group on some standard set of generators. The group category of the result may be specified as an argument to the function.

`AbelianGroup(C, Q)`

`AbelianGroup(Q)`

Construct the abelian group defined by the sequence $Q = [n_1, \ldots, n_r]$ of positive integers. The function constructs the direct product of cyclic groups $\mathbf{Z}_{n_1} \times \mathbf{Z}_{n_2} \times \cdots \times \mathbf{Z}_{n_r}$. In some categories, n_i may also be 0, denoting the infinite cyclic group $\mathbf{Z}$. If the single-argument version of the function is used, the group will be constructed in the category GrpAb; otherwise, its category will be C, where C may be GrpAb, GrpFP, GrpGPC, GrpPC or GrpPerm.

`AlternatingGroup(C, n)`

`AlternatingGroup(n)`

`Alt(C, n)`

`Alt(n)`

Construct the alternating group on n letters. If the single-argument version of the function is used, the group will be constructed in the category GrpPerm; otherwise, its category will be C, where C may be GrpFP or GrpPerm.

`CyclicGroup(C, n)`

`CyclicGroup(n)`

Construct the cyclic group of order n. If the single-argument version of the function is used, the group will be constructed in the category GrpPerm; otherwise, its category will be C, where C may be GrpAb, GrpFP, GrpGPC, GrpPC or GrpPerm.

`DihedralGroup(C, n)`

`DihedralGroup(n)`

Construct the dihedral group of order $2 * n$. If the single-argument version of the function is used, the group will be constructed in the category GrpPerm; otherwise, its category will be C, where C may be GrpFP, GrpGPC, GrpPC or GrpPerm.

`DicyclicGroup(n)`

`DicyclicGroup(A, a)`

The first intrinsic constructs the dicyclic group of order $4n$. The second, when given an abelian group A and an element a of order 2, constructs the associated dicyclic group generated by A and an x with $x^2 = a$ and $a^x = a^{-1}$ for all $x \in A$.

`SymmetricGroup(C, n)`

`SymmetricGroup(n)`

`Sym(GrpFin, n)`

`Sym(n)`

Construct the symmetric group on n letters. If the single-argument version of the function is used, the group will be constructed in the category GrpPerm; otherwise, its category will be C, where C may be GrpFP or GrpPerm.

`ExtraSpecialGroup(C, p, n : parameters)`

`ExtraSpecialGroup(p, n : parameters)`

Given a prime p and a small positive integer n, construct an extra-special group G of order p^{2n+1}. The isomorphism type of G can be selected using the parameter `Type` described below.

If the two-argument version of the function is used, the group will be constructed in the category GrpPerm; otherwise, its category will be C, where C may be GrpFP, GrpGPC, GrpPC or GrpPerm. If C is GrpFP, GrpPC or GrpPerm, the prime p must be small.

`Type` MonStgElt *Default :* "+"

Possible values for this parameter are "+" (default) and "−".

If `Type` is set to "+", the function returns for $p = 2$ the central product of n copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p.

If `Type` is set to "−", the function returns for $p = 2$ the central product of a quaternion group of order 8 and $n - 1$ copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p^2.

Example H57E8

(1) The abelian group $\mathbf{Z}_6 \times \mathbf{Z}_2 \times \mathbf{Z}_7$ in the category GrpAb:

```
> A := AbelianGroup([6, 2, 7]);
> A;
Abelian Group isomorphic to Z/2 + Z/42
Defined on 3 generators
Relations:
    6*A.1 = 0
    2*A.2 = 0
    7*A.3 = 0
```

(2) The alternating group on 6 letters as a permutation group:

```
> A6 := Alt(6);
> A6;
Permutation group A6 acting on a set of cardinality 6
Order = 360 = 2^3 * 3^2 * 5
```

```
    (1, 2)(3, 4, 5, 6)
    (1, 2, 3)
```

(3) The dihedral group of order 8 as a GrpPC:

```
> D8 := DihedralGroup(GrpPC, 4);
> D8;
GrpPC : D8 of order 8 = 2^3
PC-Relations:
  D8.2^2 = D8.3,
  D8.2^D8.1 = D8.2 * D8.3
```

(4) The symmetric group on 7 letters as a finitely presented group on generators a and b:

```
> S7<a, b> := SymmetricGroup(GrpFP, 7);
> S7;
Finitely presented group S7 on 2 generators
Relations
    a^7 = Id(S7)
    b^2 = Id(S7)
    (a * b)^6 = Id(S7)
    (a^-1 * b * a * b)^3 = Id(S7)
    (b * a^-2 * b * a^2)^2 = Id(S7)
    (b * a^-3 * b * a^3)^2 = Id(S7)
```

57.4.2 Construction of Extensions

`DirectProduct(G, H)`

Given two groups G and H belonging to the category C, construct the direct product of G and H as a group in C.

`DirectProduct(Q)`

Given a sequence Q of n groups belonging to the category C, construct the direct product $Q[1] \times Q[2] \times \ldots \times Q[n]$ as a group in the category C.

`SemidirectProduct(K, H, f:` *parameters*`)`

Given two groups K and H and a homomorphism $f : H \to \mathrm{Aut}(K)$, construct the semidirect product of K and H where the elements of H act on K via the map f. Return the semidirect product, and maps embedding H and K into the semidirect product.

`MaxDeg` RngIntElt *Default :* 1000000

The maximum degree permutation representation the algorithm will attempt.

`UseRegular` BoolElt *Default :* `false`

Setting `UseRegular` to true forces the algorithm to go via the regular representations of K and H.

Example H57E9

We define G to be the symmetric group of degree 4 and H to be the dihedral group of order 8. We then form the direct product of G and H.

```
> G := SymmetricGroup(4);
> H := DihedralGroup(3);
> D := DirectProduct(G, H);
> D;
Permutation group D acting on a set of cardinality 7
    (1, 2, 3, 4)
    (1, 2)
    (5, 6, 7)
    (5, 6)
> Order(D);
144
```

57.5 Transfer Functions Between Group Categories

Since certain group computations are possible or feasible only for particular group representations, it is often useful to transfer a group from one category to another. The functions in this section take a group and return a group isomorphic to it (or isomorphic to some related group) in another category.

`pQuotient(F, p, c: parameters)`

Given a group F in category GrpFP, a prime p and a positive integer c, construct the largest p-quotient G of F having lower exponent-p class at most c (or 127, if c is given as 0) as group in the category GrpPC. The function also returns the homomorphism from F to G.

The parameters are:

`Exponent` RngIntElt *Default :* 0

If `Exponent := m`, enforce the exponent law, $x^m = 1$, on the group.

`Metabelian` BoolElt *Default :* `false`

If `Metabelian := true`, then a consistent pcp is constructed for the largest metabelian p-quotient of F having lower exponent-p class at most c.

`Print` RngIntElt *Default :* 0

This parameter controls the volume of printing. By default its value is that returned by `GetVerbose("pQuotient")`, which is 0 unless it has been changed through use of `SetVerbose`. The effect is the following:

`Print := 0` : No output.

`Print := 1` : Report order of p-quotient at each class.

`Print := 2` : Report statistics and redundancy information about tails, consistency, collection of relations and exponent enforcement components of calculation.

`Print := 3` : Report in detail on the construction of each class.
Note that the presentation displayed is a *power-commutator* presentation (since this is the version stored by the p-quotient).

`Workspace` RngIntElt *Default :* 5000000

The amount of space requested for the p-quotient computation.

`CosetAction(G, H)`

Given a subgroup H of the group G, construct the permutation representation of G given by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The natural homomorphism $f : G \to L$;

(b) The induced permutation group L (the image of f);

(c) (if possible) The kernel K of the action (a subgroup of G).

If G is a finitely presented group, then K may be returned undefined.

The permutation representation is obtained by using the Todd-Coxeter procedure to construct the coset table for H in G. Note that G may be an infinite group: it is only necessary that the index of H in G be finite.

`CosetImage(G, H)`

Given a subgroup H of the group G, construct the image of G given by its action on the (right) coset space of H in G, returning it as a permutation group. (This is also the second return value of `CosetAction(G, H)`.)

`CosetKernel(G, H)`

Given a subgroup H of the group G, construct the kernel of G in its action on the (right) coset space of H in G. (This is also the third return value of `CosetAction(G, H)`.) This function may fail if G is a finitely presented group; it is only available when the index of H in G is very small.

`GPCGroup(G)`

Given a soluble group G, in the category GrpPerm, GrpMat, GrpAb or GrpPC, construct a polycyclic group P isomorphic to G. Currently G must be finite, if it is in the category GrpMat. In addition to returning P, the function returns an isomorphism $\phi : G \to P$.

`PCGroup(G)`

Given a finite soluble group G, in the category GrpPerm, GrpMat, GrpAb or GrpGPC, construct a group S given by a power-conjugate presentation, which is isomorphic to G. In addition to returning S, the function returns an isomorphism $\phi : G \to S$.

FPGroup(G: *parameters*)

StrongGenerators	BoolElt	*Default :* false
Random	BoolElt	*Default :* true
Max	RngIntElt	*Default :* 100
Run	RngIntElt	*Default :* 20

Given a group G, in the category GrpPerm, GrpMat, GrpGPC or GrpPC, construct a finitely presented group F isomorphic to G, by presenting the group on its given generators. For groups in the category GrpPerm and GrpMat, the Todd-Coxeter Schreier algorithm is used to construct the presentation and a choice of a presentation on the given generators or on the strong generators is available. In addition to returning F, the function returns an isomorphism $\phi : F \to G$, such that $\phi(F.i) = G.i$ for all i.

If the parameter StrongGenerators is set to true (GrpPerm and GrpMat only), the presentation will be constructed on the strong generators of G instead of the given generators. If strong generators are not already known for G, they will be constructed; in this case, the other parameters are also meaningful. The parameter Random with its associated parameters Max and Run may be used to apply the Random Schreier algorithm to construct a probable BSGS before commencing the construction of the presentation.

Example H57E10

We construct a finitely presented group G and a subgroup H, then find the permutation representation of G given by its action on the cosets of H. Since the induced permutation group L has the same order as G, the representation is faithful, and the homomorphism $f : G \to L$ is an isomorphism.

```
> G<a, b> := Group< a, b | a^3, b^3, (b * a)^4,
>     ((b^-1)^a * b^-1)^2 * b^a * b >;
> Order(G);
168
> H := sub< G | a^2 * b^2, (a * b)^2 >;
> Index(G, H);
7
> f, L := CosetAction(G, H);
> f;
Mapping from: GrpFP: G to GrpPerm: L
> L;
Permutation group L acting on a set of cardinality 7
    (1, 2, 3)(4, 7, 5)
    (1, 3, 4)(2, 5, 6)
> Order(L);
168
```

Example H57E11

A permutation representation of $\mathrm{Sp}(2,4)$.

```
> M := SymplecticGroup(2, 4);
> #M;
60
> Ms := sub< M | M.1 * M.2 >;
> Index(M, Ms);
12
> PG := CosetImage(M, Ms);
> PG;
Permutation group PG acting on a set of cardinality 12
    (1, 2, 4)(3, 5, 7)(6, 8, 10)(9, 11, 12)
    (1, 3, 2)(4, 6, 8)(5, 7, 9)(10, 12, 11)
> #PG;
60
```

Example H57E12

A finitely presented group isomorphic to $\mathrm{PSU}(3,3)$:

```
> G := PSU(3, 3);
> F<a, b>, phi := FPGroup(G);
> F;
Finitely presented group F on 2 generators
Relations
    a^8 = Id(F)
    b^8 = Id(F)
    (b * a^-1 * b)^3 = Id(F)
    b * a^-1 * b^-1 * a^-1 * b^-1 * a^-1 * b * a^-1 * b * a^-1 = Id(F)
    b^-1 * a^-2 * b^-1 * a^-2 * b^-1 * a^-1 * b^-2 * a^-1 = Id(F)
> phi(a) eq G.1 and phi(b) eq G.2;
true
```

57.6 Basic Operations

57.6.1 Accessing Group Information

The functions in this group provide access to basic information stored for a group G.

`G . i`

The i-th defining generator for G, if $i > 0$. If $i < 0$, then the inverse of the $-i$-th defining generator is returned. `G.0` is equivalent to `Identity(G)`.

`Generators(G)`

A set containing the defining generators for G.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for G.

`Generic(G)`

Given a group G in the category GrpPerm or GrpMat, return the generic group containing G, i.e., the largest group in which G is naturally embedded. The precise definition of generic group depends upon the category to which G belongs.

`Parent(g)`

The parent group G for the group element g.

Example H57E13

The Suzuki simple group $G = \mathrm{Sz}(8)$ is constructed. Its generic group is $\mathrm{GL}(4, K)$, where K is the finite field with 8 elements. The field K is constructed first, so that its generator may be given the printname z. Then the three generators of G are printed, in the standard order of indexing.

```
> K<z> := GF(2, 3);
> G := SuzukiGroup(8);
> Generic(G);
GL(4, GF(2, 3))
> Ngens(G);
3
> for i in [1..3] do
>    print "generator", i, G.i;
>    print "order", Order(G.i), "\r";
> end for;
generator 1
[  0   0   0   1]
[  0   0   1   0]
[  0   1   0   0]
[  1   0   0   0]
order 2

generator 2
```

```
[z^2   0   0   0]
[  0 z^6   0   0]
[  0   0   z   0]
[  0   0   0 z^5]
order 7

generator 3
[  1   0   0   0]
[z^2   1   0   0]
[  0   z   1   0]
[z^5 z^3 z^2   1]
order 4
```

`Orbit(G, M, x)`

Given a finitely generated group G that acts on the parent structure of x through the map (or user defined function) M, compute the orbit of x under G. Thus, for every generator g of G, $M(g)$ must return a function that can be applied to x or any other element in the parent of x.

If the orbit is infinite, this process will eventually run out of memory.

`OrbitClosure(G, M, S)`

Given a finitely generated group G acting on the universe of S through the map or user defined function M, compute the smallest subset T containing S that is G-invariant. Thus, for every generator g of G, $M(g)$ must return a function that can be applied to an arbitrary element in the universe of S.

If the orbit closure is infinite, this process will eventually run out of memory.

57.7 Operations on the Set of Elements

57.7.1 Order and Index Functions

`Order(G)`

`#G`

The order of the group G as an integer. If the order is not currently known, it will be computed. Computing the order may fail for groups in the category GrpFP; cf. Chapter 70.

`FactoredOrder(G)`

The order of the finite group G returned as a factored integer. The factorization is returned in the form of a sequence Q which is defined as follows: If $\#G = p_1^{e_1} \dots p_n^{e_n}, \quad e_i > 0$, then Q will be the integer sequence $[\langle p_1, e_1\rangle, \dots, \langle p_n, e_n\rangle]$. If the orders of G is not known, it will be computed. Computing the order may fail for groups in the category GrpFP; cf. Chapter 70.

`Index(G, H)`

The index of the subgroup H in the group G. The index is returned as an integer. Computing the index may fail for groups in the category GrpFP; cf. Chapter 70.

`FactoredIndex(G, H)`

The index of the subgroup H in the group G. H must have finite index in G. The index is returned as a factored integer. The format is the same as for `FactoredOrder`. Computing the index may fail for groups in the category GrpFP; cf. Chapter 70.

Example H57E14

Exploration of the order and index functions for a finitely presented group and its subgroup:

```
> Q<s,t,u>, h := Group< s, t, u |
>     t^2, u^17, s^2 = t^s = t, u^s = u^16, u^t = u >;
> Order(Q);
68
> FactoredOrder(Q);
[ <2, 2>, <17, 1> ]
> S := sub< Q | t*s^2, u^4 >;
> Index(Q, S);
4
> #S;
17
```

57.7.2 Membership and Equality

`g in G`

Given a group element g and a group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given a group element g and a group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given a group G and a set S of group elements belonging to a group H, where G and H belong the same generic group, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a group G and a set S of group elements belonging to a group H, where G and H belong the same generic group, return `true` if S is not a subset of G, `false` otherwise.

`H subset G`

Given groups G and H belonging to the same generic group, return `true` if H is a subgroup of G, `false` otherwise.

`H notsubset G`

Given groups G and H belonging to the same generic group, return `true` if H is not a subgroup of G, `false` otherwise.

`H eq G`

Given groups G and H belonging to the same generic group, return `true` if G and H are the same group, `false` otherwise.

`H ne G`

Given groups G and H belonging to the same generic group, return `true` if G and H are distinct groups, `false` otherwise.

57.7.3 Set Operations

`NumberingMap(G)`

Given a finite group G in the category GrpPerm, GrpMat, GrpPC or GrpAb, return a bijective mapping from the group G onto the set of integers $\{1 \ldots |G|\}$. The actual mapping depends upon the particular representation of G.

`Representative(G)`

`Rep(G)`

An element chosen from the group G.

Example H57E15

We use the function `NumberingMap` to construct the multiplication table for the dihedral group of order 12.

```
> G := DihedralGroup(6);
> f := NumberingMap(G);
> [ [ f(x*y) : y in G ] : x in G ];
[
    [ 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 ],
    [ 2, 3, 4, 5, 6, 1, 12, 7, 8, 9, 10, 11 ],
    [ 3, 4, 5, 6, 1, 2, 11, 12, 7, 8, 9, 10 ],
    [ 4, 5, 6, 1, 2, 3, 10, 11, 12, 7, 8, 9 ],
    [ 5, 6, 1, 2, 3, 4, 9, 10, 11, 12, 7, 8 ],
    [ 6, 1, 2, 3, 4, 5, 8, 9, 10, 11, 12, 7 ],
    [ 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5, 6 ],
    [ 8, 9, 10, 11, 12, 7, 6, 1, 2, 3, 4, 5 ],
    [ 9, 10, 11, 12, 7, 8, 5, 6, 1, 2, 3, 4 ],
    [ 10, 11, 12, 7, 8, 9, 4, 5, 6, 1, 2, 3 ],
```

```
    [ 11, 12, 7, 8, 9, 10, 3, 4, 5, 6, 1, 2 ],
    [ 12, 7, 8, 9, 10, 11, 2, 3, 4, 5, 6, 1 ]
]
```

57.7.4 Random Elements

`Random(G: parameters)`

`Short` BoolElt *Default :* `false`

A randomly chosen element for the group G. If a representation of the carrier set of G has already been created, then the element chosen will be genuinely random. If such a representation has not yet been created, then the *random* element is chosen by multiplying out a *random* word in the generators. Since it is not usually practical to choose words long enough to properly sample the elements of G, the element returned will usually be biased. The boolean-valued parameter `Short` is used in this situation to indicate that a short word will suffice. Thus, if `Random` is invoked with `Short` assigned the value `true` then the element is constructed using a short word.

Example H57E16

We illustrate the use of the function `Random` using the wreath product of the symmetric group of degree 4 and the cyclic group of order 6.

```
> G := WreathProduct(Sym(4), CyclicGroup(6));
> G;
Permutation group G acting on a set of cardinality 24
    (1, 5, 9, 13, 17, 21)(2, 6, 10, 14, 18, 22) (3, 7, 11, 15, 19, 23)
        (4, 8, 12, 16, 20, 24)
    (1, 2, 3, 4)
    (1, 2)
> Order(G);
1146617856
> Random(G);
(1, 17, 12, 4, 18, 10, 3, 20, 9, 2, 19, 11)(5, 22, 13, 6, 21, 15)
    (7, 24, 16)(8, 23, 14)
// We display the cycle structures of 10 random elements of G
> R := [ CycleStructure(Random(G)) : i in [1..10] ];
> R;
[
    [ <6, 1>, <3, 6> ],
    [ <9, 1>, <6, 2>, <3, 1> ],
    [ <9, 2>, <3, 2> ],
    [ <12, 1>, <9, 1>, <3, 1> ],
    [ <18, 1>, <6, 1> ],
    [ <18, 1>, <6, 1> ],
    [ <12, 1>, <6, 2> ],
```

```
    [ <6, 3>, <2, 3> ],
    [ <6, 1>, <4, 3>, <2, 3> ],
    [ <6, 3>, <3, 2> ]
]
```

`RandomProcess(G)`

`RandomProcessWithWords(G)`

`RandomProcessWithValues(G, Q)`

`RandomProcessWithWordsAndValues(G, Q)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 50
`WordGroup`	GrpSLP	*Default :*

Create a process to generate randomly chosen elements from the group G. The process uses a variant of the product-replacement method similar to the *Rattle* method of [LGM02]. The generating set stored in the process has N elements, where N is the maximum of the specified value for `Slots` and `Ngens`$(G)+1$. Initially they are the generators of G repeated as necessary and the accumulator is the identity. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call returns the current value of the accumulator, modifying the generating set as for product-replacement, and modifying the accumulator by multiplying by the new member of the generating set. Setting `Scramble := m` causes m such operations to be performed before the process is returned.

The functions with words and values create a process that returns extra group elements for each call. A process created with words returns, as second return value for each call to `Random(P)`, the `GrpSLPElt` describing the random element returned as a straight-line program in the group generators. The parameter `WordGroup` may be used to specify a particular group for the words to be elements of.

A process created with values takes as input a sequence of group elements Q giving the values assigned to each generator of G. The second value returned is the result of computing in parallel with these values as with the generators of G. In particular, if the elements of Q are homomorphic images of the generators of G, then the second return value from `Random(P)` will be the image of the first under this homomorphism.

A process created with words and values does all of the above, with the three return values of `Random(P)` being a random element of G, the straight-line program and the value.

The use of this function on a finitely-presented group G is not recommended. Since there is no reduction of words, the random elements generated may be extremely long.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the finite group G, construct a random element of G by forming a random product over the expanded generating set constructed when the process was created. For large permutation or matrix groups for which a BSGS is not known, this function should be used in preference to `Random(G)`.

If the process was created with words or values then there will be second and third return values as described under `RandomProcess` above.

`InitialiseProspector(G:`*parameters*`)`

`InitialiseProspector(G:`*parameters*`)`

Initialise a product-replacement prospector for the given group. This is an extension of the product-replacement algorithm that searches for an element $x \in G$ such that some predicate is true for this element. The prospector aims to find elements x so that the corresponding straight-line program for x is short. Statistical tests and various heuristics are used to achieve this.

Generally, output from product-replacement with short straight-line programs is not very random. Prospector aims to run product-replacement until the output looks random, then start a search for the element wanted. At all times, if the output starts to look non-random, or word lengths grow too far without finding an element, the prospector may return to a previous state of product replacement and try again, searching in a different direction. The statistical tests are used to make concrete the notion of "looks random". For permutation groups the test used is based on number of cycles of the element. For matrix groups the test statistic is the number of factors of the characteristic polynomial.

`Prospector(G, f:`*parameters*`)`

Run an initialised prospector for group G to find $x \in G$ such that $f(x)$ is true. The first return value gives the success or failure of the search. If this value is true, then the second and third return values are x and a straight-line program giving x in terms of the group generators. The parameter `MaxTries` may be set to limit the number of random selections made by the prospector when attempting to find x.

Example H57E17

We find a random pair of generators for the symmetric group of degree 300 and use a random process to find an element which is a 300-cycle as a straight-line program in the generators. The proportion of such elements is 1 in 300, so we expect the program to have length 600.

```
> SetSeed(1);
> S := Sym(300);
> repeat G := sub<S|Random(S),Random(S)>;
> until IsSymmetric(G);
> P := RandomProcessWithWords(G);
> repeat x,w := Random(P);
```

```
> until CycleStructure(x) eq [<300,1>];
> #w;
936
```

Note that the group S, known to be a symmetric group, has an efficient uniform random element generator available as above. The word length was somewhat longer than the expected value. Now we set up a prospector and use it to search for an element of the same cycle structure. The defining word for the new element should be shorter than the expected 600.

```
> InitialiseProspector(G);
true
> test := func<x|CycleStructure(x) eq [<300,1>]>;
> a,x,w := Prospector(G, test);
> a;
true
> #w;
206
> Evaluate(w, [G.1,G.2]) eq x;
true
```

57.7.5 Action on a Coset Space

`CosetTable(G, H)`

The (right) coset table for G over subgroup H relative to its defining generators.

`#CosetTable(G, f)`

The coset table for G corresponding to the permutation representation f of G, where f is a homomorphism of G onto a transitive permutation group.

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a group G and a subgroup H of G, this function returns

(a) An indexed set of elements T of G forming a right transversal for G over H;

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and $g \in G$, ϕ is defined by $\phi(g) = t_i$, where $g \in Ht_i$.

`CosetAction(G, H)`

Given a subgroup H of the group G, construct the permutation representation of G given by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The natural homomorphism $f : G \to L$;

(b) The induced group L;

(c) The kernel K of the action (a subgroup of G).

Note that G may be any type of group. If G is a finitely presented group, then K may be returned undefined.

`CosetImage(G, H)`

Given a subgroup H of the group G, construct the image L of G given by the action of G on the set of (right) cosets of H in G.

`CosetKernel(G, H)`

Given a subgroup H of the group G, construct the kernel of the action of G on the set of (right) cosets of H in G.

57.8 Standard Subgroup Constructions

Some functions described in this section may not exist or may have restrictions for some categories of groups. Details can be found in the chapters on the individual categories.

`H ^ g`

`Conjugate(H, g)`

Construct the conjugate $g^{-1}Hg$ of the group H by the element g. The group H and the element g must belong to the same generic group.

`H meet K`

Given groups H and K which belong to the same symmetric group, construct the intersection of H and K.

`CommutatorSubgroup(G, H, K)`

`CommutatorSubgroup(H, K)`

Given groups H and K, both subgroups of the group G, construct the commutator subgroup of H and K in the group G. If K is a subgroup of H, then the group G may be omitted.

`Centralizer(G, g)`

`Centraliser(G, g)`

Construct the centralizer of the element g in the group G.

`Centralizer(G, H)`
`Centraliser(G, H)`

Construct the centralizer of the group H in the group G.

`Core(G, H)`

Given a subgroup H of the group G, construct the maximal normal subgroup of G that is contained in the subgroup H.

`H ^ G`
`NormalClosure(G, H)`

Given a subgroup H of the group G, construct the normal closure of H in G.

`Normalizer(G, H)`
`Normaliser(G, H)`

Given a subgroup H of the group G, construct the normalizer of H in G.

`pCore(G, p)`

Given a group G and a prime p dividing the order of G, construct the maximal normal p-subgroup of G.

`SylowSubgroup(G, p)`
`Sylow(G, p)`

Given a group G and a prime p, construct a Sylow p-subgroup of G.

57.8.1 Abstract Group Predicates

Some functions described in this section may not exist or may have restrictions for some categories of groups. Details can be found in the chapters on the individual categories.

`IsAbelian(G)`

Returns `true` if the group G is abelian, `false` otherwise.

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise.

`IsCentral(G, H)`

Return `true` if the subgroup H of the group G lies in the centre of G, `false` otherwise.

`IsConjugate(G, g, h)`

Given a group G and elements g and h belonging to G, return the value `true` if g and h are conjugate in G. The function returns a second value if the elements are conjugate: an element k which conjugates g into h.

`IsConjugate(G, H, K)`

Given a group G and subgroups H and K belonging to G, return the value `true` if H and K are conjugate in G. The function returns a second value if the subgroups are conjugate: an element z which conjugates H into K.

`IsExtraSpecial(G)`

Given a group G is a p-group G, return `true` if G is extra-special, `false` otherwise.

`IsMaximal(G, H)`

Returns `true` if the subgroup H of the group G is a maximal subgroup of G. This function is evaluated by constructing the permutation representation of G on the cosets of H and testing this representation for primitivity. For this reason, the use of `IsMaximal` should be avoided if the index of H in G exceeds a one hundred thousand.

`IsNilpotent(G)`

Return `true` if the group G is nilpotent, `false` otherwise.

`IsNormal(G, H)`

Return `true` if the subgroup H of the group G is a normal subgroup of G, `false` otherwise.

`IsPerfect(G)`

Return `true` if the group G is perfect, `false` otherwise.

`IsSelfNormalizing(G, H)`
`IsSelfNormalising(G, H)`

Return `true` if the subgroup H of the group G is self-normalizing in G, `false` otherwise.

`IsSimple(G)`

Return `true` if the group G is simple, `false` otherwise.

`IsSoluble(G)`
`IsSolvable(G)`

Return `true` if the group G is soluble, `false` otherwise.

`IsSpecial(G)`

Given a p-group G, return `true` if G is special, `false` otherwise.

`IsSubnormal(G, H)`

Return `true` if the subgroup H of the group G is subnormal in G, `false` otherwise.

`IsTrivial(G)`

Return `true` if G is trivial, `false` otherwise.

57.9 Characteristic Subgroups and Normal Structure

57.9.1 Characteristic Subgroups and Subgroup Series

Some functions described in this section may not exist or may have restrictions for some categories of groups. Details can be found in the chapters on the individual categories.

`Centre(G)`
`Center(G)`

Construct the centre of the group G.

`Hypercentre(G)`
`Hypercenter(G)`

Construct the hypercentre of the group G (the stationary term of the upper central series).

`DerivedLength(G)`

The derived length of G. If G is non-soluble, the function returns the number of terms in the series terminating with the soluble residual.

`DerivedSeries(G)`

The derived series of the group G. The series is returned as a sequence of subgroups.

`DerivedSubgroup(G)`
`DerivedGroup(G)`

The derived subgroup of the group G.

`FittingSubgroup(G)`

The Fitting subgroup of the group G.

`FrattiniSubgroup(G)`

Given a group G that is a p-group, return the Frattini subgroup.

`JenningsSeries(G)`

Given a p-group G, return the Jennings series for G. The series is returned as a sequence of subgroups.

`LowerCentralSeries(G)`

The lower central series of G. The series is returned as a sequence of subgroups.

`NilpotencyClass(G)`

The nilpotency class of the group G. If the group is not nilpotent, the value -1 is returned.

`H ^ G`

`NormalClosure(G, H)`

The normal closure of the subgroup H of group G.

`NormalLattice(G)`

The normal subgroups of G arranged as a lattice.

`NormalSubgroups(G)`

The normal subgroups of G.

`pCentralSeries(G, p)`

Given a soluble group G, and a prime p dividing $|G|$, return the lower p-central series for G. The series is returned as a sequence of subgroups.

`Radical(G)`

The maximal normal solvable subgroup of the group G.

`SolubleResidual(G)`

`SolvableResidual(G)`

The solvable residual of the group G.

`SubnormalSeries(G, H)`

Given a group G and a subnormal subgroup H of G, return a sequence of subgroups commencing with G and terminating with H, such that each subgroup is normal in the previous one. If H is not subnormal in G, the empty sequence is returned.

`UpperCentralSeries(G)`

The upper central series of G. The series is returned as a sequence of subgroups commencing with the trivial subgroup. Since the algorithm used requires the conjugacy classes of G, this function is much more restricted in its range of application than `DerivedSeries` and `LowerCentralSeries`.

57.9.2 The Abstract Structure of a Group

`CompositionFactors(G)`

Given a finite group G in the category GrpPerm, GrpMat, GrpPC of GrpAb, return a sequence S of tuples that represent the composition factors of G, ordered according to some composition series of G. Each tuple is a triple of integers f, d, q that defines the isomorphism type of the corresponding composition factor. A triple $< f, d, q >$ describes a simple group as follows. The integer f defines the family to which the group belongs, and d and q are the parameters of the family. The length of the sequence S is the number of composition factors of G. The families are listed in Tables 1 and 2 on page 1495.

`AbelianInvariants(G)`

`Invariants(G)`

Given an abelian group G in the category GrpPerm, GrpMat, GrpPC of GrpAb, return a sequence Q containing the types of each p-primary component of G.

`AbelianBasis(G)`

Given an abelian group G in the category GrpPerm, GrpPC of GrpAb, return sequences B and I where I contains the types of each p-primary component of G and B contains corresponding elements of G which have the order given and generate G.

57.10 Conjugacy Classes of Elements

There are three aspects of the conjugacy problem for elements: determining whether two elements are conjugate in a group G, determining a set of representatives for the conjugacy classes of elements of G, and listing all the elements in a particular class of G. The algorithms used depend on the category of G. If G is in category GrpPerm or GrpMat, conjugacy is determined by means of a backtrack search over base-images. If G is in category GrpPC, testing conjugacy is performed by transforming each element into a standard representative of its conjugacy class by an orbit-stabilizer process that works down a sequence of increasing quotients of G. Conjugacy testing for a group G in category GrpGPC is only possible if G is nilpotent. In this case, an algorithm by E. Lo [Lo98] is used.

Some functions described in this section may not exist or may have restrictions for some categories of groups. Details can be found in the chapters on the individual categories.

`Class(H, x)`

`Conjugates(H, x)`

Given a group H and an element x belonging to a group K such that H and K are subgroups of the same symmetric group, this function returns the set of conjugates of x under the action of H. If $H = K$, the function returns the conjugacy class of x in H.

`ClassMap(G:` *parameters*`)`

Given a group G, construct the conjugacy classes and the class map f for G. For any element x of G, $f(x)$ will be the index of the conjugacy class of x in the sequence returned by the `Classes` function.

If G is a permutation group, the construction may be controlled using the parameters `Orbits`, `WeakLimit` and `StrongLimit`. If the parameter `Orbits` is set `true`, the classes are computed as orbits of elements under conjugation and the class map is stored as a list of images of the elements of G (a list of length $|G|$). This option gives fast evaluation of the class map but is practical only in the case of very small groups. With `Orbits := false`, `WeakLimit` and `StrongLimit` are used to control the random classes algorithm (see function `Classes`).

`ConjugacyClasses(G: parameters)`

`Classes(G: parameters)`

`WeakLimit`	RngIntElt	*Default :* 200
`StrongLimit`	RngIntElt	*Default :* 500
`Reps`	[GrpFinElt]	*Default :*
`Al`	MonStg	*Default :*

Construct a set of representatives for the conjugacy classes of G. The classes are returned as a sequence of triples containing the element order, the class length and a representative element for the class. The parameters `Reps` and `Al` enable the user to select the algorithm that is to be used when G is a permutation or matrix group.
`Reps := Q`: Create the classes of G by assuming that Q is a sequence of class representatives for G. The orders and lengths of the classes will be computed and checked for consistency.
`Al := "Action"`: Create the classes of G by computing the orbits of the set of elements of G under the action of conjugation. This option is only feasible for small groups.
`Al := "Random"`: Construct the conjugacy classes of elements for a permutation or matrix group G using an algorithm that searches for representatives of all conjugacy classes of G by examining a random selection of group elements and their powers. The behaviour of this algorithm is controlled by two associated optional parameters `WeakLimit` and `StrongLimit`, whose values are positive integers n_1 and n_2, say. Before describing the effect of these parameters, some definitions are needed: A mapping $f : G \to I$ is called a *class invariant* if $f(g) = f(g^h)$ for all $g, h \in G$. For permutation groups, the cycle structure of g is a readily computable class invariant. In matrix groups, the primary invariant factors are used where possible, or the characteristic or minimal polynomials otherwise. Two elements g and h are said to be *weakly conjugate* with respect to the class invariant f if $f(g) = f(h)$. By definition, conjugacy implies weak conjugacy, but the converse is false. The random algorithm first examines n_1 random elements and their powers, using a test for weak conjugacy. It then proceeds to examine a further n_2 random elements and their powers, using a test for ordinary conjugacy. The idea behind this strategy is that the algorithm should attempt to find as many classes as possible using the very cheap test for weak conjugacy, before employing the more expensive ordinary conjugacy test to recognize the remaining classes.
`Al := "Extend"`: Construct the conjugacy classes of G by first computing classes in a quotient G/N and then extending these classes to successively larger quotients G/H until the classes for $G/1$ are known. More precisely, a maximal series of subgroups $1 = G_0 < G_1 < \cdots < G_r = R < G$ is computed such that R is the (solvable) radical of G and G_{i+1}/G_i is elementary abelian. A representation of G/R is computed using an algorithm of Derek Holt and its classes computed and represented as elements of G. To extend to the next larger quotient, a group is computed from each class which acts on the transversal. Each distinct orbit in

that action gives rise to a new class. To compute the classes of G/R, the default algorithm (excluding the extension method) is used. The same set of parameters is passed on, so you can control limits in the random classes method if it is chosen. The limitations of the algorithm are that R may be trivial, in which case nothing is done except to call a different algorithm, or one or more of the sections may be so large as to prohibit computing the action on the transversal. This algorithm is currently only available for permutation groups.

`ClassRepresentative(G, x)`

Given a group G for which the conjugacy classes are known and an element x of G, return the designated representative for the conjugacy class of G containing x.

`IsConjugate(G, g, h)`

Given a group G and elements g and h belonging to G, return the value `true` if g and h are conjugate in G. The function returns a second value if the elements are conjugate: an element k which conjugates g into h.

`IsConjugate(G, H, K)`

Given a group G and subgroups H and K belonging to G, return the value `true` if G and H are conjugate in G. The function returns a second value if the subgroups are conjugate: an element z which conjugates H into K.

`Exponent(G)`

The exponent of the group G.

`NumberOfClasses(G)`
`Nclasses(G)`

The number of conjugacy classes of elements for the group G.

`PowerMap(G)`

Given a group G, construct the power map for G. Suppose that the order of G is m and that G has r conjugacy classes. When the classes are determined by MAGMA, they are numbered from 1 to r. Let C be the set of class indices $\{1, \ldots, r\}$. The *power map* f for G is the mapping

$$f : C \times \mathbf{Z} \to C$$

where the value of $f(i, j)$ for $i \in C$ and $j \in \mathbf{Z}$ is the number of the class which contains x_i^j, where x_i is a representative of the i-th conjugacy class.

Example H57E18

The conjugacy classes of the Mathieu group M_{11} can be constructed as follows:

```
> M11 := sub<Sym(11) | (1,10)(2,8)(3,11)(5,7), (1,4,7,6)(2,11,10,9)>;
> Classes(M11);
Conjugacy Classes of group M11
------------------------------
[1]     Order 1       Length 1
        Rep Id(M11)

[2]     Order 2       Length 165
        Rep (3, 10)(4, 9)(5, 6)(8, 11)

[3]     Order 3       Length 440
        Rep (1, 2, 4)(3, 5, 10)(6, 8, 11)

[4]     Order 4       Length 990
        Rep (3, 6, 10, 5)(4, 8, 9, 11)

[5]     Order 5       Length 1584
        Rep (1, 3, 6, 2, 8)(4, 7, 10, 9, 11)

[6]     Order 6       Length 1320
        Rep (1, 11, 2, 6, 4, 8)(3, 10, 5)(7, 9)

[7]     Order 8       Length 990
        Rep (1, 4, 5, 6, 2, 7, 11, 10)(8, 9)

[8]     Order 8       Length 990
        Rep (1, 7, 5, 10, 2, 4, 11, 6)(8, 9)

[9]     Order 11      Length 720
        Rep (1, 11, 9, 10, 4, 3, 7, 2, 6, 5, 8)

[10]    Order 11      Length 720
        Rep (1, 9, 4, 7, 6, 8, 11, 10, 3, 2, 5)
```

57.11 Conjugacy Classes of Subgroups

MAGMA contains a new algorithm for computing representatives of the conjugacy classes of subgroups. Let R denote the maximal normal soluble subgroup of the finite group G. The algorithm first constructs representatives for the conjugacy classes of subgroups of $Q = G/R$, and then successively extends these to larger and larger quotients of G until G itself is reached. If G is soluble, then Q is trivial and so its subgroups are known. If G is non-soluble, we attempt to locate the quotient in a database of groups with trivial Fitting subgroup. This database contains all such groups of order up to 216 000, and all such which are perfect of order up to 1 000 000. If Q is found then either all its subgroups, or its maximal subgroups are read from the database. (In some cases only the maximal subgroups are stored.) If Q is not found then we attempt to find the maximal subgroups of Q using a method of Derek Holt. For this to succeed all simple factors of the socle of Q must be found in a second database which currently contains all simple groups of order less than 1.6×10^7, as well as M_{24}, HS, J_3, McL, $Sz(32)$ and $L_6(2)$. There are also special routines to handle numerous other groups. These include: A_n for $n \leq 999$, $L_2(q)$, $L_3(q)$, $L_4(q)$ and $L_5(q)$ for all q, $S_4(q)$, $U_3(q)$ and $U_4(q)$ for all q, $L_d(2)$ for $d \leq 14$, and the following groups: $L_6(3)$, $L_7(3)$, $U_6(2)$, $S_8(2)$, $S_{10}(2)$, $O_8^{\pm}(2)$, $O_{10}^{\pm}(2)$, $S_6(3)$, $O_7(3)$, $O_8^-(3)$, $G_2(4)$, $G_2(5)$, ${}^3D_4(2)$, ${}^2F_4(2)'$, Co_2, Co_3, He, Fi_{22}.

If we have only maximal subgroups of Q, and more are required, we apply the algorithm recursively to the maximal subgroups to determine all subgroups of Q. This may take some time.

57.11.1 Conjugacy Classes of Subgroups

In this section we describe the functions that allow a user to create representatives of the conjugacy classes of subgroups, possibly subject to conditions. The main function, `Subgroups`, finds representatives for conjugacy classes of subgroups subject to certain user-supplied conditions on the order. The alternative functions `ElementaryAbelianSubgroups` and `AbelianSubgroups`, `CyclicSubgroups`, `NilpotentSubgroups`, `SolubleSubgroups`, `PerfectSubgroups`, `NonsolvableSubgroups`, `SimpleSubgroups` and `RegularSubgroups` allow the user to construct particular classes of subgroups.

Most of the features described in this section are currently only available for groups in the category `GrpPerm`, `GrpMat` or `GrpPC`.

`SubgroupClasses(G: parameters)`

`Subgroups(G: parameters)`

Representatives for the conjugacy classes of subgroups for the group G. The subgroups are returned as a sequence of records where the i-th record contains:

(a) A representative subgroup H for the i-th conjugacy class (field name `subgroup`).

(b) The order of the subgroup (field name `order`).

(c) The number of subgroups in the class (field name `length`).

(d) [Optionally] A presentation for H (field name `presentation`).

`Presentation` BOOLELT *Default :* `false`

`Presentation := true`: In the case in which G is a permutation group, construct a presentation for each subgroup.

`OrderEqual` RngIntElt *Default :*

`OrderEqual := n`: Only construct subgroups having order equal to n.

`OrderDividing` RngIntElt *Default :*

`OrderDividing := n`: Only construct subgroups having order dividing n.

`IsNormal` BoolElt *Default :* `false`

`IsNormal := true`: Only construct normal subgroups.

`IsRegular` BoolElt *Default :* `false`

`IsRegular := true`: In the case in which G is a permutation group, only construct regular subgroups.

`LayerSizes` SeqEnum *Default :* see below

`LayerSizes := [ 2, 5, 3, 4, 7, 3, 11, 2, 17, 1]` is equivalent to the default. When constructing an Elementary Abelian series for the group, attempt to split 2-layers of size gt 2^5, 3-layers of size gt 3^4, etc. The implied exponent for 13 is 2 and for all primes greater than 17 the exponent is 1.

`ElementaryAbelianSubgroups(G: parameters)`

Representatives for the conjugacy classes of elementary abelian subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`AbelianSubgroups(G: parameters)`

Representatives for the conjugacy classes of abelian subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`CyclicSubgroups(G: parameters)`

Representatives for the conjugacy classes of cyclic subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`NilpotentSubgroups(G: parameters)`

Representatives for the conjugacy classes of nilpotent subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`SolubleSubgroups(G: parameters)`

`SolvableSubgroups(G: parameters)`

Representatives for the conjugacy classes of solvable subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`NonsolvableSubgroups(G: parameters)`

Representatives for the conjugacy classes of nonsolvable subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`PerfectSubgroups(G: parameters)`

Representatives for the conjugacy classes of perfect subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`SimpleSubgroups(G: parameters)`

Representatives for the conjugacy classes of non-abelian simple subgroups for the group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`RegularSubgroups(G: parameters)`

Representatives for the conjugacy classes of regular subgroups for the permutation group G. The subgroups are returned as a sequence of records having the same format as `Subgroups`. The optional parameters are also the same as for `Subgroups`.

`SetVerbose("SubgroupLattice", i)`

Turn on verbose printing for the subgroup algorithm. The level i can be 2 for maximal printing or 1 for moderate printing. The algorithm works down an elementary abelian series of the group and at each level, the possible extensions of each subgroup are listed.

`Class(G, H)`

`Conjugates(G, H)`

The G-conjugacy class of subgroups containing the group H.

Example H57E19

We construct the conjugacy classes of subgroups for the dihedral group of order 12.

```
> G := DihedralGroup(6);
> S := Subgroups(G);
> S;
Conjugacy classes of subgroups
------------------------------
[ 1]    Order 1            Length 1
        Permutation group acting on a set of cardinality 6
        Order = 1
          Id($)
[ 2]    Order 2            Length 3
        Permutation group acting on a set of cardinality 6
          (2, 6)(3, 5)
[ 3]    Order 2            Length 3
        Permutation group acting on a set of cardinality 6
          (1, 4)(2, 3)(5, 6)
[ 4]    Order 2            Length 1
        Permutation group acting on a set of cardinality 6
          (1, 4)(2, 5)(3, 6)
[ 5]    Order 3            Length 1
        Permutation group acting on a set of cardinality 6
          (1, 5, 3)(2, 6, 4)
[ 6]    Order 4            Length 3
        Permutation group acting on a set of cardinality 6
          (2, 6)(3, 5)
          (1, 4)(2, 5)(3, 6)
[ 7]    Order 6            Length 1
        Permutation group acting on a set of cardinality 6
          (1, 5, 3)(2, 6, 4)
          (1, 4)(2, 5)(3, 6)
[ 8]    Order 6            Length 1
        Permutation group acting on a set of cardinality 6
          (2, 6)(3, 5)
          (1, 5, 3)(2, 6, 4)
[ 9]    Order 6            Length 1
        Permutation group acting on a set of cardinality 6
          (1, 4)(2, 3)(5, 6)
          (1, 5, 3)(2, 6, 4)
[10]    Order 12           Length 1
        Permutation group acting on a set of cardinality 6
          (2, 6)(3, 5)
          (1, 5, 3)(2, 6, 4)
          (1, 4)(2, 5)(3, 6)
> // We extract the representative subgroup for class 7
> h := S[7]`subgroup;
> h;
```

```
Permutation group h acting on a set of cardinality 6
    (1, 3, 5)(2, 4, 6)
    (1, 4)(2, 5)(3, 6)
```

57.11.2 The Poset of Subgroup Classes

In addition to finding representatives for conjugacy classes of subgroups, MAGMA allows the user to create the poset L of subgroup classes. The elements of the poset correspond to the conjugacy classes of subgroups. Two lattice elements a and b are joined by an edge if either some subgroup of the conjugacy class a is a maximal subgroup of some subgroup of conjugacy class b or vice-versa. The elements of L are called *subgroup-poset elements* and are numbered from 1 to n, where n is the cardinality of L. Various functions allow the user to identify maximal subgroups, normalizers, centralizers and other relatives in the lattice. Given an element e of L, one can easily create the subgroup H of G corresponding to e and one can also create the element of L corresponding to a subgroup of G.

The features described in this section are currently only available for groups in the category GrpPerm or GrpPC.

57.11.2.1 Creating the Poset of Subgroup Classes

`SubgroupLattice(G)`

Create the poset L of subgroup classes of G.

`Properties` BOOLELT *Default :* `false`

`Properties := true`: As the subgroup classes are put into the poset, record their abstract type, i.e., elementary abelian, abelian, nilpotent, soluble, simple or perfect.

`Centralizers` BOOLELT *Default :* `false`

`Centralizers := true`: As each subgroup class e is put into the poset, record the class in which the centralizers of the subgroups of e lie.

`Normalizers` BOOLELT *Default :* `false`

`Normalizers := true`: As each subgroup class e is put into the poset, record the class in which the normalizers of the subgroups of e lie.

Example H57E20

We create the subgroup poset for the group ASL$(2, 3)$.

```
> G := ASL(2, 3);
> L := SubgroupLattice(G : Properties := true, Normalizers:= true,
>                            Centralizers:= true);
> L;
Partially ordered set of subgroup classes
----------------------------------------

[ 1]  Order 1 Length 1 C = [20] N = [20]
```

```
      Maximal Subgroups:
---
[ 2]  Order 2 Length 9 Cyclic. C = [16] N = [16]
      Maximal Subgroups: 1
[ 3]  Order 3 Length 12 Cyclic. C = [14] N = [14]
      Maximal Subgroups: 1
[ 4]  Order 3 Length 24 Cyclic. C = [10] N = [10]
      Maximal Subgroups: 1
[ 5]  Order 3 Length 4 Cyclic. C = [15] N = [18]
      Maximal Subgroups: 1
---

```

57.11.2.2 Operations on Subgroup Class Posets

In the following, L is the poset of subgroup classes for a group G.

`#L`

The cardinality of L, i.e., the number of conjugacy classes of subgroups of G.

`L ! i`

Create the i-th element of the poset L. The elements of L are sorted so that classes i and j of groups whose orders o_i and o_j are the products of e_i and e_j prime numbers respectively will be ordered so that i comes before j is $e_i < e_j$ or $e_i = e_j$ and $o_i < o_j$.

`L ! H`

Create the element of the poset L corresponding to the subgroup H of the group G.

`Bottom(L)`

Create the bottom of the poset L, i.e., the element of L corresponding to the trivial subgroup of G. If the poset was created with restrictions on the type of subgroups constructed, the bottom of the poset may not be the trivial subgroup.

`Top(L)`

Create the top of the poset L, i.e., the element of L corresponding to G.

`Random(L)`

Create a random element of L.

Example H57E21

We create the subgroup lattice of $A\Gamma L(1, 8)$ and locate the Fitting subgroup in the lattice.

```
> G := AGammaL(1, 8);
> L := SubgroupLattice(G);
> L;

Subgroup Lattice
----------------

[ 1]  Order 1 Length 1
      Maximal Subgroups:
---
[ 2]  Order 2 Length 7
      Maximal Subgroups: 1
[ 3]  Order 3 Length 28
      Maximal Subgroups: 1
[ 4]  Order 7 Length 8
      Maximal Subgroups: 1
---
[ 5]  Order 4 Length 7
```

```
      Maximal Subgroups: 2
[ 6]  Order 6 Length 28
      Maximal Subgroups: 2 3
[ 7]  Order 21 Length 8
      Maximal Subgroups: 3 4
---
[ 8]  Order 8 Length 1
      Maximal Subgroups: 5
[ 9]  Order 12 Length 7
      Maximal Subgroups: 3 5
---
[10]  Order 24 Length 7
      Maximal Subgroups: 6 8 9
[11]  Order 56 Length 1
      Maximal Subgroups: 4 8
---
[12]  Order 168 Length 1
      Maximal Subgroups: 7 10 11

> F := FittingSubgroup(G);
> F;
Permutation group F acting on a set of cardinality 8
Order = 8 = 2^3
    (1, 2)(3, 6)(4, 8)(5, 7)
    (1, 6)(2, 3)(4, 7)(5, 8)
    (1, 5)(2, 7)(3, 4)(6, 8)
> L!F;
8
```

We now construct a chain from the bottom to the top of the lattice.

```
> H := Bottom(L);
> Chain := [H];
> while H ne Top(L) do
>     H := Representative(MinimalOvergroups(H));
>     Chain := Append(Chain, H);
> end while;
> Chain;
[ 1, 2, 5, 8, 10, 12 ]
```

57.11.2.3 Operations on Poset Elements

In the following, L is the poset of subgroups for a group G. Elements of L are identified with the integers $[1..\#L]$.

`IntegerRing() ! e`

The integer corresponding to poset element e.

`e eq f`

Returns `true` if and only if poset elements e and f are equal.

`e ge f`

Returns `true` if and only if poset element e contains poset element f.

`e ge f`

Returns `true` if and only if poset element e strictly contains poset element f.

`e le f`

`e subset f`

Returns `true` if and only if poset element e is contained in poset element f.

`e lt f`

Returns `true` if and only if poset element e is strictly contained in poset element f.

57.11.2.4 Class Information from a Conjugacy Class Poset

In the following, L is the poset of subgroups for a group G. Elements of L are identified with the integers $[1..\#L]$.

`Group(e)`

The subgroup of G that is the chosen class representative corresponding to the element e of the poset L.

`Centraliser(e, f)`

`Centralizer(e, f)`

Given poset elements e and f, return the poset element that corresponds to the class of subgroups that contains the centralizers of the subgroups of class f (taken in a subgroup of class e). If no subgroup of class f lies in class e, the construction fails.

`Normaliser(e, f)`

`Normalizer(e, f)`

Given poset elements e and f, return the poset element that corresponds to the class of subgroups that contain the normalizers of the subgroups of class f (taken in a subgroup of class e). If no subgroup of class f lies in class e, the construction fails.

`Length(e)`

The number of subgroups in the class corresponding to e.

`Order(e)`

The order of the subgroup of G corresponding to e.

`MaximalSubgroups(e)`

The maximal subgroups of e, returned as a set of poset elements.

`MinimalOvergroups(e)`

The minimal overgroups of e, returned as a set of poset elements.

`NumberOfInclusions(e, f)`

The number of elements of the conjugacy class of subgroups e that lie in a fixed representative of the conjugacy class of subgroups f.

57.12 Cohomology

In the following description, G is a group in the category `GrpPerm`, p is a prime number, and K is the finite field of order p. Further, F is a finitely presented group having the same number of generators as G, and is such that its relations are satisfied by the corresponding generators of G. In other words, the mapping taking the i-th generator of F to the i-th generator of G must be an epimorphism. Usually this mapping will be an isomorphism, although this is not mandatory.

`pMultiplicator(G, p)`

Given the group G and a prime p, return the invariant factors of the p-part of the Schur multiplicator of G.

`pCover(G, F, p)`

Given the group G and the finitely presented group F such that G is an epimorphic image of G in the sense described above, return a presentation for the p-cover of G, constructed as an extension of the p-multiplier by F.

`CohomologicalDimension(G, M, i)`

Given the group G, the $K[G]$-module M and an integer i (equal to 1 or 2), return the dimension of the i-th cohomology group of G acting on M.

`ExtensionProcess(G, M, F)`

Create an extension process for the group G by the module M.

`Extension(P, Q)`

`#NextExtension(P)`

Return the next extension of G as defined by the process P.
Assume that F is isomorphic to the permutation group G, and that we wish to determine presentations for one or more extensions of the K-module M by F, where K is the field of p elements. We first create an extension process using `ExtensionProcess(G, M, F)`. The possible extensions of M by G are in one-one correspondence with the elements of the second cohomology group $H^2(G, M)$ of G acting on M. Let $b_1, \ldots, b_l$ be a basis of $H^2(G, M)$. A general element of $H^2(G, M)$ therefore has the form $a_1b_1 + \cdots + a_lb_l$ and so can be defined by a sequence Q of l integers $[a_1, \ldots, a_l]$. Now, to construct the corresponding extension of M by G we call the function `Extension(P, Q)`. The required extension is returned as a finitely presented group. If all the extensions are required then they may be obtained successively by making p^l calls to the function `NextExtension`.

`SplitExtension(G, M, F)`

The split extension of the module M by the group G.

57.13 Characters and Representations

A set of functions are provided for computing with the characters and representations of a group. A full account of the character functions may be found in Chapter 91. Full details of the functions for constructing and analyzing representations may be found in Chapter 89. For the reader's convenience we include here a description of the basic functions for creating characters and representations.

Some functions described in this section may be missing or may have slightly different calling sequences for some categories of groups. For a complete description of the features available for a special category of groups, we refer to the chapter devoted to that category.

57.13.1 Character Theory

`CharacterDegrees(G)`

Given a finite pc-group G, return the sequence $[\langle d_1, c_1\rangle, langled_2, c_2\rangle, \ldots]$, where c_i is the number of irreducible characters of G having degree d_i. For details of the algorithm see Conlon [Con90b].

`CharacterTable(G)`

Construct the table of irreducible characters for the group G.

`PermutationCharacter(G)`

Given a group G represented as a permutation group, construct the character of G afforded by the defining permutation representation of G.

`PermutationCharacter(G, H)`

Given a group G and some subgroup H of G, construct the ordinary character of G afforded by the permutation representation of G given by the action of G on the coset space of the subgroup H in G.

57.13.2 Representation Theory

We describe the main functions for creating $K[G]$-modules for finite groups. The machinery for working with these modules is described in Chapter 89.

`GModule(G, S)`

Let G be a group defined on r generators and let S be a subalgebra of the matrix algebra $M_n(R)$, also defined by r non-singular matrices. It is assumed that the mapping from G to S defined by $\phi : G.i \mapsto S.i$, for $i = 1, \ldots, r$, extends to a group homomorphism. Let M be the natural module for the matrix algebra S. The function `GModule` gives M the structure of an $S[G]$-module, where the action of the i-th generator of G on M is given by the i-th generator of S.

`GModule(G, A, B)`

Given a finite group G, a normal subgroup A of G and a normal subgroup B of A such that the section A/B is elementary abelian of order p^n, create the $K[G]$-module M corresponding to the action of G on A/B, where K is the field $\mathbf{F}_p$. If B is trivial, it may be omitted. The function returns:

(a) the module M; and,

(b) the homomorphism $\phi : A/B \to M$.

`PermutationModule(G, H, R)`

Given a finite group G and a ring R, create the $R[G]$-module for G corresponding to the permutation action of G on the cosets of H.

`PermutationModule(G, R)`

Given a finite permutation group G and a ring R, create the natural permutation module for G over R.

Example H57E22

The permutation module for the group M_{10} over $GF(2)$ may be created as follows:

```
> m10 := PermutationGroup< 10 |  (1, 3, 9, 10, 2, 8, 7, 6, 4, 5),
>                                (1, 7)(2, 4, 3, 6, 8, 10, 9, 5) >;
> p := PermutationModule(m10, GF(2));
> p : Maximal;

GModule p of dimension 10 over GF(2)
Generators of acting algebra:
```

```
[0 0 1 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 0 1 0]
[0 0 0 0 1 0 0 0 0 0]
[1 0 0 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0]
[0 0 0 0 0 0 0 0 0 1]
[0 1 0 0 0 0 0 0 0 0]

[0 0 0 0 0 0 1 0 0 0]
[0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 0 1 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 1 0 0]
[1 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 1]
[0 0 0 0 1 0 0 0 0 0]
[0 0 0 0 0 0 0 0 1 0]
```

Example H57E23

The group G defined below is the split extension of an elementary abelian group E of order 16 by $Alt(6)$. After setting up the group, we construct the module M for G corresponding to its action on E.

```
> G := PermutationGroup< 16 |
>         (1, 15, 7, 5, 12)(2, 9, 13, 14, 8)(3, 6, 10, 11, 4),
>         (1, 4, 5)(2, 8, 10)(3, 12, 15)(6, 13, 11)(7, 9, 14),
>         (1, 16)(2, 3)(4, 5)(6, 7)(8, 9)(10, 11)(12, 13)(14, 15) >;
> CS := ChiefSeries(G);
> [ Order(H) : H in CS ];
[ 5760, 16, 1 ]
> M := GModule(G, CS[2]);
> M:Maximal;

GModule M of dimension 4 over GF(2)
Generators of acting algebra:

[0 1 0 0]
[0 1 1 0]
[0 0 1 1]
[1 0 0 1]

[0 0 1 0]
[0 0 0 1]
```

```
[1 0 1 0]
[0 1 0 1]

[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
```

57.14 Databases of Groups

MAGMA contains the following databases of groups:

Small Groups: Contains all groups of order up to 1000, excluding orders 512 and 768.

Perfect Groups: This database contains all perfect groups up to order 50000, and many classes of perfect groups up to order one million. Each group is defined by means of a finite presentation. Further information is also provided which allows the construction of permutation representations.

Rational Maximal Matrix Groups: Contains rational maximal finite matrix groups and their invariant forms, for small dimensions (up to 31 at V2.9 and above). Each entry can be accessed either as a matrix group or as a lattice.

Quaternionic Matrix Groups: A database of the finite absolutely irreducible subgroups of $\mathrm{GL}_n(\mathcal{D})$ where $\mathcal{D}$ is a definite quaternion algebra whose centre has degree d over $\mathbf{Q}$ and $nd \leq 10$. Each entry can be accessed either as a matrix group or as a lattice.

Transitive Permutation Groups: MAGMA has a database containing all transitive permutation groups having degree up to 22.

Primitive Permutation Groups: MAGMA has a database containing all primitive permutation groups having degree up to 50.

For a description of these databases, we refer to Chapter 66.

58 PERMUTATION GROUPS

Chapter 58
PERMUTATION GROUPS

58.1 Introduction

58.1.1 Terminology

A permutation group G is a group of bijections $X \to X$, for some set X. The group G is said to *act* on X and the elements of G are called permutations (of the set X). A given permutation group G may have actions on sets other than the one on which it is defined. Thus, any set upon which G has a legitimate action will be called a G-set. The set X is called the *natural G-set* for the group G, and the action of G on X is called the *natural action* of G. Note that the group G also has a natural induced action on the G-closure of any *derived set* of X (see Section 14.8.1). MAGMA expects the G-set X to be of finite cardinality n. Usually, X will be $\{1, 2, \ldots, n\}$, but, as we shall see below, X may be a set of strings, or any other legitimate MAGMA set.

The elements of a G-set are called *points*. Let Y be a G-set for G. The (possibly empty) subset of Y whose points are fixed by every permutation of G, is called the *fixed-point set* for G, while the subset of Y consisting of points moved by some permutation of G is called the *support* of G. Similarly, for an element g of G the *fixed-point set* and the *support* of g are, respectively, the subsets of Y consisting of the points fixed and moved by g. The *degree* of G is defined to be the cardinality of the natural G-set of G; whereas the *degree* of an element g of G is defined to be the cardinality of the support of g, i.e. the number of points moved by g.

Permutation groups in MAGMAare limited to degree less than 2^{30}.

58.1.2 The Category of Permutation Groups

The family of all permutation groups of finite degree forms a category. The objects are the permutation groups and the morphisms are group homomorphisms. The MAGMA designation for this category of permutation groups is `GrpPerm`.

58.1.3 The Construction of a Permutation Group

Every permutation group acting on a set X is created as a subgroup of the symmetric group $\mathrm{Sym}(X)$. Thus, the construction of a general permutation group is a two-step process:

(i) The appropriate symmetric group, $\mathrm{Sym}(X)$, is constructed;

(ii) The required group G is then defined as a subgroup of $\mathrm{Sym}(X)$.

For convenience, a constructor `PermutationGroup< ... >`, which combines these two steps, is provided.

58.2 Creation of a Permutation Group

58.2.1 Construction of the Symmetric Group

`Sym(n)`

`SymmetricGroup(n)`

Given an integer $n \geq 1$, create the generic permutation group acting on the natural G-set $\Omega = \{1, 2, \ldots, n\}$, i.e. the symmetric group $\mathrm{Sym}(\Omega)$. Initially, only a structure table is created for $\mathrm{Sym}(n)$, so that, in particular, generators are not defined. This function is normally used to provide a context for the creation of elements and subgroups of $\mathrm{Sym}(n)$. If structural computation is attempted with the group created by `Sym(n)`, then generators will be created dynamically.

`Sym(X)`

`SymmetricGroup(X)`

Given a finite set X of cardinality $n \geq 1$, create the generic group G of permutations of X – the symmetric group $\mathrm{Sym}(X)$. Initially, only a structure table is created for $\mathrm{Sym}(X)$, so that, in particular, generators are not defined. This function is normally used to provide a context for the creation of elements and subgroups of $\mathrm{Sym}(X)$. If structural computation is attempted with the group created by `Sym(X)`, then generators will be created dynamically. Although the group G is defined on the set X, G is represented internally as a group of permutations of the set $\Omega = \{1, 2, \ldots, n\}$. Translation between X and Ω is done at input/output time. The precise representation can be found by using the `Labelling` function. If X is an indexed set then the indexing of elements of X determines the correspondence.

`StandardGroup(G)`

Return a group H isomorphic to G, but acting on the standard set $\{ 1, \ldots, n\}$. This function is useful when the natural G-set for G is not the standard set. If the natural G-set for G is the standard set, G is returned. The isomorphism from G to H is also returned.

Example H58E1

We define the symmetric group on the set of strings { "*a*" "*b*" "*c*" "*d*" }:

```
> S4 := Sym({ "a", "b", "c", "d" });
> S4;
Symmetric group S4 acting on a set of cardinality 4
Order = 24 = 2^3 * 3
> GSet(S4);
GSet{@ c, b, a, d @}
```

We define the symmetric group of degree 10 acting on the set $\{0, 1, \ldots, 9\}$.

```
> G := Sym({ 0..9 });
```

```
> G;
Symmetric group G acting on a set of cardinality 10
Order = 3628800 = 2^8 * 3^4 * 5^2 * 7
> GSet(G);
GSet{@ 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 @}
```

58.2.2 Construction of a Permutation

Throughout this subsection we shall assume that the permutation group G has natural G-set X.

`elt< G | L >`

Given a permutation group G defined as acting on the set $X = \{x_1, \ldots, x_n\}$ of cardinality $n \geq 1$, and a list L of distinct elements $a_1, a_2, \ldots, a_n$ of X, construct the element g of G defined by $x_i \to a_i$, for $i = 1, \ldots, n$. Unless G is known to be the generic permutation group of degree n, the permutation will be tested for membership of G, and if g is not an element of G, the function will fail. If g does lie in G, g will have G as its parent. Since the membership test may involve constructing a base and strong generating set for G, this constructor may occasionally be very costly. Hence, a permutation g should be defined as an element of a subgroup of the generic group only when membership of G is required by subsequent operations involving g.

`G ! Q`

Given a permutation group G defined as acting on the set $X = \{x_1, \ldots, x_n\}$ of cardinality $n \geq 1$, and a sequence $Q = [a_1, a_2, \ldots, a_n]$ of distinct elements of X, construct the permutation g of X defined by $x_i \to a_i$, for $i = 1, \ldots, n$. This permutation will have G as its parent structure. As in the case of the `elt`-constructor, the operation will fail if g is not an element of G and the same observations concerning the cost of membership testing apply.

`G ! (...)(...)...(...)`

Given a permutation group G defined as acting on the set $X = \{x_1, x_2, \ldots, x_n\}$, construct the permutation g corresponding to the given product of cycles. Adjacent letters must be separated by commas. Further, *cycles of length one must be omitted*. The coercion operator ! may be omitted only within the context of the standard constructors `sub<>`, `ncl<>` and `quo<>`. Once the permutation g has been constructed, it will be tested for membership in G. If it is not a member, the construction fails.

`G ! \(...)(...)...(...)`

Given a permutation group G defined as acting on the set $X = \{1..n\}$, construct the permutation g corresponding to the given product of literal cycles of integers. Adjacent integers must be separated by commas. Once the permutation g has been constructed, it will be tested for membership in G. If it is not a member, the construction fails. This construction is strongly recommended when creating large permutations to avoid overhead in constructing unnecessarily large parse trees by MAGMA.

`G ! Q`

Given a permutation group G defined as acting on the set $X = \{1..n\}$, construct the permutation g corresponding to the given product of cycles. The indexed sets in Q must be disjoint subsets of X, which are interpreted as the disjoint cycles of the permutation being constructed. Cycles of length 1 may be omitted, but do not have to be omitted. Once the permutation g has been constructed, it will be tested for membership in G. If it is not a member, the construction fails. Note that the `Cycle` function produces results suitable for use as members of Q.

`ElementToSequence(g)`

`Eltseq(g)`

The sequence Q of images of the G-set of g. In particular, it has the property that `Parent(g)!Eltseq(g) eq g`.

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity permutation in the permutation group G.

Example H58E2

The three different constructions are illustrated by the following code, which assigns to each of the variables x, y and z the permutation (1)(2,3)(4,5,6).

```
> S6 := Sym(6);
> x := elt<S6 | 1,3,2,5,6,4>;
> x;
(2, 3)(4, 5, 6)
> y := S6![1,3,2,5,6,4];
> y;
(2, 3)(4, 5, 6)
> z := S6!(2,3)(4,5,6);
> z;
(2, 3)(4, 5, 6)
> S6!1;
Id(S6)
```

58.2.3 Construction of a General Permutation Group

`PermutationGroup< X | L >`

Suppose that the cardinality of the set X is n. Construct the permutation group G acting on the set X generated by the permutations defined by the list L. A term of the list L must be an object of one of the following types:

(a) A sequence of n elements of X defining a permutation of X (note that this is only well-defined when X is an indexed set);

(b) A set or sequence of sequences of type (a);

(c) An element of $\mathrm{Sym}(X)$;

(d) A set or sequence of elements of $\mathrm{Sym}(X)$;

(e) A subgroup of $\mathrm{Sym}(X)$;

(f) A set or sequence of subgroups of $\mathrm{Sym}(X)$.

Each element or group specified by the list must belong to the *same* generic permutation group. The group G will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of G consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list.

The `PermutationGroup` constructor is shorthand for the two statements:

```
SX := Sym(X); G := sub< SX | L >;
```

where `sub< ... >` is the subgroup constructor described in the next subsection.

`PermutationGroup< n | L >`

Construct the permutation group G acting on the set $X = \{1, 2, \ldots, n\}$ generated by the permutations defined by the list L. The possibilities for the terms of the list L are the same as for the constructor `PermutationGroup< X | L >`.

Example H58E3

The Hessian group generated by the permutations $(1,2,4)(5,6,8)(3,9,7)$ and $(4,5,6)(7,9,8)$ may be created by the statement:

```
> H := PermutationGroup< 9 | (1,2,4)(5,6,8)(3,9,7), (4,5,6)(7,9,8) >;
> H;
Permutation group H acting on a set of cardinality 9

       (4, 5, 6)(7, 9, 8)
```

58.3 Elementary Properties of a Group

58.3.1 Accessing Group Information

The functions in this group provide access to basic information stored for a permutation group G.

`G . i`

The i-th defining generator for G. A negative subscript indicates that the inverse of the generator is to be created. The identity element of G will be created by $G.0$.

`Degree(G)`

The degree of the permutation group G.

`Generators(G)`

A set of elements of G that generate G.

`GeneratorsSequence(G)`

The sequence of elements used to define the group G. Any occurrences of the identity element or any repetitions of a generator, as removed by `Generators(G)`, are retained in this sequence. This function has the same effect as the expression `[G.i : i in [1..Ngens(G)]]` .

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for G.

`FewGenerators(G)`

A typically short sequence of random elements generating the group. Especially when groups are generated as subgroups, the result of `FewGenerators` is a much shorter sequence than returned by `GeneratorsSequence`.

`Generic(G)`

The generic group containing G, i.e. the symmetric group in which G is naturally embedded.

`Parent(g)`

The parent group G for the permutation g.

`GSet(G)`

The natural G-set for the permutation group G.

Example H58E4

Consider the group G of order 648 generated by the permutations (1,6,7)(2,5,8,3,4,9)(11,12) and (1,3)(4,9,12)(5,8,10,6,7,11).

```
> G := PermutationGroup< 12 | (1,6,7)(2,5,8,3,4,9)(11,12),
>                             (1,3)(4,9,12)(5,8,10,6,7,11) >;
> G;
Permutation group G acting on a set of cardinality 12
    (1, 6, 7)(2, 5, 8, 3, 4, 9)(11, 12)
    (1, 3)(4, 9, 12)(5, 8, 10, 6, 7, 11)
> G.1;
(1, 6, 7)(2, 5, 8, 3, 4, 9)(11, 12)
> G.1*G.2;
(1, 7, 3, 9, 2, 8)(4, 12, 5, 10, 6, 11)
> Degree(G);
12
> GSet(G);

    (1, 6, 7)(2, 5, 8, 3, 4, 9)(11, 12)
    (1, 3)(4, 9, 12)(5, 8, 10, 6, 7, 11)
]
```

58.3.2 Group Order

Unless the order is already known, each of the functions in this family will create a base and strong generating set for the group if one does not already exist.

`Order(G)`
`#G`

The order of the group G as an integer. If the order is not currently known, a base and strong generating set will be constructed for G.

`FactoredOrder(G)`

The order of the group G returned as a factored integer. The factorization is returned in the form of a sequence Q which is defined as follows: If $\#G = p_1^{e_1} \dots p_n^{e_n}, \quad e_i \neq 0$, then Q will be the integer sequence $[< p_1, e_1 >, \dots, < p_n, e_n >]$. If the order of G is not known, it will be computed.

58.3.3 Abstract Properties of a Group

`IsAbelian(G)`

Returns `true` if the group G is abelian, `false` otherwise.

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise.

`IsSpecial(G)`

Given a p-group G, return `true` if G is special, `false` otherwise.

`IsExtraSpecial(G)`

Given a group G is a p-group G, return `true` if G is extra-special, `false` otherwise.

`IsNilpotent(G)`

Returns `true` if the group G is nilpotent, `false` otherwise.

`IsSoluble(G)`
`IsSolvable(G)`

Returns `true` if the group G is soluble, `false` otherwise. Uses the algorithm of Sims [Sim90].

`IsPerfect(G)`

Returns `true` if the group G is perfect, `false` otherwise.

`IsSimple(G)`

Returns `true` if the group G is simple, `false` otherwise.

`IsWreathProduct(G)`

Returns `true` if the group G is isomorphic to a wreath product $A \wr B$, where B is transitive, and `false` otherwise. If true, then three subgroups of G, call them A, B, C, are also returned. In this case we have G isomorphic to `WreathProduct(A, CosetImage(B, C))`.

Example H58E5

We determine the orders of those subgroups of the Mathieu group M_{24} which are perfect but not simple. We use the function `PerfectSubgroups` which returns a representative from each conjugacy class of perfect subgroups.

```
> load m24;
Loading "/home/magma/libs/pergps/m24"
M24 - Mathieu group on 24 letters - degree 24
Order 244 823 040 = 2^10 * 3^3 * 5 * 7 * 11 * 23;  Base 1,2,3,4,5,6,7
Group: G
> time S := PerfectSubgroups(G);
Time: 29.460
> [ Order(H) : R in S | not IsSimple(H) where H := R`subgroup ];
[ 120, 120, 120, 180, 180, 240, 240, 336, 336, 336, 336, 504, 720, 1008, 1080,
  960, 960, 960, 1344, 1344, 1344, 1920, 2688, 2688, 2688, 2688, 2688, 2880,
  3840, 3840, 5760, 10752, 11520, 11520, 40320, 21504, 21504, 32256, 64512,
  69120, 322560 ]
```

58.4 Homomorphisms

Homomorphisms are a central concept in group theory, and MAGMA provides extensive facilities for group homomorphisms. Many useful homomorphisms are returned by constructors and intrinsic functions. Examples of these are the `quo` constructor, the `sub` constructor and intrinsic functions such as `OrbitAction`, `BlocksAction`, `FPGroup` and `RadicalQuotient`, which are described in more detail elsewhere in this chapter. In this section we describe how the user may create their own homomorphisms with domain a permutation group.

`hom< G -> H | L >`

Given the permutation group G, construct the homomorphism $f : G \to H$ given by the generator images in L. H must be a group. The clause L may be any one of the following types:

(a) A list of elements of H, giving images of the generators of G;

(b) A list of pairs, where the first in the pair is an element of G and the second its image in H;

(c) A sequence of elements of H, as in (a);

(d) A set or sequence of pairs, as in (b);

Each image element specified by the list must belong to the *same* group H. In the cases where pairs are given the given elements of G must generate G.

`Domain(f)`

The domain of the homomorphism f.

`Codomain(f)`

The codomain of the homomorphism f.

`Image(f)`

The image or range of the homomorphism f. This will be a subgroup of the codomain of f. The algorithm computes the image and kernel simultaneously (see [LGPS91]).

`Kernel(f)`

The kernel of the homomorphism f. This will be a normal subgroup of the domain of f. The algorithm computes the image and kernel simultaneously (see [LGPS91]).

`IsHomomorphism(G, H, Q)`

Return the value `true` if the sequence Q defines a homomorphism from the group G to the group H. The sequence Q must have length `Ngens(G)` and must contain elements of H. The i-th element of Q is interpreted as the image of the i-th generator of G and the function decides if these images extend to a homomorphism. If so, the homomorphism is also returned. The algorithm employed is described in [LGPS91].

Example H58E6

Consider the group G of order 648 generated by the permutations (1,6,7)(2,5,8,3,4,9)(11,12) and (1,3)(4,9,12)(5,8,10,6,7,11). We construct a permutation representation of G of degree 8 by considering the conjugation action of G on one of its elements. We then construct the preimage of a normal subgroup of the image.

```
> G := PermutationGroup< 12 | (1,6,7)(2,5,8,3,4,9)(11,12),
>                             (1,3)(4,9,12)(5,8,10,6,7,11) >;
> #G;
648
> x := G ! (1, 2, 3)(7, 8, 9)(10, 11, 12);
> x_class := {@ x ^ y : y in G @};
> #x_class;
8
> S := SymmetricGroup(8);
> images := [S![Index(x_class, x_class[i]^(G.j)):i in [1..8]] :j in [1..2]];
> f := hom< G -> S | images>;
```

The map f is the homomorphism of G onto the group induced by the action of the element x. We computer the images of some elements and then find the image and kernel of f.

```
> (G.1*G.-2) @ f;
(2, 5, 7)(3, 8, 6)
> ((G.1) @ f) * ((G.2) @ f) ^ -1;
(2, 5, 7)(3, 8, 6)
> H := Image(f);
> H;
Permutation group acting on a set of cardinality 8
Order = 24 = 2^3 * 3
  (1, 2, 3, 4, 6, 5)(7, 8)
  (1, 2, 8, 4, 6, 7)(3, 5)
> Kernel(f);
Permutation group acting on a set of cardinality 12
Order = 27 = 3^3
  (1, 2, 3)(4, 6, 5)(7, 8, 9)(10, 12, 11)
  (4, 5, 6)(7, 9, 8)
  (7, 9, 8)(10, 11, 12)
```

We now find the preimage of $O_2(H)$ as a subgroup of G.

```
> pCore(H, 2) @@ f;
Permutation group acting on a set of cardinality 12
Order = 216 = 2^3 * 3^3
  (4, 5, 6)(7, 9, 8)
  (1, 2, 3)(4, 6, 5)(7, 8, 9)(10, 12, 11)
  (1, 4, 2, 5, 3, 6)(7, 12, 9, 11, 8, 10)
  (1, 10, 3, 11, 2, 12)(4, 9, 5, 8, 6, 7)
  (2, 3)(4, 5)(8, 9)(11, 12)
  (7, 9, 8)(10, 11, 12)
```

58.5 Building Permutation Groups

Examples of permutation groups are routinely constructed by taking one or more standard groups and applying some extension procedure to construct a group having the given groups as subgroups or quotient groups. In the first subsection we describe functions which construct some well-known groups and in the following subsection we give functions for constructing direct and wreath products.

58.5.1 Some Standard Permutation Groups

A number of functions are provided which construct various standard groups. The effect of these functions is to construct the group on some standard set of generating permutations.

`AbelianGroup(GrpPerm, Q)`

Construct the abelian group defined by the sequence $Q = [n_1, \ldots, n_r]$ of positive integers. The function constructs the direct product of cyclic groups

$$Z(n_1) \times Z(n_2) \times \cdots \times Z(n_r).$$

`AlternatingGroup(GrpPerm, n)`

`AlternatingGroup(n)`

`Alt(n)`

Construct the alternating group of degree n on generators $(3, 4, \ldots, n)$ and $(1, 2, 3)$, if n is odd, or $(1, 2)(3, 4, \ldots, n)$ and $(1, 2, 3)$, if n is even.

`CyclicGroup(GrpPerm, n)`

`CyclicGroup(n)`

Construct the cyclic group of order n with generator $(1, 2, \ldots, n)$.

`DihedralGroup(GrpPerm, n)`

`DihedralGroup(n)`

Construct the dihedral group of degree n and order $2 * n$ on generators $(1, 2, \ldots, n)$ and $(1, n)(2, n-1)\cdots$.

`Sym(GrpPerm, n)`

`SymmetricGroup(GrpPerm, n)`

`Sym(n)`

`SymmetricGroup(n)`

Construct the symmetric group of degree n on generators $(1, 2, \ldots, n)$ and $(1, 2)$.

`ExtraSpecialGroup(GrpPerm, p, n : parameters)`

`ExtraSpecialGroup(p, n : parameters)`

Given a small prime p and a small positive integer n, construct an extra-special group G of order p^{2n+1} in the category `GrpPerm`. The isomorphism type of G can be selected using the parameter `Type`.

`Type` MonStgElt *Default :* "+"

Possible values for this parameter are "+" (default) and "−".

If `Type` is set to "+", the function returns for $p = 2$ the central product of n copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p.

If `Type` is set to "−", the function returns for $p = 2$ the central product of a quaternion group of order 8 and $n - 1$ copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p^2.

`YoungSubgroup(L)`

`Full` RngIntElt *Default :* `false`

Given a sequence L of positive integers, compute the Young subgroup parameterized by L, i.e., the direct product of the symmetric groups on L_i points. If the optional parameter `Full` is given, construct the group as a subgroup of the symmetric group on `Full` elements.

Example H58E7

(1) The abelian group $Z_2 \times Z_2 \times Z_4$:

```
> A := AbelianGroup(GrpPerm, [2, 2, 4] );
> A;
Permutation group A acting on a set of cardinality 8
Order = 16 = 2^4
    (1, 2)
    (3, 4)
    (5, 6, 7, 8)
```

(2) The alternating group of degree 12:

```
> A12 := AlternatingGroup(GrpPerm, 12);
> A12;
Permutation group A12 acting on a set of cardinality 12
Order = 239500800 = 2^9 * 3^5 * 5^2 * 7 * 11
    (1, 2)(3, 4, 5, 6, 7, 8, 9, 10, 11, 12)
    (1, 2, 3)
```

(3) The cyclic group Z_{24}:

```
> Z24 := CyclicGroup(GrpPerm, 24);
> Z24;
Permutation group Z24 on a set of cardinality 24
```

```
Order = 24 = 2^3 * 3
    (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15,
        16, 17, 18, 19, 20, 21, 22, 23, 24)
```

(4) The dihedral group of order 24:

```
> D12 := DihedralGroup(GrpPerm, 12);
> D12;
Permutation group D12 acting on a set of cardinality 12
Order = 24 = 2^3 * 3
    (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12)
    (1, 12)(2, 11)(3, 10)(4, 9)(5, 8)(6, 7)
```

(5) The symmetric group of degree 8:

```
> S8 := SymmetricGroup(GrpPerm, 8);
> S8;
Symmetric group S8 acting on a set of cardinality 8
Order = 40320 = 2^7 * 3^2 * 5 * 7
```

58.5.2 Direct Products and Wreath Products

`DirectProduct(G, H)`

Given two permutation groups G and H, construct the direct product D of G and H as an intransitive group having degree equal to the sum of the degrees of G and H. In addition, the sequences I of inclusions and P of projections are returned, satisfying $I[i] : K_i \to D(K_i)$ and $P[i] : D \to K_i$ (where $K_1 = G, K_2 = H$ and $D(K)$ is the group K represented naturally as a subgroup of D).

`DirectProduct(Q)`

Given a sequence Q of n permutation groups, construct the direct product $Q[1] \times Q[2] \times \ldots \times Q[n]$ as an intransitive group of degree equal to the sum of the degrees of the groups $Q[i]$, $(i = 1, \ldots, n)$. In addition, the sequences I of inclusion and P of projections are returned, satisfying $I[i] : Q[i] \to D(Q[i])$ and $P[i] : D \to Q[i]$ (where $D(K)$ is the group K represented naturally as a subgroup of D).

`PrimitiveWreathProduct(G, H)`

Given permutation groups G and H, construct the wreath product $G \wr H$ of G and H, where $G \wr H$ has product action.

`PrimitiveWreathProduct(Q)`

Given a sequence Q of n permutation groups, construct the iterated wreath product $T = (\ldots (Q[1] \wr Q[2]) \wr \ldots \wr Q[n])$, where T has product action.

`WreathProduct(G, H)`

Given permutation groups G and H, construct the wreath product $W = G \wr H$ of G and H, where $G \wr H$ has imprimitive action. The function also returns the sequence of `Degree(`H`)` inclusions of G into W, the inclusion of H into W and the projection of W onto H.

`WreathProduct(Q)`

Given a sequence Q of n permutation groups, construct the iterated wreath product $W = (\ldots(Q[1] \wr Q[2]) \wr \ldots \wr Q[n])$, where W has imprimitive action.

`WreathProduct(B)`

Given a block system B of some permutation group G, compute the wreath-product corresponding to B.

`WreathProduct(G, B)`

Compute the smallest wreath product W to the block system B of G such that $G \subseteq W$. Also return the complement as a subgroup of W. The third parameter is a subgroup which is isomorphic to the action within a block.

Example H58E8

We define G to be the symmetric group of degree 4 and H to be the dihedral group of order 8. We then proceed to form the direct, primitive-wreath and wreath products of G and H.

```
> G := SymmetricGroup(GrpPerm, 4);
> H := DihedralGroup(GrpPerm, 3);
> D := DirectProduct(G, H);
> D;
Permutation group D acting on a set of cardinality 7
Order = 144 = 2^4 * 3^2
    (1, 2, 3, 4)
    (1, 2)
    (5, 6, 7)
    (5, 6)
> T := PrimitiveWreathProduct(G, H);
> T;
Permutation group T acting on a set of cardinality 64
Order = 82944 = 2^10 * 3^4
    (2, 5, 17)(3, 9, 33)(4, 13, 49)(6, 21, 18)(7, 25, 34)(8, 29, 50)
       (10, 37, 19) (11, 41, 35)(12, 45, 51) (14, 53, 20)(15, 57, 36)
       (16, 61, 52)(23, 26, 38) (24, 30, 54)(27, 42, 39)(28, 46, 55)
       (31, 58, 40) (32, 62, 56)(44, 47, 59)(48, 63, 60)
    (2, 5)(3, 9)(4, 13)(7, 10)(8, 14)(12, 15)(18, 21)(19 , 25)(20, 29)
       (23, 26)(24, 30)(28, 31)(34, 37)(35 , 41)(36, 45)(39, 42)(40, 46)
       (44, 47)(50, 53)(51 , 57)(52, 61)(55, 58)(56, 62)(60, 63)
    (1, 2, 3, 4)(5, 6, 7, 8)(9, 10, 11, 12)(13, 14, 15, 16)(17, 18, 19, 20)
       (21, 22, 23, 24)(25, 26, 27, 28)(29, 30, 31, 32)(33, 34, 35, 36)
```

```
       (37, 38, 39, 40)(41, 42, 43, 44)(45, 46, 47, 48)(49, 50, 51, 52)
       (53, 54, 55, 56)(57, 58, 59, 60)(61, 62, 63, 64)
    (1, 2)(5, 6)(9, 10)(13, 14)(17, 18)(21, 22)(25, 26)( 29, 30)(33, 34)
       (37, 38)(41, 42)(45, 46)(49, 50)( 53, 54)(57, 58)(61, 62)
> W := WreathProduct(G, H);
> W;
Permutation group W acting on a set of cardinality 12
Order = 82944 = 2^10 * 3^4
    (1, 5, 9)(2, 6, 10)(3, 7, 11)(4, 8, 12)
    (1, 5)(2, 6)(3, 7)(4, 8)
    (1, 2, 3, 4)
    (1, 2)
```

58.6 Permutations

58.6.1 Coercion

`G ! g`

Given a subgroup G of $\mathrm{Sym}(X)$ and a permutation g belonging to $\mathrm{Sym}(X)$ that is contained in G, embed g in G. Thus, this operator changes the parent of g to be G.

`G !! H`

Given a group H whose natural G-set X is a subset of the natural G-set Y for the group G, embed H as a subgroup of G. The operator fails if the image of H in $\mathrm{Sym}(Y)$ is not a subgroup of G.

58.6.2 Arithmetic with Permutations

`g * h`

Product of permutation g and permutation h, where g and h belong to the same generic group U. If g and h both belong to the same proper subgroup G of U, then the result will be returned as an element of G; if g and h belong to subgroups H and K of a subgroup G of U, then the product is returned as an element of G. Otherwise, the product is returned as an element of U.

`g ^ n`

The n-th power of the permutation g, where n is a positive, negative or zero integer.

`g / h`

Product of the permutation g by the inverse of the permutation h, i.e. the element $g * h^{-1}$. Here g and h must belong to the same generic group U. The rules for determining the parent group of g/h are the same as for $g * h$.

`g ^ h`

Conjugate of the permutation g by the permutation h, i.e. the element $h^{-1} * g * h$. Here g and h must belong to the same generic group U. The rules for determining the parent group of g^h are the same as for $g * h$.

`(g, h)`

Commutator of the permutations g and h, i.e. the element $g^{-1} * h^{-1} * g * h$. Here g and h must belong to the same generic group U. The rules for determining the parent group of (g, h) are the same as those for $g * h$.

`(g`$_1$`, ..., g`$_r$`)`

Given r permutations $g_1, \ldots, g_r$ belonging to a common group, return their commutator. Commutators are *left-normed*, so they are evaluated from left to right.

58.6.3 Properties of Permutations

`CycleStructure(g)`

Given a permutation g belonging to a group of degree n, return the partition of n corresponding to the cycles of g. This partition is returned in the form of a sequence Q of pairs, where the terms of Q correspond to the distinct cycle lengths of g. The value of the term $Q[i]$ is a tuple $< l_i, n_i >$ belonging to $\mathbf{Z} \times \mathbf{Z}$. Here l_i is the length of a cycle of g and n_i is the number of cycles of length l_i.

`Degree(g)`

Given a permutation g, return the degree of g, i.e. the number of points moved by g.

`IsEven(g)`

Returns `true` if the permutation g is an even permutation, `false` otherwise.

`Sign(g)`

Return 1 if the permutation g is even, return -1 if g is odd.

`Order(g)`

Order of the permutation g.

58.6.4 Predicates for Permutations

`g eq h`

Given permutations g and h belonging to the same generic group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given permutations g and h belonging to the same generic group, return `true` if g and h are distinct elements, `false` otherwise.

`IsId(g)`

`IsIdentity(g)`

Returns `true` if the permutation g is the identity permutation.

Example H58E9

We illustrate the permutation operations by applying them to some elements of Sym(9).

```
> G := Sym(9);
> x := G ! (1,2,4)(5,6,8)(3,9,7);
> y := G ! (4,5,6)(7,9,8);
> x*y;

```

58.6.5 Set Operations

The creation of a base and strong generating set (BSGS) for a permutation group G provides us with a very compact representation of the set of elements of G. A particular BSGS imposes an order on the elements of G (lexicographic ordering of base images). It thus makes sense to talk about the 'number' of a group element relative to a particular BSGS.

`G * H`

Given permutation groups G and H, where G and H both belong to the same generic group, form the set product $\{g * h | g \in G, h \in H\}$ as a set of group elements.

`ElementSet(G, H)`

Given a group G and a subgroup H of G, return the elements of H in the form of a set of elements of G. This function is only applicable to very small groups.

`NumberingMap(G)`

A bijective mapping from the group G onto the set of integers $\{1 \ldots |G|\}$. The actual mapping depends upon the base and strong generating set chosen for G.

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 20

Create a process to generate randomly chosen elements from the finite group G. The process is based on the product-replacement algorithm of [CLGM+95], modified by the use of an accumulator. At all times, N elements are stored where N is the maximum of the specified value for `Slots` and `Ngens`$(G)+1$. Initially, these are just the generators of G. As well, one extra group element is stored, the accumulator. Initially, this is the identity. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses one of the elements in the slots and multiplies it into the accumulator. The element in that slot is replaced by the product of it and another randomly chosen slot. The random value returned is the new accumulator value. Setting `Scramble := m` causes m such operations to be performed before the process is returned.

`Random(G: parameters)`

`Short`	BoolElt	*Default :* `false`

A randomly chosen element for the group G. If a BSGS is known for G, then the distribution will be uniform over G. If no BSGS is known, then the *random* element is chosen by multiplying out a *random* word in the generators. Since it is usually not practical to choose words long enough to properly sample the elements of G, the element returned will usually be biased. The boolean-valued parameter `Short` is used in this situation to indicate that a short word will suffice. Thus, if `Random` is invoked with `Short` assigned the value `true` then the element is constructed using a short word.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the finite group G, construct a random element of G by forming a random product over the expanded generating set constructed when the process was created. For large degree groups, or groups for which a BSGS is not known, this function should be used in preference to `Random(G)`.

`Representative(G)`

`Rep(G)`

An element chosen from the permutation group G.

Example H58E10

We use the function `NumberingMap` to construct the multiplication table for the dihedral group of order 12.

```
> G := DihedralGroup(GrpPerm, 6);
> f := NumberingMap(G);
> [ [ f(x*y) : y in G ] : x in G ];
[
    [ 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 ],
    [ 2, 3, 4, 5, 6, 1, 12, 7, 8, 9, 10, 11 ],
    [ 3, 4, 5, 6, 1, 2, 11, 12, 7, 8, 9, 10 ],
    [ 4, 5, 6, 1, 2, 3, 10, 11, 12, 7, 8, 9 ],
    [ 5, 6, 1, 2, 3, 4, 9, 10, 11, 12, 7, 8 ],
    [ 6, 1, 2, 3, 4, 5, 8, 9, 10, 11, 12, 7 ],
    [ 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5, 6 ],
    [ 8, 9, 10, 11, 12, 7, 6, 1, 2, 3, 4, 5 ],
    [ 9, 10, 11, 12, 7, 8, 5, 6, 1, 2, 3, 4 ],
    [ 10, 11, 12, 7, 8, 9, 4, 5, 6, 1, 2, 3 ],
    [ 11, 12, 7, 8, 9, 10, 3, 4, 5, 6, 1, 2 ],
    [ 12, 7, 8, 9, 10, 11, 2, 3, 4, 5, 6, 1 ]
]
```

Example H58E11

We illustrate the use of the function `Random` using the wreath product of the symmetric group of degree 4 and the cyclic group of order 6.

```
> G := WreathProduct( Sym(4), CyclicGroup(GrpPerm, 6));
> G;
Permutation group G acting on a set of cardinality 24
    (1, 5, 9, 13, 17, 21)(2, 6, 10, 14, 18, 22) (3, 7, 11, 15, 19, 23)
        (4, 8, 12, 16, 20, 24)
    (1, 2, 3, 4)
    (1, 2)
> Order(G);
```

```
1146617856
> Random(G);
(1, 17, 12, 4, 18, 10, 3, 20, 9, 2, 19, 11)(5, 22, 13, 6, 21, 15)
    (7, 24, 16)(8, 23, 14)
```

We display the cycle structures of 10 random elements of G.

```
> R := [ CycleStructure(Random(G)) : i in [1..10] ];
> R;
[
    [ <6, 1>, <3, 6> ],
    [ <9, 1>, <6, 2>, <3, 1> ],
    [ <9, 2>, <3, 2> ],
    [ <12, 1>, <9, 1>, <3, 1> ],
    [ <18, 1>, <6, 1> ],
    [ <18, 1>, <6, 1> ],
    [ <12, 1>, <6, 2> ],
    [ <6, 3>, <2, 3> ],
    [ <6, 1>, <4, 3>, <2, 3> ],
    [ <6, 3>, <3, 2> ]
]
```

58.7 Conjugacy

`Class(H, x)`

`Conjugates(H, x)`

Given a group H and an element x belonging to a group K such that H and K are subgroups of the same symmetric group, this function returns the set of conjugates of x under the action of H. If $H = K$, the function returns the conjugacy class of x in H.

`ConjugacyClasses(G: parameters)`

`Classes(G: parameters)`

Construct a set of representatives for the conjugacy classes of G. The classes are returned as a sequence of triples containing the element order, the class length and a representative element for the class. The parameters `Reps` and `Al` enable the user to select the algorithm that is to be used.

`Reps` [GrpPermElt] *Default :*

`Reps :=` Q: Create the classes of G by using the random algorithm but using the group elements in Q as the "random" elements tried. The element orders and lengths of the classes will be computed and checked for consistency.

`Reps` [<GrpPermElt, RngIntElt>]

`Reps :=` Q Create the classes of G assuming that the first elements of the tuples in Q form a complete set of conjugacy class representatives and the corresponding integer is the size of the conjugacy class. The only check performed is that the class sizes sum to the group order.

`Al`	MonStgElt	*Default :* "*Default*"
`WeakLimit`	RngIntElt	*Default :* 500
`StrongLimit`	RngIntElt	*Default :* 5000

`Al := "Action"`: Create the classes of G by computing the orbits of the set of elements of G under the action of conjugation. This option is only feasible for small groups.
`Al := "Random"`: Construct the conjugacy classes of elements for a permutation group G using an algorithm that searches for representatives of all conjugacy classes of G by examining a random selection of group elements and their powers. The behaviour of this algorithm is controlled by two associated optional parameters `WeakLimit` and `StrongLimit`, whose values are positive integers n_1 and n_2, say. Before describing the effect of these parameters, some definitions are needed: A mapping $f : G \to I$ is called a class invariant if $f(g) = f(g^h)$ for all $g, h \in G$. For permutation groups, the cycle structure of g is a readily computable class invariant. Two elements g and h are said to be *weakly conjugate* with respect to the class invariant f if $f(g) = f(h)$. By definition, conjugacy implies weak conjugacy, but the converse is false. The random algorithm first examines n_1 random elements and their powers, using a test for weak conjugacy. It then proceeds to examine a further n_2 random elements and their powers, using a test for ordinary conjugacy. The idea behind this strategy is that the algorithm should attempt to find as many classes as possible using the very cheap test for weak conjugacy, before employing the more expensive ordinary conjugacy test to recognize the remaining classes.
`Al := "Inductive"`: Use G. Butler's inductive method to compute the classes. See Butler [But94] for a description of the algorithm. The action and random algorithms are used by this algorithm to find the classes of any small groups it is called upon to deal with.
`Al := "Extend"`: Construct the conjugacy classes of G by first computing classes in a quotient G/N and then extending these classes to successively larger quotients G/H until the classes for $G/1$ are known. More precisely, a series of subgroups $1 = G_0 < G_1 < \cdots < G_r = R < G$ is computed such that R is the (solvable) radical of G and G_{i+1}/G_i is elementary abelian. The radical quotient G/R is computed and its classes and centralizers of their representatives found and pulled back to G. The parameters `TFAl` and `ASAl` control the algorithm used to compute the classes of G/R.

To extend from G/G_{i+1} to the next larger quotient G/G_i, an affine action of each centralizer on a quotient of the elementary abelian layer G_{i+1}/G_i is computed. Each distinct orbit in that action gives rise to a new class of the larger quotient (see Mecky and Neubuser [MN89]).

`Al := "Default"`: First some special cases are checked for: If `IsAltsym(G)` then the classes of G are computed from the partitions of `Degree(G)`. If G is solvable, an isomorphic representation of G as a pc-group is computed and the classes computed in that representation. In general, the action algorithm will be used if $|G| \leq 5000$, otherwise the extension algorithm will be applied.

`TFAl` MonStgElt *Default :* "*Default*"

This parameter controls the algorithm used to compute the classes of a group with trivial Fitting subgroup, such as the group G/R in the description of the `"Extend"` method. The possible settings are the same as for `Al`, except that `"Extend"` is not a valid choice. The `"Action"`, `"Random"` and `"Inductive` settings behave as described above. The default algorithm is Derek Holt's generalisation of the Cannon/Souvignier fusion method to all classes of the group. The original fusion algorithm used fusion only on classes within a direct product normal subgroup, see [CS97]. Holt has extended the use of fusion to all conjugacy classes, avoiding the random part of the Cannon/Souvignier method. This algorithm must use another algorithm to find the classes of almost simple groups arising from the socle of the TF-group. The algorithm used for this is controlled by the parameter `ASAl`.

`ASAl` MonStgElt *Default :* "*Default*"

This parameter controls the algorithm used to compute the classes of an almost simple group from within the default TF-group algorithm. The possibilities for this parameter are as for `TFAl`. The default algorithm first determines if `Altsym(G)` is true. If so, classes are deduced from the partitions of `Degree(G)`. Next, if the order of G is ≤ 5000 then the action algorithm is used. If the socle of G has the correct order to be $PSL(2, q)$, for some q, then the random algorithm is used on G. Otherwise the inductive algorithm is used.

`Centralisers` BoolElt *Default :* `false`

A flag to force the storing of the centralisers of the class representatives with the class table. This does not apply to the action algorithm. In the case of the extension algorithm, this will do extra work to lift the centralisers through the final elementary abelian layer.

`PowerMap` BoolElt *Default :* `false`

A flag to force the storing of whatever power map information is produced by the classes algorithm used. In the case of the extension algorithm, this flag forces the computation of the full power map en-route, and may take considerably longer than not doing so. However, it is overall faster to set this flag true when the `PowerMap` is going to be computed anyway.

`ClassRepresentative(G, x)`

Given a group G for which the conjugacy classes are known and an element x of G, return the designated representative for the conjugacy class of G containing x.

`ClassCentraliser(G, i)`

The centraliser of the representative element stored for conjugacy class number i in group G. The group computed is stored with the class table for reference by future calls to this function.

`ClassMap(G:` *parameters*`)`

Given a group G, construct the conjugacy classes and the class map f for G. For any element x of G, $f(x)$ will be the index of the conjugacy class of x in the sequence returned by the `Classes` function. If the parameter `Orbits` is set `true`, the classes are computed as orbits of elements under conjugation and the class map is stored as a list of images of the elements of G (a list of length $|G|$). This option gives fast evaluation of the class map but is practical only in the case of very small groups. With `Orbits := false`, `WeakLimit` and `StrongLimit` are used to control the random classes algorithm (see function `Classes`).

`IsConjugate(G, g, h:` *parameters*`)`

Given a group G and elements g and h belonging to G, return the value `true` if g and h are conjugate in G. The function returns a second value if the elements are conjugate: an element k which conjugates g into h. The method used is the backtrack search of Leon [Leo97]. This search may be speeded considerably by knowledge of (subgroups of) the centralizers of g and h in G. The parameters relate to these subgroups.

`Centralizer`	MonStgElt	*Default :* "*Default*"
`LeftSubgroup`	GrpPerm	*Default :* $\langle g \rangle$
`RightSubgroup`	GrpPerm	*Default :* $\langle h \rangle$

The `LeftSubgroup` and `RightSubgroup` parameters enable the user to supply known subgroups of the centralizers of g and h respectively to the algorithm. By default, the cyclic subgroups generated by g and h are the known subgroups. The `Centralizer` parameter controls whether the algorithm starts by computing one or both centralizers in full before the conjugacy test. The `"Default"` behaviour is to compute the left centralizer, i.e. $C_G(g)$, unless either a left or right subgroup is specified, in which case no centralizer calculation is done. Other possible values are the four possibilities `"Left"` which forces computation of $C_G(g)$, `"Right"` which forces $C_G(h)$ to be computed, `"Both"` which computes both centralizers, and `"None"` which will compute no centralizers.

`IsConjugate(G, H, K:` *parameters*`)`

Given a group G and subgroups H and K of G, return the value `true` if H and K are conjugate in G. The function returns a second value if the subgroups are conjugate: an element z which conjugates H into K. The method used is the backtrack search of Leon [Leo97].

`Compute`	MonStgElt	*Default :* "*Default*"

This parameter may be set to any of "Both", "Default", "Left", "None", or "Right". This controls which normalisers are computed before starting the conjugacy test. The default strategy is currently "Left", which computes the normalizer of H in G before starting the conjugacy test between H and K. The greater the difference between H and K and their normalizers in G, the more helpful to the search it is to compute their normalizers.

`LeftSubgroup`	GrpPerm	*Default :* H
`RightSubgroup`	GrpPerm	*Default :* K

Instead of having the `IsConjugate` function compute the normalizers of H and K, the user may supply any known subgroup of G normalizing H (as `LeftSubgroup`) or normalizing K (as `RightSubgroup`) to be used as the normalizing groups to aid the search.

`Exponent(G)`

The exponent of the group G. This is computed as the product of the exponents of the Sylow subgroups fo G.

`NumberOfClasses(G)`

`Nclasses(G)`

The number of conjugacy classes of elements for the group G.

`PowerMap(G)`

Given a group G, construct the power map for G. Suppose that the order of G is m and that G has r conjugacy classes. When the classes are determined by Magma, they are numbered from 1 to r. Let C be the set of class indices $\{1, \ldots, r\}$ and let Z be the set of integers. The *power map* f for G is the mapping

$$f : C \times Z \to C$$

where the value of $f(i, j)$ for $i \in C$ and $j \in Z$ is the number of the class which contains x_i^j, where x_i is a representative of the i-th conjugacy class.

`AssertAttribute(G, "Classes", Q)`

Assert the class representatives of G. The action taken is identical to using the `ConjugacyClasses` function described above, with the parameter `Reps` set to Q. Thus Q may be a sequence of group elements or a sequence of tuples giving class representatives and class lengths.

Example H58E12

The conjugacy classes of the Mathieu group M_{11} can be constructed as follows:

```
> SetSeed(2);
> M11 := sub<Sym(11) | (1,10)(2,8)(3,11)(5,7), (1,4,7,6)(2,11,10,9)>;
> Classes(M11);
Conjugacy Classes of group M11
------------------------------
[1]     Order 1       Length 1
        Rep Id(M11)

[2]     Order 2       Length 165
        Rep (3, 10)(4, 9)(5, 6)(8, 11)

[3]     Order 3       Length 440
        Rep (1, 2, 4)(3, 5, 10)(6, 8, 11)

[4]     Order 4       Length 990
        Rep (3, 6, 10, 5)(4, 8, 9, 11)

[5]     Order 5       Length 1584
        Rep (1, 3, 6, 2, 8)(4, 7, 10, 9, 11)

[6]     Order 6       Length 1320
        Rep (1, 11, 2, 6, 4, 8)(3, 10, 5)(7, 9)

[7]     Order 8       Length 990
        Rep (1, 4, 5, 6, 2, 7, 11, 10)(8, 9)

[8]     Order 8       Length 990
        Rep (1, 7, 5, 10, 2, 4, 11, 6)(8, 9)

[9]     Order 11      Length 720
        Rep (1, 11, 9, 10, 4, 3, 7, 2, 6, 5, 8)

[10]    Order 11      Length 720
        Rep (1, 9, 4, 7, 6, 8, 11, 10, 3, 2, 5)
```

Example H58E13

The default values for the random class algorithm are adequate for a large variety of groups. We look at what happens when we vary the parameters in the case of the Higman-Sims simple group represented on 100 letters. In this case the default strategy reduces to a random search. The first choice of parameters does not look at enough random elements. Increasing the limit on the number of random elements examined will ensure the algorithm succeeds.

```
> G := sub<Sym(100) |
```

```
>    (2,8,13,17,20,22,7)(3,9,14,18,21,6,12)(4,10,15,19,5,11,16)
>        (24,77,99,72,64,82,40)(25,92,49,88,28,65,90)(26,41,70,98,91,38,75)
>        (27,55,43,78,86,87,45)(29,69,59,79,76,35,67)(30,39,42,81,36,57,89)
>        (31,93,62,44,73,71,50)(32,53,85,60,51,96,83)(33,37,58,46,84,100,56)
>        (34,94,80,61,97,48,68)(47,95,66,74,52,54,63),
>    (1,35)(3,81)(4,92)(6,60)(7,59)(8,46)(9,70)(10,91)(11,18)(12,66)(13,55)
>        (14,85)(15,90)(17,53)(19,45)(20,68)(21,69)(23,84)(24,34)(25,31)(26,32)
>        (37,39)(38,42)(40,41)(43,44)(49,64)(50,63)(51,52)(54,95)(56,96)(57,100)
>        (58,97)(61,62)(65,82)(67,83)(71,98)(72,99)(74,77)(76,78)(87,89) >;
>  K := Classes(G:WeakLimit := 20, StrongLimit := 50);
Runtime error in 'Classes': Random classes algorithm failed
> K := Classes(G: WeakLimit := 20, StrongLimit := 100);
> NumberOfClasses(G);
24
```

As the group has only 24 classes, the first random search could have succeeded by looking at 50 elements. On this occasion it did not, but looking at 100 elements did succeed.
We print the order, length and cycle structure for each conjugacy class.

```
> [ < k[1], k[2], CycleStructure(k[3]) > : k in K ];
[
       <1, 1, [ <1, 100> ]>,
       <2, 5775, [ <2, 40>, <1, 20> ]>,
       <2, 15400, [ <2, 50> ]>,
       <3, 123200, [ <3, 30>, <1, 10> ]>,
       <4, 11550, [ <4, 20>, <2, 10> ]>,
       <4, 173250, [ <4, 20>, <2, 6>, <1, 8> ]>,
       <4, 693000, [ <4, 20>, <2, 8>, <1, 4> ]>,
       <5, 88704, [ <5, 20> ]>,
       <5, 147840, [ <5, 20> ]>,
       <5, 1774080, [ <5, 19>, <1, 5> ]>,
       <6, 1232000, [ <6, 15>, <2, 5> ]>,
       <6, 1848000, [ <6, 12>, <3, 6>, <2, 4>, <1, 2> ]>,
       <7, 6336000, [ <7, 14>, <1, 2> ]>,
       <8, 2772000, [ <8, 10>, <4, 4>, <2, 2> ]>,
       <8, 2772000, [ <8, 10>, <4, 3>, <2, 3>, <1, 2> ]>,
       <8, 2772000, [ <8, 10>, <4, 4>, <2, 2> ]>,
       <10, 2217600, [ <10, 8>, <5, 4> ]>,
       <10, 2217600, [ <10, 10> ]>,
       <11, 4032000, [ <11, 9>, <1, 1> ]>,
       <11, 4032000, [ <11, 9>, <1, 1> ]>,
       <12, 3696000, [ <12, 6>, <6, 3>, <4, 2>, <2, 1> ]>,
       <15, 2956800, [ <15, 6>, <5, 2> ]>,
       <20, 2217600, [ <20, 4>, <10, 2> ]>,
       <20, 2217600, [ <20, 4>, <10, 2> ]>
]
```

We construct the power map and tabulate the second, third and fifth powers of each class.

```
> p := PowerMap(G);
```

```
> [ < i, p(i, 2), p(i, 3), p(i, 5) > : i in [1 .. #K] ];
[
    <1, 1, 1, 1>,
    <2, 1, 2, 2>,
    <3, 1, 3, 3>,
    <4, 4, 1, 4>,
    <5, 2, 5, 5>,
    <6, 2, 6, 6>,
    <7, 2, 7, 7>,
    <8, 8, 8, 1>,
    <9, 9, 9, 1>,
    <10, 10, 10, 1>,
    <11, 4, 3, 11>,
    <12, 4, 2, 12>,
    <13, 13, 13, 13>,
    <14, 7, 14, 14>,
    <15, 6, 15, 15>,
    <16, 7, 16, 16>,
    <17, 8, 17, 2>,
    <18, 9, 18, 3>,
    <19, 20, 19, 19>,
    <20, 19, 20, 20>,
    <21, 12, 5, 21>,
    <22, 22, 9, 4>,
    <23, 17, 23, 5>,
    <24, 17, 24, 5>
]
```

58.8 Subgroups

58.8.1 Construction of a Subgroup

`sub< G | L >`

Given the permutation group G, construct the subgroup H of G, generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) A sequence of n integers defining a permutation of G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic permutation group. The subgroup H will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of H consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list.

`ncl< G | L >`

Given the permutation group G, construct the subgroup H of G that is the *normal closure* of the subgroup H generated by the elements specified by the list L (see [BC82]), where the possibilities for L are the same as for the `sub`-constructor.

Example H58E14

The group PGL$(2,7)$ in its natural action on projective points is generated by the set of permutations $\{(1,2,3,4,5,6,7),(2,4,3,7,5,6),(1,8)(2,7)(3,4)(5,6)\}$. Using the above syntax, the group may be defined in any of the following ways:
(a) By means of a list of generating permutations written as products of cycles:

```
> PGL27 := sub< Sym(8) | (1,2,3,4,5,6,7), (2,4,3,7,5,6), (1,8)(2,7)(3,4)(5,6)>;
> PGL27;
Permutation group PGL27 acting on a set of cardinality 8
    (1, 2, 3, 4, 5, 6, 7)
    (2, 4, 3, 7, 5, 6)
    (1, 8)(2, 7)(3, 4)(5, 6)
```

(b) By means of a list of integer sequences representing generators:

```
> PGL27 := sub< Sym(8) |
>               [2,3,4,5,6,7,1,8], [1,4,7,3,6,2,5,8], [8,7,4,3,6,5,2,1] >;
```

(c) In terms of preassigned elements of the symmetric group of degree 8:

```
> S8 := Sym(8);
> a := S8!(1,2,3,4,5,6,7);
> b := S8!(2,4,3,7,5,6);
> c := S8!(1,8)(2,7)(3,4)(5,6);
> PGL27 := sub<S8 | a, b, c>;
```

(d) By means of a set of generators:

```
> S8 := Sym(8);
> gens := { S8 | (1,2,3,4,5,6,7), (2,4,3,7,5,6), (1,8)(2,7)(3,4)(5,6) };
> PGL27 := sub<S8 | gens>;
```

(e) By means of a sequence of generators:

```
> S8 := Sym(8);
> gens := [ S8 | (1,2,3,4,5,6,7), (2,4,3,7,5,6), (1,8)(2,7)(3,4)(5,6) ];
> PGL27 := sub<S8 | gens>;
```

Example H58E15

A representation H of a 2-generator transitive group G in its action on unordered pairs is constructed as follows:

```
> G := AlternatingGroup(7);
> deg1 := Degree(G);
> pairs := [ { i, j } : j in [i+1..deg1], i in [1..deg1-1] ];
> deg2 := #pairs;
> h1 := [ Position(pairs, pairs[i] ^ G.1): i in [1..deg2] ];
> h2 := [ Position(pairs, pairs[i] ^ G.2): i in [1..deg2] ];
> H := sub<Sym(deg2) | h1, h2>;
> H;
Permutation group H acting on a set of cardinality 21
 (2,3,4,5,6)(7,8,9,10,11)(12,16,19,21,15)(13,17,20,14,18),
 (1,7,2)(3,8,12)(4,9,13)(5,10,14)(6,11,15)
```

Example H58E16

We illustrate the `ncl`-constructor by using it to construct the derived subgroup of the Hessian group H. We exploit the fact that the derived subgroup may be obtained as the normal closure of the subgroup generated by the commutators of the generators of H.

```
> H := PermutationGroup< 9 | (1,2,4)(5,6,8)(3,9,7), (4,5,6)(7,9,8) >;
> Order(H);
216
> D := ncl< H | (H.1, H.2) >;
> D;
Permutation group D acting on a set of cardinality 9
Order = 72 = 2^3 * 3^2
    (1, 7, 3, 6)(4, 5, 9, 8)
    (2, 9, 3, 5)(4, 6, 7, 8)
    (2, 6, 3, 8)(4, 5, 7, 9)
```

58.8.2 Membership and Equality

`g in G`

Given a permutation g and a permutation group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given a permutation g and a permutation group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given a permutation group G and a set S of permutations belonging to a group H, where G and H belong the same generic group, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a permutation group G and a set S of permutations belonging to a group H, where G and H belong the same generic group, return `true` if S is not a subset of G, `false` otherwise.

`H subset G`

Given permutation groups G and H belonging to the same generic group, return `true` if H is a subgroup of G, `false` otherwise.

`H notsubset G`

Given permutation groups G and H belonging to the same generic group, return `true` if H is not a subgroup of G, `false` otherwise.

`H eq G`

Given permutation groups G and H belonging to the same generic group, return `true` if G and H are the same group, `false` otherwise.

`H ne G`

Given permutation groups G and H belonging to the same generic group, return `true` if G and H are distinct groups, `false` otherwise.

58.8.3 Elementary Properties of a Subgroup

`Index(G, H)`

The index of the subgroup H in the group G. The index is returned as an integer. If the orders of G and H are not known, they will be computed.

`FactoredIndex(G, H)`

The index of the subgroup H in the group G. The index is returned as a factored integer. The format is the same as for `FactoredOrder`. If the orders of G and H are not known, they will be computed.

`IsCentral(G, H)`

Returns `true` if the subgroup H of the group G lies in the centre of G, `false` otherwise.

`IsNormal(G, H)`

Returns `true` if the subgroup H of the group G is a normal subgroup of G, `false` otherwise.

`IsSelfNormalizing(G, H)`

`IsSelfNormalising(G, H)`

Returns `true` if the subgroup H of the group G is self-normalizing in G, `false` otherwise.

`IsSubnormal(G, H)`

Returns `true` if the subgroup H of the group G is subnormal in G, `false` otherwise.

58.8.4 Standard Subgroups

Unless the order is already known, each of the functions in this family will create a base and strong generating set for the group if one does not already exist.

`H ^ g`

`Conjugate(H, g)`

Construct the conjugate $g^{-1} * H * g$ of the permutation group H by the permutation g. The group H and the element g must belong to the same symmetric group.

`H meet K`

Given groups H and K which belong to the same symmetric group, construct the intersection of H and K. The intersection is found using the backtrack search of J. Leon [Leo97].

`IntersectionWithNormalSubgroup(G, N)`

`Check` BoolElt *Default :* `true`

Given groups G and N which belong to the same symmetric group and so that G normalises N, construct the intersection of G and N. The algorithm used is that of Cooperman, Finkelstein and Luks [CFL89], which uses a permutation representation of double the degree of G and N. Setting `Check` to `false` suppresses checking that G normalises N.

`CommutatorSubgroup(G, H, K)`

`CommutatorSubgroup(H, K)`

Given groups H and K, both subgroups of the group G, construct the commutator subgroup of H and K in the group G. If K is a subgroup of H, then the group G may be omitted. The algorithm used is described in [BC82].

`Centralizer(G, g: parameters)`

`Centraliser(G, g: parameters)`

Construct the centralizer of the permutation g in the group G; g and G must belong to a common symmetric group. A backtrack search through G as described in [Leo97] is employed.

`Subgroup`	GrpPerm	*Default :*

The parameter `Subgroup` may be used to supply a known subgroup of the centralizer. This may speed the search.

`Centralizer(G, H)`

`Centraliser(G, H)`

Construct the centralizer of the group H in the group G; G and H must belong to a common symmetric group. A backtrack search through G as described in [Leo97] is employed.

`CentralizerOfNormalSubgroup(G, H)`

Given G and H, belonging to a common symmetric group, with the restriction that H is a normal subgroup of G, construct the centralizer of H in G. A polynomial-time reduction algorithm described in Beals [Bea93] is used.

`SectionCentraliser(G, H, K)`

`SectionCentralizer(G, H, K)`

Return the full preimage in G of the centralizer in G/K of H/K. H and K must be normal subgroups of G with K contained in H. An algorithm of Luks [Luk93] is employed which involves computing the core of a subgroup in a group having twice the degree of G.

`Core(G, H)`

Given a subgroup H of the permutation group G, construct the maximal normal subgroup of G that is contained in the subgroup H. The algorithm employs repeated conjugation and intersection using the backtrack search of Leon [Leo97].

`H ^ G`

`NormalClosure(G, H)`

Given a subgroup H of the permutation group G, construct the normal closure of H in G.

`Normalizer(G, H: parameters)`

`Normaliser(G, H: parameters)`

`Subgroup`	GrpPerm	*Default :* H
`Bound`	RngIntElt	*Default :*

Given a subgroup H of the group G, construct the normalizer of H in G. A backtrack search as described in Leon [Leo97] is employed.

The parameter `Subgroup` may be used to pass the search a known subgroup of the normalizer. The default value of the starting subgroup is H. If `Bound` is set, the search will be terminated once the normalizing group found has order at least equal to `Bound`. If this does not happen, the search will complete as normal.

`SymmetricNormalizer(G)`

`Subgroup`	GrpPerm	*Default :* H
`Bound`	RngIntElt	*Default :*

`SymmetricNormaliser(G)`

Given a permutation group G acting on the set X, return the normalizer of G in the symmetric group on X. The parameters are as for `Normalizer` above.

`SylowSubgroup(G, p)`

`Sylow(G, p)`

Given a group G and a prime p, construct a Sylow p-subgroup of G. The algorithm used is that of Cannon, Cox and Holt [CCH97].

Example H58E17

We illustrate the use of these functions by applying them to a group of degree 30.

```
> M := PermutationGroup< 30 |
>         (1,2,3)(4,14,8)(5,15,9)(6,13,7)(25,27,26),
>         (4,20,13)(5,21,14)(6,19,15)(16,17,18)(27,28,29),
>         (1, 15)(2, 13)(3, 14)(4, 22)(5, 23)(6, 24)(7, 18)(8, 16)
>           (9, 17)(10, 21)(11, 19)(12, 20)(25, 29)(26, 27)(28, 30) >;
> FactoredOrder(M);
[ <2, 8>, <3, 10>, <5, 1> ]
> S2 := SylowSubgroup(M, 2);
> S2;
Permutation group S2 acting on a set of cardinality 30
Order = 256 = 2^8
    (1, 10)(2, 11)(3, 12)(4, 8)(5, 9)(6, 7)(13, 19)(14, 20)(15, 21)
        (16, 22)(17, 23)(18, 24)
    (1, 24)(2, 22)(3, 23)(4, 14)(5, 15)(6, 13)(7, 19)(8, 20)(9, 21)
        (10, 18)(11, 16)(12, 17)
    (4, 8)(5, 9)(6, 7)(13, 19)(14, 20)(15, 21)
    (4, 14)(5, 15)(6, 13)(7, 19)(8, 20)(9, 21)(25, 26)(29, 30)
```

```
    (1, 4)(2, 5)(3, 6)(7, 12)(8, 10)(9, 11)(13, 23)(14, 24)(15, 22)
        (16, 21)(17, 19)(18, 20)(25, 26)
    (27, 28)(29, 30)
    (27, 29)(28, 30)
    (25, 26)(29, 30)
```

We try to find a second Sylow subgroup $S2a$ that has trivial intersection with $S2$.

```
> b := exists(t){ x : x in M | Order(S2 meet S2^x) eq 1 };
> b;
true
> S2a := S2^t;
> N := Normalizer(M, S2);
> N;
Permutation group N acting on a set of cardinality 30
Order = 768 = 2^8 * 3
    (4, 8)(5, 9)(6, 7)(13, 19)(14, 20)(15, 21)
    (4, 14)(5, 15)(6, 13)(7, 19)(8, 20)(9, 21)
    (1, 10)(2, 11)(3, 12)(4, 8)(5, 9)(6, 7)(13, 19)(14, 20)(15, 21)
        (16, 22)(17, 23)(18, 24)
    (1, 24)(2, 22)(3, 23)(4, 14)(5, 15)(6, 13)(7, 19)(8, 20)(9, 21)
        (10, 18)(11, 16)(12, 17)
    (1, 22, 12)(2, 23, 10)(3, 24, 11)(4, 21, 13)(5, 19, 14)(6, 20, 15)
        (7, 8, 9)(16, 17, 18)
    (27, 29)(28, 30)
    (1, 14, 24, 4)(2, 15, 22, 5)(3, 13, 23, 6)(7, 12, 19, 17)(8, 10, 20, 18)
        (9, 11, 21, 16)(29, 30)
    (4, 14)(5, 15)(6, 13)(7, 19)(8, 20)(9, 21)(25, 26)(29, 30)
    (27, 28)(29, 30)
```

Thus the Sylow 2-subgroup is normalized by an element of order 3.

58.8.5 Maximal Subgroups

`IsMaximal(G, H: parameters)`

`Al` MonStgElt *Default :* "*Subgroups*"

Returns `true` if the subgroup H of the group G is a maximal subgroup of G. The algorithm used depends on the value of the parameter `Al`. The default value `Subgroups` computes the maximal subgroups of G if the index of H in G is over 1000 and the maximal subgroups are computable.The subgroup H is then tested for conjugacy with each class found. In the other cases, or when the `Al` parameter is set to `CosetImage`, the function is evaluated by first calling `IsProbablyMaximal` and if that returns `true` then constructing the permutation representation of G on the cosets of H and testing this representation for primitivity.

IsProbablyMaximal(G, H: *parameters*)

Tries RngIntElt *Default :* 20

Given a group G and a subgroup H of G, this function performs a probabilistic test for the maximality of H in G. The test involves adjoining random elements of G to H and determining if the result G. If not, then `false` is returned, otherwise `true` s returned. The number of random elements used is controlled by the parameter `Tries`, which is set to 20 by default.

MaximalSubgroups(G: *parameters*)

Construct the sequence of maximal subgroup classes of G. This is equivalent to the command `Subgroups(G: Al := "Maximal")`. The same parameters as for `Subgroups` are available to limit the search. The algorithm is described in [CH04].

Example H58E18

The `Subgroups` family of commands can deal with fairly large groups. We look at the maximal subgroups of the group of the $4 \times 4 \times 4$ Rubik's cube. This group has order about 1.7×10^{55}.

```
> load rubik444;
Loading "/home/magma/libs/pergps/rubik444"
The automorphism group of the 4 x 4 x 4 Rubik cube.
The group is represented as a permutation group of degree 72.
Its order is
2^50 * 3^29 * 5^9 * 7^7 * 11^4 * 13^2 * 17^2 * 19^2 * 23^2.
Group: G
> time max := MaximalSubgroups(G);
Time: 100.559
> #max;
46
> [Index(G, x`subgroup) : x in max];
[ 51090942171709440000, 51090942171709440000, 9161680528000,
9161680528000, 4509264634875, 4509264634875, 316234143225,
316234143225, 96197645544, 96197645544, 1577585295,
1577585295, 2496144, 2496144, 1961256, 1961256, 1307504,
1307504, 346104, 346104, 42504, 42504, 2187, 1352078,
1352078, 735471, 735471, 134596, 134596, 10626, 10626, 2024,
2024, 120, 276, 276, 56, 24, 24, 105, 28, 8, 35, 2, 2, 2 ]
```

58.8.6 Conjugacy Classes of Subgroups

`SubgroupClasses(G: parameters)`

`Subgroups(G: parameters)`

Representatives for the conjugacy classes of subgroups for the group G. The subgroups are returned as a sequence of records where the i-th record contains:

(a) A representative subgroup H for the i-th conjugacy class (field name `subgroup`).

(b) The order of the subgroup (field name `order`).

(c) The number of subgroups in the class (field name `length`).

(d) [Optional] A presentation for H (field name `presentation`).

`Al` MonStgElt *Default :* "*All*"

`Al := "All"`: Construct all subgroups of G.
`Al := "Maximal"`: Only construct maximal subgroups of G. This option reduces the number of intersections with any elementary abelian layer that need be considered and eliminates the need to recursively apply the algorithm.
`Al := "Normal"`: Only construct normal subgroups of G. This option does not use database lookup to find the normal subgroups of the radical quotient of G and also reduces the number of intersections with any layer that need be considered.

`LayerSizes` SeqEnum *Default :* See below

`LayerSizes := [ 2, 5, 3, 4, 7, 3, 11, 2, 17, 1]` is equivalent to the default. When constructing an Elementary Abelian series for the group, attempt to split 2-layers of size gt 2^5, 3-layers of size gt 3^4, etc. The implied exponent for 13 is 2 and for all primes greater than 17 the exponent is 1.

`Series` SeqEnum *Default :* See below

Use the given elementary abelian series rather than constructing the default series. The first subgroup in the series must be the solvable radical of G. The subgroups must form a descending chain of normal subgroups of G, such that each quotient is elementary abelian. The last subgroup in the series must be either elementary abelian or trivial.

`Presentation` BoolElt *Default :* `false`

`Presentation := true`: Construct a presentation for each subgroup.

`OrderEqual` RngIntElt *Default :*

`OrderEqual := n`: Only construct subgroups having order equal to n.

`OrderDividing` RngIntElt *Default :*

`OrderDividing := n`: Only construct subgroups having order dividing n.

`OrderMultipleOf` RngIntElt *Default :*

`OrderMultipleOf := n`: Only construct subgroups having order a multiple of n.

`IndexLimit` RngIntElt *Default :*

`IndexLimit := n`: Only construct subgroups having index in G less than or equal to n.

`IsElementaryAbelian` BoolElt *Default :* `false`

`IsElementaryAbelian := true`: Only construct elementary abelian subgroups of G.

`IsCyclic` BoolElt *Default :* `false`

`IsCyclic := true`: Only construct cyclic subgroups of G.

`IsAbelian` BoolElt *Default :* `false`

`IsAbelian := true`: Only construct abelian subgroups of G.

`IsNilpotent` BoolElt *Default :* `false`

`IsNilpotent := true`: Only construct nilpotent subgroups of G.

`IsSolvable` BoolElt *Default :* `false`

`IsSolvable := true`: Only construct solvable subgroups of G.

`IsNotSolvable` BoolElt *Default :* `false`

`IsNotSolvable := true`: Only construct insolvable subgroups of G.

`IsPerfect` BoolElt *Default :* `false`

`IsPerfect := true`: Only construct perfect subgroups of G.

`IsRegular` BoolElt *Default :* `false`

`IsRegular := true`: Only construct regular subgroups of G.

`IsTransitive` BoolElt *Default :* `false`

`IsTransitive := true`: Only construct transitive subgroups of G.

The Algorithm: (See Cannon, Cox and Holt [CCH01]) This command proceeds by first constructing an elementary abelian series for G together with G's radical quotient Q. We first attempt to locate the quotient in a database of groups with trivial Fitting subgroup. This database contains all such groups of order up to 216 000, and all such which are perfect of order up to 1 000 000. If Q is found then either all its subgroups, or its maximal subgroups are read from the database. (In some cases only the maximal subgroups are stored.) If Q is not found then we attempt to find the maximal subgroups of Q using a method of Derek Holt. For this to succeed all simple factors of the socle of Q must be found in a second database which currently contains all simple groups of order less than 1.6×10^7, as well as M_{24}, HS, J_3, McL, $Sz(32)$ and $L_6(2)$. There are also special routines to handle numerous other groups. These include: A_n for $n \leq 999$, $L_2(q)$, $L_3(q)$, $L_4(q)$, $L_5(q)$, $L_6(q)$ and $L_7(q)$ for all q, $U_3(q)$ for q prime and $q = 8, 9, 16, 25$, $U_4(q)$ for $q = 4, 5, 7$, $S_4(q)$ for all odd q and even $q \leq 16$, $L_d(2)$ for $d \leq 14$, and the following groups: $U_6(2)$, $S_8(2)$, $S_{10}(2)$, $O_8^{\pm}(2)$, $O_{10}^{\pm}(2)$, $S_6(3)$, $O_7(3)$, $O_8^{-}(3)$, $G_2(4)$, $G_2(5)$, ${}^3D_4(2)$, ${}^2F_4(2)'$, Co_2, Co_3, He, Fi_{22}.

If we have only maximal subgroups of Q, and more are required, we apply the algorithm recursively to the maximal subgroups to determine all subgroups of Q. This may take some time.

The subgroups are then extended to the whole group by stepwise extension through each layer of the elementary abelian series. For each layer this involves determining all possible intersections of a subgroup with this layer and all extensions with this intersection.

The limitations are that the simple factors of the socle of Q must be in the database, which is limited as above. Further, it may take some time to construct all subgroups from the maximal subgroups first found, and, if there is a large elementary abelian layer, there will be many possible intersections, which could also make the algorithm prohibitively slow.

There are numerous parameters for this function which allow the user to place restrictions on which subgroup classes are constructed. Using these restrictions may help overcome the problems noted above.

`SubgroupsLift(G, A, B, Q`: *parameters*`)`

This function isolates one step of the extension process used by the `Subgroups` family of functions. Q is a sequence of records such as returned by `Subgroups`(G). A and B are normal subgroups of G with A/B elementary abelian. The records in Q are interpreted as subgroups of G/A, which are lifted to all possible corresponding subgroups of G/B, subject to the parameters given.

`LowIndexSubgroups(G, n`: *parameters*`)`

`LowIndexSubgroups(G, t`: *parameters*`)`

Returns a sequence of subgroups of G, each with index at most n. The sequence will contain one representative from each conjugacy class of G-subgroups satisfying the index constraint. The algorithm used is described in Cannon, Holt, Slattery & Steel [CHSS03].

The previous version of the algorithm is available by setting the parameter `Algorithm` to the string `"Subgroups"`. In this case the group G is subject to the same restrictions as the group input to the `Subgroups` function above.

In the second form t should be a pair of integers $\langle a, b\rangle$, and subgroups with index in the interval $[a, b]$ will be returned.

Other parameters are `Presentation` which may be set `true` to return a second sequence of presentations of the groups found, and `Print` which may be set to a positive integer to turn on diagnostic printing of the progress of the algorithms.

Example H58E19

With the `Subgroups` family of commands we can get the entire collection of (classes of) subgroups of a group G. We look at the double cover of M_{12}.

```
> load m12cover;
Loading "/home/magma/libs/pergps/m12cover"
```

```
The two-fold cover of the Mathieu group M12 on 24 letters.
Order is 190080 = 2^7 * 3^3 * 5 * 11.
Group: G
> time s := SubgroupClasses(G);
Time: 4.469
> #s;
293
```

This may be too many. The parameters allow us to restrict attention to a subset of the subgroups. We specify that the function is to return only the elementary abelian 2-subgroups of G.

```
> se := SubgroupClasses(G : IsElementaryAbelian := true,
>               OrderMultipleOf := 2);
> #se;
14
> se : Minimal;
Conjugacy classes of subgroups
------------------------------

        GrpPerm: $, Degree 24, Order 2^4
```

Example H58E20

Using the `SubgroupLattice` function we obtain a representative subgroup for each conjugacy class together with the inclusion relations between subgroups.
WARNING: *Computing the inclusions is very time consuming and should only be performed for small groups.*

```
> G := PSL(2,9);
> time L := SubgroupLattice(G);
Time: 0.200
> L;

[21]  Order 60   Length 6   Maximal Subgroups: 10 12 14
---
[22]  Order 360  Length 1   Maximal Subgroups: 17 18 19 20 21
> NumberOfInclusions(L!5, L!20);
6
> L[5];
Permutation group acting on a set of cardinality 10
Order = 5
  (1, 8, 9, 3, 4)(2, 7, 5, 10, 6)
```

The order and class length of each class of subgroups is listed, along with the information about where to find the maximal subgroups of a member of this class. Further information about

inclusions is available from the lattice. We see that 6 members of class 5 are contained in any fixed member of class 20.

58.8.7 Classes of Subgroups Satisfying a Condition

`NormalSubgroups(G: parameters)`

Construct the sequence of normal subgroup classes of G. This is equivalent to `Subgroups(G: Al := "Normal")`. The same parameters as for `Subgroups` are available to limit the search.

`ElementaryAbelianSubgroups(G: parameters)`

Construct the sequence of elementary abelian subgroups of G. This is equivalent to `Subgroups(G: IsElementaryAbelian := true)`. The same parameters as for `Subgroups` are available to limit the search.

`CyclicSubgroups(G: parameters)`

Construct the sequence of cyclic subgroups of G. This is equivalent to `Subgroups(G: IsCyclic := true)`. The same parameters as for `Subgroups` are available to limit the search.

`AbelianSubgroups(G: parameters)`

Construct the sequence of abelian subgroups of G. Equivalent to `Subgroups(G: IsAbelian := true)`. The same parameters as for `Subgroups` are available to limit the search.

`NilpotentSubgroups(G: parameters)`

Construct the sequence of nilpotent subgroups of G. This is equivalent to `Subgroups(G: IsNilpotent := true)`. The same parameters as for `Subgroups` are available to limit the search.

`SolvableSubgroups(G: parameters)`

Construct the sequence of solvable subgroups of G. This is equivalent to `Subgroups(G: IsSolvable := true)`. The same parameters as for `Subgroups` are available to limit the search.

`PerfectSubgroups(G: parameters)`

Construct the sequence of perfect subgroups of G. Equivalent to `Subgroups(G: IsNotSolvable := true)`. The same parameters as for `Subgroups` are available to limit the search.

`NonsolvableSubgroups(G: parameters)`

Construct the sequence of insolvable subgroups of G. This is equivalent to `Subgroups(G: IsNotSolvable := true)`. The same parameters as for `Subgroups` are available to limit the search.

`SimpleSubgroups(G: parameters)`

Construct the sequence of non-abelian simple subgroup classes of G. This is equivalent to `Subgroups(G: Al := "Simple")`. The same parameters as for `Subgroups` are available to limit the search.

58.9 Quotient Groups

58.9.1 Construction of Quotient Groups

`quo< G | L >`

Given the permutation group G, construct the quotient group $Q = G/N$, where N is the normal closure of the subgroup of G generated by the elements specified by L. The clause L is a list of one or more items of the following types:

(a) A sequence of n integers defining a permutation of G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic permutation group. The function returns

(a) the quotient group Q, and

(b) the natural homomorphism $f : G \to Q$.

Currently, the quotient group is constructed via the regular representation of the quotient, so the application of this operator is restricted to the case where the index of N in G is small. The representation of the quotient group that is returned is the result of a degree reduction applied to the regular representation, so need not be regular. The generators of the quotient are images of the generators of G.

The second return value is the epimorphism from G to the resulting quotient group.

`G / N`

Given a normal subgroup N of the permutation group G, construct the quotient of G by N. Currently, the quotient group is constructed via the regular representation of the quotient, so the application of this operator is restricted to the case where the index of N in G is small. The representation of the quotient group that is returned is the result of a degree reduction applied to the regular representation, so need not be regular. The generators of the quotient are images of the generators of G.

Example H58E21

The quotient of Sym(4) by the Klein 4-group is constructed by the following statement:

```
> Q, f := quo< Sym(4) | (1,2)(3,4), (1,3)(2,4) >;
> Q;
Permutation group Q acting on a set of cardinality 3
Order = 6 = 2 * 3
    (2, 3)
    (1, 2)
```

58.9.2 Abelian, Nilpotent and Soluble Quotients

A number of standard quotients may be constructed. The method first constructs a presentation for the permutation group and then applies the appropriate fp-group algorithm.

`AbelianQuotient(G)`

The maximal abelian quotient G/G' of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism $\pi : G \to G/G'$ is returned as second value.

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient Q of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism $\pi : G \to Q$ is returned as second value.

`pQuotient(G, p, c)`

Given a permutation group G, a prime p and a positive integer c, construct a pc-presentation for the largest p-quotient P of G having lower exponent-p class at most c. If c is given as 0, then the limit 127 is placed on the class.

The function also returns the natural homomorphism π from G to P, a sequence S describing the definitions of the pc-generators of P and a flag indicating whether P is the maximal p-quotient of G.

The k-th element of S is a sequence of two integers, describing the definition of the k-th pc-generator $P.k$ of P as follows.

- If $S[k] = [0, r]$, then $P.k$ is defined via the image of $G.r$ under π.
- If $S[k] = [r, 0]$, then $P.k$ is defined via the power relation for $P.r$.
- If $S[k] = [r, s]$, then $P.k$ is defined via the conjugate relation involving $P.r^{P.s}$.

`NilpotentQuotient(G, c)`

This function returns the class c nilpotent quotient of G, together with the epimorphism π from G onto this quotient.

`SolvableQuotient(G)`

`SolubleQuotient(G)`

The function returns the largest soluble quotient S of the permutation group G together with the epimorphism $\pi : G \to S$.

Example H58E22

The soluble quotient of the wreath product of Sym(6) with the dihedral group of order 12 is easily constructed:

```
> G := WreathProduct( Sym(6), DihedralGroup(6));
> #G;
1671768834048000000
> SQ, phi := SolubleQuotient(G);
SQ;
GrpPC : SQ of order 768 = 2^8 * 3
PC-Relations:
    SQ.1^2 = SQ.5,
    SQ.2^2 = Id(SQ),
    SQ.3^2 = Id(SQ),
    SQ.4^2 = Id(SQ),
    SQ.5^3 = Id(SQ),
    SQ.6^2 = Id(SQ),
    SQ.7^2 = Id(SQ),
    SQ.8^2 = Id(SQ),
    SQ.9^2 = Id(SQ),
    SQ.2^SQ.1 = SQ.2 * SQ.5,
    SQ.3^SQ.1 = SQ.3 * SQ.4 * SQ.6 * SQ.8,
    SQ.4^SQ.1 = SQ.4 * SQ.9,
    SQ.4^SQ.2 = SQ.4 * SQ.6 * SQ.7 * SQ.8,
    SQ.5^SQ.2 = SQ.5^2,
    SQ.5^SQ.3 = SQ.5 * SQ.7,
    SQ.5^SQ.4 = SQ.5 * SQ.6 * SQ.8,
    SQ.6^SQ.1 = SQ.6 * SQ.8,
    SQ.6^SQ.2 = SQ.7 * SQ.8,
    SQ.6^SQ.5 = SQ.6 * SQ.7 * SQ.8 * SQ.9,
    SQ.7^SQ.1 = SQ.8,
    SQ.7^SQ.2 = SQ.9,
    SQ.7^SQ.5 = SQ.7 * SQ.9,
    SQ.8^SQ.1 = SQ.7 * SQ.9,
    SQ.8^SQ.2 = SQ.6 * SQ.9,
    SQ.8^SQ.5 = SQ.6 * SQ.9,
    SQ.9^SQ.1 = SQ.6 * SQ.8 * SQ.9,
    SQ.9^SQ.2 = SQ.7,
    SQ.9^SQ.5 = SQ.7
```

58.10 Permutation Group Actions

58.10.1 G-Sets

Let G be a group. A *G-set* is a pair (Y, f), where Y is a set and $f : Y \times G \to Y$ is a mapping such that

$$(a) \qquad f(f(y, g), h) = f(y, gh), \quad \text{for all } g, h \in G$$

and

$$(b) \qquad f(y, 1) = y, \quad \text{for all } y \in Y.$$

The mapping f defines the *action* of G on the set Y.

If G is defined as a permutation group acting on the set X and Y is another G-set then there is a homomorphism of G^X into G^Y.

We distinguish three types of G-set for a permutation group G. The set on which G is defined will be referred to as the *natural G-set* and the action of G on X as the *natural action* of G.

Let A be a set. A *derived set* of A is defined (recursively) as follows:

(i) A subset of A is a derived set;

(ii) A set of k-subsets of A is a derived set;

(iii) A set of k-sequences of A is a derived set;

(iv) A set of ordered partitions of A is a derived set;

(v) A subset of a cartesian product of derived sets of A is a derived set.

The natural action of G on X induces a natural action on the G-closure Y of any derived set of X. Such a set Y is also a G-set. For example, a subset of X is a G-set for G if and only if it is a union of orbits for G.

Finally, a *general G-set* is an arbitrary set Y with an action f satisfying the conditions (a) and (b).

The notion of a G-set enables the user to work with several different actions of G. Rather than having to always work with the image of G with respect to an action on a set Y, the user may specify the required operation in terms of G.

58.10.2 Creating a G-Set

`GSetFromIndexed(G, Y)`

Given a group G and an indexed set Y with the same cardinality as the natural G-set, return a G-set corresponding to the natural bijection between the labelling L (= Labelling(G)) of G and Y. Explicitly, the bijection is

$$\phi : L \to Y : l \mapsto Y[\text{Position}(L, l)].$$

Then the returned G-set is the set Y endowed with the action

$$f : Y \times G \to Y : (y, p) \mapsto \phi(p(\phi^{-1}(y))).$$

`GSet(G, X, Y)`

`GSet(G, Y)`

Return the smallest derived G-set containing Y as a subset under the action of G on X. If X is omitted, then the natural action will be assumed. In practice, the set Y is expanded until for each element y of the expanded Y, the image of y under each generator of G under the action described by X is also in Y. The action of G on Y is then the action induced by the action of G on X.

`GSet(G)`

Given a permutation group G, return the G-set corresponding to the natural action of G.

`GSet(G, Y, f)`

Construct the smallest G-set containing Y as a subset with the given action f. The map f must satisfy the requirements of a G-set action. In particular, the domain of f must be a superset of $Y \times G$, the codomain a superset of Y and the two conditions listed at the beginning of this section must be met.

`Action(Y)`

The map giving the action of the group on the G-set Y.

`Group(Y)`

The group associated with the G-set Y.

`Labelling(G)`

Given a permutation group G of degree n, return an indexed set giving the internal mapping of the natural G-set of G onto the set $\{1, \ldots, n\}$, where n is the degree of G.

`Degree(g, Y)`

`Degree(g)`

Given an element g of a permutation group G and a G-set Y, return the cardinality of the subset of Y consisting of points that are moved by g. If Y is omitted, the natural G-set X is assumed.

`Degree(G, Y)`

`Degree(G)`

Given a G-set Y, return the cardinality of Y. If Y is omitted, the natural G-set X is assumed.

`Support(g, Y)`

`Support(g)`

Given an element g of a permutation group G and a G-set Y, return the subset of Y consisting of points that are moved by g. If Y is omitted, the natural G-set X is assumed.

`Support(G, Y)`

`Support(G)`

Given a permutation group G and a G-set Y, return the subset of Y consisting of points that are moved by at least one element of G. If Y is omitted the natural G-set for G is assumed.

Example H58E23

We construct a G-set with a user defined action. Our example will take a group G and a normal subgroup N of index 4. The G-set will be the irreducible characters of N, with the usual G action obtained from permuting the elements of N by conjugation. As this is not a derived set we will define the action via a map.

```
> G := PGammaL(2, 9);
> N := PSL(2, 9);
> CT := CharacterTable(N);
> X := SequenceToSet(CT);
> XxG := CartesianProduct(X, G);
> f := map< XxG -> X | x :-> x[1]^x[2] >;
> Y := GSet(G, X, f);
```

This defines our G-set `Y`. The inertia group of a character is its stabilizer in this action. Let us compute an inertia group.

```
> chi := CT[2];
> I := Stabilizer(G, Y, chi);
> Index(G, I);
2
> [#o : o in Orbits(G, Y)];
[ 1, 1, 1, 2, 2 ]
```

We find that two of the characters have inertia groups of index 2 in G, while three are G-invariant.

58.10.3 Images, Orbits and Stabilizers

`x ^ g`

Given a permutation group G with natural G-set X and an object x which is an element of some derived G-set of X, find the image of x under G.

`Image(g, Y, y)`

`Image(g, y)`

Given a permutation g belonging to a group G, a G-set Y, and an element y of Y, find the image of y under g. If y is an element of some derived G-set of G, the set Y may be omitted.

`Fix(g, Y)`

`Fix(g)`

Given a permutation g belonging to a group G and a G-set Y, construct the fixed-point set of g in its action on Y. In the case in which Y is the natural G-set, Y may be omitted. The fixed-point set is returned as a subset of points of Y.

`Fix(G, Y)`

`Fix(G)`

The fixed-point set of the permutation group G in its action on the G-set Y (or the natural G-set for G if Y is omitted).

`x ^ G`

Given a permutation group G with natural G-set X and an element x belonging to some derived G-set of X, construct the orbit of x under G. The orbit is returned as a G-set.

`Cycle(e, x)`

Let e be an element of a permutation group defined as acting on a set containing x. Returns the set of images of x under repeated application of e as an indexed set with x the first element. This gives the cycle containing x in the disjoint cycle representation of e.

`CycleDecomposition(e)`

Let e be an element of a permutation group defined as acting on a set X. Returns a sequence of indexed sets partitioning X, each of which is a cycle of e. This gives the full disjoint cycle representation of e.

`Orbit(G, Y, y)`

`Orbit(G, y)`

Given a permutation group G, a G-set Y, and an element y belonging to Y, construct the orbit of y under G. The orbit is returned as a G-set. If y is an element of some derived G-set of G, the set Y may be omitted.

`Orbits(G, Y)`

`Orbits(G)`

Given a permutation group G and a G-set Y, construct the orbits of G on Y. If the set Y is omitted, the orbits of G on its natural G-set are constructed. The orbits are returned as a sequence of G-sets.

`OrbitRepresentatives(G)`

Given a permutation group G, construct the orbits of G on its natural G-set. The orbit descriptions are returned as a sequence of tuples $\langle l, r \rangle$ giving the length l and a representative r of each orbit of G on its support.

This function stores *only* the orbit representatives and so is more space-efficient than `Orbits`. However, it should be used only if the user wants to determine just the orbit representatives; queries about the orbits containing other elements of the support will cause further computation.

`OrbitClosure(G, Y, S)`

`OrbitClosure(G, S)`

Given a subset S of the G-set Y, construct the smallest G-invariant subset of Y that contains S. If Y is the natural G-set for G it may be omitted.

`IsConjugate(G, Y, y, z)`

`IsConjugate(G, y, z)`

Given elements y and z belonging either to a G-set Y or to a (restricted) derived set of Y, return the value `true` if there exists an element $g \in G$ such that $y^g = z$. Otherwise, return `false`. If such an element exists, then it is returned as the second value of the function. If y and z belong to the natural G-set, then Y may be omitted. Currently, y and z are restricted to being elements, sets of elements, multisets of elements, sequences of elements, ordered partitions, or unordered partitions of Y.

`Stabilizer(G, Y, y)`

`Stabiliser(G, Y, y)`

`Stabilizer(G, y)`

`Stabiliser(G, y)`

Given a permutation group G and a G-set Y, and an object y which is either an element, a sequence of elements, a set of elements, an ordered partition or a tuple over the G-set Y, find the stabilizer of y in G. The stabilizer is returned as a subgroup of G. If Y is the natural G-set, it may be omitted.

`IsPrimitive(G, Y)`

`IsPrimitive(G)`

Returns `true` if G acts primitively on the G-set Y. If Y is the natural G-set, the set Y may be omitted.

`IsTransitive(G, Y)`

`IsTransitive(G)`

Returns `true` if G acts transitively on the G-set Y. If Y is the natural G-set, the set Y may be omitted.

`IsTransitive(G, Y, k)`

`IsTransitive(G, k)`

Returns `true` if G acts k-transitively on the G-set Y. If Y is the natural G-set, the set Y may be omitted.

`IsSharplyTransitive(G, Y, k)`

`IsSharplyTransitive(G, k)`

Returns `true` if G acts sharply k-transitively on the G-set Y. If Y is the natural G-set, the set Y may be omitted.

`Transitivity(G, Y)`

`Transitivity(G)`

The degree of transitivity of G acting on the G-set Y. The set Y may be omitted if it is the same as the natural G-set.

`IsRegular(G, Y)`

`IsRegular(G)`

Returns `true` if G acts regularly on the G-set Y. If Y is the natural G-set, the set Y may be omitted. The algorithm used is that of Sims, see [CB92].

`IsSemiregular(G, Y)`

`IsSemiregular(G)`

Returns `true` if G acts semiregularly on the G-set Y. If Y is the natural G-set, the set Y may be omitted. The algorithm used is a variation of Sims' regularity test, see [CB92].

`IsSemiregular(G, Y, S)`

`IsSemiregular(G, S)`

Given a permutation group G, a G-set Y for G, and a union of orbits S for G in its action on Y, return `true` if G acts semiregularly on S. If Y is the natural G-set, then Y may be omitted.

`IsFrobenius(G)`

Returns `true` if the permutation group G is a Frobenius group with respect to its natural action, `false` otherwise. (A group G defined as acting on X is Frobenius if it acts transitively but non-regularly on X and if the pointwise stabilizer of any two distinct points of X is the trivial group.)

Example H58E24

We apply some of these functions to the Mathieu group M_{24}, taking as generators the following three permutations:

$$(1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,24),$$

$$(2,16,9,6,8)(3,12,13,18,4)(7,17,10,11,22)(14,19,21,20,15),$$

$$(1,22)(2,11)(3,15)(4,17)(5,9)(6,19)(7,13)(8,20)(10,16)(12,21)(14,18)(23,24).$$

```
> M24 := sub< Sym(24) |
>  (1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,24),
>  (2,16,9,6,8)(3,12,13,18,4)(7,17,10,11,22)(14,19,21,20,15),
>  (1,22)(2,11)(3,15)(4,17)(5,9)(6,19)(7,13)(8,20)(10,16)(12,21)(14,18)(23,24)>;
> M24;
Permutation group M24 acting on a set of cardinality 24
    (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20,
       21, 22, 24)
    (2, 16, 9, 6, 8)(3, 12, 13, 18, 4)(7, 17, 10, 11, 22)(14, 19, 21, 20, 15)
    (1, 22)(2, 11)(3, 15)(4, 17)(5, 9)(6, 19)(7, 13)(8, 20)(10, 16)(12, 21)
       (14, 18)(23, 24)
```

Choosing a random element x of M_{24}, we use it to compute some images.

```
> x := Random(M24);
> 1^x;
7
> [1,2,3,4]^x;
```

```
[ 7, 9, 8, 17 ]
> { 1,2,3,4}^x;
{ 17, 7, 8, 9 }
```

We find the stabilizer of the point 1, which is the group M_{23}.

```
> S1 := Stabilizer(M24, 1);
> S1;
Permutation group S1 acting on a set of cardinality 24
Order = 10200960 = 2^7 * 3^2 * 5 * 7 * 11 * 23
    (2, 16, 9, 6, 8)(3, 12, 13, 18, 4)(7, 17, 10, 11, 22)(14, 19, 21, 20, 15)
    (7, 17, 22)(8, 11, 13)(9, 14, 12)(10, 20, 19)(15, 23, 18)(16, 21, 24)
    (3, 6, 18)(5, 16, 14)(7, 21, 22)(8, 19, 17)(9, 20, 24)(11, 12, 13)
    (6, 18, 15)(7, 19, 16)(8, 13, 11)(9, 10, 22)(12, 21, 20)(14, 17, 24)
    (4, 12, 6, 19)(5, 22, 24, 8)(7, 17, 20, 14)(9, 15, 13, 18)(10, 21)(11, 16)
    (6, 22, 7)(8, 13, 11)(9, 20, 16)(10, 18, 21)(12, 15, 19)(14, 24, 23)
    (5, 12, 21)(6, 15, 18)(7, 22, 8)(9, 16, 17)(10, 14, 13)(11, 24, 19)
```

We next compute the stabilizer of the sequence $[1, 2, 3, 4, 5]$.

```
> SQ := Stabilizer(M24, [1,2,3,4,5]);
> SQ;
Permutation group SQ acting on a set of cardinality 24
Order = 48 = 2^4 * 3
    (6, 18, 15)(7, 19, 16)(8, 13, 11)(9, 10, 22)(12, 21, 20)(14, 17, 24)
    (7, 17, 22)(8, 11, 13)(9, 14, 12)(10, 20, 19)(15, 23, 18)(16, 21, 24)
    (6, 22, 7)(8, 13, 11)(9, 20, 16)(10, 18, 21)(12, 15, 19)(14, 24, 23)
> Orbits(SQ);
[
    GSet{@ 1 @},
    GSet{@ 2 @},
    GSet{@ 3 @},
    GSet{@ 4 @},
    GSet{@ 5 @},
    GSet{@ 6,18, 22, 15, 21, 9, 7, 23, 19, 20, 24, 10,
    14, 17, 16 12 @},
    GSet{@ 8, 13, 11 @}
]
```

The five fixed points together with the orbit of length 3 form a block of a $5-(24, 8, 1)$ design. By computing the orbit of this block under M_{24}, we obtain all the blocks of the design.

```
> B := { 1,2,3,4,5,8,11,13};
> D := B^M24;
> #D;
759
```

Finally, we check that the set stabilizer of the block $\{ 1, 2, 3, 4, 5, 8, 11, 13\}$ has index 759 in M_{24}.

```
> Index(M24, Stabilizer(M24, { 1,2,3,4,5,8,11,13}));
759
```

58.10.4 Action on a G-Space

`Action(G, Y)`

Given a permutation group G defined to be acting on X and a set Y, construct the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the set Y. The function returns:

(a) The natural homomorphism $\phi : G \to L$;

(b) The induced group L;

(c) The kernel of the action (a subgroup of G).

`ActionImage(G, Y)`

Given a permutation group G defined to be acting on X and a set Y, construct the permutation group L giving the action of G on the set Y.

`ActionKernel(G, Y)`

Construct the kernel of the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the G-set Y.

`IsFaithful(G, Y)`

Returns `true` if the action of G on the G-set Y is faithful.

Example H58E25

We take the group PSL(3, 4) acting on projective points and construct its representation on flags (point-line pairs). In order to construct the flags, we need to find a line. If H is the stabilizer of a point α in PSL(3, 4) in its action on projective points, then a line consists of α together with the points in any non-trivial orbit of $O_2(G)$.

```
> G := ProjectiveSpecialLinearGroup(3, 4);
> O2 := pCore( Stabilizer(G, 1), 2 );
> O2;
Permutation group O2 acting on a set of cardinality 21
Order = 16 = 2^4
       (3, 4)(5, 7)(9, 16)(10, 17)(11, 15)(13, 18)(14, 19)(20, 21)
       (3, 20)(4, 21)(5, 15)(7, 11)(9, 10)(13, 19)(14, 18)(16, 17)
       (2, 8)(5, 15)(6, 12)(7, 11)(9, 17)(10, 16)(13, 18)(14, 19)
       (2, 12)(5, 11)(6, 8)(7, 15)(9, 16)(10, 17)(13, 19)(14, 18)
> flag := < 1, Orbit(O2, 2) >;
> flag;
<1, GSet{@ 2, 6, 8, 12 @}>
> flags := GSet(G, Orbit(G, flag));
> #flags;
105
> GOnFlags := ActionImage(G, flags);
> GOnFlags;
Permutation group GOnFlags acting on a set of
```

```
cardinality 105
Order = 20160 = 2^6 * 3^2 * 5 * 7
> Stabilizer(GOnFlags, Rep(flags));
Permutation group acting on a set of cardinality 105
Order = 192 = 2^6 * 3
```

58.10.5 Action on Orbits

The operations described here are concerned with the class of G-sets consisting of G-invariant subsets of the natural G-set. Because of the special nature of such G-sets, more efficient algorithms are available for computing with homomorphisms of G induced by the action of G on such a G-set. See Butler [But85] for more details.

`OrbitAction(G, T)`

The homomorphism $f : G \to L$ induced by the action of G on the G-invariant subset T of X (a union of orbits).

`OrbitImage(G, T)`

The group L defined by the action of G on the G-invariant subset T of X (a union of orbits).

`OrbitKernel(G, T)`

The kernel of the homomorphism $f : G \to L$, where the group L gives the action of G on the G-invariant subset T of X (a union of orbits).

`IsOrbit(G, S)`

Returns `true` if the subset S of Support(G) is invariant under G.

Example H58E26

We study an intransitive group of degree 36 generated by the permutations

$$(3, 17, 26)(4, 16, 25)(5, 18, 27)(8, 15, 24),$$
$$(1, 32, 10)(2, 31, 11)(3, 35, 12)(6, 30, 15),$$
$$(12, 33, 24)(13, 29, 20)(14, 28, 19)(17, 30, 21),$$
$$(6, 26, 33)(7, 22, 34)(8, 21, 35)(9, 23, 36).$$

```
> G := PermutationGroup< 36 | (3, 17, 26)(4, 16, 25)(5, 18, 27)(8, 15, 24),
>                             (1, 32, 10)(2, 31, 11)(3, 35, 12)(6, 30, 15),
>                             (12, 33, 24)(13, 29, 20)(14, 28, 19)(17, 30, 21),
>                             (6, 26, 33)(7, 22, 34)(8, 21, 35)(9, 23, 36) >;
> IsTransitive(G);
false
> Orbit(G, 1);
```

```
GSet{@ 1, 32, 10 @}
> O := Orbits(G);
> O;
[
    GSet{@ 1, 32, 10 @},
    GSet{@ 2, 31, 11 @},
    GSet{@ 4, 16, 25 @},
    GSet{@ 5, 18, 27 @},
    GSet{@ 7, 22, 34 @},
    GSet{@ 9, 23, 36 @},
    GSet{@ 13, 29, 20 @},
    GSet{@ 14, 28, 19 @}
    GSet{@ 3, 17, 35, 26, 30, 12, 8, 33, 15, 21, 24, 6 @},
]
> Order(G);
933120
```

We see that the group is intransitive having eight orbits of size 3 and one orbit of size 12. We consider the action of G on the orbit of size 12.

```
> f := OrbitAction(G, O[9]);
> f;
Mapping from: GrpPerm: G to GrpPerm: $
> Im := Image(f);
> Im;
Permutation group acting on a set of cardinality 12
Order = 11520 = 2^8 * 3^2 * 5
    (1, 6, 9)(3, 5, 8)
    (4, 11, 8)(6, 10, 7)
    (6, 8)(7, 11)
    (2, 8, 10)(4, 12, 6)
    (3, 10, 8)(4, 6, 9)
> Ker := Kernel(f);
> Ker;
Permutation group acting on a set of cardinality 36
Order = 81 = 3^4
    (4, 16, 25)(5, 18, 27)
    (7, 22, 34)(9, 23, 36)
    (13, 29, 20)(14, 28, 19)
    (1, 32, 10)(2, 31, 11)(4, 25, 16)(5, 27, 18)
> IsElementaryAbelian(Ker);
true
```

Thus G has an elementary abelian normal subgroup of order 81 which is the kernel of the restriction of G to the orbit of size 12.

58.10.6 Action on a G-invariant Partition

This section describes the functions supplied by MAGMA for computing with block systems for a permutation group.

`IsBlock(G, S)`

Given a transitive permutation group G with natural G-set X, and a subset S of X, return `true` if S is a block for G in its action on X.

`IsPrimitive(G)`

Returns `true` if the transitive permutation group G is primitive.

`MaximalPartition(G)`

Construct a G-invariant partition P for the transitive permutation group G with natural G-set X. The partition P is maximal in the sense that there is no G-invariant partition P' of X such that some block of P' properly contains a block of the partition P. The block system is returned as a partition of X. If G is primitive, the partition with one block is returned.

`MinimalPartition(G: parameters)`

Construct a non-trivial G-invariant partition P of the natural G-set X of the transitive permutation group G. The partition P is minimal in the sense that there is no G-invariant partition P' of X such that some block of P' is properly contained in some block of the partition P. The block system is returned as a partition of X. If G is primitive, or if no partition satisfying the side-conditions (see below) is found, then the empty set is returned. The algorithm used is based on Schönert & Seress [SS94].

`Block := S` { ELT } *Default :* []

If S is non-empty, then the partition P must possess a block B such that S is a subset of B. In this case the algorithm used is that of Atkinson, [Atk75].

`MinimalPartitions(G: parameters)`

Construct all non-trivial minimal G-invariant partitions of the natural G-set X of the transitive permutation group G. A partition P is minimal in the sense that there is no G-invariant partition P' of X such that some block of P' is properly contained in some block of the partition P.

The minimal block systems are returned as a sequence of sets of sets. If G is primitive, the function returns the empty sequence.

The algorithm used is based on Schönert & Seress [SS94].

`Limit := n` RNGINTELT *Default :* ∞

The function will return after creating at most n block systems. This option is useful in situations where, say, two distinct minimal blocks systems are required for a reduction algorithm.

`AllPartitions(G)`

Construct all non-trivial G-invariant partitions of the natural G-set X of the transitive permutation group G. The structure returned is a set containing one block from each such partition. The block chosen is the block containing the first element of `Labelling(G)`.

`BlocksAction(G, P)`
`BlocksAction(G, P)`
`BlocksAction(G, P)`
`BlocksAction(G, P)`

Given a transitive permutation group G with natural G-set X and a G-invariant partition P of X, construct the group L induced by the action of G on the blocks of P. In the second form, P is specified by giving a single block of the partition. The function returns

(a) The natural homomorphism $f : G \to L$;

(b) The induced group;

(c) The kernel of the action (a subgroup of G).

The relationship between the supports of G and L is given by the returned mapping, which may also be used as a map from `Labelling(G)` to `Labelling(L)`. In the forward direction this takes each element in the support of G to its block number in the support of L, while in the reverse direction this takes a block number to a representative of the block.

`BlocksImage(G, P)`
`BlocksImage(G, P)`
`BlocksImage(G, P)`
`BlocksImage(G, P)`

Given a transitive permutation group G with natural G-set X and a G-invariant partition P of X, construct the group induced by the action of G on the blocks of P. In the second form, P is specified by giving a single block of the partition.

`BlocksKernel(G, P)`
`BlocksKernel(G, P)`
`BlocksKernel(G, P)`
`BlocksKernel(G, P)`

Given a transitive permutation group G with natural G-set X and a G-invariant partition P of X, construct the kernel of the action of G on the blocks of P. In the second form, P is specified by giving a single block of the partition.

Example H58E27

An imprimitive group of degree 100 constructed by Capel has several different block systems.

```
> G := sub< Sym(100) |
>   (1,21,41,61,81)(2,82,62,42,22)(3,23,43,63,83)(4,84,64,44,24)
>     (5,25,45,65,85)(6,86,66,46,26)(7,27,47,67,87)(8,88,68,48,28)
>     (9,29,49,69,89)(10,90,70,50,30)(11,31,51,71,91)(12,92,72,52,32)
>     (13,33,53,73,93)(14,94,74,54,34)(15,35,55,75,95)(16,96,76,56,36)
>     (17,37,57,77,97)(18,98,78,58,38)(19,39,59,79,99)(20,100,80,60,40),
>   (1,4,6,7,10)(2,3,5,8,9)(11,19,17,15,14)(12,20,18,16,13)(21,24,26,27,30)
>      (22,23,25,28,29)(31,39,37,35,34)(32,40,38,36,33)(41,44,46,47,50)
>      (42,43,45,48,49)(51,59,57,55,54)(52,60,58,56,53)(61,64,66,67,70)
>      (62,63,65,68,69)(71,79,77,75,74)(72,80,78,76,73)(81,84,86,87,90)
>      (82,83,85,88,89)(91,99,97,95,94)(92,100,98,96,93),
>   (1,11,2,12)(3,13,4,14)(5,16,6,15)(7,17,8,18)(9,20,10,19)(21,31,22,32)
>      (23,33,24,34)(25,36,26,35)(27,37,28,38)(29,40,30,39)(41,51,42,52)
>      (43,53,44,54)(45,56,46,55)(47,57,48,58)(49,60,50,59)(61,71,62,72)
>      (63,73,64,74)(65,76,66,75)(67,77,68,78)(69,80,70,79)(81,91,82,92)
>      (83,93,84,94)(85,96,86,95)(87,97,88,98)(89,100,90,99) >;
> MaxPart := MaximalPartition(G);
> #MaxPart;
2
> MaxPart;
GSet{@
    { 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 31, 32, 33, 34, 35,
    36, 37, 38, 39, 40, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 71,
    72, 73, 74, 75, 76, 77, 78, 79, 80, 91, 92, 93, 94, 95, 96, 97,
    98, 99, 100 },
    { 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 21, 22, 23, 24, 25, 26, 27, 28,
    29, 30, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 61, 62, 63, 64,
    65, 66, 67, 68, 69, 70, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90 }
@}
> MinPart := MinimalPartition(G);
> #MinPart;
50
```

We see that the group has a (maximal) system of imprimitivity consisting of 2 blocks of size 50 and a (minimal) system of imprimitivity consisting of 50 blocks of size 2.

```
> Parts := MinimalPartitions(G);
> [ #p : p in Parts ];
[ 50, 50, 50, 50, 20, 50 ]
```

Thus the group has six distinct minimal G-invariant partitions. Of these five have 50 blocks of size two while the remaining one has 20 blocks of size 5. We examine the action of G on one of the partitions into 50 blocks of size 2.

```
> f, Im, Ker := BlocksAction(G, Parts[1]);
> f;
Mapping from: GrpPerm: G to GrpPerm: Im
```

```
> Im;
Permutation group Im acting on a set of cardinality 50
Order = 7812500 = 2^2 * 5^9
    (1, 11, 31, 32, 12)(2, 13, 33, 34, 14)(3, 15, 35, 36, 16)
         (4, 17, 37, 38, 18) (5, 19, 39, 40, 20)(6, 21, 41, 42, 22)
         (7, 23, 43, 44, 24)(8, 25, 45, 46, 26)(9, 27, 47, 48, 28)
         (10, 29, 49, 50, 30)
    (1, 2, 3, 4, 5)(6, 10, 9, 8, 7)(11, 14, 16, 17, 20)(12, 13, 15, 18, 19)
         (21, 29, 27, 25, 24)(22, 30, 28, 26, 23)(31, 34, 36, 37, 40)
         (32, 33, 35, 38, 39)(41, 49, 47, 45, 44)(42, 50, 48, 46, 43)
    (1, 6)(2, 7)(3, 8)(4, 9)(5, 10)(11, 21, 12, 22)(13, 23, 14, 24)
        (15, 26, 16, 25)(17, 27, 18, 28)(19, 30, 20, 29)(31, 41, 32, 42)
        (33, 43, 34, 44)(35, 46, 36, 45)(37, 47, 38, 48)(39, 50, 40, 49)
> Ker;
Permutation group Ker acting on a set of cardinality 100
Order = 1
```

Thus, G acts faithfully on this block system.

Example H58E28

When analyzing a permutation group, it is sometimes necessary to reduce it to its primitive components. This can be done by using the constituent homomorphism and blocks homomorphism functions. We illustrate their use by analyzing the group of Rubik's cube, represented as a permutation group on 48 letters:

```
> G := sub<Sym(48) |
>     (1,3,8,6)(2,5,7,4)(9,48,15,12)(10,47,16,13)(11,46,17,14),
>     (6,15,35,26)(7,22,34,19)(8,30,33,11)(12,14,29,27)(13,21,28,20),
>     (1,12,33,41)(4,20,36,44)(6,27,38,46)(9,11,26,24)(10,19,25,18),
>     (1,24,40,17)(2,18,39,23)(3,9,38,32)(41,43,48,46)(42,45,47,44),
>     (3,43,35,14)(5,45,37,21)(8,48,40,29)(15,17,32,30)(16,23,31,22),
>     (24,27,30,43)(25,28,31,42)(26,29,32,41)(33,35,40,38)(34,37,39,36) >;
> O1 := Orbits(G);
> O1;
[
    GSet{@ 1, 3, 6, 8, 9, 11, 12, 14, 15, 17, 24, 26, 27, 29,
     30, 32, 33, 35, 38, 40, 41, 43, 46, 48 @},
    GSet{@ 2, 4, 5, 7, 10, 13, 16, 18, 19, 20, 21, 22, 23, 25, 28,
     31, 34, 36, 37, 39, 42, 44, 45, 47 @}
]
```

Thus, G has two orbits, each of size 24. We consider the restriction of the action of G to the first of these orbits.

```
> f1, Im1, Ker1 := OrbitAction(G, O1[1]);
> FactoredOrder(Im1);
[ <2, 7>, <3, 9>, <5, 1>, <7, 1> ]
> IsPrimitive(Im1);
false
```

```
> P1 := MinimalPartition(Im1);
> #P1;
8
> f2, Im2, Ker2 := BlocksAction(Im1, P1);
> FactoredOrder(Im2);
[ <2, 7>, <3, 2>, <5, 1>, <7, 1> ]
> IsPrimitive(Im2);
true
> IsSymmetric(Im2);
true
> FactoredOrder(Ker2);
[ <3, 7> ]
> IsElementaryAbelian(Ker2);
true
```

Hence the group obtained by restricting G to its first orbit is isomorphic to $Sym(8)$ acting on an elementary abelian normal subgroup of order 3^7. We next investigate the kernel $Ker1$ of the restriction of G to the first orbit of length 24. We know that $Ker1$ must fix all the points in the first orbit of G so we first take its restriction to the second orbit.

```
> f3, Im3, Ker3 := OrbitAction(Ker1, O1[2]);
> IsTransitive(Im3);
true
> FactoredOrder(Im3);
[ <2, 20>, <3, 5>, <5, 2>, <7, 1>, <11, 1> ]
> FactoredOrder(Ker3);
[]
> IsPrimitive(Im3);
false
```

The kernel acts transitively and faithfully on the second orbit. As it is imprimitive, we look at its action on a system of imprimitivity.

```
> P := MinimalPartition(Im3);
> f4, Im4, Ker4 := BlocksAction(Im3, P);
> Im4;
Permutation group Im4 acting on a set of cardinality 12
Order = 239500800 = 2^9 * 3^5 * 5^2 * 7 * 11
    (10, 12, 11)
    (9, 12, 11)
    (8, 12, 9)
    (7, 9)(8, 12)
    (6, 9, 10)
    (5, 6, 9)
    (4, 6, 9)
    (3, 6, 9)
    (2, 6, 9, 5)(4, 10)
    (1, 9, 6, 5)(4, 10)
> IsPrimitive(Im4);
true
```

```
> IsAlternating(Im4);
true
> FactoredOrder(Ker4);
[ <2, 11> ]
> IsElementaryAbelian(Ker4);
true
```

The kernel of the restriction of G to the first orbit is isomorphic to $Alt(12)$ acting on an elementary abelian group of order 2^{11}. So we now know the composition factors of G together with an indication of how they fit together.

58.10.7 Action on a Coset Space

`CosetAction(G, H: parameters)`

Given a subgroup H of the group G, construct the permutation representation of G given by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The natural homomorphism $f : G \to L$;

(b) The induced group L;

(c) The kernel K of the action (a subgroup of G).

Note that G may be any type of group. If G is a finitely presented group, then K may be returned undefined.

`Al` MonStgElt *Default :* "*Default*"

`Al := "Wang"`: Construct the coset action using Wang da Fang's algorithm which builds the action up the stabilizer chains of G and H, using a sequence of induction and block image operations. This algorithm is particularly efficient when H has fixed points that are not fixed points of G, and is the default choice when H is trivial.

`Al := "Canonical"`: Compute the cosets using an orbit algorithm, which describes each coset found by computing a canonical element of that coset. The canonical element is one with the minimal base image in the group G. The algorithm is due to Richardson, [Ric73].

`Al := "Default"`: Choose one of the above to use.

`CosetImage(G, H: parameters)`

Given a subgroup H of the group G, construct the image L of G given by the action of G on the set of (right) cosets of H in G. L is returned as a permutation group. Possible parameters are as for the previous function.

`CosetKernel(G, H)`

Given a subgroup H of the group G, construct the kernel of the action of G on the set of (right) cosets of H in G.

58.10.8 Reduced Permutation Actions

If a permutation group is intransitive or imprimitive, then orbit actions and blocks actions provide natural permutation representations of lower degree.

`TransitiveQuotient(G)`

Returns the transitive constituent of G acting on its longest orbit, together with the action homomorphism and the kernel of the action. If G is transitive then the return values are G, the identity map on G, and the trivial subgroup of G.

`PrimitiveQuotient(G)`

For a transitive group G, returns the blocks image of G acting on a maximal block system, together with the action homomorphism and the kernel of the action. If G is primitive then the return values are G, the identity map on G, and the trivial subgroup of G.

`DegreeReduction(G)`

Use a combination of orbit images and blocks images to attempt to find a faithful permutation representation of G with lower degree than G. The second return value is the isomorphism from G to the representation found. If no lower degree faithful representation is found then G and the identity map on G is returned.

58.10.9 The Jellyfish Algorithm

The Jellyfish reduction algorithm was introduced in [LNPS06]. See this article for an explanation of the name "Jellyfish". It attempts to find faithful low degree permutation representations for a family of large-base primitive permutation groups. We now define the target family as given in [LNPS06]. Consider the group $W = S_n \wr S_r$, as a permutation group in its primitive action on the set of r-tuples of k-subsets of the chosen n-set (see `PrimitiveWreathProduct`). Let M be the socle of W, $M = A_n^r$. Let G be any subgroup of W, with $M \leq G$, such that the conjugation action of G on the r copies of A_n in M is transitive. A group T is in the target family of the algorithm if T is permutation isomorphic to some such G, having $n > 2rk^2$, and $rk > 1$. The degree of such a T is $\binom{n}{k}^r$, and any such T is primitive. The image sought by the algorithm has degree nk. The utility of the algorithm is that any primitive group not in the target family is either alternating, symmetric, or has a short base.

The algorithm is one-sided Monte-Carlo in that, if it reports success, then it has found a faithful representation of the group. There is a small probability that the algorithm will find no faithful representation, even when the group given is in the target family.

Note that the Jellyfish algorithm implemented in Magma may succeed even when the input group is not in the target family. In all cases, success of the algorithm guarantees a faithful representation of the group.

The Magma implementation offers functions for testing the group for applicability of the Jellyfish algorithm. If successful, this test constructs data structures as in the cited article for quick evaluation of the homomorphism to the low-degree representation found and stores these with the group. There are also functions to compute the image and

preimage of elements under the representation map. The preimage function is an addition to the algorithms given in [LNPS06], using an extension of their data structure. The preimage algorithm is nearly linear in the degree of the large degree primitive group.

`JellyfishConstruction(G: parameters)`

`Limit` RngIntElt *Default :*

Attempt to construct a set of jellyfish for G. If unsuccessful, return false. Otherwise, construct data structures corresponding to T1 and T5 of [LNPS06], attach them to G, and return `true`. The parameter `Limit` controls how many attempts are made to find the orbits of the point stabilizer of G, which is the initial step in constructing a jellyfish. This construction phase terminates after a sequence of `Limit` random elements of G fails to change the orbits found. If the orbits found so far are not the orbits of a point stabilizer in G, the algorithm may fail. The same limit is used in the next phase, constructing the first jellyfish. The current default is the maximum of 15 and $2\lfloor \log_2 d \rfloor$, where d is the degree of G.

`JellyfishImage(G)`

If the `JellyfishConstruction` function applied to G has returned `true`, return the faithful image of G found by the jellyfish algorithm. Otherwise an error results. If the `JellyfishConstruction` has not yet been applied to G, then it is applied first with default parameters. A failure here results in an error.

`JellyfishImage(G, x)`

If the `JellyfishConstruction` function applied to G has returned `true`, return the image of x as a permutation of the jellyfish. The function will attempt this for any x in the same symmetric group as G. The algorithm may fail when $x \notin G$, in which case an error results, and this proves that x is not in G. It is possible for this map to succeed when x is not in G. In recognition of this, the parent of the result will be a symmetric group. If the `JellyfishConstruction` has not yet been applied to G, then it is applied first with default parameters. A failure here results in an error.

`JellyfishPreimage(G, x)`

If the `JellyfishConstruction` function applied to G has returned `true`, return the preimage of x as a permutation in the symmetric group of G. The element x is assumed to be a permutation of the jellyfish for G. The function will attempt this for any x in the same symmetric group as the `JellyfishImage` of G. The algorithm may fail when x is not in the image group, in which case an error results. It is possible for this map to succeed when x is not in the image group. In recognition of this, the parent of the result will be a symmetric group. If the `JellyfishConstruction` has not yet been applied to G, then it is applied first with default parameters. A failure here results in an error.

58.11 Normal and Subnormal Subgroups

58.11.1 Characteristic Subgroups and Normal Series

`DerivedSeries(G)`

The derived series of the group G. The series is returned as a sequence of subgroups. The algorithm used is described in [BC82].

`CompositionSeries(G)`

A composition series of the group G, ie. a descending chain of normal subgroups, such that each quotient is a simple group. The series is returned as a sequence of subgroups.

`CommutatorSubgroup(G)`
`DerivedSubgroup(G)`
`DerivedGroup(G)`

The derived subgroup of the group G.

`SolubleResidual(G)`
`SolvableResidual(G)`

The solvable residual (the last term of the derived series) of the group G.

`DerivedLength(G)`

The derived length of G. If G is non-soluble, the function returns the number of terms in the series terminating with the soluble residual.

`LowerCentralSeries(G)`

The lower central series of G. The series is returned as a sequence of subgroups, the first of which is the group G. The algorithm used is described in [BC82].

`NilpotencyClass(G)`

The nilpotency class of the group G. If the group is not nilpotent, the value -1 is returned.

`UpperCentralSeries(G)`

The upper central series of G. The series is returned as a sequence of subgroups commencing with the trivial subgroup. The algorithm used is to compute the centre of G and then section centralisers (see [Luk93]) up the chain. This requires computing cores of subgroups, so this function is more restricted in its range of application than `DerivedSeries` and `LowerCentralSeries`.

`Centre(G)`
`Center(G)`

Construct the centre of the group G. The centre is found by applying the function `CentralizerOfNormalSubgroup` to G in G.

`Hypercentre(G)`
`Hypercenter(G)`

Construct the hypercentre of the group G (the stationary term of the upper central series).

`pCore(G, p)`

Given a group G and a prime p, construct the maximal normal p-subgroup of G. The algorithm employed is described in Unger [Ung06b].

`pCoreQuotient(G, p)`

Given a group G and a prime p, construct the quotient of G by `K := pCore(G, p)`. The return values are the quotient, Q, represented as a permutation group of the same degree as G, the quotient map from G onto Q, and K.

`FittingSubgroup(G)`

The Fitting subgroup of the group G. It is computed as the product of the p-cores of the radical of G.

`FrattiniSubgroup(G)`

Given a group G, return the Frattini subgroup. For p-groups this is computed as the derived group with pth powers of the generators added. Solvable groups are converted to their `GrpPC` representation and the problem solved there. Non-solvable groups are treated by finding their maximal subgroups and forming the intersection, so are subject to the same restrictions as the `MaximalSubgroups` command.

`JenningsSeries(G)`

Given a p-group G, return the Jennings series for G. The series is returned as a sequence of subgroups.

`pCentralSeries(G, p)`

Given a soluble group G, and a prime p dividing $|G|$, return the lower p-central series for G. The series is returned as a sequence of subgroups.

`SubnormalSeries(G, H)`

Given a group G and a subnormal subgroup H of G, return a sequence of subgroups commencing with G and terminating with H, such that each subgroup is normal in the previous one. If H is not subnormal in G, the empty sequence is returned.

Example H58E29

We compute the various series in the wreath product of the symmetric group of degree 4 with the dihedral group of order 8 (a soluble group).

```
> G := WreathProduct(Sym(4), DihedralGroup(4));
> G;
Permutation group G acting on a set of cardinality 16
    (1, 5, 9, 13)(2, 6, 10, 14)(3, 7, 11, 15)(4, 8, 12, 16)
    (1, 13)(2, 14)(3, 15)(4, 16)(5, 9)(6, 10)(7, 11)(8, 12)
    (1, 2, 3, 4)
    (1, 2)
> [ FactoredOrder(H) : H in DerivedSeries(G) ];
[
    [ <2, 15>, <3, 4> ],
    [ <2, 12>, <3, 4> ],
    [ <2, 9>, <3, 4> ],
    [ <2, 8>, <3, 4> ],
    [ <2, 8> ],
    []
]
> DerivedLength(G);
5
> [ FactoredOrder(H) : H in LowerCentralSeries(G) ];
[
    [ <2, 15>, <3, 4> ],
    [ <2, 12>, <3, 4> ],
    [ <2, 10>, <3, 4> ],
    [ <2, 9>, <3, 4> ],
    [ <2, 8>, <3, 4> ]
]
> NilpotencyClass(G);
-1
> Centre(G);
Permutation group acting on a set of cardinality 16
Order = 1
    Id($)
> pCentralSeries(G, 2);
[
    [ <2, 15>, <3, 4> ],
    [ <2, 12>, <3, 4> ],
    [ <2, 10>, <3, 4> ],
    [ <2, 9>, <3, 4> ],
    [ <2, 8>, <3, 4> ]
]
> [ FactoredOrder(H) : H in pCentralSeries(G, 3) ];
[
    [ <2, 15>, <3, 4> ]
```

```
]
```

58.11.2 Maximal and Minimal Normal Subgroups

`MaximalNormalSubgroup(G)`

A maximal normal subgroup of G. The trivial subgroup is returned if G is simple. The algorithm takes homomorphic reductions to a primitive group and then uses O'Nan-Scott type considerations to get its result.

`MinimalNormalSubgroups(G)`

The minimal normal subgroups of G. These are obtained by first computing the socle of G and then splitting off the normal factors.

58.11.3 Lattice of Normal Subgroups

`NormalSubgroups(G)`

The normal subgroups of G. These are determined by the method of Cannon and Souvignier [CS].

`NormalLattice(G)`

The normal subgroup lattice of G. The subgroups are first found using the same algorithm as the function `NormalSubgroups` and then inclusions are determined.

Example H58E30

We determine all normal subgroups of the wreath product of $Sym(8)$ and the dihedral group of order 8.

```
> G := WreathProduct(Sym(8), DihedralGroup(4));
> Order(G);
21143266346926080000
> time N := NormalSubgroups(G);
Time: 1.050
> #N;
29
> [ < Order(H`subgroup), FactoredOrder(H`subgroup) > : H in N ];
[
    <1, []>,
    <165181768335360000, [ <2, 24>, <3, 8>, <5, 4>, <7, 4> ]>,
    <330363536670720000, [ <2, 25>, <3, 8>, <5, 4>, <7, 4> ]>,
    <660727073341440000, [ <2, 26>, <3, 8>, <5, 4>, <7, 4> ]>,
    <1321454146682880000, [ <2, 27>, <3, 8>, <5, 4>, <7, 4> ]>,
    <1321454146682880000, [ <2, 27>, <3, 8>, <5, 4>, <7, 4> ]>,
    <1321454146682880000, [ <2, 27>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
```

```
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <2642908293365760000, [ <2, 28>, <3, 8>, <5, 4>, <7, 4> ]>,
    <5285816586731520000, [ <2, 29>, <3, 8>, <5, 4>, <7, 4> ]>,
    <5285816586731520000, [ <2, 29>, <3, 8>, <5, 4>, <7, 4> ]>,
    <5285816586731520000, [ <2, 29>, <3, 8>, <5, 4>, <7, 4> ]>,

    <21143266346926080000, [ <2, 31>, <3, 8>, <5, 4>, <7, 4> ]>
]
```

58.11.4 Composition and Chief Series

`ChiefFactors(G)`

Given a group G, return a sequence of the isomorphism types $< f, d, q, m >$ of the chief factors. An isomorphism type in a chief factor should be understood as the direct product of m copies of the simple group described by $< f, d, q >$ (see `CompositionFactors` below). For the algorithm, see Unger [Ung].

`ChiefSeries(G)`

Given a group G, return the chief series of G and a sequence of the corresponding isomorphism types $< f, d, q, m >$ of the chief factors. An isomorphism type in a chief factor should be understood as the direct product of m copies of the simple group described by $< f, d, q >$ (see `CompositionFactors` below). The series will be organised to include the soluble radical of G, and, if G is insoluble, the socle of the quotient of G by the soluble radical.

f	Family name
1	A(d, q)
2	B(d, q)
3	C(d, q)
4	D(d, q)
5	G$(2, q)$
6	F$(4, q)$
7	E$(6, q)$
8	E$(7, q)$
9	E$(8, q)$
10	2A(d, q)
11	2B$(2, q)$
12	2D(d, q)
13	3D$(4, q)$
14	2G$(2, q)$
15	2F$(4, q)$
16	2E$(6, q)$
17	Alternating(d)
18	Sporadic group — see Table 2.
19	Cyclic(q)

25	M
26	J_4

Table 2: Sporadic groups

`CompositionFactors(G)`

Given a permutation group G, return a sequence S of tuples that represent the composition factors of G, ordered according to some composition series of G. Each tuple is a triple of integers f, d, q that defines the isomorphism type of the corresponding composition factor. A triple $\langle f, d, q\rangle$ describes a simple group as follows. The integer f defines the family to which the group belongs, and d and q are the parameters of the family. The length of the sequence S is the number of composition factors of G. The algorithm used is the "tabular" algorithm of Kantor [Kan91], extended to be valid for groups of degree $\leq 10^7$. The families are listed in Tables 1 and 2 on page 1590.

Example H58E31

We illustrate the function `CompositionFactors` by applying it to the group associated with Rubik's cube.

```
> G := sub<Sym(48) |
>     (1,3,8,6)(2,5,7,4)(9,48,15,12)(10,47,16,13)(11,46,17,14),

58.11.5 The Socle

`Socle(G)`

The socle of the group G. This is computed using the algorithms described in Cannon and Holt [CH97].

`SocleFactor(G)`

A simple factor of the socle of the group G.

`SocleFactors(G)`

The simple factors of the socle of the group G. The index of each factor in the sequence corresponds to the points of the image group of `SocleAction` and `SocleImage`.

`SocleSeries(G)`

A chain of subgroups

$$S_1, S_1 \times S_2, \ldots, S_1 \times \ldots \times S_r,$$

where $S_1, ..., S_r$ are the simple factors of the socle of the primitive group G.

`EARNS(G)`

The elementary abelian regular normal subgroup (EARNS) of the primitive group G. If G does not have an EARNS, then the trivial subgroup is returned. The algorithm used is that of Neumann [Neu86].

`IsAffine(G)`

Decide if the permutation group G is of primitive affine type. If so, the elementary abelian regular normal subgroup of G is returned as second return value. If the group G is either intransitive or transitive and imprimitive or primitive and not of affine type, then the result will be false (only). This function combines `IsTransitive`, `IsPrimitive` and `EARNS`.

`AffineAction(G)`

Given a primitive group G which has a non-trivial elementary abelian regular normal subgroup A, construct the representation of G given by the action of G on elements of the elementary abelian group A. The image is realised as a point-stabilizer in G and the kernel of the action is A. As with the other action functions, `AffineAction` returns the homomorphism, the image and the kernel of the action.

`AffineImage(G)`

Given a primitive group G which has an elementary abelian regular normal subgroup A, construct the permutation group that results from the action of G on elements of the elementary abelian group A. This image is realised as a point-stabilizer in G.

`AffineKernel(G)`

Given a primitive group G which has a non-trivial elementary abelian regular normal subgroup A, construct the kernel of the action of G on elements of the elementary abelian group A. This kernel equals A.

`SocleAction(G)`

Given a non-trivial permutation group G which has trivial Fitting subgroup, construct the permutation representation of G given by the action of G on the simple factors of N. Note that a primitive group has a perfect socle if and only if it has no elementary abelian regular normal subgroup. As with the other action functions, `SocleAction` returns the homomorphism, the image and the kernel of the action. The socle factor corresponding to point i in the support of the image group is the ith element in the sequence `SocleFactors(G)`.

`SocleImage(G)`

Given a non-trivial permutation group G which has trivial Fitting subgroup, construct the permutation group L induced by the action of G on the simple factors of N.

`SocleKernel(G)`

Given a non-trivial permutation group G which has trivial Fitting subgroup, construct the kernel of the action of G on the simple factors of N.

`SocleQuotient(G)`

Given a permutation group G which has trivial Fitting subgroup, construct a permutation representation of G/N. If U_i denote the simple factors of N, then the degree of the result is bounded by $\sum_i |Out(U_i)|$ (see Cannon and Souvignier [CS]). Note that a primitive group has a perfect socle if and only if it has no elementary abelian regular normal subgroup. `SocleQuotient` returns G/N, the quotient homomorphism and the kernel of the map (which is the socle of G).

`RefineSection(G, M, N)`

Given M, N normal subgroups of G with $N < M$, return a sequence of G-normal subgroups $L_1, \ldots, L_r$ with $N = L_0$, $L_i < L_{i+1}$ and $L_r = M$ such that each of the quotients L_{i+1}/L_i is either elementary abelian or a direct product of non-abelian simple groups.

Example H58E32

We examine the normal structure of a primitive group, the primitive-wreath product of Sym(5) and Sym(3) (with product action).

```
> G := PrimitiveWreathProduct(Sym(5), Sym(3));
> FactoredOrder(G);
[ <2, 10>, <3, 4>, <5, 3> ]
> E := EARNS(G);
> E;
Permutation group E acting on a set of cardinality 125
Order = 1
> DerivedSeries(G);
[
    Permutation group G acting on a set of cardinality 125
    Order = 10368000 = 2^10 * 3^4 * 5^3
    Permutation group acting on a set of cardinality 125
    Order = 2592000 = 2^8 * 3^4 * 5^3,
    Permutation group acting on a set of cardinality 125
    Order = 864000 = 2^8 * 3^3 * 5^3,
    Permutation group S acting on a set of cardinality 125
    Order = 216000 = 2^6 * 3^3 * 5^3
]
> S := Socle(G);
> S;
Permutation group S acting on a set of cardinality 125

58.11.6 The Soluble Radical and its Quotient

Very efficient algorithms have been developed for computing invariants such as subgroups, normal subgroups and conjugacy classes of elements for soluble groups defined by means of polycyclic presentations. Almost all such algorithms employ a top-down *Lifting Strategy*. Let P be a quotient-invariant property for a soluble group. In general, an algorithm that constructs the set of elements or subgroups $X_P(G)$ satisfying property P for the group G, proceeds as follows: Let G be a non-simple soluble group and let N be a normal subgroup of G. The set $X_P(G/N)$ is constructed and its elements are lifted back into G, thereby yielding $X_P(G)$. This process is usually iterated with successive normal subgroups N being chosen as the terms of some descending normal series (e.g., an elementary abelian series).

In generalizing this approach to permutation groups, our approach has been to construct the soluble radical R of G, use special methods to solve the problem for the quotient G/R, and then proceed (as in the case of a soluble group) to lift the solution down the successive terms of an elementary abelian series for G using the Lifting Strategy. Derek Holt has shown that the quotient group G/R has a faithful permutation representation of degree no greater than that of G.

The functions in this section enable the user to construct the radical, its quotient and an elementary abelian series.

`Radical(G)`
`SolubleRadical(G)`
`SolvableRadical(G)`

Given a group G, return the maximal normal solvable subgroup of G. The algorithm used is described in Unger [Ung06b].

`RadicalQuotient(G)`

Given a group G, compute a representation of the quotient G/R where R is the (solvable) radical of G. The resulting representation has the same degree as G. Both the permutation group Q isomorphic to G/R and a homomorphism $\phi : G \to Q$ are returned. The algorithm proceeds by repeatedly applying `AbelianNormalQuotient` up the terms of the derived series of the radical. The third return value is R, the radical of G and the kernel of the homomorphism.

`ElementaryAbelianSeries(G: parameters)`

`ElementaryAbelianSeries(G, N: parameters)`

`LayerSizes` SeqEnum[RngIntElt] *Default :* []

An elementary abelian series is a chain of normal subgroups $R = N_1 > N_2 > ... > N_r = 1$ with the property that the quotient of each pair of successive terms in the series is elementary abelian and that there is no group $R < H < G$ such that H/R is elementary abelian and H normal in G. The top of the series R is called the solvable radical and is the maximal normal solvable subgroup of G.

In the second form N must be a normal subgroup of G and the returned series has the form $R = N_1 > N_2 > ... > N_r = N$, so is an elementary abelian series for G/N.

The parameter `LayerSizes` controls possible refinement of the series. The default is no refinement. As an example, take `LayerSizes := [ 2, 5, 3, 4, 7, 3, 11, 2, 17, 1]`. When constructing an elementary abelian series for the group, attempt to split 2-layers of size gt 2^5, 3-layers of size gt 3^4, etc. The implied exponent for 13 is 2 and for all primes greater than 17 the exponent is 1. Setting `LayerSizes` to `[2, 1]` will attempt to split all layers, resulting in a portion of a chief series for G.

`ElementaryAbelianSeriesCanonical(G)`

Gives a similar result to using `ElementaryAbelianSeries`, except the series returned depends only on the isomorphism type of the solvable radical, and consists of characteristic subgroups of G. This function may be slower than `ElementaryAbelianSeries`.

Example H58E33

We illustrate these functions by considering the group of degree 16 generated by the following permutations:

$$(1, 8, 11, 3, 6, 14, 15, 10)(2, 7, 12, 4, 5, 13, 16, 9),$$
$$(1, 2)(3, 16, 9, 14, 8, 12)(4, 15, 10, 13, 7, 11),$$
$$(1, 13, 12, 16)(2, 14, 11, 15)(7, 9)(8, 10),$$

```
> G := PermutationGroup< 16 |
>         (1, 8, 11, 3, 6, 14, 15, 10)(2, 7, 12, 4, 5, 13, 16, 9),
>         (1, 2)(3, 16, 9, 14, 8, 12)(4, 15, 10, 13, 7, 11),
```

```
>         (1, 13, 12, 16)(2, 14, 11, 15)(7, 9)(8, 10) >;
> Radical(G);

]
```

58.11.7 Complements and Supplements

`Complements(G, M)`

Given a group G and a normal subgroup M, this function returns a sequence containing one representative from each conjugacy class of complements of M in G.

`Complements(G, M, N)`

Given a group G, a normal subgroup M of G and a normal subgroup N of G, that is strictly contained in M, the function returns a sequence comprising representatives for the conjugacy classes of complements of M/N in G/N, as subgroups of G.

`HasComplement(G, M)`

The group M must be a normal subgroup of G. Returns whether M has a complement in G and, if so, one such complement.

`Supplements(G, M)`

Given a group G and a soluble normal subgroup M of G, the function returns a sequence containing one representative from each conjugacy class of minimal supplements for M in G.

`Supplements(G, M, N)`

Given a group G, a normal subgroup M of G and a normal subgroup N of G such that (a), N is strictly contained in M, and (b), M/N is soluble, the function returns a sequence comprising representatives for the conjugacy classes of minimal supplements of M/N in G/N, as subgroups of G.

`HasSupplement(G, M)`

The group M must be a soluble normal subgroup of G. Returns whether M has a proper supplement in G and, if so, one such supplement.

Example H58E34

We illustrate these functions by considering a normal subgroup H of the group G of degree 16 generated by the following permutations:

$$(1,3,2,4)(5,16,6,13)(7,14,8,15)(9,12,11,10),$$
$$(1,16,9)(2,15,12)(3,14,11)(4,13,10)(6,8,7).$$

```
> G := PermutationGroup< 16 |
>         (1, 3, 2, 4)(5, 16, 6, 13)(7, 14, 8, 15)(9, 12, 11, 10),
>         (1, 16, 9)(2, 15, 12)(3, 14, 11)(4, 13, 10)(6, 8, 7) >;
Permutation group G acting on a set of cardinality 16
Order = 165888 = 2^11 * 3^4
    (1, 3, 2, 4)(5, 16, 6, 13)(7, 14, 8, 15)(9, 12, 11, 10)
    (1, 16, 9)(2, 15, 12)(3, 14, 11)(4, 13, 10)(6, 8, 7)
> H := ncl< G | (6, 7, 8)(14, 16, 15) >;
> H;
Permutation group H acting on a set of cardinality 16
Order = 6912 = 2^8 * 3^3
   (6, 7, 8)(14, 16, 15)
   (6, 7, 8)(13, 14, 15)
   (6, 7, 8)(9, 12, 11)
   (5, 8, 7)(13, 14, 15)
   (6, 7, 8)(10, 11, 12)
   (1, 2, 3)(6, 7, 8)
   (2, 4, 3)(6, 7, 8)
```

```
> C := Complements(G, H);
> C;
[
   Permutation group acting on a set of cardinality 16
   Order = 24 = 2^3 * 3
       (3, 4)(5, 14)(6, 15)(7, 16)(8, 13)(10, 12)
       (2, 4)(6, 7)(9, 14)(10, 15)(11, 13)(12, 16)
       (1, 14)(2, 15)(3, 16)(4, 13)(7, 8)(10, 11)
       (1, 14, 9)(2, 13, 10)(3, 16, 12)(4, 15, 11)(6, 8, 7)
]
```

So the normal subgroup has one conjugacy class of complements. We check that the representative subgroup is indeed a complement for H.

```
> K := C[1];
> IsTrivial(K meet H );
true
> #K * #H eq #G;
true
```

58.11.8 Abelian Normal Subgroups

`AbelianNormalSubgroup(G)`

An abelian normal subgroup of G. If none exists, the trivial subgroup is returned.

`AbelianNormalQuotient(G, H)`

A quotient of G by an abelian normal subgroup that contains the abelian normal subgroup H. The quotient is represented as a permutation group of the same degree as G. The other values returned are the quotient epimorphism and its kernel K. The kernel K will contain H, $\#K$ and $\#H$ will have the same prime divisors, and if H is elementary abelian then so is K.

`SolubleNormalQuotient(G, H)`

A quotient of G by a soluble normal subgroup that contains the soluble normal subgroup H. The quotient is represented as a permutation group of the same degree as G. The other values returned are the quotient epimorphism and its kernel K. As with `AbelianNormalQuotient`, K will contain H, and $\#K$ and $\#H$ will have the same prime divisors.

`ElementaryAbelianNormalSubgroup(G)`

An elementary abelian normal subgroup of G. If none exists, the trivial subgroup is returned. The group returned is the last non-trivial group in an elementary abelian series for the radical of G.

`pElementaryAbelianNormalSubgroup(G, p)`

An elementary abelian normal p-subgroup of G. If none exists, the trivial subgroup is returned. The group returned is the last non-trivial group in an elementary abelian series for the p-core of G.

`MEANS(G)`

A minimal elementary abelian normal subgroup of G.

`MEANS(G, N)`

A minimal elementary abelian normal subgroup of G that lies in the elementary abelian normal subgroup N of G.

58.12 Cosets and Transversals

58.12.1 Cosets

`H * g`

Right coset of the subgroup H of the group G, where g is an element of G.

`DoubleCoset(G, H, g, K)`

The double coset $H * g * K$ of the subgroups H and K of the group G, where g is an element of G.

`DoubleCosetRepresentatives(G, H, K)`

Given a group G and two subgroups H and K of G, return a sequence S containing representatives of the H-K-double cosets in G. The first element of S is guaranteed to be the identity element of G. The second return sequence gives the sizes of the corresponding double cosets. The algorithm used refines double cosets down a chain of subgroups from G to one of H or K.

`ProcessLadder(L, G, U)`

Verbose `DoubleCosets` *Maximum :* 3

Given permutation groups $U < G$ and a sequence of permutation groups L such that $L_1 = G$, compute data for computations with the L_n-U-double cosets in G. The algorithm relies on the indices $(L_i : L_{i+1})$ (for $L_i < L_{i+1}$) or $(L_{i+1} : L_i)$ otherwise to be small. In contrast to the method used by `DoubleCosetRepresentatives`, the sequence used in the computation is a ladder, not necessarily a descending chain. For details see [Sch90].

`GetRep(p, R)`

For R being the result of a call to `ProcessLadder` and a permutation $p \in G$, return the canonical double coset representative for p.

`DeleteData(R)`

Deletes the data computed using `ProcessLadder`.

`YoungSubgroupLadder(L)`

`Full` RngIntElt *Default :* `false`

Computes a ladder from the full symmetric group down to the Young subgroup parametrised by the sequence L suitable for double coset enumeration using `ProcessLadder`. The optional parameter `Full` can be used if the Young subgroup should be considered as a subgroup of the symmetric group on `Full` points rather than on `&*L`.

`StabilizerLadder(G, d)`

Given a subgroup G of the symmetric group of degree n and a monomial in n indeterminates, compute a ladder down from the full symmetric group to the stabilizer of the monomial, suitable for processing with `ProcessLadder`.

`x in C`

Returns `true` if element g of group G lies in the coset C.

`x notin C`

Returns `true` if element g of group G does not lie in the coset C.

`C1 eq C2`

Returns `true` if the coset C_1 is equal to the coset C_2.

`C1 ne C2`

Returns `true` if the coset C_1 is not equal to the coset C_2.

`#C`

The cardinality of the coset C.

`CosetTable(G, H)`

The (right) coset table for G over subgroup H relative to its defining generators.

`#CosetTable(G, f)`

The coset table for G corresponding to the permutation representation f of G, where f is a homomorphism of G onto a transitive permutation group.

58.12.2 Transversals

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a permutation group G and a subgroup H of G, this function returns

(a) An indexed set of elements T of G forming a right transversal for G over H; and

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and $g \in G$, ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

`TransversalProcess(G, H)`

Given a permutation group G and H, a subgroup of G, create a process to run through a left transversal for H in G. The method used is a backtrack search for a canonical coset representative. `TransversalProcess` can be used when the index of H in G is too large to allow a full transversal to be created.

`TransversalProcessRemaining(P)`

The number of coset representatives the process has yet to produce. Initially this will be the index of the subgroup in the group.

`TransversalProcessNext(P)`

Advance the process to the next coset representative and return that representative. This may only be used when `TransversalProcessRemaining(P)` is positive. The first call to `TransversalProcessNext` will always give the identity element.

`ShortCosets(p, H, G)`

Computes a set of representatives for the transversal of G modulo H of all cosets that contain p. This computation does not do a full transversal of G modulo H and may therefore be used even if the index of $(G : H)$ is very large.

58.13 Presentations

In this section we describe how to compute a presentation in terms of generators and relations for a permutation group and also how to obtain a representation of a permutation as word in the defining generators.

58.13.1 Generators and Relations

`FPGroup(G)`

Construct a presentation for the permutation group G on the set of defining generators and return the presentation in the form of a finitely presented group F that is isomorphic to G. The presentation is obtained by first computing the regular representation of G and then using the Todd-Coxeter Schreier algorithm to construct a presentation on the strong generators. In this situation the strong generators are identical to the defining generators.

A group homomorphism $\phi : F \to G$, defining G as a permutation representation of F, is also returned.

`FPQuotient(G, N)`

Given a normal subgroup N of G, compute an fp-group representation F of the quotient G/N and the homomorphism $\phi : G \to F$.

`FPGroupStrong(G: parameters)`

`Random`	BoolElt	*Default :* `true`
`Run`	RngIntElt	*Default :* 20

Construct a presentation for the permutation group G on a set of strong generators and return the presentation in the form of a finitely presented group F that is isomorphic to G. In Magma, a combination of the Schreier Todd-Coxeter Sims algorithm and the Brownie-Cannon-Sims verification procedure is used to construct the presentation. See Leon [Leo80] and Gebhardt [Geb00] for more details of the individual algorithms.

If strong generators are not already known for G, they will be constructed. If strong generators have to be constructed, the parameters `Random` and `Run` may be used to control the application of the random schreier algorithm to construct a probable BSGS before commencing the construction of the presentation. If `Random` is set to false then no randomising is performed, and the algorithm becomes the straight STCS algorithm. In the case in which strong generators are already known for G, the presentation will be on these strong generators.

The presentation will have the property that it includes a presentation for each group in the stabilizer chain of the BSGS.

The group isomorphism $\phi : F \to G$, defining G as a permutation representation of F, is also returned.

58.13.2 Permutations as Words

Consider a permutation group G defined on d generators. The *word group* of G is a free group W of rank d. Then we regard G as a homomorphic image of F with associated homomorphism $\phi : W \to G$. All operations involving words in the generators of G will be performed in W.

`WordGroup(G)`

Given a permutation group G defined on d generators, return (a) a free group W on d generators represented as a group whose elements are defined by straight-line programs (SLP group), and (b) the homomorphism ϕ from W to G such that $W.i \to G.i$, for $i = 1, \ldots, d$. The group W associated with G by this function will be referred to as the *word group* for G.

`InverseWordMap(G)`

Given a permutation group G and its associated word group W with canonical homomorphism $\phi : W \to G$, construct the inverse mapping ρ. Thus, given a permutation g of G, $g@\rho$ returns an element in the preimage of g under ϕ. If the word group W does not already exist, it will be created.

`ActingWord(G, x, y)`

Given points x and y belonging to the same G-orbit of the natural G-set X, return a word w in the word group W of G such that $x^{\phi(w)} = y$. Here ϕ is the canonical homomorphism from W to G.

58.14 Automorphism Groups

The automorphism group of a permutation group may be computed in MAGMA, subject to the same restrictions on the group as when computing maximal subgroups. (That is, the non-abelian composition factors of the group must appear in a certain database.) The methods used are those described in Cannon and Holt [CH03]. Isomorphism of permutation groups may also be determined using the same methods.

`AutomorphismGroup(G: parameters)`

Compute the full automorphism group of the permutation group G.

`IsIsomorphic(G, H: parameters)`

Test whether or not the two permutation groups G and H are isomorphic as abstract groups. If so, both the result `true` and an isomorphism from G to H is returned. If not, the result `false` is returned.

Example H58E35

We take some groups of order 120 and test for isomorphism.

```
> G1 := PermutationGroup<20 |
>  [ 2, 5, 9, 11, 12, 3, 17, 13, 18, 16, 7, 15, 10, 8, 1,
>   14, 20, 19, 6, 4 ],
>  [ 3, 6, 1, 10, 14, 2, 18, 17, 15, 4, 16, 13, 12, 5, 9,
>   11, 8, 7, 20, 19 ] >;
> #G1;
120
> G2 := PermutationGroup<24 |
```

```
>   [ 2, 4, 6, 5, 1, 7, 8, 3, 13, 15, 14, 16, 11, 9, 12, 10,
>   19, 20, 18, 17, 24, 21, 22, 23 ],
>   [ 3, 1, 2, 7, 4, 9, 5, 11, 10, 6, 12, 8, 16, 15, 18, 17,
>   13, 14, 21, 23, 22, 19, 24, 20 ],
>   [ 4, 5, 7, 1, 2, 8, 3, 6, 11, 12, 9, 10, 14, 13, 16, 15,
>   18, 17, 20, 19, 23, 24, 21, 22 ] >;
> #G2;
120
> IsIsomorphic(G1, G2);
false
> flag, isom := IsIsomorphic(G1, Sym(5));
> flag;
true
> (G1.1)@ isom;
(1, 3, 5, 4, 2)
```

The reader is invited to check that `G2` is perfect while `G1` is not, so the `false` result for their isomorphism is correct. What is the automorphism group of `G2`?

```
> A := AutomorphismGroup(G2);
> #A;
120
> #Centre(G2);
2
> OuterFPGroup(A);
Finitely presented group on 1 generator
Relations
  $.1^2 = Id($)
> A.1;

    15)(2, 21, 5, 23)(3, 20, 7, 19)(6, 11, 8, 9)(10, 24, 12,
    22)(13, 17, 14, 18)
  (1, 3, 2)(4, 7, 5)(6, 9, 10)(8, 11, 12)(13, 16, 17)(14,
    15, 18)(19, 21, 22)(20, 23, 24) |--> (1, 11, 16)(2, 18,
    19)(3, 23, 6)(4, 9, 15)(5, 17, 20)(7, 21, 8)(10, 22,
    13)(12, 24, 14)
  (1, 4)(2, 5)(3, 7)(6, 8)(9, 11)(10, 12)(13, 14)(15,
    16)(17, 18)(19, 20)(21, 23)(22, 24) |--> (1, 4)(2, 5)(3,
    7)(6, 8)(9, 11)(10, 12)(13, 14)(15, 16)(17, 18)(19,
    20)(21, 23)(22, 24)
> IsInnerAutomorphism(A.4);
false
```

So the outer automorphism group of `G2` has order 2, and `A.4` gives this automorphism.

58.15 Cohomology

In the following description, G is a finite permutation group, p is a prime number, and K is the finite field of order p. Further, F is a finitely presented group having the same number of generators as G, and is such that its relations are satisfied by the corresponding generators of G. In other words, the mapping taking the i-th generator of F to the i-th generator of G must be an epimorphism. Usually this mapping will be an isomorphism, although this is not mandatory. The algorithms used are those of Holt, see [Hol84], [Hol85a] and [Hol85b].

`pMultiplicator(G, p)`

Given the group G and a prime p, return the invariant factors of the p-part of the Schur multiplicator of G.

`pCover(G, F, p)`

Given the group G and the finitely presented group F such that G is an epimorphic image of G in the sense described above, return a presentation for the p-cover of G, constructed as an extension of the p-multiplier by F.

`CohomologicalDimension(G, M, i)`

Given the group G, the $K[G]$-module M and an integer i (equal to 1 or 2), return the dimension of the i-th cohomology group of G acting on M.

`ExtensionProcess(G, M, F)`

Create an extension process for the group G by the module M.

`Extension(P, Q)`

`#NextExtension(P)`

Return the next extension of G as defined by the process P.

Assume that F is isomorphic to the permutation group G, and that we wish to determine presentations for one or more extensions of the K-module M by F, where K is the field of p elements. We first create an extension process using `ExtensionProcess(G, M, F)`. The possible extensions of M by G are in one-one correspondence with the elements of the second cohomology group $H^2(G, M)$ of G acting on M. Let $b_1, \ldots, b_l$ be a basis of $H^2(G, M)$. A general element of $H^2(G, M)$ therefore has the form $a_1 b_1 + \cdots + a_l b_l$ and so can be defined by a sequence Q of l integers $[a_1, \ldots, a_l]$. Now, to construct the corresponding extension of M by G we call the function `Extension(P, Q)`. The required extension is returned as a finitely presented group. If all the extensions are required then they may be obtained successively by making p^l calls to the function `NextExtension`.

`SplitExtension(G, M, F)`

The split extension of the module M by the group G.

Example H58E36

We construct a presentation for A_6 over its Schur multiplicator. First we find the size of the multiplicator by applying the `pMultiplicator` function to each relevant prime.

```
> G := Alt(6);
> &cat [pMultiplicator(G, p[1]): p in FactoredOrder(G)];
[ 2, 3, 1 ]
```

The multiplicator has order $2 \times 3 = 6$. We next construct the two-fold cover of A_6. We use the `FPGroup` function to get a presentation for A_6.

```
> F := FPGroup(G);
> F2 := pCover(G, F, 2);
```

Now we construct a three-fold cover of the two-fold cover to get the extension we are after. First we need a permutation representation of `F2`, the two-fold covering group.

```
> G2 := DegreeReduction(CosetImage(F2, sub<F2|>));
> Degree(G2);
144
> #G2;
720
> F6 := pCover(G2, F2, 3);
> F6;
Finitely presented group F6 on 4 generators
Relations
  F6.4^3 = Id(F6)
  (F6.1, F6.4) = Id(F6)
  (F6.2, F6.4) = Id(F6)
  (F6.3, F6.4) = Id(F6)
  F6.3^2 = Id(F6)
  (F6.1, F6.3) = Id(F6)
  (F6.2, F6.3) = Id(F6)
  F6.1^4 * F6.3 = Id(F6)
  F6.2^3 * F6.3 = Id(F6)
  F6.1^-1 * F6.2^-1 * F6.1 * F6.2 * F6.1^-1 * F6.2^-1 *
  F6.1 * F6.2 * F6.3 * F6.4 = Id(F6)
  F6.1^-1 * F6.2 * F6.1^2 * F6.2 * F6.1^2 * F6.2 *
  F6.1^-2 * F6.2 * F6.1^-1 * F6.3 * F6.4^-1 = Id(F6)
  F6.2 * F6.1 * F6.2 * F6.1 * F6.2 * F6.1 * F6.2 *
  F6.1 * F6.2 * F6.1 * F6.3 * F6.4 = Id(F6)
> AbelianQuotientInvariants(F6);
[]
```

The group `F6` is the six-fold cover of A_6. We easily see from the presentation that the 3rd and 4th generators generate a central cyclic subgroup of order 6. The sequence of invariants for the maximal abelian quotient of `F6` is empty, so `F6` is perfect.

Example H58E37

We construct an extension of A_5. This time the normal subgroup will be elementary abelian of order 2^5, with the action of A_5 being the natural permutation action.

```
> G := Alt(5);
> M := PermutationModule(G, GF(2));
> CohomologicalDimension(G, M, 2);
1
```

The dimension of the 2nd cohomology group is 1 over $\mathbf{F}_2$, so there are two possible extensions. We will construct them both.

```
> F := FPGroup(G);
> P := ExtensionProcess(G, M, F);
> E0 := Extension(P, [0]);
> E1 := Extension(P, [1]);
> AbelianQuotientInvariants(E0);
[ 2 ]
> AbelianQuotientInvariants(E1);
[]
```

The split extension, `E0`, is not perfect, but the non-split extension, `E1`, is a perfect group.

58.16 Representation Theory

A set of functions are provided for computing with the characters of a group. Full details of these functions may be found in Chapter 91. For convenience we include here two of the more useful character functions.

Also, functions are provided for computing with the modular representations of a group. Full details of these functions may be found in Chapter 89. For the reader's convenience we include here the functions which may be used to define a $R[G]$-module for a permutation group.

`CharacterTable(G: parameters)`

Construct the table of ordinary irreducible characters for the group G.

`Al` MonStgElt *Default :* "*Default*"

This parameter controls the algorithm used. The string `"DS"` forces use of the Dixon-Schneider algorithm. The string `"IR"` forces the use of Unger's induction/reduction algorithm [Ung06]. The `"Default"` algorithm is to use Dixon-Schneider for groups of order ≤ 5000 and Unger's algorithm for larger groups. This may change in future.

`DSSizeLimit` RngIntElt *Default :* 0

When the default algorithm is selected, a positive value n for `DSSizeLimit` means that before using Unger's algorithm, the full character space is split by some passes of Dixon-Schneider, restricted to using class matrices corresponding to conjugacy classes with size at most n.

`PermutationCharacter(G)`

Given a group G represented as a permutation group, construct the character of G afforded by the defining permutation representation of G.

`PermutationCharacter(G, H)`

Given a group G and some subgroup H of G, construct the ordinary character of G afforded by the permutation representation of G given by the action of G on the coset space of the subgroup H in G.

`GModule(G, S)`

Let G be a group defined on r generators and let S be a subalgebra of the matrix algebra $M_n(R)$, also defined by r non-singular matrices. It is assumed that the mapping from G to S defined by $\phi(G.i) \to S.i$, for $i = 1, \ldots, r$, is a group homomorphism. Let M be the natural module for the matrix algebra S. The function `GModule` gives M the structure of an $S[G]$-module, where the action of the i-th generator of G on M is given by the i-th generator of S.

`GModule(G, A, B)`

Given a finite group G, a normal subgroup A of G and a normal subgroup B of A such that the section A/B is elementary abelian of order p^n, create the $K[G]$-module M corresponding to the action of G on A/B, where K is the field $\mathbf{F}_p$. If B is trivial, it may be omitted. The function returns

(a) the module M; and

(b) the homomorphism $\phi : A/B \to M$.

`PermutationModule(G, H, R)`

Given a finite group G and a ring R, create the $R[G]$-module for G corresponding to the permutation action of G on the cosets of H.

`PermutationModule(G, R)`

Given a finite permutation group G and a ring R, create the natural permutation module for G over R.

Example H58E38

We refine an elementary abelian normal subgroup of a permutation group to a sequence of normal subgroups.

```
> G := PermutationGroup<24 |
>  [ 3, 4, 1, 2,23,24, 7, 8, 9,10,12,11,14,13,16,15,18,17,22,21,
>    20,19, 5, 6 ],
>  [ 7, 8,11,12,13,14,22,21,20,19,15,16,17,18, 6, 5, 4, 3, 1, 2,23,
>    24, 9,10 ] >;
> N := sub<G |
>  [ 24, 23, 6, 5, 4, 3, 10, 9, 8, 7, 14, 13, 12, 11, 18, 17, 16, 15, 22, 21,
>    20, 19, 2, 1 ],
```

```
>  [ 23, 24, 5, 6, 3, 4, 8, 7, 10, 9, 12, 11, 14, 13, 15, 16, 17, 18, 19, 20,
>    21, 22, 1, 2 ],
>  [ 2, 1, 4, 3, 6, 5, 7, 8, 9, 10, 11, 12, 13, 14, 17, 18, 15, 16, 21, 22, 19,
>    20, 24, 23 ]>;
> #N;
8
> IsNormal(G, N);
true
> IsElementaryAbelian(N);
true
> M, f := GModule(G, N);
> SM := Submodules(M);
> #SM;
4
> refined := [ x @@ f : x in SM ];
> forall{x : x in refined | IsNormal(G, x) };
true;
> [ #x : x in refined];
[ 1, 2, 4, 8 ]
```

The original elementary abelian normal subgroup of order 8 is the top of a chain of normal subgroups of length 3.

58.17 Identification

58.17.1 Identification as an Abstract Group

`NameSimple(G)`

Given a simple group G, determine the isomorphism type of G. The type is returned in the form of a triple of three integers f, d and q, where the interpretation of these integers is that given in the description of the function `CompositionFactors`.

58.17.2 Identification as a Permutation Group

The first functions described in this subsection detect whether or not a permutation group is alternating or symmetric in its natural representation. They are based on the algorithm 'Detect Alternating' outlined in [CB92].

`IsAlternating(G)`

Returns `true` if the permutation group G defined as acting on X is the alternating group $\mathrm{Alt}(X)$.

`IsSymmetric(G)`

Returns `true` if the permutation group G defined as acting on X is the symmetric group $\mathrm{Sym}(X)$.

`IsAltsym(G)`

Returns `true` if the permutation group G defined as acting on X contains the alternating group $\mathrm{Alt}(X)$.

`TwoTransitiveGroupIdentification(G)`

Given a 2-transitive group G, return a tuple giving the abstract isomorphism type of the group. This is an implementation of the method of Cameron and Cannon [CC91].

`RecogniseAlternatingOrSymmetric(G, n)`

Constructive recognition of the group G, which will succeed with probability $\geq 1-e^5$ if G is isomorphic to either the alternating or symmetric group of degree $n > 11$. The method is that of Beals *et al* [BLGN$^+$03], implemented by Colva Roney-Dougal.

The return values start with a flag indicating success or failure. If the algorithm was successful, then there are three more return values: a flag which is true when G is symmetric and false when alternating, and two programs. The first program takes an element x of an overgroup of G and produces a boolean to indicate whether $x \in G$ and a permutation representing x in the natural action of S_n (if such a permutation exists). The second taking a permutation to the corresponding element of G. The programs define mutually inverse group isomorphisms, implemented as MAGMA functions.

`IsEven(G)`

Given a permutation group G check if G is even, ie. contained in the alternating group.

Example H58E39

We give an example of `RecogniseAlternatingOrSymmetric` in use.

```
> SetSeed(1);
> a:= AlternatingGroup(13);
> h:= Stabiliser(a, {1,2});
> k:= CosetImage(a, h);
> Degree(k);
78
> worked, is_sym, bb_to_perm, perm_to_bb:=
> RecogniseAlternatingOrSymmetric(k, 13);
> worked;
true
> is_sym;
false
> x:= Sym(78)!(1, 35, 16, 28, 14, 26, 69, 5, 74)(2, 54,
> 67, 18, 51, 63, 6, 50, 77)(3, 33, 78, 12, 34, 29, 19, 15, 73)
> (4, 52, 61, 24, 49, 60, 68, 38, 64)(7, 20, 71, 17,
> 32, 11, 72, 8, 36)(9, 76, 47, 31, 56, 62, 13, 53, 59)
```

```
> (10, 70, 57, 23, 37, 22, 21, 27, 25)(30, 45, 46, 43, 42,
> 44, 40, 41, 75)(39, 55, 65)(48, 66, 58);
> x in k;
true;
> in_k, perm_image:= bb_to_perm(x);
> in_k;
true
> perm_image;
(1, 2, 3)(4, 7, 12, 6, 10, 11, 13, 9, 8)
> perm_to_bb(perm_image) eq x;
true
```

`RecogniseSymmetric(G, n: parameters)`

`maxtries`	RngIntElt	*Default :* $100n + 5000$
`Extension`	BoolElt	*Default :* `false`

The group G should be known to be isomorphic to the symmetric group S_n for some $n \geq 8$. The Bratus-Pak algorithm [BP00] (implemented by Derek Holt) is used to define an isomorphism between G and S_n. If successful, return `true`, homomorphism from G to S_n, homomorphism from S_n to G, the map from G to its word group and the map from the word group to G.

If the optional parameter `Extension` is set, then the group G should be known to be isomorphic either to S_n or to a perfect central extension $2.S_n$. In that case, the first two maps returned will be a homomorphism from G to S_n and a map from S_n to G that induces a homomorphism onto $G/Z(G)$. The sixth value returned will be `true`, if $G \cong 2.S_n$ and `false`, if $G \cong 2.A_n$.

If unsuccessful, `false` is returned. This will always occur if the input group is not isomorphic to S_n (or $2.S_n$ when `Extension` is set) with $n \geq 8$, and may occur occasionally even when G is isomorphic to S_n. The optional parameter `maxtries` (default $100n + 5000$) can be used to control the number of random elements chosen before giving up.

`SymmetricElementToWord (G, g)`

If g is an element of G which has been constructively recognised to be isomorphic to S_n (or $2.S_n$), then return `true` and element of word group for G which evaluates to g. Otherwise return `false`. This facilitates membership testing in G.

`RecogniseAlternating(G, n: parameters)`

`maxtries`	RngIntElt	*Default :* $100n + 5000$
`Extension`	BoolElt	*Default :* `false`

The group G should be known to be isomorphic to the alternating group A_n for some $n \geq 9$. The Bratus-Pak algorithm [BP00] (implemented by Derek Holt) is used to define an isomorphism between G and A_n. If successful, return `true`, homomorphism from G to A_n, homomorphism from A_n to G, the map from G to its word group and the map from the word group to G.

If the optional parameter `Extension` is set, then the group G should be known to be isomorphic either to A_n or to a perfect central extension $2.A_n$. In that case, the first two maps returned will be a homomorphism from G to A_n and a map from A_n to G that induces a homomorphism onto $G/Z(G)$. The sixth value returned will be `true`, if $G \cong 2.A_n$ and `false`, if $G \cong 2.A_n$.

If unsuccessful, `false` is returned. This will always occur if the input group is not isomorphic to A_n (or $2.A_n$ when `Extension` is set) with $n \geq 9$, and may occur occasionally even when G is isomorphic to A_n. The optional parameter `maxtries` (default $100n + 5000$) can be used to control the number of random elements chosen before giving up.

`AlternatingElementToWord (G, g)`

If g is an element of G which has been constructively recognised to be isomorphic to A_n (or $2.A_n$), then return `true` and element of word group for G which evaluates to g. Otherwise return `false`. This facilitates membership testing in G.

`GuessAltsymDegree(G: parameters)`

`maxtries`	RngIntElt	*Default :* 5000
`Extension`	BoolElt	*Default :* `false`

The group G should be believed to be isomorphic to S_n or A_n for some $n > 6$, or to $2.S_n$ or $2.A_n$ if the optional parameter `Extension` is set. This function attempts to determine n and whether G is symmetric or alternating. It does this by sampling orders of elements. It returns either `false`, if it is unable to make a decision after sampling `maxtries` elements (default 5000), or `true`, *type* and n, where *type* is "Symmetric" or "Alternating", and n is the degree. If G is not isomorphic to S_n or A_n (or $2.S_n$ or $2.A_n$ when `Extension` is set) for $n > 6$, then the output is meaningless - there is no guarantee that `false` will be returned. There is also a small probability of a wrong result or `false` being returned even when G is S_n or A_n with $n > 6$. This function was written by Derek Holt.

Example H58E40

For a group G which is believed to be isomorphic to S_n or A_n for some unknown value of $n > 6$, the function `GuessAltsymDegree` can be used to try to guess n, and then `RecogniseSymmetric` or `RecogniseAlternating` can be used to confirm the guess.

```
> SetSeed(1);
```

```
> G:= sub< GL(10,5) |
> PermutationMatrix(GF(5),Sym(10)![2,3,4,5,6,7,8,9,1,10]),
> PermutationMatrix(GF(5),Sym(10)![1,3,4,5,6,7,8,9,10,2]) >;
> GuessAltsymDegree(G);
true Alternating 10
> flag, m1, m2, m3, m4  := RecogniseAlternating(G,10);
> flag;
true
> x:=Random(G); Order(x);
8
> m1(x);
(1, 2, 4, 9, 10, 8, 6, 3)(5, 7)
> m2(m1(x)) eq x;
true
> m4(m3(x)) eq x;
true
> flag, w := AlternatingElementToWord(G,x);
> flag;
true
> m4(w) eq x;
true
> y := Random(Generic(G));
> flag, w := AlternatingElementToWord(G,y);
> flag;
false
> flag, m1, m2, m3, m4 := RecogniseAlternating(G,11);
> flag;
false
> flag, m1, m2, m3, m4 := RecogniseSymmetric(G,10);
> flag;
false
```

The nature of the `GuessAltsymDegree` function is that it assumes that its input is either an alternating or symmetric group and then tries to guess which one and the degree. As such, it is almost always correct when the input is an alternating or symmetric group, but will often return a bad guess when the input group is not of this form, as in the following example.

```
> GuessAltsymDegree(Sym(50));
true Symmetric 50
> GuessAltsymDegree(Alt(73));
true Alternating 73
> GuessAltsymDegree(PSL(5,5));
true Alternating 82
```

58.18 Base and Strong Generating Set

The key concept for representing a permutation group is that of a *base and strong generating set* (BSGS). Given a BSGS for a group, its order may be deduced immediately. Brownie, Cannon and Sims (1991) showed that it is practical, in some cases at least, to construct a BSGS for short-base groups having degree up to ten million.

The great majority of functions for computing with permutation groups require a BSGS to be present. If one is not known, MAGMA will attempt to automatically compute one. For large degree groups, the computation of a BSGS may be expensive and in such cases the user may achieve better performance through directly invoking a function which creates a BSGS. For example, if the group order is known in advance, it may be supplied to MAGMA and then a random method for computing a BSGS is applied which will use the group order as a termination condition.

In the first part of this section we present the elementary functions that use a BSGS, while towards the end we describe firstly, functions which allow the user to select and control the algorithm employed, and secondly, functions which provide access to the BSGS data structures. The material specific to BSGS should be omitted on a first reading.

58.18.1 Construction of a Base and Strong Generating Set

Computing structural information for a permutation group G requires, in most cases, a representation of the set of elements of G. MAGMA represents this set by means of a *base and strong generating set*, or *BSGS*, for G. Suppose the group G acts on the set Ω. A *base* B for G is a sequence of distinct points from Ω with the property that the identity is the only element of G that fixes B pointwise. A base B of length n determines a sequence of subgroups $G^{(i)}$, $1 \leq i \leq n+1$, where $G^{(i)}$ is the stabilizer of the first $i-1$ points of B. (In particular, $G^{(1)} = G$ and $G^{(n+1)}$ is trivial.) Given a base B for G, a subset S of G is said to be a *strong generating set* for G (with respect to B) if $G^{(i)} = \langle S \cap G^{(i)} \rangle$, for $i = 1, \ldots, n$.

`BSGS(G)`

The general procedure for constructing a BSGS. This version uses the default algorithm choices.

`SimsSchreier(G: parameters)`

`SV` BOOLELT *Default :* `true`

Construct a base and strong generating set for the group G using the standard Schreier-Sims algorithm. If the parameter `SV` is set `true` (default) the transversals are stored in the form of Schreier vectors. If `SV` is set `false`, then the transversals are stored both as lists of permutations and as Schreier vectors. If the base attribute has been previously defined for G, a variant of the Sims-Schreier algorithm will be employed, in which permutation multiplications are replaced by base image calculations wherever possible.

`RandomSchreier(G: parameters)`

`Max`	RngIntElt	*Default :* 100
`Run`	RngIntElt	*Default :* 20

Construct a probable base and strong generating set for the group G. The strong generators are constructed from a set of randomly chosen elements of G. The expectation is that, if sufficient random elements are taken, then, upon termination, the algorithm will have produced a BSGS for G. If the attribute Order is defined for G, the random Schreier will continue until a BSGS defining a group of the indicated order is obtained. In such circumstances this method is the fastest method of constructing a base and strong generating set for G. This is particularly so for groups of large degree. If nothing is known about G, the random Schreier algorithm provides a cheap way of obtaining lower bounds on the group's order and, in the case of a permutation group, on its degree of transitivity. This parameter has two associated parameters, `Max` and `Run`, which take positive integer values. The parameter `Max` specifies the number of random elements to be used (default 100). If the value of `Run` is n_2, then the algorithm terminates after n_2 consecutive random elements are found to lie in the set defined by the current BSGS (default 20). The two limits are independent of one another. It should be emphasized that unpredictable results may arise if the programmer uses the base and strong generators produced by this algorithm when, in fact, it does not constitute a BSGS for G.

`ToddCoxeterSchreier(G: parameters)`

Construct a BSGS for G using the Todd-Coxeter Schreier algorithm.

`SolubleSchreier(G: parameters)`

`SolvableSchreier(G: parameters)`

`Depth`	RngIntElt	*Default : See below*

Construct a base and strong generating set for the soluble permutation group G using the algorithm of Sims [Sim90]. The algorithm proceeds by recursively constructing the terms of the derived series. If G is not soluble then the algorithm will not terminate. In order to avoid non-termination, a limit on the number of terms in the normal subgroup chain constructed must be prescribed. The user may set this limit as the value of the parameter `Depth`. The default value, $\lceil 1.6 \ log_2 \ Degree(G) \rceil$, is based on an upper limit (due to Dixon) on the length of the derived series of a soluble permutation group. This algorithm is often significantly faster than the general Schreier-Sims algorithm.

`Verify(G: parameters)`

`Levels`	RngIntElt	*Default :* 0
`OrbitLimit`	RngIntElt	*Default :* 4,000

Given a permutation group G for which a probable BSGS is stored, verify the correctness of the BSGS. If it is not complete, proceed to complete it. The two parameters

`Levels` and `OrbitLimit` define how many levels the Todd-Coxeter-Schreier-Sims verifies before switching to the Brownie-Cannon-Sims algorithm. If `Levels` is set to n non-zero then n levels are verified by the TCSS algorithm before switching. If `Levels` is zero, the switch-over point is determined by the value of the parameter `OrbitLimit`. All levels with basic orbit length at most `OrbitLimit` are verified using TCSS. When a level is encountered with orbit length greater than this, a decision based on expected amount of work to do for this level by each algorithm determines what strategy is used for this level. Once one level uses the BCS method, all levels from then on will use it.

Example H58E41

The Higman-Sims simple group represented on 100 letters is generated by two permutations. To create a base and strong generating set for it using the Todd-Coxeter-Schreier algorithm, we can use the `ToddCoxeterSchreier` procedure as follows:

```
> G := sub<Sym(100) |
>    (2,8,13,17,20,22,7)(3,9,14,18,21,6,12)(4,10,15,19,5,11,16)

> ToddCoxeterSchreier(G);
> Order(G);
44352000
```

Example H58E42

The simple group of Rudvalis has a permutation representation of degree 4060. A generating set for the Rudvalis group, Ru, may be found in the standard MAGMA database `pergps`, where it is called `ru`. We use the random Schreier algorithm followed by the `Verify` procedure to produce a base and strong generating set. We increase the limits for `RandomSchreier` to increase the probability that a complete base and strong generating set is found. This is done as follows:

```
> load "ru";
> RandomSchreier(G : Max := 50, Run := 20);
> Order(G);
145926144000
> Verify(G);
> Order(G);
145926144000
> Base(G);
[ 1, 2, 3, 4 ]
> BasicOrbitLengths(G);
```

```
[ 4060, 2304, 780, 20 ]
```

58.18.2 Defining Values for Attributes

If the order of a permutation group is known in advance, the construction of a base and strong generating set can be greatly speeded up by taking advantage of this knowledge. The `AssertAttribute` constructor may be used to communicate this and other useful information to Magma.

```
AssertAttribute(G, "Order", n)
```

Define the order attribute for the permutation group G.

```
AssertAttribute(G, "Order", Q)
```

Define the (factored) order of the permutation group G to be Q.

```
#AssertAttribute(G, "BSGS", S)
```

Define the base and strong generating set structure S to be the BSGS for G.

Example H58E43

The ability to set the order provides a short cut when constructing a BSGS. If the order attribute is set and the random Schreier-Sims algorithm applied, it will run until a BSGS for a group of the designated order has been constructed. We illustrate this in the case of the wreath product, with product action, of Sym(42) with Alt(8).

```
> G := WreathProduct(Sym(42), Alt(8));
> AssertAttribute(G, "Order", Factorial(42)^8 * (Factorial(8) div 2));
> RandomSchreier(G);
> Order(G);

58.18.3 Accessing the Base and Strong Generating Set

`Base(G)`

A base for the permutation group G. The base is returned as a sequence of points of its natural G-set. If a base is not known, one will be constructed.

`BasePoint(G, i)`

The i-th base point for the permutation group G. A base and strong generating set must be known for G.

`BasicOrbit(G, i)`

The basic orbit at level i as defined by the current base for the permutation group G. This function assumes that a BSGS is known for G.

`BasicOrbits(G)`

The basic orbits as defined by the current base for the permutation group G. This function assumes that a BSGS is known for G. The orbits are returned as a sequence of indexed sets.

`BasicOrbitLength(G, i)`

The length of the basic orbit at level i as defined by the current base for the permutation group G. This function assumes that a BSGS is known for G.

`BasicOrbitLengths(G)`

The lengths of the basic orbits as defined by the current base for the permutation group G. This function assumes that a BSGS is known for G. The lengths are returned as a sequence of integers.

`BasicStabilizer(G, i)`

`BasicStabiliser(G, i)`

Given a permutation group G for which a base and strong generating set are known, and an integer i, where $1 \leq i \leq k$ with k the length of the base, return the subgroup of G which fixes the first $i-1$ points of the base.

`BasicStabilizerChain(G)`

`BasicStabiliserChain(G)`

Given a permutation group G, return the stabilizer chain defined by the base as a sequence of subgroups of G. If a BSGS is not already known for G, it will be created.

`IsMemberBasicOrbit(G, i, a)`

Returns `true` if the point a of Ω lies in the basic orbit at level i. This function assumes that a BSGS is known for G.

`NumberOfStrongGenerators(G)`

`Nsgens(G)`

The number of elements in the current strong generating set for G.

`NumberOfStrongGenerators(G, i)`

`Nsgens(G, i)`

The number of elements in the strong generating set for the i-th term of the stabilizer chain for G.

`SchreierVectors(G)`

The Schreier vectors corresponding to the current BSGS for the permutation group G. The vectors are returned as a sequence of integer sequences.

`SchreierVector(G, i)`

The Schreier vector corresponding the i-th term of the stabilizer chain defined by the current BSGS for the permutation group G. The vector is returned as a sequence of integers.

`StrongGenerators(G)`

A set of strong generators for the permutation group G. If they are not currently available, they will be computed.

`StrongGenerators(G, i)`

A set of strong generators for the i-th term in the stabilizer chain for the permutation group G. A BSGS must be known for G.

58.18.4 Working with a Base and Strong Generating Set

`BaseImage(x)`

Given a permutation x belonging to the group G, for which a base and strong generating set is known, form the base image of x.

`Permutation(G, Q)`

Given a permutation group G acting on the set Ω, for which a base and strong generating set are known, and a sequence Q of distinct points of Ω defining an element x of G, return x as a permutation.

`SVPermutation(G, i, a)`

The permutation of G defined by the Schreier vector at level i, which takes the point a of Ω to the base point at level i. This function assumes that a BSGS is known for G.

`SVWord(G, i, a)`

An element in the word group of G defined by the Schreier vector at level i, which takes the point a of Ω to the base point at level i. This function assumes that a BSGS is known for G.

`Strip(H, x)`

Given an element x of a permutation group G, and given a group H for which a base and strong generating set is known, returns:

(a) the value of `x in H`

(b) The residual permutation y resulting from the stripping of x with respect to the BSGS for H; and

(c) The first level i such that y is not contained in $H^{(i)}$.

`WordStrip(H, x)`

Given an element x of a permutation group G, and given a group H for which a base and strong generating set is known, returns:

(a) the value of `x in H`

(b) the residual word w (an element in the word group of G) resulting from the stripping of x with respect to the BSGS for H,

(c) The first level i such that y is not contained in $H^{(i)}$.

`BaseImageWordStrip(H, x)`

Given an element x of a permutation group G, and given a group H for which a base and strong generating set is known, returns:

(a) Whether the base image strip succeeded at all levels. Note that a true value here does *not*, on its own, imply $x \in H$.

(b) the residual word w (an element in the word group of G) resulting from the stripping of x with respect to the BSGS for H,

(c) The first level i such that the strip could not continue.

`WordInStrongGenerators(H, x)`

Given an element x of a permutation group H for which a base and strong generating set is known, returns a word in the strong generators of H which represents x. This function uses base images to determine the word for x, so giving $x \notin H$ will have unpredictable results. This function returns the inverse of the second return value of `BaseImageWordStrip`, when the latter is successful.

58.18.5 Modifying a Base and Strong Generating Set

`ChangeBase(~G, Q)`

Given a group H with a base and strong generating set, change the base of G, so that the points in the sequence Q form an initial segment of the new base.

`AddNormalizingGenerator(~H, x)`

Given a group H with a base B and strong generating set X, and an element x that normalizes H belonging to a group that contains H, extend the existing BSGS for H so that they form a BSGS for the subgroup $< H, x >$.

`ReduceGenerators(~G)`

Given a group G with a base and strong generating set, remove redundant strong generators.

58.19 Permutation Representations of Linear Groups

Each of the functions in this family returns two values:

(a) A permutation group G corresponding to the action of a designated matrix group M on a vector space V; and

(b) An indexed set of affine or projective points on which M acts, such that the indexing gives the correspondence between this set and the G-set of M.

Furthermore, most of the function in this family are parameterized by two objects: the *degree* and the *coefficient field* of the matrix group. These can be supplied in one of the following three forms:

(i) Integers n and q corresponding to the degree and the field $\mathbf{F}_q$ of M ($\mathbf{F}_{q^2}$ in the case of the unitary groups).

(ii) An integer n and a finite field K corresponding to the degree and the coefficient field of M.

(iii) A vector space $V = K^n$ on which M naturally acts.

The Suzuki group, however, is only parametrised by the field, as the degree is always four. As such, it can be described by the integer q, the field $K = \mathbf{F}_q$, or the vector space K^4.

`AffineGeneralLinearGroup(`*arguments*`)`

`AGL(`*arguments*`)`

Construct the affine general linear group $G = \mathrm{AGL}(n, q)$, i.e., the group corresponding to the action of $\mathrm{GL}(n, q)$ on the affine points of the n-dimensional vector space V over $K = \mathbf{F}_q$. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the affine points and the G-set of G.

`AffineSpecialLinearGroup(`*arguments*`)`

`ASL(`*arguments*`)`

Construct the affine special linear group $G = \mathrm{ASL}(n, q)$, i.e., the group corresponding to the action of $\mathrm{SL}(n, q)$ on the affine points of the n-dimensional vector space V over $K = \mathbf{F}_q$. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the affine points and the G-set of G.

`AffineGammaLinearGroup(`*arguments*`)`

`AGammaL(`*arguments*`)`

Construct the affine gamma linear group $G = \mathrm{A\Gamma L}(n, q)$, i.e., the group corresponding to the action of $\Gamma\mathrm{L}(n, q)$ (the automorphism group of $\mathrm{GL}(n, q)$) on the affine points of the n-dimensional vector space V over $K = \mathbf{F}_q$. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`AffineSigmaLinearGroup(`*arguments*`)`

`ASigmaL(`*arguments*`)`

Construct the affine sigma linear group $G = \mathrm{A\Sigma L}(n, q)$, i.e., the group corresponding to the action of $\Sigma\mathrm{L}(n, q)$ (the automorphism group of $\mathrm{SL}(n, q)$) on the affine points of the n-dimensional vector space V over $K = \mathbf{F}_q$. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveGeneralLinearGroup(`*arguments*`)`

`PGL(`*arguments*`)`

Construct the projective general linear group $G = \mathrm{PGL}(n, q)$, i.e., the group corresponding to the action of $\mathrm{GL}(n, q)$ on the projective points of the n-dimensional vector space V over $K = \mathbf{F}_q$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSpecialLinearGroup(`*arguments*`)`

`PSL(`*arguments*`)`

Construct the projective special linear group $G = \mathrm{PSL}(n, q)$, i.e., the group corresponding to the action of $\mathrm{SL}(n, q)$ on the projective points of the n-dimensional vector space V over $K = \mathbf{F}_q$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveGammaLinearGroup(`*arguments*`)`

`PGammaL(`*arguments*`)`

Construct an automorphism group $G = \mathrm{P\Gamma L}(n, q)$ of the projective general linear group $B = \mathrm{PGL}(n, q)$, by adding the field automorphisms of $\mathbf{F}_q$ to B. The permutation action corresponds to the natural action on 1-dimensional subspaces of the n-dimensional vector space V over the field $K = \mathbf{F}_q$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveSigmaLinearGroup(`*arguments*`)`

`PSigmaL(`*arguments*`)`

Construct an automorphism group $G = \mathrm{P\Sigma L}(n, q)$ of the projective special linear group $B = \mathrm{PSL}(n, q)$, by adding the field automorphisms of $\mathbf{F}_q$ to B. The permutation action corresponds to the natural action on 1-dimensional subspaces of the n-dimensional vector space V over the field $K = \mathbf{F}_q$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveGeneralUnitaryGroup(`*arguments*`)`

`PGU(`*arguments*`)`

Construct the projective general unitary group $G = \mathrm{PGU}(n, q)$ corresponding to the n-dimensional vector space V over the field $K = \mathbf{F}_{q^2}$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSpecialUnitaryGroup(`*arguments*`)`

`PSU(`*arguments*`)`

Construct the projective special unitary group $G = \mathrm{PSU}(n, q)$ corresponding to the n-dimensional vector space V over the field $K = \mathbf{F}_{q^2}$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of V, giving the correspondence between these vectors and the G-set of G.

`ProjectiveGammaUnitaryGroup(`*arguments*`)`

`PGammaU(`*arguments*`)`

Construct an automorphism group $G = \mathrm{P\Gamma U}(n, q)$ of the projective general unitary group $B = \mathrm{PGU}(n, q)$, by adding the field automorphisms of $\mathbf{F}_{q^2}$ to B. The permutation action corresponds to the natural action on 1-dimensional subspaces of the n-dimensional vector space V over the field $K = \mathbf{F}_{q^2}$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveSigmaUnitaryGroup(`*arguments*`)`

`PSigmaU(`*arguments*`)`

Construct the automorphism group $G = \mathrm{P\Sigma U}(n, q)$ of the projective special unitary group $B = \mathrm{PSU}(n, q)$, by adding the field automorphisms of $\mathbf{F}_{q^2}$ to B. The permutation action corresponds to the natural action on 1-dimensional subspaces of the n-dimensional vector space V over the field $K = \mathbf{F}_{q^2}$, where $n \geq 2$ and q is a prime power. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveSymplecticGroup(`*arguments*`)`

`PSp(`*arguments*`)`

Construct the projective symplectic group $G = \mathrm{PSp}(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 4. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSigmaSymplecticGroup(`*arguments*`)`

`PSigmaSp(`*arguments*`)`

Construct the group $G = \mathrm{P\Sigma Sp}(n, q)$ of the projective symplectic group $\mathrm{PSp}(n, q)$ extended by field automorphisms of $K = \mathbf{F}_q$, where V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 4. The function returns:

(a) The group G;

(b) An indexed set giving the correspondence between the points and the G-set of G.

`ProjectiveGeneralOrthogonalGroup(`*arguments*`)`

`PGO(`*arguments*`)`

Construct the projective general orthogonal group $G = \mathrm{PGO}(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an odd integer greater than or equal to 3. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveGeneralOrthogonalGroupPlus(`*arguments*`)`

`PGOPlus(`*arguments*`)`

Construct the projective general orthogonal group $G = \mathrm{PGO}^+(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveGeneralOrthogonalGroupMinus(`*arguments*`)`

`PGOMinus(`*arguments*`)`

Construct the projective general orthogonal group $G = \mathrm{PGO}^-(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSpecialOrthogonalGroup(`*arguments*`)`

`PSO(`*arguments*`)`

Construct the projective special orthogonal group $G = \mathrm{PSO}(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an odd integer greater than or equal to 3. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSpecialOrthogonalGroupPlus(`*arguments*`)`

`PSOPlus(`*arguments*`)`

Construct the projective special orthogonal group $G = \mathrm{PSO}^+(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSpecialOrthogonalGroupMinus(`*arguments*`)`

`PSOMinus(`*arguments*`)`

Construct the projective general orthogonal group $G = \mathrm{PSO}^-(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveOmega(`*arguments*`)`

`POmega(`*arguments*`)`

Construct the projective orthogonal group $G = \mathrm{P\Omega}(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an odd integer greater than or equal to 3. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveOmegaPlus(`*arguments*`)`

`POmegaPlus(`*arguments*`)`

Construct the projective orthogonal group $G = \mathrm{P\Omega}(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveOmegaMinus(`*arguments*`)`

`POmegaMinus(`*arguments*`)`

Construct the projective orthogonal group $G = \mathrm{P}\Omega(n, q)$, where $K = \mathbf{F}_q$, V is an n-dimensional vector space over K, and n is an even integer greater than or equal to 2. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`ProjectiveSuzukiGroup(`*arguments*`)`

`PSz(`*arguments*`)`

Construct the permutation representation $G = \mathrm{PSz}(q)$ of the Suzuki simple group $\mathrm{Sz}(q)$, given by its action on projective points, where q is of the form 2^{2n+1}. If K is given, its cardinality is q. If V is given, it must be 4-dimensional, and over K. The function returns:

(a) The group G;

(b) An indexed set of the generators of the 1-dimensional subspaces of $K^{(n)}$, giving the correspondence between these vectors and the G-set of G.

`AffineGroup(M)`

Given a matrix group of degree d over a finite field F, construct the semidirect product $V : M$, where $V = F^d$ is the natural M-module. The result, G, is a standard permutation group of degree $|V| = |F|^d$, where the second return value gives the correspondence between the elements of V and the standard G-set.

58.20 Permutation Group Databases

Magma includes databases that contain all transitive permutation groups of degree up to 32 and all primitive permutation groups of degree up to 4095. Descriptions of these databases may be found in Chapter 66.

58.21 Ordered Partition Stacks

Ordered partition stacks have been implemented with their own type and Magma intrinsics. They implement the data structure described very briefly in section 2 of Jeff Leon's 1997 paper [Leo97]. They can be used as an aid to implementing various backtrack searches in the Magma language.

The domain set of the partitions is always $\{1..n\}$, where n is called the degree of the stack. The basic "push" operation for these stacks involves refining an ordered partition, and the precise definition of refinement used in the Magma implementation is Definition 2 of [Leo97]. This differs from the definition in Chapter 9 of [Ser03], for instance.

The word "ordered" refers to the cells of the partition being in a fixed order. The order of points in a cell is not significant, and may vary as the data structure is manipulated.

58.21.1 Construction of Ordered Partition Stacks

`OrderedPartitionStack(n)`

Create a data structure representing a complete ordered partition stack of degree n. Initially the stack has one partition on it, which is the partition having a single block.

`OrderedPartitionStackZero(n, h)`

Create a data structure representing a zero-based ordered partition stack of degree n with height limited to h. Initially the stack has one partition on it, which is the partition having a single block, and has height 0.

58.21.2 Properties of Ordered Partition Stacks

`Degree(P)`

The degree of the ordered partition stack P.

`Height(P)`

The height of the ordered partition stack P. For a complete stack, this equals the number of cells of the finest partition on the stack.

`NumberOfCells(P, h)`

The number of cells in the partition on stack P at height h. If h is omitted it is taken to be the height of P, so giving the number of cells in the finest partition on the stack P.

`CellNumber(P, h, x)`

The number of the cell of the partition at height h in P that contains the element x. If h is omitted it is taken to be the height of P.

`CellSize(P, h, i)`

The size of cell i of the partition at height h in P. If h is omitted it is taken to be the height of P.

`Cell(P, h, i)`

The contents of cell i of the partition at height h in P as a sequence of integers. If h is omitted it is taken to be the height of P. Note that the order of the points in the returned sequence may vary, as the order of points in a cell of an ordered partition is not fixed.

`Random(P, i)`

A random element of cell i of the finest partition on P.

`Representative(P, i)`

`Rep(P, i)`

An element of cell i of the finest partition on P.

`ParentCell(P, i)`

The number of the cell that was split to first create cell number i.

58.21.3 Operations on Ordered Partition Stacks

Here are listed the basic operations provided for pushing a finer partition onto an ordered partition stack, called splitting, and for popping ordered partitions off the stack.

If the top partition on the stack has k cells, and one of these cells is split to form a finer partition, then the new cell will have number $k + 1$, and the residue of the split cell will have the same number as the cell that was split. This agrees with the definition of refinement given in [Leo97], Definition 2, but disagrees with [Ser03], Chapter 9.2, and [McK81].

`SplitCell(P, i, x)`

`SplitCell(P, i, Q)`

Attempt to refine the top partition on stack P by splitting cell i. The new cell created will be $\{x\}$ if x is in cell i, or will be the intersection of Q with cell i (in the second form), if this is not empty and not all of cell i. The new partition, if any, is pushed onto the stack. The return value is true when P is changed, false otherwise. This implements the operation in Definition 6 of [Leo97].

`SplitAllByValues(P, V)`

Refine the top partition on stack P by splitting all possible cells using the values in V. This implements the operation given in Definition 15 of [Leo97]. Cells are split in increasing order of cell number, and the resulting new cells are in the curious order given in the cited definition.

The first return value is true when P is changed, false otherwise. The second is a hash value based on which cells are split, the values from V used in the split, and the sizes of the resulting cells. It is suitable for use as an indicator function, as defined in 2-16 of [McK81].

`SplitCellsByValues(P, C, V)`

`SplitCellsByValues(P, i, V)`

Refine the top partition on stack P by splitting all cells given in C, or cell i, using the values in V. Splitting and return values are as for `SplitAllByValues`, with an important difference: cells will be split in the order given in C, and, if some cell in C does not split, the operation will be terminated there, and false returned.

`Pop(P)`

`Pop(P, h)`

Reduce the height of the partition stack P to height h, or by one if h is not given. The method used is the "retract" algorithm of [Leo97], Fig. 7.

`Advance(X, L, P, h)`

This implements the "advance" algorithm of [Leo97], Fig. 7: X is a zero-based stack of degree d say, L is a sequence of length n taking values in $\{1..d\}$, representing an unordered partition of $\{1..n\}$ into d blocks, P is a complete stack of degree n, and h is a positive integer which is at most the height of P. This is a fundamental operation in Leon's unordered partition stabilizer algorithm.

Example H58E44

We set up an ordered partition stack of degree 12, and try out a few basic operations on it. The printing of a stack shows the top partition of the stack.

```
> P := OrderedPartitionStack(12);
> P;
Partn stack, degree 12, height 1
[ 1 2 3 4 5 6 7 8 9 10 11 12]
> SplitCell(P, 1, 4);
true
> P;
Partn stack, degree 12, height 2
```

```
[ 1 2 3 12 5 6 7 8 9 10 11 | 4]
```

Note that the order of the points in cell 1 is not significant. Now we will split on the values in a vector V.

```
> V := [i mod 5 + 1: i in [0..11]];
> V;
[ 1, 2, 3, 4, 5, 1, 2, 3, 4, 5, 1, 2 ]
> SplitAllByValues(P, V);
true 119375796
> P;
Partn stack, degree 12, height 6
[ 1 6 11 | 4 | 10 5 | 9 | 8 3 | 12 2 7]
```

Only cell 1 has been split. The points corresponding to the minimum value in V remain in cell 1. The new cells are cells 2 to 6. They correspond to the higher values in V, in descending order. Now pop the stack back to height 4 and try the effect of a different split by values.

```
> Pop(P, 4);
> P;
Partn stack, degree 12, height 4
[ 1 6 11 12 2 7 8 3 | 4 | 10 5 | 9]
> V := [i mod 4 + 1: i in [0..11]];
> V;
[ 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, 4 ]
> SplitAllByValues(P, V);
true 985543242
> P;
Partn stack, degree 12, height 8
[ 1 | 4 | 5 | 9 | 8 12 | 11 7 3 | 6 2 | 10]
> Pop(P, 3);
> P;
Partn stack, degree 12, height 3
[ 1 6 2 11 7 3 8 12 9 | 4 | 5 10]
```

59 MATRIX GROUPS OVER GENERAL RINGS

Chapter 59
MATRIX GROUPS OVER GENERAL RINGS

59.1 Introduction

59.1.1 Introduction to Matrix Groups

A matrix group G may be defined over any ring R for which MAGMA has a method for computing the inverse of a matrix. However, the availability of machinery for determining structural information is dependent upon the properties of the base ring R.

We distinguish several different cases.

(i) If the ring R is a finite field then the group must be finite. If the group has moderate degree and it is possible to find a low dimensional subspace of the natural vector space for G whose orbit under G has length bounded by a million or so, then it is possible to construct a stabilizer chain representation for the group similar to that used for permutation groups (the *BSGS representation* [But76]). In order to increase the chances of finding a short orbit the Murray-O'Brien [MO95] strategy for selecting base points is used. The availability of a BSGS representation allows the structure of the group to be investigated in detail.

(ii) If the coefficient ring R is a finite field but the degree and size of the group are such that it is not possible to construct a useful BSGS representation then the group may be investigated using techniques based on a theorem of Aschbacher that classifies the maximal subgroups of $\mathrm{GL}(n, q)$. This approach is under intensive development by Leedham-Green, O'Brien and others. Code implementing some parts is documented in Chapter 65.

(iii) If the ring R is the Euclidean Ring $\mathbf{Z}/m\mathbf{Z}$, then the group must be finite. If the group has moderate degree and it is possible to find a vector in the natural R-module for G whose orbit has length bounded by a million or so, then again it is possible to compute structural information using the BSGS representation.

(iv) If the ring R has infinite cardinality and satisfies certain properties, MAGMA can sometimes determine whether the group is finite or infinite. In particular, this can be done when R is the ring of integers, the field of rational numbers, or an algebraic number field (including cyclotomic and quadratic fields). If G is infinite, and has not been created as a Lie group, then MAGMA currently provides little beyond basic arithmetic on elements.

(v) If the ring R has infinite cardinality but the group G is finite and R is either a field or an Euclidean Domain then it may be possible to construct a *BSGS representation* as above and thereby undertake structural computation.

(vi) If an (infinite) matrix group can be created as a Lie group then machinery based on Lie Theory may be used to analyse the group. The facilities for Lie groups are described in Chapter 103.

Matrix groups over rings of infinite cardinality may be created regardless as to whether they are finite or not. If the coefficient ring R is either the ring of integers, the rational field, a quadratic field, a cyclotomic field, or a number field a matrix group may then be tested for finiteness by use of the function `IsFinite`. However, most functions that determine structural properties of a group apply only to finite groups.

59.1.2 The Support

Matrix groups may be defined over any ring for which MAGMA has a method for computing matrix inverses. However, the structure algorithms assume that the group is finite and is defined over either a field, an Euclidean Domain or the Euclidean Ring $\mathbf{Z}/m\mathbf{Z}$.

59.1.3 The Category of Matrix Groups

The family of matrix groups over a particular ring R forms a category where the objects are the matrix groups and the morphisms are group homomorphisms. The collection of all matrix groups forms a family of categories indexed by the category of rings. The MAGMA designation for this family of categories of matrix groups is `GrpMat`.

59.1.4 The Construction of a Matrix Group

A group of $n \times n$ matrices defined over the ring R is created as a subgroup of the general linear group $\mathrm{GL}(n, R)$. Thus the construction of a general matrix group is a two step process:

(i) The appropriate general linear group, $\mathrm{GL}(n, R)$, is constructed;

(ii) The required group G is then defined as a subgroup of $\mathrm{GL}(n, R)$.

For convenience, a constructor `MatrixGroup< ... >`, which combines these two steps, is provided.

59.2 Creation of a Matrix Group

59.2.1 Construction of the General Linear Group

`GeneralLinearGroup(n, R)`

`GL(n, R)`

Given an integer $n \geq 1$ and a ring R, create the generic matrix group, i.e. the general linear group $\mathrm{GL}(n, R)$. Initially, only a structure table is created for $\mathrm{GL}(n, R)$, so that, in particular, generators are not defined. This function is normally used to provide a context for the creation of elements and subgroups of $\mathrm{GL}(n, R)$. If structural computation is attempted with the group created by `GeneralLinearGroup(n, R)`, then generators will be created where possible. At present, this is only permitted in the cases in which R is a finite field.

Example H59E1

We define the general linear group $\mathrm{GL}(3, K)$, where K is the finite field $\mathbf{F}_4$.

```
> K<w> := FiniteField(4);
> GL34 := GeneralLinearGroup(3, K);
> GL34;
GL(3, GF(2, 2))
```

59.2.2 Construction of a Matrix Group Element

Throughout this subsection we shall assume that the matrix group G is defined over the ring R.

`elt< G | L >`

Given a matrix group G defined as a subgroup of $\mathrm{GL}(n, R)$, and the list L of expressions a_{ij} $(1 \leq i, j \leq n)$, defining elements of the ring R, construct the $n \times n$ matrix

$$\begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{pmatrix}$$

Unless G is known to be the generic matrix group of degree n, the matrix will be tested for membership of G, and if g is not an element of G, the function will fail. If g does lie in G, g will have G as its parent. Since the membership test may involve constructing a base and strong generating set for G, this constructor may occasionally be very costly. Hence a matrix g should be defined as an element of a subgroup of the generic group only when membership of G is required by subsequent operations involving g.

`G ! Q`

Given the sequence Q of expressions a_{ij} $(1 \leq i, j \leq n)$, defining elements of the ring R, construct the $n \times n$ matrix

$$\begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{pmatrix}$$

This matrix will have G as its parent structure. As in the case of the `elt`-constructor, the operation will fail if g is not an element of G, and the same observations concerning the cost of membership testing apply.

`ElementToSequence(g)`

`Eltseq(g)`

Given an $n \times n$ matrix $g = (a_{ij}), 1 \leq i, j \leq n$, where a_{ij} is an element of the ring R, construct the sequence

$$[a_{11}, \ldots, a_{1n}, a_{21}, \ldots, a_{2n}, \ldots a_{n1}, \ldots, a_{nn}]$$

of n^2 elements of the ring R.

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity matrix in the matrix group G.

Example H59E2

The different constructions are illustrated by the following code, which assigns to each of the variables x and y an element of $\mathrm{GL}(3, 4)$.

```
> K<w> := FiniteField(4);
> GL34 := GeneralLinearGroup(3, K);
> x := elt<GL34 | w,0,1, 0,1,0, 1,0,1 >;
> x;
[w 0 1]
[0 1 0]
[1 0 1]
> y := GL34 ! [w,0,1, 0,1,0, 1,0,1];
> y;
[w 0 1]
[0 1 0]
[1 0 1]
> GL34 ! 1;
[1 0 0]
[0 1 0]
[0 0 1]
```

59.2.3 Construction of a General Matrix Group

`MatrixGroup< n, R | L >`

Construct the matrix group G of degree n over the ring R generated by the matrices defined by the list L. A term of the list L must be an object of one of the following types:

(a) A sequence of n^2 elements of R defining a matrix of $\mathrm{GL}(n, R)$;

(b) A set or sequence of sequences of type (a);

(c) An element of $\mathrm{GL}(n, R)$;

(d) A set or sequence of elements of $\mathrm{GL}(n, R)$;

(e) A subgroup of $\mathrm{GL}(n, R)$;

(f) A set or sequence of subgroups of $\mathrm{GL}(n, R)$.

Each element or group specified by the list must belong to the *same* generic matrix group. The group G will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of G consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list. Repetitions of an element and occurrences of the identity element are removed.

The `MatrixGroup` constructor is shorthand for the two statements:

```
GL := GeneralLinearGroup(n, R);
G := sub< GL | L >;
```

where `sub< ... >` is the subgroup constructor described in the next subsection.

Example H59E3

We use the `MatrixGroup` constructor to define a small subgroup of $\mathrm{GL}(3, 4)$.

```
> K<w> := FiniteField(4);
> H := MatrixGroup< 3, K | [1,w,0, 0,1,0, 1,w^2,1], [w,0,0, 0,1,0, 0,0,w] >;
> H;
MatrixGroup(3, GF(2, 2))
Generators:
[  1   w   0]
[  0   1   0]
[  1 w^2   1]

[w 0 0]
[0 1 0]
[0 0 w]
> Order(H);
96
```

Example H59E4

We present a function which will construct the Sylow p-subgroup of $\mathrm{GL}(n, K)$, where K is a finite field of characteristic p.

```
> GLSyl := function(n, K)
>    R := MatrixRing(K, n);
>    e := func< i, j | MatrixUnit(R, i, j) >;
>    return MatrixGroup< n, K | { R!1 + a*e(i,j) : a in K, j in [i+1],
>          i in [1 .. n - 1] | a ne 0 } >;
> end function;
> T := GLSyl(3, GF(8));
> FactoredOrder(T);
[ <2, 9> ]
> FactoredOrder(GL(3, GF(8)));
[ <2, 9>, <3, 2>, <7, 3>, <73, 1> ]
```

59.2.4 Changing Rings

`ChangeRing(G, S)`

Given a matrix group G with base ring R, construct a new matrix group H with base ring S derived from G by coercing entries of the generators of G from R into S.

`ChangeRing(G, S, f)`

Given a matrix group G with base ring R, construct a new matrix group H with base ring S derived from G by applying f to the entries of the generators of G.

`RestrictField(G, S)`

Given a matrix group G with base ring K, a finite field, and S a subfield of K, construct the matrix group H with base ring S obtained by restricting the scalars of the components of elements of G into S, together with the restriction map from G onto H.

`ExtendField(G, L)`

Given a matrix group G with base ring K, a finite field, and L an extension of K, construct the matrix group H with base ring L obtained by lifting the components of elements of G into L, together with the inclusion homomorphism from G into H.

59.2.5 Coercion between Matrix Structures

A square non-singular matrix may be defined as an element of any of the following structures:

- A subring of the complete matrix ring $M_n(R)$;
- A subgroup of the general linear group $\mathrm{GL}(n, R)$;
- A submodule of the matrix module $M^{(m \times n)}(R)$.

The coercion operator may be used to transfer matrices between any two of these three structures.

`R ! g`

Transfer the matrix g from a group into a matrix ring R.

`G ! r`

Transfer the matrix r from a ring into a matrix group G.

`M ! g`

Transfer the matrix g from a group into a matrix module M.

`G ! m`

Transfer the matrix m from a module into a matrix group G.

59.2.6 Accessing Associated Structures

The functions in this group provide access to basic information stored for a matrix group G.

`G . i`

The i-th defining generator for the matrix group G. A negative subscript indicates that the inverse of the generator is to be created. $G.0$ is `Identity(G)`.

`Degree(G)`

The degree of the matrix group G.

`Generators(G)`

A set containing the defining generators for the matrix group G.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for the matrix group G.

`CoefficientRing(G)`

`BaseRing(G)`

The coefficient ring for the matrix group G.

`RSpace(G)`

Given a matrix group G of degree n defined over a ring R, return the space $R^{(n)}$, where the action is multiplication by elements of R, i.e. scalar action.

`VectorSpace(G)`

Given a matrix group G of degree n defined over a field K, return the space $K^{(n)}$, where the action is multiplication by elements of K, i.e. scalar action.

`GModule(G)`

The natural $R[G]$-module for the matrix group G.

`Generic(G)`

The generic group containing the matrix group G, i.e. the general linear group in which G is naturally embedded.

`Parent(G)`

The power structure for the group G (the set consisting of all matrix groups).

59.3 Homomorphisms

Homomorphisms are an important part of group theory, and MAGMA supports homomorphisms between groups. Many useful homomorphisms are returned by constructors and intrinsic functions. Examples of these are the `quo` constructor, the `sub` constructor and intrinsic functions such as `OrbitAction` and `FPGroup`, which are described in more detail elsewhere in this chapter. In this section we describe how the user may create their own homomorphisms with domain a matrix group.

`hom< G - >`

Given the matrix group G, construct the homomorphism $f : G \to H$ given by the generator images in L. H must be a group. The clause L may be any one of the following types:

(a) A list of elements of H, giving images of the generators of G;

(b) A list of pairs, where the first in the pair is an element of G and the second its image in H, where pairs may be given in either of the (equivalent) forms `<g,h>` or `g -> h`;

(c) A sequence of elements of H, as in (a);

(d) A set or sequence of pairs, as in (b);

Each image element specified by the list must belong to the *same* group H. In the cases where pairs are given the given elements of G must generate G.

`Domain(f)`

The domain of the homomorphism f.

`Codomain(f)`

The codomain of the homomorphism f.

`Image(f)`

The image or range of the homomorphism f. This will be a subgroup of the codomain of f. The algorithm computes the image and kernel simultaneously (see [LGPS91]).

`Kernel(f)`

The kernel of the homomorphism f. This will be a normal subgroup of the domain of f. The algorithm computes the image and kernel simultaneously (see [LGPS91]).

`IsHomomorphism(G, H, Q)`

Return the value `true` if the sequence Q defines a homomorphism from the group G to the group H. The sequence Q must have length `Ngens(G)` and must contain elements of H. The i-th element of Q is interpreted as the image of the i-th generator of G and the function decides if these images extend to a homomorphism. If so, the homomorphism is also returned.

Example H59E5

We construct the usual degree 2 matrix representation of the dihedral group of order 20, and a homomorphism from it to the symmetric group of degree 5.

```
> K<z> := CyclotomicField(20);
> zz := RootOfUnity(10, K);
> i := RootOfUnity(4, K);
> cos := (zz+ComplexConjugate(zz))/2;
> sin := (zz-ComplexConjugate(zz))/(2*i);
> gl := GeneralLinearGroup(2, K);
> M := sub< gl | [cos, sin, -sin, cos], [-1,0,0,1]>;
> #M;
20
> S := SymmetricGroup(5);
> f := hom<M->S |[S|(1,2,3,4,5), (1,5)(2,4)]>;
> Codomain(f);
Symmetric group S acting on a set of cardinality 5
Order = 120 = 2^3 * 3 * 5
> Image(f);
Permutation group acting on a set of cardinality 5
Order = 10 = 2 * 5
  (1, 2, 3, 4, 5)
  (1, 5)(2, 4)
> Kernel(f);

59.3.1 Construction of Extensions

`DirectProduct(G, H)`

Given two matrix groups G and H of degrees m and n respectively, construct the direct product of G and H as a matrix group of degree $m + n$.

`DirectProduct(Q)`

Given a sequence Q of n matrix groups, construct the direct product $Q[1] \times Q[2] \times \ldots \times Q[n]$ as a matrix group of degree equal to the sum of the degrees of the groups $Q[i]$, $(i = 1, \ldots, n)$.

`SemiLinearGroup(G, S)`

Given a matrix group G over the finite field K and a subfield S of K, construct the semilinear extension of G over the subfield S.

`TensorWreathProduct(G, H)`

Given a matrix group G and a permutation group H, construct action of the wreath product on the tensor power of G by H, which is the (image of) the wreath product in its action on the tensor power (of the space that G acts on). The degree of the new group is d^k where d is the degree of G and k is the degree of H.

`WreathProduct(G, H)`

Given a matrix group G and a permutation group H, construct the wreath product $G \wr H$ of G and H.

Example H59E6

We define G to be $\mathrm{SU}(3, 4)$ and H to be the symmetric group of order 6. We then proceed to form the direct product of G with itself and the tensor and wreath products of G and H.

```
> K<w> := FiniteField(4);
> G := SpecialUnitaryGroup(3, K);
> D := DirectProduct(G, G);
> D;
MatrixGroup(6, GF(2, 2))
Generators:

```

59.4 Operations on Matrices

59.4.1 Arithmetic with Matrices

`g * h`

The product of matrix g and matrix h, where g and h belong to the same generic group U. If g and h both belong to the same proper subgroup G of U, then the result will be returned as an element of G; if g and h belong to subgroups H and K of a subgroup G of U then the product is returned as an element of G. Otherwise, the product is returned as an element of U.

`g ^ n`

The n-th power of the matrix g, where n is a positive or negative integer.

`g / h`

The product of the matrix g by the inverse of the matrix h, i.e. the element $g * h^{-1}$. Here g and h must belong to the same generic group U. The rules for determining the parent group of g/h are the same as for $g * h$.

`g ^ h`

The conjugate of the matrix g by the matrix h, i.e. the element $h^{-1} * g * h$. Here g and h must belong to the same generic group U. The rules for determining the parent group of g^h are the same as for $g * h$.

`(g, h)`

The commutator of the matrices g and h, i.e. the element $g^{-1} * h^{-1} * g * h$. Here g and h must belong to the same generic group U. The rules for determining the parent group of (g, h) are the same as those for $g * h$.

`(g1, ..., gr)`

Given r matrices $g_1, \ldots, g_r$ belonging to a common group, return their commutator. Commutators are *left-normed*, so they are evaluated from left to right.

Example H59E7

These operations will be illustrated using the group GL$(3, 4)$.

```
> K<w> := FiniteField(4);
> GL34 := GeneralLinearGroup(3, K);
> x := GL34 ! [1,w,0, 0,w,1, w^2,0,1];
> y := GL34 ! [1,0,0, 1,w,0, 1,1,w];
> x;
[  1   w   0]
[  0   w   1]
[w^2   0   1]
> y;
[1 0 0]
[1 w 0]
```

```
[1 1 w]
> x*y;
[w^2 w^2   0]
[w^2   w   w]
[  w   1   w]
> x^10;
[  w   w   1]
[  w   1   1]
[  w w^2   w]
> x^-1;
[w^2 w^2 w^2]
[  1   w   w]
[  w   w w^2]
> x^y;
[w^2 w^2   0]
[  0 w^2   1]
[w^2 w^2   w]
> x/y;
[  0   1   0]
[  0 w^2 w^2]
[  w   w w^2]
> (x, y);
[  0   w   w]
[  w w^2   1]
[w^2   w w^2]
> (x,y,y);
[w^2   w w^2]
[w^2   w   0]
[w^2   1   w]
```

Arithmetic with group elements is not limited to elements of finite groups. We illustrate with a group of degree 3 over a function field.

```
> P<a,b,c,m,x,y,z> := FunctionField(RationalField(), 7);
> S := MatrixGroup< 3, P | [1,a,b,0,1,c,0,0,1],
>                          [1,0,m,0,1,0,0,0,1],
>                          [1,x,y,0,1,z,0,0,1] >;
>
> t := S.1 * S.2;
> t;
[    1     a b + m]
[    0     1     c]
[    0     0     1]
> t^-1;
[          1          -a a*c - b - m]
[          0           1          -c]
[          0           0           1]
> Determinant(t);
1
```

```
> t^2;
[              1              2*a a*c + 2*b + 2*m]
[              0                1             2*c]
[              0                0               1]
```

59.4.2 Predicates for Matrices

`g eq h`

Given matrices g and h belonging to the same generic group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given matrices g and h belonging to the same generic group, return `true` if g and h are distinct elements, `false` otherwise.

`IsIdentity(g)`

`IsId(g)`

Returns `true` if the matrix g is the identity matrix.

`IsScalar(g)`

Returns `true` if the matrix g is a scalar matrix.

59.4.3 Matrix Invariants

All of the functions for computing invariants of a square matrix apply to the elements of a matrix group. Here only operations of interest in the context of group elements are described. The reader is referred to chapter 26 for a complete list of functions applicable to matrices.

`Degree(g)`

The degree of the matrix g, i.e. the number of rows/columns of g.

`HasFiniteOrder(g)`

Returns `true` iff the matrix g has finite order. The second return value is the order if it is finite. The function rigorously proves its result (i.e., the result is not probable). Let R be the ring over which g is defined, and let the degree of the group in which g lies be n. If R is finite, then the first return value is trivially `true`.

If R is the integer ring then the function works as follows. Suppose first that g has finite order o. By a theorem of Minkowski (see Theorem 1.4 [KP02]), for any odd prime p, the reduction mod p of g has order o. Let $f(x) \in R[x]$ be the minimal polynomial of g. The matrix subalgebra generated by g is isomorphic to the quotient ring $R[x]/\langle f(x)\rangle$, so the order o of g equals the order of x mod $f(x)$.

For arbitrary g, the algorithm computes the order, $\bar{o}$, of the reduction of g modulo a small odd prime. If $\bar{o}$ is a possible order of an integer matrix of g's dimensions (see Theorem 2.7 *op. cit.*) then this is repeated with a larger prime. If this gives a different order, or the first attempt gave an impossible order, then g has infinite order. We now compute $x^{\bar{o}}$ mod $f(x)$. If this is 1, then $\bar{o}$ is the order of g, otherwise g has infinite order.

If R is the rational field then a necessary condition for g to have finite order is that $f(x)$ has integer coefficients, thus the above algorithm applies in this case.

If R is an algebraic number field of degree d over $\mathbf{Q}$ (including cyclotomic and quadratic fields), then the standard companion matrix blowup is applied to g to obtain a $(nd) \times (nd)$ matrix over $\mathbf{Q}$, and the above algorithm is then applied to this matrix.

`Order(g)`

`Proof` BoolElt *Default :* `true`

Given an element g of finite order belonging to a matrix group, this function returns the order of g. If g has infinite order, a runtime error results. In the case of a matrix group over a finite field, the algorithm described in [CLG97a] is used. In all other cases, simple powering of g is used.

The parameter `Proof` is associated with the case when the coefficient ring for g is a finite field. In that case, if `Proof` is set to `false`, then difficult integer factorizations will not attempted. In this situation two values are returned of which the first is a multiple n of the order of g. and the second value indicates whether n is known to be the exact order of g.

`FactoredOrder(g)`

`Proof` BoolElt *Default :* `true`

Given an element g of finite order belonging to a matrix group, this function returns the order of g as a factored integer. If g has infinite order, a runtime error results. If g has infinite order, the function generates a runtime error. In the case of a matrix group over a finite field, the algorithm described in [CLG97a] is used. In all other cases, simple powering of g is used. In that case it is more efficient to use this

function rather than factorizing the integer returned by `Order(g)`. If g has infinite order, an error ensues.

If the parameter `Proof` is `false`, then difficult integer factorizations are not attempted and the first return value F may contain composite numbers (so that the factorization expands to a multiple of the order of g); in any case the second return value indicates whether F is known to be the exact factored order of g.

`ProjectiveOrder(g)`

`Proof` BoolElt *Default :* `true`

The projective order n of the matrix g, and a scalar s such that $g^n = sI$. The projective order of g is the smallest n such that g^n is a scalar matrix (not just the identity matrix), and it always divides the true order of A. The parameter `Proof` is as for `Order`.

`FactoredProjectiveOrder(A)`

`Proof` BoolElt *Default :* `true`

Given a square invertible matrix A over a finite field K, return the projective order n of A in factored form and a scalar $s \in K$ such that $A^n = sI$. The parameter `Proof` is as for `FactoredOrder`.

`CentralOrder(g : parameters)`

`CentralOrder(g)`

`Proof` BoolElt *Default :* `true`

Return the smallest n such that g^n is central in its parent group. If g is a matrix and the optional parameter `Proof` is `false`, then accept a multiple of this value; the second value returned is `true` if the answer is exact.

`Determinant(g)`

The determinant of the matrix g.

`Trace(g)`

The trace of the matrix g.

`CharacteristicPolynomial(g: parameters)`

`Al` MonStgElt *Default :* "*Modular*"

`Proof` BoolElt *Default :* `true`

Given a matrix g belonging to a subgroup of $\mathrm{GL}(n, R)$, where R is a field or Euclidean Domain, return the characteristic polynomial of g as an element of the univariate polynomial ring over R. For details on the parameters, see the function `CharacteristicPolynomial` in the chapter on matrices.

`MinimalPolynomial(g)`

Given a matrix g belonging to a subgroup of $\mathrm{GL}(n, R)$, where R is a field or Z, return the minimal polynomial of g as an element of the univariate polynomial ring over R.

Example H59E8

We illustrate the matrix operations by applying them to some elements of $\mathrm{GL}(3, 4)$.

```
> K<w> := FiniteField(4);
> GL34 := GeneralLinearGroup(3, K);
> x := GL34 ! [w,0,1, 0,1,0, 1,0,1];
> x;
[w 0 1]
[0 1 0]
[1 0 1]
> Degree(x);
3
> Determinant(x);
w^2
> Trace(x);
w
> Order(x);
15
> m<t> := MinimalPolynomial(x);
> m;
t^3 + w*t^2 + w^2
> Factorization(m);
[
    <t + 1, 1>,
    <t^2 + w^2*t + w^2, 1>
]
> c<t> := CharacteristicPolynomial(x);
> c;
t^3 + w*t^2 + w^2
```

59.5 Global Properties

Unless otherwise noted, the functions in this section assume that a BSGS-representation for the group can be constructed.

59.5.1 Group Order

Unless the order is already known, each of the functions in this family will create a base and strong generating set for the group if one does not already exist.

`IsFinite(G)`

Given a matrix group G, return whether G is finite together with the order of G if G is finite. The function rigorously proves its result (i.e., the result is not probable). Let R be the ring over which G is defined, and let the degree of G be n. If R is finite, then the first return value is trivially `true`.

If R is the integer ring or rational field, then the function works as follows. The function successively generates random elements of G and tests whether each element has infinite order via the function `HasFiniteOrder`; if so, then the non-finiteness of G is proven. Otherwise, at regular intervals, the function attempts to construct a positive definite form fixed by G (see the function `PositiveDefiniteForm` in the chapter on matrix groups over $\mathbf{Q}$ and $\mathbf{Z}$), using a finite number of steps; if one is successively constructed, then the finiteness of G is proven. The number of steps attempted for the positive definite form constructed is increased as the algorithm progresses; if G is finite, such a form must exist and will be found when enough steps are tried, while if G is infinite, an element of infinite order is found very quickly in practice.

If R is an algebraic number field of degree d over $\mathbf{Q}$ (including cyclotomic and quadratic fields), then the standard companion matrix blowup is applied to the generators of G to obtain an isomorphic matrix group of (nd) over $\mathbf{Q}$, and the above algorithm is then applied to this matrix group.

`Order(G)`

`#G`

The order of the group G as an integer. If the order is not currently known, a base and strong generating set will be constructed for G. If G has infinite order, an error ensues.

`FactoredOrder(G)`

The order of the group G returned as a factored integer. The format is the same as for `FactoredIndex`. If the order of G is not known, it will be computed. If G has infinite order, an error ensues.

Example H59E9

```
> G := MatrixGroup<2,Integers()|[1,1,0,1],[0,1,-1,0]>;
> IsFinite(G);
false
> G24, e := ChangeRing(G, Integers(24));
> Order(G24);
9216
```

```
> G.-1*G.2;
[ 1  1]
[-1  0]
> (G.-1*G.2) @ e;
[ 1  1]
[23  0]
> (G24.2^2) @@ e;
[23  0]
[ 0 23]
```

59.5.2 Membership and Equality

`g in G`

Given a matrix g and a matrix group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given a matrix g and a matrix group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given a matrix group G and a set S of matrices belonging to a group H, where G and H belong to the same generic group, return `true` if S is a subset of G, `false` otherwise.

`H subset G`

Given matrix groups G and H belonging to the same generic group, return `true` if H is a subgroup of G, `false` otherwise.

`S notsubset G`

Given a matrix group G and a set S of matrices belonging to a group H, where G and H belong to the same generic group, return `true` if S is not a subset of G, `false` otherwise.

`H notsubset G`

Given matrix groups G and H belonging to the same generic group, return `true` if H is not a subgroup of G, `false` otherwise.

`H eq G`

Given matrix groups G and H belonging to the same generic group, return `true` if G and H are the same group, `false` otherwise.

`H ne G`

Given matrix groups G and H belonging to the same generic group, return `true` if G and H are distinct groups, `false` otherwise.

59.5.3 Set Operations

The creation of a base and strong generating set for a matrix group G provides us with a very compact representation of the set of elements of G. A particular BSGS imposes an order on the elements of G (lexicographic ordering of base images). It thus makes sense to talk about the 'number' of a group element relative to a particular BSGS.

`NumberingMap(G)`

A bijective mapping from the group G onto the set of integers $\{1 \dots |G|\}$. The actual mapping depends upon the base and strong generating set chosen for G.

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 20

Create a process to generate randomly chosen elements from the finite group G. The process is based on the product-replacement algorithm of [CLGM$^+$95], modified by the use of an accumulator. At all times, N elements are stored where N is the maximum of the specified value for `Slots` and `Ngens`$(G)+1$. Initially, these are just the generators of G. As well, one extra group element is stored, the accumulator. Initially, this is the identity. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses one of the elements in the slots and multiplies it into the accumulator. The element in that slot is replaced by the product of it and another randomly chosen slot. The random value returned is the new accumulator value. Setting `Scramble := m` causes m such operations to be performed before the process is returned.

`Random(G: parameters)`

`Short`	BoolElt	*Default :* `false`

A randomly chosen element for the group G. If a BSGS is known for G, then the element chosen will be genuinely random. If no BSGS is known, then the *random* element is chosen by multiplying out a *random* word in the generators. Since it is not usually practical to choose words long enough to properly sample the elements of G, the element returned will usually be biased. The boolean-valued parameter `Short` is used in this situation to indicate that a short word will suffice. Thus, if `Random` is invoked with `Short` assigned the value `true` then the element is constructed using a short word.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the finite group G, construct a random element of G by forming a random product over the expanded generating set constructed when the process was created. For large degree groups, or groups for which a BSGS is not known, this function should be used in preference to `Random(G)`.

Example H59E10

We use the random function to sample the orders of elements in the group $\mathrm{GL}(20, 16)$.

```
> G := GeneralLinearGroup(20, GF(16));
> RP := RandomProcess(G);
> [ FactoredOrder(Random(RP)) : i in [1..20] ];
[
    [ <3, 1>, <5, 1> ],
    [ <3, 2>, <5, 1>, <7, 1>, <11, 1>, <13, 1>, <17, 1>, <31, 1>, <41, 1>,
    <61681, 1> ],
    [ <3, 1>, <5, 1>, <17, 1>, <23, 1>, <89, 1>, <257, 1>, <397, 1>, <683, 1>,
    <2113, 1> ],
    [ <3, 1>, <5, 1> ],
    [ <3, 2>, <5, 1>, <7, 1>, <11, 1>, <13, 1>, <17, 1>, <31, 1>, <41, 1>,
    <61681, 1> ],
    [ <3, 1>, <31, 1>, <8191, 1> ],
    [ <3, 2>, <5, 1>, <7, 1>, <11, 1>, <13, 1>, <17, 1>, <31, 1>, <41, 1>,
    <61681, 1> ],
    [ <3, 3>, <5, 1>, <7, 1>, <13, 1>, <17, 1>, <19, 1>, <29, 1>, <37, 1>,
    <43, 1>, <73, 1>, <109, 1>, <113, 1>, <127, 1>, <257, 1> ],
    [ <5, 1> ],
    [ <3, 1>, <5, 1> ],
    [ <3, 1>, <5, 2>, <11, 1>, <17, 1>, <31, 1>, <41, 1>, <53, 1>, <157, 1>,
    <1613, 1>, <2731, 1>, <8191, 1> ],
    [ <3, 2>, <5, 1>, <7, 1>, <13, 1>, <17, 1>, <97, 1>, <241, 1>, <257, 1>,
    <673, 1> ],
    [ <3, 1>, <5, 1>, <17, 1>, <29, 1>, <43, 1>, <113, 1>, <127, 1>, <257, 1>,
    <65537, 1> ],
    [ <3, 1>, <5, 2>, <11, 1>, <29, 1>, <31, 1>, <41, 1>, <43, 1>, <113, 1>,
    <127, 1> ],
    [ <3, 1>, <5, 2>, <11, 1>, <17, 1>, <31, 1>, <41, 1>, <53, 1>, <157, 1>,
    <1613, 1>, <2731, 1>, <8191, 1> ],
    [ <3, 2>, <5, 2>, <11, 1>, <13, 1>, <17, 1>, <31, 1>, <41, 1>, <61, 1>,
    <151, 1>, <257, 1>, <331, 1>, <1321, 1> ],
    [ <3, 1>, <5, 1>, <11, 1>, <31, 1>, <41, 1>, <257, 1>, <61681, 1>,
    <4278255361, 1> ],
    [ <3, 2>, <5, 1>, <7, 1>, <11, 1>, <13, 1>, <17, 1>, <31, 1>, <41, 1>,
    <61681, 1> ],
    [ <3, 1>, <5, 1>, <17, 1>, <23, 1>, <89, 1>, <257, 1>, <397, 1>, <683, 1>,
    <2113, 1> ], [ <3, 2>, <5, 1>, <7, 1>, <11, 1>, <13, 1>, <23, 1>, <31, 1>,
    <41, 1>, <89, 1>, <397, 1>, <683, 1>, <2113, 1> ]
]
```

59.6 Abstract Group Predicates

`IsAbelian(G)`

Returns `true` if the group G is abelian, `false` otherwise.

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise.

`IsNilpotent(G)`

Returns `true` if the group G is nilpotent, `false` otherwise.

`IsSoluble(G)`
`IsSolvable(G)`

Returns `true` if the group G is soluble, `false` otherwise.

`IsPerfect(G)`

Returns `true` if the group G is perfect, `false` otherwise.

`IsSimple(G)`

Returns `true` if the group G is simple, `false` otherwise.

Example H59E11

We illustrate the functions of the last two section by applying them to a group of degree 6 over the field $\mathbf{F}_9$.

```
> F9<w> := GF(9);
> y := w^6;  z := w^2;
> J2A2 := MatrixGroup< 6, F9 | [y, 1-y, z,0,0,0, 1-y ,z, -1,0,0,0, z, -1,1+y,
>                               0,0,0,0,0,0, z, 1+y, y, 0,0,0,1+y, y, -1, 0,
>                               0,0, y ,-1,1-y],
>                              [1+y, z, y, 0,0,0, z, 1+y, z, 0,0,0, y, z, 1+y,

true
> IsSpecial(S2);
false
```

59.7 Conjugacy

`Class(H, x)`

`Conjugates(H, x)`

Given a group H and an element x belonging to a group K such that H and K are subgroups of the same general linear group, this function returns the set of conjugates of x under the action of H. If $H = K$, the function returns the conjugacy class of x in H.

`ClassMap(G)`

Given a group G, construct the conjugacy classes and the class map f for G. For any element x of G, $f(x)$ will be the conjugacy class representative chosen by the `Classes` function.

`ConjugacyClasses(G: parameters)`

`Classes(G: parameters)`

`WeakLimit`	RngIntElt	*Default :* 500
`StrongLimit`	RngIntElt	*Default :* 5000
`Al`	MonStgElt	*Default :*

Construct a set of representatives for the conjugacy classes of the matrix group G. The classes are returned as a sequence of triples containing the element order, the class length and a representative element for the class. The parameter `Al` enables the user to select the algorithm that is to be used.

`Al := "Action"`: Create the classes of G by computing the orbits of the set of elements of G under the action of conjugation. This option is only feasible for small groups.

`Al := "Random"`: Construct the conjugacy classes of elements for a matrix group G using an algorithm that searches for representatives of all conjugacy of G by examining a random selection of group elements and their powers. The behaviour of this algorithm is controlled by two associated optional parameters `WeakLimit` and `StrongLimit`, whose values are positive integers n_1 and n_2, say. Before describing the effect of these parameters, some definitions are needed: A mapping $f : G \to I$ is called a class invariant if $f(g) = f(g^h)$ for all $g, h \in G$. In matrix groups, the primary invariant factors are used where possible, or the characteristic or minimal polynomials otherwise. Two matrices g and h are said to be *weakly conjugate* with respect to the class invariant f if $f(g) = f(h)$. By definition, conjugacy implies weak conjugacy, but the converse is false. The random algorithm first examines n_1 random elements and their powers, using a test for weak conjugacy. It then proceeds to examine a further n_2 random elements and their powers, using a test for ordinary conjugacy. The idea behind this strategy is that the algorithm should attempt to find as many classes as possible using the very cheap test for weak conjugacy, before employing the more expensive ordinary conjugacy test to recognize the remaining classes.

`Al := "Extend"`: Construct the conjugacy classes of G by first computing classes in a quotient G/N and then extending these classes to successively larger quotients G/H until the classes for $G/1$ are known. More precisely, a series of subgroups $1 = G_0 < G_1 < \cdots < G_r = R < G$ is computed such that R is the (solvable) radical of G and G_{i+1}/G_i is elementary abelian. The radical quotient G/R is computed and its classes and centralizers of their representatives found using the permutation group algorithm, and pulled back to G. The parameters `TFAl` and `ASAl` control the algorithm used to compute the classes of G/R. See the GrpPerm chapter for more information on these parameters.

To extend from G/G_{i+1} to the next larger quotient G/G_i, an affine action of each centralizer on a quotient of the elementary abelian layer G_{i+1}/G_i is computed. Each distinct orbit in that action gives rise to a new class of the larger quotient (see Mecky and Neubuser [MN89]).

`Al := "Lifting"`: Construct a permutation representation for G, compute the classes of the representation, and lift them back to G through the kernel of the representation. Successful when the kernel is small. Currently uses the permutation action of G on its first basic orbit as the permutation representation.

`Al := "Classic"`: Construct the conjugacy classes by enumeration of class invariants. This algorithm is only available for classical groups. It has only been implemented for groups containing the special linear group and for the conformal unitary group.

Default: The classic algorithm will be used if G is recognised to contain the special linear group (using IsLinearGroup), or if G is known to be conformal unitary group in the standard representation (that is, if G was constructed by ConformalUnitaryGroup). The action algorithm will be used if $|G| \leq 2000$. If G is soluble then classes are computed in a PC-representation of G. When $|G| > 2000$ and the base ring of G is a finite field then the Extension algorithm is used. Otherwise the Lifting algorithm is used, unless the kernel size exceeds 10000. If there is a big kernel and the base ring of the group can be embedded in a field then the extension algorithm is used. Otherwise the random algorithm will be applied with the limits given by the parameters `WeakLimit` and `StrongLimit`. If that fails to compute all the classes and $|G| \leq 100000$, then the action algorithm will be used.

`ClassRepresentative(G, x)`

Given a group G for which the conjugacy classes are known and an element x of G, return the designated representative for the conjugacy class of G containing x.

`ClassCentraliser(G, i)`

The centraliser of the representative element stored for conjugacy class number i in group G. The group computed is stored with the class table for reference by future calls to this function.

`ClassInvariants(G, g)`

`ClassInvariants(G, i)`

The invariants for the conjugacy class of g in G or the conjugacy class number i in G. The type of invariants may vary depending on the group. This is only available for groups, for which the *classic* algorithm for computing conjugacy classes is available.

`ClassRepresentativeFromInvariants(G, p, h, t)`

Given a group G, for which the *classic* algorithm for computing conjugacy classes is available, and the class invariants p, h and t, return the standard class representative for the conjugacy class in G with the given invariants.

`IsConjugate(G, g, h)`

Given a group G and elements g and h belonging to G, return the value `true` if g and h are conjugate in G. The function returns a second value in the event that the elements are conjugate: an element k which conjugates g into h.

`IsConjugate(G, H, K)`

Given a group G and subgroups H and K belonging to G, return the value `true` if H and K are conjugate in G. The function returns a second value in the event that the subgroups are conjugate: an element z which conjugates H into K.

`IsGLConjugate(H, K)`

Given H and K, both subgroups of the same general linear group $G = GL_n(q)$, return the value `true` if H and K are conjugate in G. The function returns a second value in the event that the subgroups are conjugate: an element z which conjugates H into K. The algorithm is described in Roney-Dougal [RD04].

`Exponent(G)`

The exponent of the group G.

`NumberOfClasses(G)`

`Nclasses(G)`

The number of conjugacy classes of elements for the group G.

`PowerMap(G)`

Given a group G, construct the power map for G. Suppose that the order of G is m and that G has r conjugacy classes. When the classes are determined by MAGMA, they are numbered from 1 to r. Let C be the set of class indices $\{1, \ldots, r\}$ and let P be the set of integers $\{1, \ldots, m\}$. The *power map* f for G is the mapping,

$$f : C \times P \to C$$

where the value of $f(i, j)$ for $i \in C$ and $j \in P$ is the number of the class which contains x_i^j, where x_i is a representative of the i-th conjugacy class.

`AssertAttribute(G, "Classes", Q)`

Given a group G, and a sequence Q of k distinct elements of G, one from each conjugacy class, use Q to define the classes attribute of G. The sequence Q may be either a sequence of elements of G or, preferably, a sequence of pairs `<GrpMatElt, RngIntElt>` giving class representatives and their class length. In this latter case, no backtrack searches are performed.

Example H59E12

We take a group from the database of rational matrix groups and compute its conjugacy classes. The group has degree 12 and is written over the integers.

```
> DB := RationalMatrixGroupDatabase();
> G := Group(DB, 12, 3);
> FactoredOrder(G);
[ <2, 17>, <3, 8>, <5, 2> ]
> CompositionFactors(G);
    G
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  C(2, 3)               = S(4, 3)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  C(2, 3)               = S(4, 3)
    *
    |  Cyclic(2)
    1
```

The conjugacy classes of `G` are computed as follows:

```
> time cl := Classes(G);
Time: 18.580
> #cl;
1325
```

The group has 1325 conjugacy classes of elements.

59.8 Subgroups

59.8.1 Construction of Subgroups

`sub< G | L >`

Given the matrix group G, construct the subgroup H of G generated by the elements specified by the list L, where L is a list of one or more items of the following types:

(a) A sequence of n integers defining a matrix of G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic matrix group. The subgroup H will be constructed as a subgroup of some group which contains each of the elements and groups specified in the list.

The generators of H consist of the elements specified by the terms of the list L together with the stored generators for groups specified by terms of the list. Repetitions of an element and occurrences of the identity element are removed.

`ncl< G | L >`

Given the matrix group G, construct the subgroup H of G that is the *normal closure* of the subgroup H generated by the elements specified by the list L, where the possibilities for L are the same as for the `sub`-constructor.

Example H59E13

We define $O^-(4,2)$ as a subgroup of $\mathrm{GL}(4,2)$. Recall that $O^-(4,2)$ is isomorphic to S_5. We then locate a subset of its generators that lie within the subgroup isomorphic to A_5.

```
> GL42 := GeneralLinearGroup(4, GF(2));
> Ominus42 := sub< GL42 | [1,0,0,0, 1,1,0,1, 1,0,1,0, 0,0,0,1 ],
>                         [0,1,0,0, 1,0,0,0, 0,0,1,0, 0,0,0,1 ],
>                         [0,1,0,0, 1,0,0,0, 0,0,1,0, 0,0,1,1 ] >;
> Order(Ominus42);
120
> H := sub< Ominus42 | $.1, $.3 >;
print Order(H);
10
> N := ncl< Ominus42 | $.1, $.3 >;
> Order(N);
60
```

59.8.2 Elementary Properties of Subgroups

`Index(G, H)`

The index of the subgroup H in the group G. The index is returned as an integer. If the orders of G and H are not known, they will be computed.

`FactoredIndex(G, H)`

The index of the subgroup H in the group G. The index is returned as a factored integer. The factorization is returned in the form of a sequence Q which is defined as follows: If $[G : H] = p_1^{e_1} \dots p_n^{e_n}, \quad e_i \neq 0$, then Q will be the integer sequence $[< p_1, e_1 >, \dots, < p_n, e_n >]$. If the orders of G and H are not known, they will be computed.

`IsCentral(G, H)`

Returns `true` if the subgroup H of the group G lies in the centre of G, `false` otherwise.

`IsMaximal(G, H)`

Returns `true` if the subgroup H of the group G is a maximal subgroup of G. This function is evaluated by constructing the permutation representation of G on the cosets of H and testing this representation for primitivity. For this reason, the use of `IsMaximal` should be avoided if the index of H in G exceeds a few thousand.

`IsNormal(G, H)`

Returns `true` if the subgroup H of the group G is a normal subgroup of G, `false` otherwise.

`IsSubnormal(G, H)`

Returns `true` if the subgroup H of the group G is subnormal in G, `false` otherwise.

59.8.3 Standard Subgroups

`H ^ g`

`Conjugate(H, g)`

Construct the conjugate $g^{-1} * H * g$ of the matrix group H by the matrix g. The group H and the element g must belong to a common matrix group.

`H meet K`

Given groups H and K which belong to the same matrix group, construct the intersection of H and K.

`CommutatorSubgroup(G, H, K)`

`CommutatorSubgroup(H, K)`

Given subgroups H and K of the group G, construct the commutator subgroup of H and K as a subgroup of G. If K is a subgroup of H, then G may be omitted.

`Centralizer(G, g)`

Construct the centralizer of the matrix g in the group G; g and G must belong to a common matrix group.

`Centralizer(G, H)`

Construct the centralizer of the group H in the group G; G and H must belong to a common matrix group.

`Core(G, H)`

Given a subgroup H of the matrix group G, construct the maximal normal subgroup of G that is contained in the subgroup H.

`H ^ G`

`NormalClosure(G, H)`

Given a subgroup H of the matrix group G, construct the normal closure of H in G.

`Normalizer(G, H)`

Given a subgroup H of the group G, construct the normalizer of H in G.

`SylowSubgroup(G, p)`

`Sylow(G, p)`

Given a group G and a prime p, construct the Sylow p-subgroup of G.

`pCore(G, p)`

Given a group G and a prime p dividing the order of G, construct the maximal normal p-subgroup of G.

59.8.4 Low Index Subgroups

`LowIndexSubgroups(G, R : parameters)`

`LowIndexSubgroups(G, R: parameters)`

Given a matrix group G, and an expression R defining a positive integer range (see below), determine the conjugacy classes of subgroups of G whose indices lie in the range specified by R. The subgroups are returned as a sequence of subgroups of G. The argument R is one of the following:

(a) An integer n representing the range $[1, n]$;

(b) A tuple $< a, b >$ representing the range $[a, b]$.

The subgroups are constructed using an algorithm due to Leedham-Green & O'Brien [LGO02]. In practice, the algorithm is most useful for small values of n, say up to 8.

The algorithm proceeds by iteratively constructing better approximations to finite presentations for G/K, where K is the intersection of kernels of all homomorphisms from G into S_n, and applying `LowIndexSubgroups` to the resulting finitely-presented group. The output information displayed for various values of the `Print` parameter about the number and existence of putative subgroups of index at most n refers to the current finite presentation only, may change as this presentation is further refined, and need not be reflected in the final answer.

`Limit` RngIntElt *Default :* ∞

Terminate after finding n conjugacy classes of subgroups satisfying the designated conditions.

`Print` RngIntElt *Default :* 0

The `Print` parameter takes values from 0 to 3. The information displayed

Example H59E14

```
> G := GL (4, 5);
> L := LowIndexSubgroups (G, 4);
> #L;
3
> L[3];
MatrixGroup(4, GF(5))
Generators:
    [4 0 0 4]
    [1 0 0 0]
    [0 4 0 0]
    [0 0 4 0]

    [4 0 0 3]
    [3 0 0 0]
    [0 4 0 0]
```

```
[0 0 4 0]

[4 0 0 1]
[4 0 0 0]
[0 4 0 0]
[0 0 4 0]

[4 0 0 2]
[2 0 0 0]
[0 4 0 0]
[0 0 4 0]
```

59.8.5 Conjugacy Classes of Subgroups

`SubgroupClasses(G: parameters)`

`Subgroups(G: parameters)`

Representatives for the conjugacy classes of subgroups for the group G. The subgroups are returned as a sequence of records where the i-th record contains:

(a) A representative subgroup H for the i-th conjugacy class (field name `subgroup`).

(b) The order of the subgroup (field name `order`).

(c) The number of subgroups in the class (field name `length`).

(d) [Optional] A presentation for H (field name `presentation`).

`Al` MonStgElt *Default :* "*All*"

`Al := "All"`: Construct all subgroups of G.
`Al := "Maximal"`: Only construct maximal subgroups of G. This option reduces the number of intersections with any elementary abelian layer that need be considered and eliminates the need to recursively apply the algorithm.
`Al := "Normal"`: Only construct normal subgroups of G. This option does not use database lookup to find the normal subgroups of the radical quotient of G and also reduces the number of intersections with any layer that need be considered.

`LayerSizes` SeqEnum *Default :* See below

`LayerSizes := [ 2, 5, 3, 4, 7, 3, 11, 2, 17, 1]` is equivalent to the default. When constructing an Elementary Abelian series for the group, attempt to split 2-layers of size gt 2^5, 3-layers of size gt 3^4, etc. The implied exponent for 13 is 2 and for all primes greater than 17 the exponent is 1.

`Series` SeqEnum *Default :* See below

Use the given elementary abelian series rather than constructing the default series. The first subgroup in the series must be the solvable radical of G. The subgroups must form a descending chain of normal subgroups of G, such that each quotient

is elementary abelian. The last subgroup in the series must be either elementary abelian or trivial.

`Presentation` BoolElt *Default :* `false`

`Presentation := true`: Construct a presentation for each subgroup.

`OrderEqual` RngIntElt *Default :*

`OrderEqual := n`: Only construct subgroups having order equal to n.

`OrderDividing` RngIntElt *Default :*

`OrderDividing := n`: Only construct subgroups having order dividing n.

`OrderMultipleOf` RngIntElt *Default :*

`OrderMultipleOf := n`: Only construct subgroups having order a multiple of n.

`IndexLimit` RngIntElt *Default :*

`IndexLimit := n`: Only construct subgroups having index in G less than or equal to n.

`IsElementaryAbelian` BoolElt *Default :* `false`

`IsElementaryAbelian := true`: Only construct elementary abelian subgroups of G.

`IsCyclic` BoolElt *Default :* `false`

`IsCyclic := true`: Only construct cyclic subgroups of G.

`IsAbelian` BoolElt *Default :* `false`

`IsAbelian := true`: Only construct abelian subgroups of G.

`IsNilpotent` BoolElt *Default :* `false`

`IsNilpotent := true`: Only construct nilpotent subgroups of G.

`IsSolvable` BoolElt *Default :* `false`

`IsSolvable := true`: Only construct solvable subgroups of G.

`IsNotSolvable` BoolElt *Default :* `false`

`IsNotSolvable := true`: Only construct insolvable subgroups of G.

`IsPerfect` BoolElt *Default :* `false`

`IsPerfect := true`: Only construct perfect subgroups of G.

The Algorithm: (See Cannon, Cox and Holt [CCH01]) This command proceeds by first constructing an elementary abelian series for G together with G's radical quotient Q as a permutation group. (Thus this function is limited to matrix groups over fields, where the group has a BSGS.) The required subgroups of Q are then found as for permutation groups. We first attempt to locate the quotient in a database of groups with trivial Fitting subgroup. This database contains all such groups of order up to 216 000, and all such which are perfect of order up to 1 000 000. If Q is found then either all its subgroups, or its maximal subgroups are read from the database. (In some cases only the maximal subgroups are stored.) If Q is

not found then we attempt to find the maximal subgroups of Q using a method of Derek Holt. For this to succeed all simple factors of the socle of Q must be found in a second database which currently contains all simple groups of order less than 1.6×10^7, as well as M_{24}, HS, J_3, McL, $Sz(32)$ and $L_6(2)$. There are also special routines to handle numerous other groups. These include: A_n for $n \leq 999$, $L_2(q)$, $L_3(q)$, $L_4(q)$ and $L_5(q)$ for all q, $U_3(q)$ for q prime and $q = 8, 9, 16, 25$, $U_4(q)$ for $q = 4, 5, 7$, $S_4(q)$ for all odd q and even $q \leq 16$, $L_d(2)$ for $d \leq 14$, and the following groups: $L_6(3)$, $L_7(3)$, $U_6(2)$, $S_8(2)$, $S_{10}(2)$, $O_8^{\pm}(2)$, $O_{10}^{\pm}(2)$, $S_6(3)$, $O_7(3)$, $O_8^-(3)$, $G_2(4)$, $G_2(5)$, ${}^3D_4(2)$, ${}^2F_4(2)'$, Co_2, Co_3, He, Fi_{22}.

If we have only maximal subgroups of Q, and more are required, we apply the algorithm recursively to the maximal subgroups to determine all subgroups of Q. This may take some time.

The subgroups of Q are then pulled back to G and extended to the whole group by stepwise extension through each layer of the elementary abelian series. For each layer this involves determining all possible intersections of a subgroup with this layer and all extensions with this intersection.

The limitations are that the simple factors of the socle of Q must be in the list above. Further, it may take some time to construct all subgroups from the maximal subgroups first found, and, if there is a large elementary abelian layer, there will be many possible intersections, which could also make the algorithm prohibitively slow.

There are numerous parameters for this function which allow the user to place restrictions on which subgroup classes are constructed. Using these restrictions may help overcome the problems noted above.

`MaximalSubgroups(G:` *parameters*`)`

Construct the sequence of maximal subgroup classes of the matrix group G. This is equivalent to the command `Subgroups(G: Al := "Maximal")`. The same parameters as for `Subgroups` are available to limit the search.

`SubgroupsLift(G, A, B, Q:` *parameters*`)`

This function isolates one step of the extension process used by the `Subgroups` family of functions. Q is a sequence of records such as returned by `Subgroups(G)`. A and B are normal subgroups of G with A/B elementary abelian. The records in Q are interpreted as subgroups of G/A, which are lifted to all possible corresponding subgroups of G/B, subject to the parameters given.

59.9 Quotient Groups

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

59.9.1 Construction of Quotient Groups

`quo< G | L >`

Given the matrix group G, construct the quotient group $Q = G/N$, where N is the normal closure of the subgroup of G generated by the elements specified by L. The clause L is a list of one or more items of the following types:

(a) A sequence of n integers defining a matrix of G;

(b) A set or sequence of sequences of type (a);

(c) An element of G;

(d) A set or sequence of elements of G;

(e) A subgroup of G;

(f) A set or sequence of subgroups of G.

Each element or group specified by the list must belong to the *same* generic matrix group. The function returns

(a) the quotient group Q, and

(b) the natural homomorphism $f : G \to Q$.

Currently in MAGMA, the quotient group is constructed via the regular representation of the quotient, so that the application of this operator is restricted to the case where the index of N in G is small. The representation of the quotient that is returned is the result of applying degree reduction to the regular representation, so need not be regular.

The generators of the quotient group correspond to the generators of G.

`G / N`

Given a normal subgroup N of the matrix group G, construct the quotient of G by N. Currently in MAGMA, the quotient group is constructed via the regular representation of the quotient, so the application of this operator is restricted to the case where the index of N in G is small. The representation of the quotient that is returned is the result of applying degree reduction to the regular representation, so need not be regular.

Example H59E15

We determine the structure of a quotient in a soluble subgroup of $\mathrm{GL}(3, 5)$.

```
> G := MatrixGroup< 3, GF(5) | [0,1,0, 1,0,0, 0,0,1], [0,1,0, 0,0,1, 1,0,0 ],
>                                    [2,0,0, 0,1,0, 0,0,1] >;
> Order(G);
384
> Q, f := quo< G | G.2 >;
> Q;
Permutation group Q of degree 8
    (1, 2)(3, 4)(5, 6)(7, 8)
```

```
    Id(Q)
    (1, 3, 5, 7)(2, 4, 6, 8)
> IsAbelian(Q);
true
> AbelianInvariants(Q);
[ 4, 2 ]
```

59.9.2 Abelian, Nilpotent and Soluble Quotients

A number of standard quotients may be constructed. The method first constructs a presentation for the matrix group and then applies the appropriate fp-group algorithm.

`AbelianQuotient(G)`

The maximal abelian quotient G/G' of the group G as `GrpAb` (cf. chapter 69). The natural epimorphism $\pi : G \to G/G'$ is returned as second value.

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient Q of the group G as `GrpAb` (cf. chapter 69). The natural epimorphism $\pi : G \to Q$ is returned as second value.

`pQuotient(G, p, c)`

Given a matrix group G, a prime p and a positive integer c, construct a pc-presentation for the largest p-quotient P of G having lower exponent-p class at most c. If c is given as 0, then the limit 127 is placed on the class.

The function also returns the natural homomorphism π from G to P, a sequence S describing the definitions of the pc-generators of P and a flag indicating whether P is the maximal p-quotient of G.

The k-th element of S is a sequence of two integers, describing the definition of the k-th pc-generator $P.k$ of P as follows.

- If $S[k] = [0, r]$, then $P.k$ is defined via the image of $G.r$ under π.
- If $S[k] = [r, 0]$, then $P.k$ is defined via the power relation for $P.r$.
- If $S[k] = [r, s]$, then $P.k$ is defined via the conjugate relation involving $P.r^{P.s}$.

`NilpotentQuotient(G, c)`

This function returns the class c nilpotent quotient of the matrix group G, together with the epimorphism π from G onto this quotient.

`SolvableQuotient(G)`

`SolubleQuotient(G)`

The function returns the largest soluble quotient S of the matrix group G together with the epimorphism $\pi : G \to S$.

PCGroup(G)

For a solvable group G, the function returns an isomorphic group of type GrpPC together with an isomorphism from G to the new group. If G is not solvable, then the call to PCGroup will result in an error.

Example H59E16

We take a degree 10 matrix group over the integers and compute its maximal abelian and soluble quotients. The epimorphisms supplied by these two functions may be used to pass between the group and its quotients.

```
> DB := RationalMatrixGroupDatabase();
> G := Group(DB, 10, 2);
> G : Minimal;
MatrixGroup(10, Integer Ring) of order 4147200
> A := AbelianQuotient(G); A;
Abelian Group isomorphic to Z/2 + Z/2 + Z/2
Defined on 3 generators
Relations:
  2*A.1 = 0
  2*A.2 = 0
  2*A.3 = 0
> S, f := SolubleQuotient(G); S;
GrpPC : S of order 32 = 2^5
PC-Relations:
  S.2^2 = S.4,
  S.2^S.1 = S.2 * S.4,
  S.3^S.2 = S.3 * S.4 * S.5
> G.1 @ f;
S.1 * S.4 * S.5
> S.5 @@ f in DerivedGroup(G);
true
```

59.10 Matrix Group Actions

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

59.10.1 Orbits and Stabilizers

Let G be a matrix group and let M be its natural module. Now G has an action on the elements and submodules of M. A derived G-set for G consists of the closure under the natural action of G of one of the following:

- A set of vectors of M;
- A set of k element subsets of vectors of M;
- A set of k element sequences of vectors of M;
- A set of submodules of M, each of which has fixed dimension k;
- A cartesian product of G-sets.

`u * g`

Given an element g belonging to the matrix group G with natural module M and an element u of this module, return the vector $u * g$.

`y ^ g`

Given an element g belonging to the matrix group G with natural module M and an object y which is an element of some derived G-set of M, find the image of y under g.

`y ^ G`

`Orbit(G, y)`

Given a matrix group G with natural module M and an object y which is either a vector of M, a submodule of M, or a tuple whose components are either vectors or submodules, find the orbit of y under G.

`OrbitBounded(G, y, b)`

Given a matrix group G with natural module M and an object y which is either a vector of M, a submodule of M, or a tuple whose components are either vectors or submodules, return `true` if the orbit of y under G has length less than or equal to b. Otherwise the function returns `false`. If it returns `true`, then the orbit of y is returned as the second value.

`Orbits(G)`

Given a matrix group G with natural R-module M, construct the orbits of G on the vectors of M. The orbits are returned as a sequence of sets.

`LineOrbits(G)`

Given a matrix group G with natural R-module M, construct the orbits of G on the rank-1 submodules of M. The orbits are returned as a sequence of sets.

`OrbitClosure(G, S)`

Given a matrix group G with natural module M and a set S of vectors or subspaces of M, return the union of orbits of the elements of S under the natural action of G on M.

`Stabilizer(G, y)`

Given a matrix group G with natural module M and an object y which is either a vector of M, a submodule of M, or a tuple whose components are either vectors or submodules, determine the stabilizer of y in G.

Example H59E17

We continue with the group $J2A2$ introduced above.

```
> V := RSpace(G);
> u := V![1,0,0,0,0,0];
> U := sub< V | u >;
> x := < u, U >;
> W := sub< V | u, u*G.1 >;
> u^G.1;
(w^6 w^3 w^2   0   0   0)

> #Orbit(H, x);
252
> #Orbit(H, W);
28
```

59.10.2 Orbit and Stabilizer Functions for Large Groups

In this section we describe a number of constructions for orbits and stabilizers which in certain circumstances may be applicable to much larger groups than the functions described above.

`OrbitsOfSpaces(G, k)`

Determine representatives and lengths for the orbits of all k-dimensional subspaces of the natural vector space under action of a matrix group defined over a prime field; return a sequence of tuples each containing an orbit length and representative. This function is very space-efficient and hence has a significantly larger range than the general-purpose `Orbits`; however, only representatives and lengths are stored. Theoretical details of the algorithm used may be found in O'Brien [O'B90].

`NumberOfFixedSpaces(x, s)`

`NumberOfFixedSpaces(x, s)`

Return number of subspaces of dimension s fixed by matrix x.

Example H59E18

```
> G := GL (4, 5);
> H := ExteriorSquare (G);
> H;
MatrixGroup(6, GF(5))
Generators:
    [2 0 0 0 0 0]
    [0 2 0 0 0 0]
    [0 0 1 0 0 0]
    [0 0 0 2 0 0]
    [0 0 0 0 1 0]
    [0 0 0 0 0 1]

    [0 0 0 1 0 0]
    [1 0 0 0 1 0]
    [1 0 0 0 0 0]
    [0 1 0 0 0 1]
    [0 1 0 0 0 0]
    [0 0 1 0 0 0]
> O := OrbitsOfSpaces (H, 2);
```

We see that there are four orbits:

```
> O;
[
    <
        4836,
        Vector space of degree 6, dimension 2 over GF(5)
        Generators:
        (1 0 0 0 0 0)
        (0 1 0 0 0 0)
        Echelonized basis:
        (1 0 0 0 0 0)
        (0 1 0 0 0 0)
    >,
    <
        96720,
        Vector space of degree 6, dimension 2 over GF(5)
        Generators:
        (1 0 1 1 0 0)
        (0 1 0 0 0 0)
        Echelonized basis:
        (1 0 1 1 0 0)
        (0 1 0 0 0 0)
    >,
    <
        251875,
        Vector space of degree 6, dimension 2 over GF(5)
```

```
        Generators:
        (1 0 0 0 1 0)
        (0 1 0 0 0 0)
        Echelonized basis:
        (1 0 0 0 1 0)
        (0 1 0 0 0 0)
    >,
    <
        155000,
        Vector space of degree 6, dimension 2 over GF(5)
        Generators:
        (1 0 1 1 1 0)
        (0 1 1 1 0 0)
        Echelonized basis:
        (1 0 1 1 1 0)
        (0 1 1 1 0 0)
    >
]
```

We compute the number of spaces of dimension 2 fixed by $H.1$ and the number of spaces of dimension 3 fixed by $H.2$.

```
> NumberOfFixedSpaces(H.1, 2);
1023
> NumberOfFixedSpaces(H.2, 3);
2
```

`EstimateOrbit(G, v: parameters)`

`EstimateOrbit(G, U: parameters)`

`MaxSize`	RngIntElt	*Default :* 10000
`NumberCoincidences`	RngIntElt	*Default :* 15

Estimate the size of the orbit of the vector v or subspace U of natural vector space under the action of matrix group G by constructing at most `MaxSize` random elements of the orbit and counting at most `NumberCoincidences` coincidences. The function returns a lower bound, upper bound, and estimate of size; if insufficient coincidences are found to estimate the orbit size, the function returns 0. Theoretical details of the algorithm used may be found in Eick, Leedham-Green and O'Brien [ELGO02].

`ApproximateStabiliser(G, A, U: parameters)`

`ImageGenerators`	SeqEnum	*Default :* []
`MaxSize`	RngIntElt	*Default :* 10000
`NumberCoincidences`	RngIntElt	*Default :* 15
`OrderCheck`	BoolElt	*Default :* `false`

A is image of representation of G and A acts on U, a subspace or vector. Approximate the stabiliser of U under A. We assume either a $1-1$ correspondence between generators of G and those of A, or between generators of G and those elements of A supplied as `ImageGenerators`. Elements of G whose images in A fix U are obtained by constructing at most `MaxSize` elements of the orbit of U under A or until we find `Numbercoincidences` repetitions in this orbit; if `OrderCheck` is `true`, report the order of the subgroup S of A which is found. Return preimage of S in G and S, together with a lower bound, upper bound, and estimate of the size of orbit of U. If insufficient coincidences are found to estimate the orbit size, the function returns these last values as 0.

Example H59E19

```
> G := GL (4, 5);
> A := ExteriorSquare (G);
> V := VectorSpace (GF (5), 6);
> U := sub < V | [Random (V): i in [1..2]]>;
> U;
Vector space of degree 6, dimension 2 over GF(5)
Generators:
(4 3 2 1 0 2)
(3 2 2 4 4 1)
Echelonized basis:
(1 0 2 0 2 4)
(0 1 3 2 4 2)
> EstimateOrbit (A, U);
209316 594421 324272
> H, B, lb, ub, estimate := ApproximateStabiliser (G, A, U);
> #H, #B;
460800 230400
```

`StabiliserOfSpaces(Q)`

Determine the subgroup of $GL(d, F)$, for F a finite field, which stabilises the sequence Q of subspaces of the natural vector space. The function also returns generators for the largest unipotent subgroup of the stabiliser. For a description of this algorithm, see Schwingel [Sch00]; this implementation was prepared by Eamonn O'Brien.

Example H59E20

```
> V := VectorSpace(GF (3), 4);
> Spaces := [sub< V | [1,1,0,2]>, sub < V | [ 1, 0, 2, 0 ], [ 0, 1, 0, 0]>];
> S, P := StabiliserOfSpaces(Spaces);
> #S;
5184
> P;
[
    [1 1 0 0]
    [0 1 0 0]
    [0 1 1 0]
    [0 1 0 1],

    [2 0 2 0]
    [0 1 0 0]
    [1 0 0 0]
    [1 0 2 1],

    [1 0 1 2]
    [0 1 0 0]
    [0 0 2 2]
    [0 0 1 0]
]
```

Thus, the unipotent subgroup generated by P has order 3^3.

`IsUnipotent(G)`

If G is a p-subgroup of $GL(d, F)$, where F is a finite field of characteristic p, then return `true`, else return `false`.

`UnipotentStabiliser(G, U:` *parameters*`)`

Given a unipotent subgroup G of $GL(d, F)$, for F a finite field, U a subspace of the natural vector space, determine the stabiliser in G of U. The function returns the stabiliser in G of U, the *canonical* element C of the orbit of U under G, an element x of G such that $U^x = C$, and an SLP for x as an element of `WordGroup`(G). This function does *not* compute the orbit of U under G, but instead constructs the canonical element of the orbit. Hence it can be used to decide whether or not two subspaces belong to the same orbit. For a description of this algorithm, see [Sch00]; this implementation was prepared by Elliot Costi.

Example H59E21

```
> V := VectorSpace(GF (3), 4);
> G := sub< GL (4, 3) |
>     [ 1, 1, 0, 0, 0, 1, 0, 0, 0, 1, 1, 0, 0, 1, 0, 1 ],
>     [ 2, 0, 2, 0, 0, 1, 0, 0, 1, 0, 0, 0, 1, 0, 2, 1 ],
>     [ 1, 0, 1, 2, 0, 1, 0, 0, 0, 0, 2, 2, 0, 0, 1, 0 ] >;
> U := sub < V | [ 1, 2, 0, 1 ],[ 2, 2, 1, 0 ]>;
> S, C, x, w := UnipotentStabiliser(G, U);
> S;
MatrixGroup(4, GF(3))
Generators:
    [2 1 2 0]
    [0 1 0 0]
    [1 1 0 0]
    [1 1 2 1]
> #S;
3
> Index(G, S);
9
```

So the stabiliser of U has order 3 and U lies in an orbit of size 9. We print the canonical element of the orbit of U under G. The element x maps U to C and w evaluates to x.

```
> C;
Vector space of degree 4, dimension 2 over GF(3)
Echelonized basis:
(1 0 0 0)
(0 1 2 0)
>  U^x;
Vector space of degree 4, dimension 2 over GF(3)
Echelonized basis:
(1 0 0 0)
(0 1 2 0)
> W, phi := WordGroup (G);
>  phi (w);
[1 0 2 1]
[0 1 0 0]
[0 0 0 1]
[0 0 2 2]
```

59.10.3 Action on Orbits

`OrbitAction(G, T)`

Given a matrix group G with natural module M, and a set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T and construct the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the set Y. The function returns:

(a) The natural homomorphism $\phi : G \to L$;

(b) The induced group L;

(c) The kernel of the action (a subgroup of G).

`OrbitActionBounded(G, T, b)`

Given a matrix group G with natural module M, and a set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T. If the cardinality of Y does not exceed b, then construct the homomorphism $\phi : G \to L$, where the permutation group L gives the action of G on the set Y. In this case the function returns:

(a) The boolean value `true`.

(b) The natural homomorphism $\phi : G \to L$;

(c) The induced group L;

(d) The kernel of the action (a subgroup of G). If the cardinality of Y exceeds b, simply return `false`. (The action of G on Y is not constructed in this case).

`OrbitImage(G, T)`

Given a matrix group G with natural module M, and a set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T and return the permutation group L giving the action of G on Y.

`OrbitImageBounded(G, T, b)`

Given a matrix group G with natural module M, and set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T. If the cardinality of Y does not exceed b, return `true` together with the permutation group L giving the action of G on Y. If the cardinality of Y does exceed b, the action is not constructed and the single value `false` is returned.

`OrbitKernel(G, T)`

Given a matrix group G with natural module M, and a set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T and return the the kernel of the action of G on Y.

`OrbitKernelBounded(G, T, b)`

Given a matrix group G with natural module M, and set T consisting of either (a) elements of M, (b) submodules of M or (c) tuples, form the G-closure Y of T. If the cardinality of Y does not exceed b, return the boolean value `true` together with the kernel of the action of G on Y. If the cardinality of Y does exceed b, the kernel is not constructed and the single value `false` is returned.

Example H59E22

We look for a small G-set for the group $J2A2$ (defined above) by examining eigenspaces of its generators. Having found a reasonably sized set, we then construct a permutation representation for G on this set.

```
> [ Factorization(CharacteristicPolynomial(G.i)) : i in [1..3] ];
[
    [
          <x^3 + w^5*x^2 + w^3*x + 2, 1>,
          <x^3 + w^7*x^2 + w*x + 2, 1>
    ],
    [
          <x + 2, 6>
    ],
    [
         <x + w^2, 3>,
         <x + w^6, 3>
    ]
]
> y := Eigenspace(G.2, -2);
> y;
Vector space of degree 6, dimension 3 over GF(3, 2)
Echelonized basis:
(1 0 0 1 2 1)
(0 1 0 2 1 2)
(0 0 1 1 2 1)
> #Orbit(G, y);
280
> P := OrbitImage(G, y);
> P;
Permutation group P of degree 280
> Order(P);
604800
> CompositionFactors(P);
    G
    |  J2
    1
```

Thus, our group has the simple group J_2 of Janko as a composition factor.

```
> Order(G);
```

```
1209600
```

Hence the kernel of this action has order 2.

59.10.4 Action on a Coset Space

`CosetAction(G, H)`

Given a subgroup H of the group G, construct the permutation representation of G given by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The natural homomorphism $f : G \to L$;

(b) The induced permutation group L;

(c) The kernel K of the action (a subgroup of G).

`CosetImage(G, H)`

Given a subgroup H of the group G, construct the image L of G given by the action of G on the set of (right) cosets of H in G. L is returned as a permutation group.

`CosetKernel(G, H)`

Given a subgroup H of the group G, construct the kernel of the action of G on the set of (right) cosets of H in G.

Example H59E23

We construct $G = \mathrm{SL}(3, 3)$, a subgroup H of G, and the permutation representation of G given by its action on the cosets of H.

```
> G := MatrixGroup< 3, GF(3) | [0,2,0, 1,1,0, 0,0,1], [0,1,0, 0,0,1, 1,0,0] >;
> Order(G);
5616
> H := sub< G | G.1^2, G.2 >;
> Order(H);
216
> P := CosetImage(G, H);
> P;
Permutation group P of degree 26
    (1, 2)(3, 4, 6, 5, 7, 9)(8, 11)(10, 13, 15, 20, 18, 17)
      (12, 16, 21, 14, 19, 24)(23, 26)
    (2, 3, 5)(4, 6, 8)(7, 10, 14)(9, 12, 17)(11, 15, 20)(13, 18, 23)
      (16, 22, 21)(19, 25, 24)
```

59.10.5 Action on the Natural G-Module

A set of functions is provided for working with the action of G on the natural G-module M, for a matrix group G defined over a finite field. Many of these functions are similar to those presented in the general module chapter.

`GModule(G)`

The natural $R[G]$-module M for the matrix group G.

`IsIrreducible(G)`

Given a matrix group G, return `true` iff G acts irreducibly on its natural module M. If G acts reducibly on M, a proper submodule S of M is also returned.

`SubmoduleAction(G, S)`

Given a matrix group G and a submodule S of the natural module M of G, return the action homomorphism f of G on S, together with the image of f.

`SubmoduleImage(G, S)`

Given a matrix group G and a submodule S of the natural module M of G, return the image of the action homomorphism of G on S.

`QuotientModuleAction(G, S)`

Given a matrix group G and a submodule S of the natural module M of G, return the quotient action homomorphism f of G on S, together with the image of f.

`QuotientModuleImage(G, S)`

Given a matrix group G and a submodule S of the natural module M of G, return the quotient image of the action homomorphism of G on S.

`IsAbsolutelyIrreducible(G)`

Given a matrix group G, return `true` if and only if G acts absolutely irreducibly on its natural module M. In addition, if G is absolutely irreducible, the function returns the (matrix algebra) generator of the endomorphism algebra E of M (which is always a field), and the dimension of E.

`AbsoluteRepresentation(G)`

Given an irreducible matrix group G, return the isomorphic reduced-degree absolute representation A of G, which is over the absolute field of the natural module M of G and is absolutely irreducible, together with the corresponding isomorphism.

`MinimalField(G)`

Given a matrix group G defined over a finite field K, return the minimal subfield of K over which G can be realised.

59.11 Normal and Subnormal Subgroups

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

59.11.1 Characteristic Subgroups and Subgroup Series

`Centre(G)`
`Center(G)`

Construct the centre of the group G.

`DerivedLength(G)`

The derived length of the matrix group G. If G is non-soluble, the function returns the number of terms in the series terminating with the soluble residual.

`DerivedSeries(G)`

The derived series of the group G. The series is returned as a sequence of subgroups.

`CommutatorSubgroup(G)`
`DerivedSubgroup(G)`
`DerivedGroup(G)`

The derived subgroup of the group G.

`#FittingSubgroup(G)`

The Fitting subgroup of the group G.

`LowerCentralSeries(G)`

The lower central series of the matrix group G. The series is returned as a sequence of subgroups.

`NilpotencyClass(G)`

The nilpotency class of the group G.

`H ^ G`
`NormalClosure(G, H)`

The normal closure of the subgroup H of group G.

`SolubleResidual(G)`
`SolvableResidual(G)`

The solvable residual of the group G.

`SubnormalSeries(G, H)`

Given a group G and a subnormal subgroup H of G, return a sequence of subgroups commencing with G and terminating with H, such that each subgroup is normal in the previous one. If H is not subnormal in G, the empty sequence is returned.

`UpperCentralSeries(G)`

The upper central series of the matrix group G. The series is returned as a sequence of subgroups. As the algorithm used requires the conjugacy classes of G, this function is much more restricted in its range of application than `DerivedSeries` and `LowerCentralSeries`.

Example H59E24

We demonstrate some of the series functions by applying them to a soluble subgroup of $\mathrm{GL}(3,5)$.

```
> G := MatrixGroup< 3, GF(5) | [0,1,0, 1,0,0, 0,0,1],
>                              [0,1,0, 0,0,1, 1,0,0],
>                              [2,0,0, 0,1,0, 0,0,1] >;
> Order(G);
384
> DerivedGroup(G);
MatrixGroup(3, GF(5, 1))
Generators:
[0 0 1]
[1 0 0]
[0 1 0]

[2 0 0]
[0 3 0]
[0 0 1]
> D := DerivedSeries(G);
> [ Order(d) : d in D ];
[ 384, 48, 16, 1 ]
> L := LowerCentralSeries(G);
> [ Order(l) : l in L ];
[ 384, 48 ]
> K := sub< G | [ 2,0,0, 0,3,0, 0,0,2 ] >;
> S := SubnormalSeries(G, K);
> [ Order(s) : s in S ];
[ 384, 16, 4 ]
```

59.11.2 The Soluble Radical and its Quotient

The functions in this section enable the user to construct the radical, its quotient and an elementary abelian series. They are currently restricted to matrix groups where a base and strong generating set can be constructed and the base ring is either a field or can be embedded into a field.

`Radical(G)`
`SolubleRadical(G)`
`SolvableRadical(G)`

Given a group G, return the maximal normal solvable subgroup of G. The algorithm is to compute the radical quotient map, and then compute its kernel. The algorithm used is described in Unger [Ung06b].

`RadicalQuotient(G)`

Given a group G, compute a permutation representation of the quotient G/R where R is the (solvable) radical of G. Both the permutation group Q isomorphic to G/R and a homomorphism $\phi : G \to Q$ are returned. The third return value is R, the radical of G and the kernel of the homomorphism. The algorithm used is described in Unger [Ung06b].

`ElementaryAbelianSeries(G: parameters)`

`LayerSizes` SeqEnum[RngIntElt] *Default :* []

An elementary abelian series is a chain of normal subgroups $R = N_1 > N_2 > ... > N_r = 1$ with the property that the quotient of each pair of successive terms in the series is elementary abelian and that there is no group $R < H < G$ such that H/R is elementary abelian and H normal in G. The top of the series R is called the solvable radical and is the maximal normal solvable subgroup of G.

The parameter `LayerSizes` controls possible refinement of the series. As an example, take `LayerSizes := [ 2, 5, 3, 4, 7, 3, 11, 2, 17, 1]`. When constructing an elementary abelian series for the group, attempt to split 2-layers of size gt 2^5, 3-layers of size gt 3^4, etc. The implied exponent for 13 is 2 and for all primes greater than 17 the exponent is 1. Setting `LayerSizes` to `[2, 1]` will attempt to split all layers, resulting in a portion of a chief series for G.

`ElementaryAbelianSeriesCanonical(G)`

Gives a similar result to using `ElementaryAbelianSeries`, except the series returned depends only on the isomorphism type of the solvable radical, and consists of characteristic subgroups of G. This function may be slower than `ElementaryAbelianSeries`.

59.11.3 Composition and Chief Factors

The functions in this section enable the user to find the composition factors of a matrix group. They are restricted to matrix groups where a base and strong generating set can be constructed. The chief series and factors functions are further restricted to groups where the base ring is either a field or can be embedded into a field.

`CompositionFactors(G)`

Given a matrix group G, return a sequence S of tuples that represent the composition factors of G, ordered according to some composition series of G. Each tuple is a triple of integers f, d, q that defines the isomorphism type of the corresponding composition factor. A triple $< f, d, q >$ describes a simple group as follows. The integer f defines the family to which the group belongs, and d and q are the parameters of the family. The length of the sequence S is the number of composition factors of G. The numbering of the simple group families is given in Tables 1 and 2 of the chapter on permutation groups on page 1590.

`ChiefFactors(G)`

Given a group G, return a sequence of the isomorphism types $< f, d, q, m >$ of the chief factors. An isomorphism type in a chief factor should be understood as the direct product of m copies of the simple group described by $< f, d, q >$ (see `CompositionFactors` above). For the algorithm, see Unger [Ung].

`ChiefSeries(G)`

Given a group G, return the chief series of G and a sequence of the corresponding isomorphism types $< f, d, q, m >$ of the chief factors. An isomorphism type in a chief factor should be understood as the direct product of m copies of the simple group described by $< f, d, q >$ (see `CompositionFactors` above). The series will be organised to contain the soluble radical of G, and, if G is insoluble, the socle of the quotient of G by the soluble radical.

Example H59E25

We get the chief factors of a group of degree 4 defined over the cyclotomic field of order 8.

```
> L<zeta_8> := CyclotomicField(8);
> w := -( - zeta_8^3 - zeta_8^2 + zeta_8);
> // Define sqrt(q)
> rt2 := -1/6*w^3 + 5/6*w;
> // Define sqrt(-1)
> ii := -1/6*w^3 - 1/6*w;
> f := rt2;
> t := f/2 + (f/2)*ii;
> GL4L := GeneralLinearGroup(4, L);
>
> A := GL4L ! [ 1/2, 1/2, 1/2, 1/2,
>             1/2,-1/2, 1/2,-1/2,
```

```
>             1/2, 1/2,-1/2,-1/2,
>             1/2,-1/2,-1/2, 1/2 ];
>
> B := GL4L ! [ 1/f,   0, 1/f,   0,
>               0, 1/f,   0, 1/f,
>             1/f,   0,-1/f,   0,
>               0, 1/f,   0,-1/f ];
>
> g4 := GL4L ! [  1, 0, 0, 0,
>                 0, 1, 0, 0,
>                 0, 0, 1, 0,
>                 0, 0, 0,-1 ];
>
> D1 := GL4L ! [ 1, 0, 0, 0,
>               0,ii, 0, 0,
>               0, 0, 1, 0,
>               0, 0, 0,ii ];
>
> D3 := GL4L ! [ t, 0, 0, 0,
>               0, t, 0, 0,
>               0, 0, t, 0,
>               0, 0, 0, t ];
>
> G3 := sub< GL4L | A, B, g4, D1, D3 >;
> Order(G3);

```

59.12 Coset Tables and Transversals

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

`CosetTable(G, H)`

The (right) coset table for the group G over subgroup H relative to its defining generators.

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a matrix group G and a subgroup H of G, this function returns

(a) A set of elements T of G forming a right transversal for G over H; and

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and $g \in G$, ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

59.13 Presentations

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

59.13.1 Presentations

`FPGroup(G)`

Construct a presentation for the matrix group G on the set of defining generators and return the presentation in the form of a finitely presented group F that is isomorphic to G. The presentation is obtained by first computing the regular representation of G and then using the Todd-Coxeter Schreier algorithm to construct a presentation on the strong generators. In this situation the strong generators are identical to the defining generators.

A group homomorphism $\phi : F \to G$, defining G as a matrix representation of F, is also returned.

`FPGroupStrong(G)`

Construct a presentation for the matrix group G on a set of strong generators and return the presentation in the form of a finitely presented group F that is isomorphic to G. In MAGMA, the Todd-Coxeter Schreier algorithm is used to construct the presentation. If strong generators are not already known for G, they will be constructed. In the case in which strong generators are already known for G, the presentation will be on these strong generators.

The presentation will have the property that it contains presentations for all stabilizer subgroups defined by the BSGS.

The group homomorphism $f : F \to G$, defining G as a matrix representation of F, is also returned.

59.13.2 Matrices as Words

Consider a matrix group G defined on d generators. The *word group* of G is a free group W of rank d. Then we regard G as a homomorphic image of F with associated homomorphism $\phi : W \to G$. All operations involving words in the generators of G will be performed in W.

`WordGroup(G)`

Given a matrix group G defined on d generators, return (a) a free group W on d generators as an SLP-group, and (b) the homomorphism ϕ from W to G such that $W.i \to G.i$, for $i = 1, \ldots, d$. The group W associated with G by this function will be referred to as the *word group* for G.

`InverseWordMap(G)`

Given a matrix group G and its associated word group W with canonical homomorphism $\phi : W \to G$, construct the inverse mapping ρ. Thus, given a matrix g of G, $g@\rho$ returns an element in the preimage of g under ϕ. If the word group W does not already exist, it will be created.

59.14 Automorphism Groups

The automorphism group of a finite matrix group may be computed in MAGMA, subject to the same restrictions on the group as when computing maximal subgroups. (That is, all of the non-abelian composition factors of the group must appear in a certain database.) The methods used are those described in Cannon and Holt [CH03]. The existence of an isomorphism between a given matrix group and any other type of finite group (`GrpPerm` or `GrpPC`) may also be determined using similar methods.

`AutomorphismGroup(G: parameters)`

Given a finite matrix group G, construct the full automorphism group F of G. The function returns the full automorphism group of G as a group of mappings (i.e., as a group of type `GrpAuto`). The automorphism group F is also computed as a finitely presented group and can be accessed via the function `FPGroup(F)`. A function `PermutationRepresentation` is provided that when applied to F, attempts to construct a faithful permutation representation of reasonable degree. The algorithm described in Cannon and Holt [CH03] is used.

`SmallOuterAutGroup` RNGINTELT *Default :* 20000

`SmallOuterAutGroup :=` t: Specify the strategy for the backtrack search when testing an automorphism for lifting to the next layer. If the outer automorphism group O at the previous level has order at most t, then the regular representation of O is used, otherwise the program tries to find a smaller degree permutation representation of O.

`Print` RNGINTELT *Default :* 0

The level of verbose printing. The possible values are 0, 1, 2 or 3.

`PrintSearchCount` RNGINTELT *Default :* 1000

`PrintSearchCount := s`: If `Print := 3`, then a message is printed at each s-th iteration during the backtrack search for lifting automorphisms.

Further information about the construction of the automorphism group and a description of machinery for computing with group automorphisms may be found in Chapter 67.

Example H59E26

We construct a 3-dimensional matrix group over $GF(4)$ and determine the order of its automorphism group.

```
> k<w> := GF(4);
> G := MatrixGroup< 3, k |
> [w^2, 0, 0, 0, w^2, 0, 0, 0, w^2],
> [w^2, 0, w^2, 0, w^2, w^2, 0, 0, w^2],
> [1, 0, 0, 1, 0, w, w^2, w^2, 0],
> [w, 0, 0, w^2, 1, w^2, w, w, 0],
> [w, 0, 0, 0, w, 0, 0, 0, w] >;
> G;
MatrixGroup(3, GF(2^2))
Generators:
    [w^2   0   0]
    [  0 w^2   0]
    [  0   0 w^2]

    [w^2   0 w^2]
    [  0 w^2 w^2]
    [  0   0 w^2]

    [  1   0   0]
    [  1   0   w]
    [w^2 w^2   0]

    [  w   0   0]
    [w^2   1 w^2]
    [  w   w   0]

    [  w   0   0]
    [  0   w   0]
    [  0   0   w]
> #G;
576
> A := AutomorphismGroup(G);
> #A;
3456
> OuterOrder(A);
72
> F := FPGroup(A);
```

```
> P := DegreeReduction(CosetImage(F, sub<F|>));
> P;
Permutation group P acting on a set of cardinality 48
```

Thus, we see that G has an automorphism group of order 3456 and the quotient group of A consisting of outer automorphisms, has order 72. The automorphism group may be realised as a permutation group of degree 48.

`IsIsomorphic(G, H: parameters)`

Test whether or not the two finite groups G and H are isomorphic as abstract groups. If so, both the result `true` and an isomorphism from G to H is returned. If not, the result `false` is returned. The algorithm described in Cannon and Holt [CH03] is used.

`SmallOuterAutGroup` RngIntElt *Default :* 20000

`SmallOuterAutGroup :=` t: Specify the strategy for the backtrack search when testing an automorphism for lifting to the next layer. If the outer automorphism group O at the previous level has order at most t, then the regular representation of O is used, otherwise the program tries to find a smaller degree permutation representation of O.

`Print` RngIntElt *Default :* 0

The level of verbose printing. The possible values are 0, 1, 2 or 3.

`PrintSearchCount` RngIntElt *Default :* 1000

`PrintSearchCount :=` s: If `Print := 3`, then a message is printed at each s-th iteration during the backtrack search for lifting automorphisms.

Example H59E27

We construct a 3-dimensional point group of order 8 and test it for isomorphism with the dihedral group of order 8 given as a permutation group.

```
> n := 4;
> N := 4*n;
> K<z> := CyclotomicField(N);
> zz := z^4;
> i := z^n;
> cos := (zz+ComplexConjugate(zz))/2;
> sin := (zz-ComplexConjugate(zz))/(2*i);
> GL := GeneralLinearGroup(3, K);
> G := sub< GL | [ cos, sin, 0,
>                 -sin, cos, 0,
>                    0,   0, 1 ],
>
>                [  -1,   0, 0,
>                    0,   1, 0,
>                    0,   0, 1 ] >;
```

```
>
>  #G;
8
> D8 := DihedralGroup(4);
> D8;
Permutation group G acting on a set of cardinality 4
Order = 8 = 2^3
    (1, 2, 3, 4)
    (1, 4)(2, 3)
> #D8;
8
> bool, iso := IsIsomorphic(G, D8);
> bool;
true
> iso;
Homomorphism of MatrixGroup(3, K) of order 2^3 into
GrpPerm: D8, Degree 4, Order 2^3 induced by
    [ 0  1  0]
    [-1  0  0]
    [ 0  0  1] |--> (1, 2, 3, 4)

    [-1  0  0]
    [ 0  1  0]
    [ 0  0  1] |--> (1, 3)
```

59.15 Representation Theory

A set of functions are provided for computing with the characters of a group. Full details of these functions may be found in Chapter 91. For convenience we include here two of the more useful character functions.

Also, functions are provided for computing with the modular representations of a group. Full details of these functions may be found in Chapter 89. For the reader's convenience we include here the functions which may be used to define a $K[G]$-module for a matrix group.

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

`LinearCharacters(G)`

A sequence containing the linear characters for the group G.

`CharacterTable(G: parameters)`

Construct the table of ordinary irreducible characters for the group G.

`Al` MonStgElt *Default :* `"Default"`

This parameter controls the algorithm used. The string `"DS"` forces use of the Dixon-Schneider algorithm. The string `"IR"` forces the use of Unger's induction/reduction algorithm [Ung06]. The `"Default"` algorithm is to use Dixon-Schneider for groups of order ≤ 5000 and Unger's algorithm for larger groups. This may change in future.

`DSSizeLimit` RngIntElt *Default :* 0

When the default algorithm is selected, a positive value n for `DSSizeLimit` means that before using Unger's algorithm, the full character space is split by some passes of Dixon-Schneider, restricted to using class matrices corresponding to conjugacy classes with size at most n.

`PermutationCharacter(G, H)`

Given a group G and a subgroup H of G, construct the ordinary character afforded by the representation of G given by its action on the coset space of the subgroup H.

`GModule(G)`

The natural $R[G]$-module for the matrix group G.

`GModule(G, A)`

Let A be a matrix ring defined over the ring R and let G be a finite group defined on m generators. Let M denote the underlying module of A. Suppose there is a one-to-one correspondence between the generators of G and the generators $[A_1, \ldots, A_m]$ of A. The function `GModule` creates the $R[G]$-module corresponding to an action of G on M defined by A, where the action of the i-th generator of G on M is given by A_i.

`GModule(G, Q)`

Let A be a matrix ring defined over the ring R and let G be a finite group defined on m generators. Let M denote the underlying module of A. Given a sequence Q of m elements of A, the function `GModule` creates the $R[G]$-module corresponding to an action of G on M defined by Q, where the action of the i-th generator of G on M is given by $Q[i]$.

`GModule(G, A, B)`

Let A and B be normal subgroups of G such that B is contained in A. Further, assume that A/B is elementary abelian of order p^n, p a prime. Let K denote the field of p elements. This function constructs a $K[G]$-module corresponding to the action of the group G on the elementary abelian section A/B of G. The map from A to the $K[G]$-module's underlying vector space is also returned.

`PermutationModule(G, H, R)`

The permutation module for the matrix group G over the ring R defined by its action on the cosets of the subgroup H.

`ChangeOfBasisMatrix(G, S)`

Given a matrix group G and a submodule S of its natural module, return an invertible matrix with topmost rows a basis for S. Conjugating by the inverse of this matrix puts the generators of G into a block form that exhibits their action on S and the quotient module.

Example H59E28

We use the module machinery to refine an elementary abelian normal subgroup by finding a normal subgroup contained in it.

```
> G := MatrixGroup<4, IntegerRing(4) |
>  [ 3, 3, 1, 3, 0, 2, 2, 3, 3, 0, 1, 3, 3, 2, 2, 1 ],
>  [ 2, 2, 3, 3, 0, 3, 1, 1, 3, 0, 1, 1, 2, 0, 1, 2 ] >;
> #G;
660602880
> H := pCore(G, 2);
> FactoredOrder(H);
[ <2, 15> ]
> IsElementaryAbelian(H);
true
> M, f := GModule(G, H, sub<H|>);
> SM := Submodules(M);
> #SM;
3
```

One of these submodules is 0, one is all `M`, we are interested in the one in the middle. Note that the result returned by `Submodules` is sorted by dimension.

```
> N := SM[2] @@ f;
> N;
MatrixGroup(4, IntegerRing(4))
Generators:
  [3 0 0 0]
  [0 3 0 0]
  [0 0 3 0]
  [0 0 0 3]
```

We have found `N`, a normal subgroup of `G`, contained in the 2-core, with order 2.

59.16 Base and Strong Generating Set

59.16.1 Introduction

Computing structural information for a matrix group G requires, in most cases, a representation of the set of elements of G. MAGMA represents this set by means of a *base and strong generating set, or BSGS* for G. Suppose the group G has the natural module M. A *base* B for G is a sequence of distinct elements and submodules of M with the property that the identity is the only element of G that fixes B pointwise. A base B of length n determines a sequence of subgroups $G^{(i)}$, $1 \leq i \leq n+1$, where $G^{(i)}$ is the stabilizer of the first $i-1$ points of B. Given a base B for G, a subset S of G is said to be a *strong generating set* for G if $G^{(i)} = \langle S \cap G^{(i)} \rangle$, for $i = 1, \ldots, n$.

Unlike permutation groups, however, the orbits of the i-th base point under the stabilizer $G^{(i)}$ are not bounded by the degree, but rather, by (where the base point is a 1-dimensional subspace) $(q^n - 1)/(q - 1)$ where q is the cardinality of the coefficient field and n is the degree of G. Clearly, it is essential to find small orbits if one is to compute with matrix groups in this manner. Unfortunately, there are no methods which are guaranteed to find short orbits. There are, however, some heuristics developed by Scott Murray and Eamonn O'Brien which often find good base points. These heuristics are used in MAGMA if the most likely standard base point would generate an orbit longer than 10000 (this bound may be changed).

59.16.2 Controlling Selection of a Base

Given the difficulties in automatically finding a good base for a matrix group, it is possible to apply the Murray-O'Brien base point selection procedure and preset a suitable base manually.

`GoodBasePoints(G: parameters)`

Apply the Murray–O'Brien base point selection procedure and return a sequence of vectors or subspaces according to the parameters. The procedure computes and sorts a collection of eigenspaces $[V_1, \ldots, V_m]$ for a generating set for the matrix group G. The default action is then to return $[V_1.1, \ldots, V_m.1, V_1.2, \ldots]$ where each new vector is only added if it is not in the span of the preceding vectors.

`Slots` RNGINTELT *Default :* 10

Expand the number of generators to work with to `Slots` matrices by adding random words in the generators of G.

`NoCycle` RNGINTELT *Default :* `false`

If `NoCycle := true`, instead of cycling through the eigenspaces, return the sequence $[V_1.1, \ldots, V_1.(\dim V_1), V_2.1, \ldots]$, with the addition of each vector subject to the same condition above.

`Eigenspaces` RNGINTELT *Default :* `false`

If `Eigenspaces := true`, then return the subsequence of the eigenspaces where all the eigenspaces have dimension $d \leq 10$. If there are no such eigenspaces, all the eigenspaces are returned.

```
AssertAttribute(G, "Base", B)
```

Set the base of the matrix group G to be $[B[1], \ldots, B[n]]$ where the tuple B has n components. An error will be reported if the matrix group G already has a base set.

```
HasAttribute(G, "Base")
```

Return whether the matrix group G has a base set, and if so, the base.

```
AssertAttribute(GrpMat, "FirstBasicOrbitBound", n)
```

Set the limit for the size of the first basic orbit to be n. If n is non-zero and the orbit of the first base point (a 1-dimensional subspace generated by a standard basis vector) has length exceeding n, then the Murray-O'Brien base point selection procedure is used to find a point more likely to have a short orbit. This assertion will affect all matrix groups. If $n = 1$ then use of the Murray-O'Brien procedure is guaranteed.

```
HasAttribute(GrpMat, "FirstBasicOrbitBound")
```

Get the limit for the size of the first basic orbit. This will always return `true` and the limit.

59.16.3 Construction of a Base and Strong Generating Set

The functions described below give user control of the construction of a base and strong generating set (BSGS) of a finite matrix group.

Many functions described in this chapter require a group to have a BSGS. In case the given group does not have a BSGS, then one will be constructed using the default algorithm, which is equivalent to using the `BSGS` procedure described below.

It should be noted that if the user constructs a BSGS for a group G using the `RandomSchreier` procedure, then other functions that require a BSGS will assume that the random BSGS is a complete BSGS. If this is not the case then results will be unpredictable.

```
BSGS(G)
```

```
BSGS(G, str)
```

The general procedure for constructing a base and strong generating set for the matrix group G. This version uses the default algorithm choices. Currently this is as follows: if the order of the group is known to the program then a BSGS is constructed using the random Schreier algorithm, if not then the Sims-Todd-Coxeter-Schreier procedure is used. If `str` is the name of a sporadic group, we assume that G is a representation for this group and choose base points specific to this group. This should ensure better performance. Information on the progress of these algorithms may be obtained by setting the verbose flags `RandomSchreier` and `STCS` true.

`RandomSchreier(G: parameters)`

`RandomSchreier(G, str : parameters)`

`Run` RngIntElt *Default :* 40

Construct a probable base and strong generating set for the group G. The strong generators are constructed from a set of randomly chosen elements of G. The expectation is that if sufficiently many random elements are taken then, upon termination, the algorithm will have produced a BSGS for G. If the attribute Order is defined for G, the random Schreier will continue until a BSGS defining a group of the indicated order is obtained. In such circumstances this method is the fastest method of constructing a base and strong generating set for G. This is particularly so for groups of large degree. If nothing is known about G, the random Schreier algorithm provides a cheap way of obtaining lower bounds on the group's order. This procedure has one associated parameter `Run`, which takes a positive integer value. If the value of `Run` is n, then the algorithm terminates after n consecutive random elements are found to lie in the set defined by the current BSGS (default 40). This will happen even if the Order attribute is defined for G. It should be emphasized that unpredictable results may arise if the user uses the base and strong generators produced by this algorithm, when, in fact, it does not constitute a complete BSGS for G. The `Verify` procedure, described below, may be used to check the completeness of the BSGS constructed by this function.

If `str` is the name of a sporadic group, we assume that G is a representation for this group and choose base points specific to this group. This should ensure better performance.

Information on the progress of this algorithm may be obtained by setting the verbose flag `RandomSchreier` to true.

`ToddCoxeterSchreier(G)`

Construct a BSGS for the matrix group G using the Sims-Todd-Coxeter-Schreier algorithm. Information on the progress of this algorithm may be obtained by setting the verbose flag `STCS` to true.

`Verify(G)`

Given a matrix group G for which a possible BSGS is stored, verify the correctness of the BSGS. If it is not complete, proceed to complete it. The Sims-Todd-Coxeter-Schreier method is used.

If G has no BSGS stored, then use of `Verify` is equivalent to using the `BSGS` procedure described above.

Information on the progress of these algorithms may be obtained by setting the verbose flags `RandomSchreier` and `STCS` true.

59.16.4 Defining Values for Attributes

```
AssertAttribute(G, "Order", n)
```
```
AssertAttribute(G, "Order", Q)
```

Define the order of the matrix group G to be the integer n (factored integer Q).

```
AssertAttribute(G, "IsVerified", b)
```

If the boolean variable b is `true`, the existing pseudo strong generators for the matrix group G (possibly created by `RandomSchreier`) are to be taken as correct.

```
HasAttribute(G, "Order")
```
```
HasAttribute(G, "FactoredOrder")
```

Returns `true` iff the order of the group G is known. In that case, the order is also returned as the second value of the function.

```
HasAttribute(G, "IsVerified")
```

Returns `true` iff the matrix group G has a verified set of strong generators.

59.16.5 Accessing the Base and Strong Generating Set

```
Base(G)
```

A base for the matrix group G. The base is returned as a sequence of points of Ω. If a base is not known, one will be constructed.

```
BasePoint(G, i)
```

The i-th base point for the matrix group G. A base and strong generating set must be known for G.

```
BasicOrbit(G, i)
```

The basic orbit at level i as defined by the current base for the matrix group G. This function assumes that a BSGS is known for G.

```
BasicOrbitLength(G, i)
```

The length of the basic orbit at level i as defined by the current base for the matrix group G. This function assumes that a BSGS is known for G.

```
BasicOrbitLengths(G)
```

The lengths of the basic orbits as defined by the current base for the matrix group G. This function assumes that a BSGS is known for G. The lengths are returned as a sequence of integers.

`BasicStabilizer(G, i)`

`BasicStabiliser(G, i)`

Given a matrix group G for which a base and strong generating set are known, and an integer i, where $1 \leq i \leq k$ with k the length of the base, return the subgroup of G which fixes the first $i-1$ points of the base.

`BasicStabilizerChain(G)`

`BasicStabiliserChain(G)`

Given a matrix group G, return the stabilizer chain defined by the base as a sequence of subgroups of G. If a BSGS is not already known for G, it will be created.

`NumberOfStrongGenerators(G)`

`Nsgens(G)`

The number of elements in the current strong generating set for the matrix group G.

`StrongGenerators(G)`

A set of strong generators for the matrix group G. If they are not currently available, they will be computed.

59.17 Soluble Matrix Groups

The functions described in this section apply only to finite groups for which a base and strong generating set may be constructed.

59.17.1 Conversion to a PC-Group

`PolycyclicGenerators(G)`

Construct a polycyclic generating sequence for the soluble group G.

`PCGroup(G)`

Given a soluble group G, construct a group S in category `GrpPC`, isomorphic to G. In addition to returning S, the function returns an isomorphism $\phi : G \to S$.

59.17.2 Soluble Group Functions

`pCentralSeries(G, p)`

Given a soluble group G, and a prime p dividing $|G|$, return the lower p-central series for G. The series is returned as a sequence of subgroups.

59.17.3 p-group Functions

`IsSpecial(G)`

Given a p-group G, return `true` if G is special, `false` otherwise.

`IsExtraSpecial(G)`

Given a p-group G, return `true` if G is extraspecial, `false` otherwise.

`FrattiniSubgroup(G)`

Given a p-group G, return the Frattini subgroup.

`JenningsSeries(G)`

Given a p-group G, return the Jennings series for G. The series is returned as a sequence of subgroups.

59.17.4 Abelian Group Functions

`AbelianInvariants(G)`

`Invariants(G)`

Given an abelian group G, return a sequence Q containing the types of each p-primary component of G.

60 MATRIX GROUPS OVER FINITE FIELDS

Chapter 60
MATRIX GROUPS OVER FINITE FIELDS

60.1 Introduction

If a matrix group G is defined over a finite field then, provided that the group is not too large, we can construct a BSGS-representation for G and consequently apply the standard algorithms for group structure as described in Chapter 59. However, there are many examples of groups having moderately small dimension where we cannot find a BSGS-representation.

In this chapter we describe techniques for computing with matrix groups that do not assume that a BSGS-representation is available. Thus, the techniques described here apply to matrix groups possibly having much larger order or much larger dimension than those that can be handled with the techniques of Chapter 59.

The `CompositionTree` package introduced in Section 60.6, which includes the collection of LMG (large matrix group) functions described in Section 60.7, provides a framework for such investigations. The package was prepared by Henrik Bäärnhielm, Derek Holt, C.R. Leedham-Green and E.A. O'Brien, and includes code prepared by Peter Brooksbank, Elliot Costi, Heiko Dietrich, Alice Niemeyer, and Csaba Schneider.

For recent surveys of work in this area, we refer the reader to [O'B06, O'B11].

The techniques described in this chapter fall roughly into two categories.

(a) Functions based on Aschbacher's theorem classifying maximal subgroups of the general linear group. The main thrust of this work is to devise a framework for computing arbitrary structural information for a matrix group without the use of a BSGS-representation.

(b) Functions which employ Monte Carlo and Las Vegas algorithms to determine some property of the group.

60.2 Finding Elements with Prescribed Properties

`RandomElementOfOrder(G, n : parameters)`

`Central`	BoolElt	*Default :* `false`
`Proof`	BoolElt	*Default :* `true`
`Randomiser`	GrpRandProc	*Default :*
`MaxTries`	RngIntElt	*Default :* 100

Given a finite matrix group G, this intrinsic attempts to locate an element x of order n in G by random search. If such an element is found, then the return values are the boolean value `true`, the element x, and an SLP for this element.

If `Central` is `true`, then an element is sought which has order n modulo the centre of G. If `Proof` is `false`, then the element returned may have order a multiple of n. In either case, the final return value indicates whether the element returned is known to have the precise order. The parameter `MaxTries` specifies the maximum number of random elements that are chosen. The parameter `Randomiser` specifies the random process that is to be used to construct the element and the SLP returned for the element is in the word group associated with this process. The default value of `Randomiser` is the process `RandomProcessWithWords(G)`.

`RandomElementOfNormalClosure(G, N)`

Given a group G and a subgroup N of G, this intrinsic returns a random element of the normal closure of N in G. Note that G may be a permutation or matrix group. The algorithm is due to Leedham-Green and O'Brien [LGO02].

`InvolutionClassicalGroupEven(G : parameters)`

`SmallCorank`	BoolElt	*Default :* `false`
`Case`	MonStgElt	*Default :* "*unknown*"

Let G be a quasisimple classical group in its natural representation and in even characteristic. If G is of type Ω^+ or Ω^- then it must have even degree at least 4 and be defined over a field with at least 4 elements. The corank of an involution I is the rank of $I - \mathtt{Identity}(G)$. This function returns an involution I of corank in $[d/4, \ldots, d/2]$, the SLP for I in `WordGroup`(G), and the corank of the involution. The parameter `Case` should be one of `"SL"`, `"Sp"`, `"SU"`, `"Omega-"`, or `"Omega+"`. If `SmallCorank` is `true`, then accept involution of small corank. The algorithm used to construct the involution is described in [DLLGO13]; it was implemented by Heiko Dietrich.

60.3 Monte Carlo Algorithms for Subgroups

`CentraliserOfInvolution(G, g : parameters)`

`Central`	BoolElt	*Default :* `false`
`NumberRandom`	RngIntElt	*Default :* 100
`CompletionCheck`	UserProgram	*Default :*

Given an involution g in G, this function returns the centraliser C of g in G using an algorithm of John Bray [Bra00]. Since it is Monte Carlo, it may return only a subgroup of the centraliser. If `Central` is `true`, the projective centraliser of g will be constructed: its elements commute with g modulo the centre of G.

The optional argument `CompletionCheck` is a function which can be used to determine when we have constructed the centraliser. It takes the following arguments: the parent group G; the proposed centraliser C; the involution g. By default, the algorithm completes when 20 generators have been found for the centraliser or when `NumberRandom` elements have been considered.

`CentraliserOfInvolution(G, g, w : parameters)`

`Randomiser`	GrpRandProc	*Default :*
`Central`	BoolElt	*Default :* `false`
`NumberRandom`	RngIntElt	*Default :* 100
`CompletionCheck`	UserProgram	*Default :*

Given an involution g in a matrix group G together with a SLP w corresponding to g, this function returns the centraliser C of g in G and SLPs for the generators of C. The algorithm used is due to John Bray [Bra00]. Since it is Monte Carlo, it may return a proper subgroup of the centraliser. If `Central` is `true`, the projective centraliser of g is constructed: its elements commute with g modulo the centre of G.

The parameter `Randomiser` specifies the random process that is to be used to construct the centraliser. By default `Randomiser` is the value returned by `RandomProcessWithWords (G)`. The SLP for g must lie in the word group of this process. The optional argument `CompletionCheck` is a function which can be used to determine when we have constructed the centraliser. It takes four arguments: the parent group G; the proposed centraliser C; the involution g; and the list of the SLPs for the generators of C. By default, the algorithm completes when 20 generators have been found for the centraliser or when `NumberRandom` elements have been considered.

`AreInvolutionsConjugate(G, x, wx, y, wy : parameters)`

`Randomiser`	GrpRandProc	*Default :*
`MaxTries`	RngIntElt	*Default :* 100

This Monte Carlo algorithm attempts to construct an element c of the group G which conjugates the involution x to the involution y. The corresponding SLPs for x and y are wx and wy respectively. If such an element c is found, then three values are returned: `true`, c and the SLP for c. Otherwise, the boolean value `false` is returned. At most `MaxTries` random elements are considered.

The parameter `Randomiser` specifies the random process to be used. By default `Randomiser` is the value returned by `RandomProcessWithWords (G)`. The SLPs for x and y must lie in the word group of this process and the SLP for c will also lie in this word group.

`NormalClosureMonteCarlo(G, H )`

`NormalClosureMonteCarlo(G, H : parameters)`

`slpsH`	[]	*Default :* []
`ErrorProb`	FltRatElt	*Default :* 9/10
`SubgroupChainLength`	RngIntElt	*Default :* `Degree(H)`

This Monte Carlo algorithm constructs the normal closure N of H in G. If SLPs of the generators of H in the generators of G are supplied via the parameter

slpsH, then the function also returns SLPs for the generators of N. The parameter SubgroupChainLength is used to specify an upper bound on the length of any subgroup chain in H. The probability that N is a proper subgroup of the normal closure is bounded above by ErrorProb, assuming that SubgroupChainLength is correctly set.

DerivedGroupMonteCarlo(G : *parameters*)

Randomiser	GrpRandProc	*Default :*
NumberGenerators	RngIntElt	*Default :* 10
MaxGenerators	RngIntElt	*Default :* 100

Given a matrix group G defined over a finite field, this intrinsic returns the derived group of G, and a list of SLPs of its generators in the generators of G. The SLPs are elements of the word group of the random process. The algorithm is Monte Carlo and may return a proper subgroup of the derived group. The parameter Randomiser specifies the random process to be used. By default Randomiser is the value returned by RandomProcessWithWords (G). At least NumberGenerators and at most MaxGenerators will be constructed for the derived group.

IsProbablyPerfect(G : *parameters*)

NumberRandom	RngIntElt	*Default :* 100

This intrinsic attempts to prove that a matrix or permutation group G is perfect by establishing that its generators are in G'. Since it is Monte-Carlo, there is a small probability of error. If the function returns true, then G is perfect; if it returns false, then G might still be perfect. Each call considers NumberRandom random elements.

The algorithm is due to Leedham-Green and O'Brien [LGO02] and it uses NormalSubgroupRandomElement.

Example H60E1

We illustrate IsProbablyPerfect with a subgroup of $GU(4, 9)$.

```
> G := GU(4, 9);
> N := sub<G | (G.1, G.2)>;
```

The generators of N have been chosen to be a normal generating set for the derived group of G.

```
> IsProbablyPerfect(N);
false
> x := NormalSubgroupRandomElement(G, N);
> x;
[$.1^68 $.1^34 $.1^26 $.1^55]
[$.1^23 $.1^78 $.1^16 $.1^72]
[$.1^42  $.1^2 $.1^24      2]
[$.1^11 $.1^66 $.1^13 $.1^29]
>  L := sub< G | N, x>;
```

```
> IsProbablyPerfect(L);
true
```

We now consider $SO(7,5)$ and $\Omega(7,5)$.

```
> G := SO(7, 5);
> IsProbablyPerfect(G);
false
> G := Omega(7, 5);
> IsProbablyPerfect(G);
true
```

60.4 Aschbacher Reduction

60.4.1 Introduction

An on-going international research project seeks to develop algorithms to explore the structure of groups having either large order or large degree. The approach relies on the following theorem of Aschbacher [Asc84]:

A matrix group G acting on the finite dimensional $K[G]$-module V over a finite field K satisfies at least one of the following conditions (which we have simplified slightly for brevity):

(i) G acts reducibly on V;

(ii) G acts semilinearly over an extension field of K;

(iii) G acts imprimitively on V;

(iv) G preserves a nontrivial tensor-product decomposition of V;

(v) G has a normal subgroup N, acting absolutely irreducibly on V, which is an extraspecial p-group or 2-group of symplectic type;

(vi) G preserves a tensor-induced decomposition of V;

(vii) G acts (modulo scalars) linearly over a proper subfield of K;

(viii) G contains a classical group in its natural action over K;

(ix) G is almost simple modulo scalars.

The philosophy underpinning the research program is to attempt to decide that G lies in at least one of the above categories, and to calculate the associated isomorphism or decomposition explicitly.

Groups in Category (i) can be recognised easily by means of the Meataxe functions described in the chapter on R-modules.

Groups which act irreducibly but not absolutely irreducibly on V fall theoretically into Category (ii), and furthermore act linearly over an extension field of K. In fact, absolute irreducibility can be tested using the built-in MAGMA functions and, by redefining their

field to be an extension field L of K and reducing, they can be rewritten as absolutely irreducible groups of smaller dimension, but over L instead of K. We can therefore concentrate on absolutely irreducible matrix groups.

The `CompositionTree` package currently includes functions which seek to decide membership in all categories.

60.4.2 Primitivity

Let G be a subgroup of $\mathrm{GL}(d, q)$ and assume that G acts irreducibly on the underlying vector space V. Then G acts *imprimitively* on V if there is a non-trivial direct sum decomposition

$$V = V_1 \oplus V_2 \oplus \ldots \oplus V_r$$

where $V_1, \ldots, V_r$ are permuted by G. In such a case, each block V_i has the same dimension or size, and we have the *block system* $\{V_1, \ldots, V_r\}$. If no such system exists, then G is *primitive*.

Theoretical details of the algorithm used may be found in Holt, Leedham-Green, O'Brien, and Rees [HLGOR96b].

`SetVerbose ("Smash", 1)` will provide information on the progress of the algorithm.

`IsPrimitive(G:` *parameters*`)`

`BlockSizes` [RngIntElt] *Default :* []

Given a matrix group G defined over a finite field, this intrinsic returns `true` if G is primitive, `false` if G is not primitive, or `"unknown"` if no decision can be reached.

If `BlockSizes` is supplied, then the search is restricted to systems of imprimitivity whose block sizes are given in the sequence `BlockSizes` only. Otherwise all valid sizes will be considered.

`ImprimitiveBasis(G)`

Given a matrix group G defined over a finite field which is imprimitive, this intrinsic returns the change-of-basis matrix which exhibits the block structure for G.

`Blocks(G)`

Given a matrix group G defined over a finite field which is imprimitive, this intrinsic returns the blocks of imprimitivity of G.

`BlocksImage(G)`

Given a matrix group G defined over a finite field which is imprimitive, this intrinsic returns the group induced by the action of G on the system of imprimitivity.

`ImprimitiveAction(G, g)`

Given a matrix group G defined over a finite field which is imprimitive and an element g of G, this intrinsic returns action of g on blocks of imprimitivity as a permutation.

Example H60E2

We construct an imprimitive group by taking the wreath product of $GL(4, 7)$ with S_3.

```
> MG := GL (4, 7);
> PG := Sym (3);
> G := WreathProduct (MG, PG);
>
> IsPrimitive (G);
false
```

We investigate the block system for G.

```
> B := Blocks (G);
> B;
> #B;
4
> B[1];
Vector space of degree 12, dimension 4 over GF(7)
Generators:
(0 0 0 0 1 0 0 0 0 0 0 0)
(0 0 0 0 0 1 0 0 0 0 0 0)
(0 0 0 0 0 0 1 0 0 0 0 0)
(0 0 0 0 0 0 0 1 0 0 0 0)
Echelonized basis:
(0 0 0 0 1 0 0 0 0 0 0 0)
(0 0 0 0 0 1 0 0 0 0 0 0)
(0 0 0 0 0 0 1 0 0 0 0 0)
(0 0 0 0 0 0 0 1 0 0 0 0)
```

Now we obtain a permutation representation of G in its action on the blocks.

```
> P := BlocksImage (G);
> P;
Permutation group P acting on a set of cardinality 3
    (1, 2, 3)
    (2, 3)
> g := G.4 * G.3;
> ImprimitiveAction (G, g);
(1, 2)
```

60.4.3 Semilinearity

Let G be a subgroup of $\mathrm{GL}(d, q)$ and assume that G acts absolutely irreducibly on the underlying vector space V. Assume that a normal subgroup N of G embeds in $\mathrm{GL}(d/e, q^e)$, for $e > 1$, and a $d \times d$ matrix C acts as multiplication by a scalar λ (a field generator of $\mathbf{F}_{q^e}$) for that embedding.

We say that G acts as a *semilinear* group of automorphisms on the d/e-dimensional space if and only if, for each generator g of G, there is an integer $i = i(g)$ such that $Cg = gC^i$, that is, g corresponds to the field automorphism $\lambda \to \lambda^i$. If so, we have a map from G to the (cyclic) group $\mathrm{Aut}(GF(q^e))$, and C centralises the kernel of this map, which thus lies in $\mathrm{GL}(d, q^e)$.

Theoretical details of the algorithm used may be found in Holt, Leedham-Green, O'Brien and Rees [HLGOR96a].

`SetVerbose ("SemiLinear", 1)` will provide information on the progress of the algorithm.

`IsSemiLinear(G)`

Given a matrix group G defined over a finite field, this intrinsic returns `true` if G is semilinear, `false` if G is not semilinear, or `"unknown"` if no decision can be reached.

`DegreeOfFieldExtension(G)`

Let G be a subgroup of $K = \mathrm{GL}(d, q)$. The intrinsic returns the degree e of the extension field of F_q over which G is semilinear.

`CentralisingMatrix(G)`

Let G be a semilinear subgroup of $K = \mathrm{GL}(d, q)$. The intrinsic returns the matrix C which centralises the normal subgroup of G which acts linearly over the extension field of F_q.

`FrobeniusAutomorphisms(G)`

Let G be a semilinear subgroup of $K = \mathrm{GL}(d, q)$ and let C be the corresponding centralising matrix. The intrinsic returns a sequence S of positive integers, one for each generator g_i of G. The element $S[i]$ is the least positive integer such that $g_i^{-1} C g_i = C^{S[i]}$.

`WriteOverLargerField(G)`

Let G be a semilinear subgroup of $\mathrm{GL}(d, q)$ with extension degree e. This intrinsic returns:

(i) The normal subgroup N of the matrix group G which is the kernel of the map from G to C_e; this subgroup acts linearly over the extension field of K and is precisely the centraliser of C in G.

(ii) A cyclic group E of order e which is isomorphic to G/N.

(iii) A sequence of images of the generators of G in E.

Example H60E3

We analyse a semilinear group.

```
> P := GL(6,3);
> g1 := P![0,1,0,0,0,0,-1,0,0,0,0,0,
>          0,0,1,0,0,0,0,0,0,1,0,0,0,0,0,0,1,0,0,0,0,0,0,1];
> g2 := P![-1,0,0,0,1,0,0,-1,0,0,0,1,
>          -1,0,0,0,0,0,0,-1,0,0,0,0,0,0,-1,0,0,0,0,0,0,-1,0,0];
> g3 := P![1,0,0,0,0,0,0,-1,0,0,0,0,
>          0,0,1,0,0,0,0,0,0,-1,0,0,0,0,0,0,1,0,0,0,0,0,0,-1];
> G := sub <P | g1, g2, g3 >;
>
> IsSemiLinear (G);
true
> DegreeOfFieldExtension (G);
2
> CentralisingMatrix (G);
[2 2 0 0 0 0]
[1 2 0 0 0 0]
[0 0 2 2 0 0]
[0 0 1 2 0 0]
[0 0 0 0 2 2]
[0 0 0 0 1 2]
> FrobeniusAutomorphisms (G);
[ 1, 1, 3 ]
> K, E, phi := WriteOverLargerField (G);
```

The group K is the kernel of the homomorphism from G into E.

```
> K.1;
[0 1 0 0 0 0]
[2 0 0 0 0 0]
[0 0 1 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
```

The return value E is the cyclic group of order e while *phi* gives the sequence of images of $G.i$ in E.

```
> E;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*E.1 = 0
>
> phi;
[ 0, 0, E.1 ]
```

60.4.4 Tensor Products

Let G be a subgroup of $\mathrm{GL}(d, K)$, where $K = GF(q)$, and let V be the natural $K[G]$-module. We say that G preserves a tensor decomposition of V as $U \otimes W$ if there is an isomorphism of V onto $U \otimes W$ such that the induced image of G in $\mathrm{GL}(U \otimes W)$ lies in $\mathrm{GL}(U) \circ \mathrm{GL}(W)$.

Theoretical details of the algorithm used may be found in Leedham-Green and O'Brien [LGO97b, LGO97a].

The verbose flag `SetVerbose ("Tensor", 1)` will provide information on the progress of the algorithm.

`IsTensor(G: parameters)`

`Factors` [SeqEnum] *Default :* []

Given a matrix group G defined over a finite field, this intrinsic returns `true` if G preserves a non-trivial tensor decomposition, `false` if G is does not preserve a tensor decomposition, or `"unknown"` if no decision can be reached.

A sequence of valid dimensions for potential factors may be supplied using the parameter `Factors`. Then for each element $[u, w]$ of the sequence `Factors`, the algorithm will search for decompositions of V as $U \otimes W$, where U must have dimension u and W must have dimension w only. If this parameter is not set, then all valid factorisations will be considered.

`TensorBasis(G)`

Given a matrix group G defined over a finite field that admits a tensor decomposion, this intrinsic returns the change-of-basis matrix which exhibits the tensor decomposition of G.

`TensorFactors(G)`

Given a matrix group G defined over a finite field that admits a tensor decomposion, this intrinsic returns two groups which are the tensor factors of G.

`IsProportional(X, k)`

Given a matrix group G defined over a finite field that admits a tensor decomposition, this intrinsic returns `true` if and only if the matrix X is composed of $k \times k$ blocks which differ only by scalars. If this is indeed the case, the tensor decomposition of X is also returned.

Example H60E4

We define a subgroup of $GL(6, 3)$ which admits a non-trivial tensor decomposition.

```
> P := GL(6, 3);
>
> g := P![ 0, 1, 1, 2, 1, 0, 2, 2, 1, 2, 1, 1, 1, 0, 2, 1, 2, 2, 1, 2, 2,
>          2, 2, 0, 0, 0, 1, 0, 0, 1, 0, 1, 0, 0, 2, 2 ];
>
> h := P![ 1, 0, 2, 1, 1, 2, 0, 0, 2, 0, 0, 2, 2, 0, 1, 0, 2, 1, 2, 1, 2,
```

```
>          2, 1, 1, 0, 2, 0, 1, 0, 0, 0, 0, 0, 2, 1, 2 ];
>
> G := sub< P | g, h >;
> IsTensor(G);
true
> C := TensorBasis(G);
```

So C is the change-of-basis matrix. If we conjugate $G.1$ by C, we obtain a visible Kronecker product.

```
> G.1^C;
[0 0 2 0 2 0]
[0 0 2 2 2 2]
[2 0 0 0 2 0]
[2 2 0 0 2 2]
[0 0 0 0 1 0]
[0 0 0 0 1 1]
>
```

We use the function `IsProportional` to verify that $G.1^C$ is a Kronecker product.

```
> IsProportional(G.1^C, 2);
true
<
 [2 0]
 [2 2],
 [0 1 1]
 [1 0 1]
 [0 0 2]
>
```

Finally, we display the tensor factors.

```
> A := TensorFactors(G);
> A[1];
MatrixGroup(2, GF(3))
Generators:
    [1 2]
    [2 2]

    [2 0]
    [2 2]
> A[2];
MatrixGroup(3, GF(3))
Generators:
    [0 1 0]
    [1 2 1]
    [1 2 0]

    [0 1 1]
    [1 0 1]
```

```
[0 0 2]
```

60.4.5 Tensor-induced Groups

Let G be a subgroup of $\mathrm{GL}(d, K)$, where $K = \mathbf{F}_q$ and $q = p^e$ for some prime p, and let V be the natural $K[G]$-module. Assume that d has a proper factorisation as u^r. We say that G is tensor-induced if G preserves a decomposition of V as

$$U_1 \otimes U_2 \otimes \cdots \otimes U_r$$

where each U_i has dimension $u > 1$, $r > 1$, and the set of U_i is permuted by G. If G is tensor-induced, then there is a homomorphism of G into the symmetric group S_r.

Theoretical details of the algorithm used may be found in Leedham-Green and O'Brien [LGO02].

`SetVerbose ("TensorInduced", 1)` will provide information on the progress of the algorithm.

`IsTensorInduced(G : parameters)`

`InducedDegree` RngIntElt *Default :* "*All*"

Given a matrix group G defined over a finite field, return `true` if G is tensor-induced, `false` if G is not tensor-induced, and `"unknown"` if no decision can be reached.

If the value of the parameter `InducedDegree` is set to r, then the algorithm will search for homomorphisms into the symmetric group of degree r only. Otherwise is will consider all valid degrees.

`TensorInducedBasis(G)`

Given a matrix group G defined over a finite field that is tensor-induced, this intrinsic returns the change-of-basis matrix which exhibits that G is tensor-induced.

`TensorInducedPermutations(G)`

Given a matrix group G defined over a finite field that is tensor-induced, this intrinsic returns a sequence whose i-th entry is the homomorphic image of $G.i$ in S_r.

`TensorInducedAction(G, g)`

Given a matrix group G defined over a finite field that is tensor-induced, this intrinsic returns the tensor-induced action of the element $g \in G$.

Example H60E5

We illustrate the use of the functions for determining if a matrix group is tensor-induced.

```
> G := GL(2, 3);
> S := Sym(3);
> G := TensorWreathProduct(G, S);
> IsTensorInduced(G);
true
```

We next recover the permutations.

```
> TensorInducedPermutations(G);
[
    Id(S),
    Id(S),
    (1, 2, 3),
    (1, 2)
]
```

Hence $G.1$ and $G.2$ are in the kernel of the homomorphism from G to S. We extract the change-of-basis matrix C and then conjugate $G.1$ by C, thereby obtaining a visible Kronecker product.

```
> C := TensorInducedBasis(G);
> x := G.1^C;
> x;
[2 0 0 0 0 0 0 0]
[0 2 0 0 0 0 0 0]
[0 0 2 0 0 0 0 0]
[0 0 0 2 0 0 0 0]
[1 0 0 0 1 0 0 0]
[0 1 0 0 0 1 0 0]
[0 0 1 0 0 0 1 0]
[0 0 0 1 0 0 0 1]
```

Finally, we verify that $x = G.1^C$ is a Kronecker product for each of 2 and 4.

```
> IsProportional(x, 2);
true
<[2 0]
[0 2], [1 0 0 0]
[0 1 0 0]
[2 0 2 0]
[0 2 0 2]>
> IsProportional(x, 4);
true
<[2 0 0 0]
[0 2 0 0]
[0 0 2 0]
[0 0 0 2], [1 0]
[2 2]>
```

60.4.6 Normalisers of Extraspecial r-groups and Symplectic 2-groups

Let $G \leq GL(d, q)$, where $d = r^m$ for some prime r. If G is contained in the normaliser of an r-group R, of order either r^{2m+1} or 2^{2m+2}, then either R is extraspecial (in the first case), or R is a 2-group of symplectic type (that is, a central product of an extraspecial 2-group with the cyclic group of order 4).

If $d = r$ is an odd prime, we use the Monte Carlo algorithm of Niemeyer [Nie05] to decide whether or not G normalises such a subgroup. Otherwise, the corresponding intrinsic `IsExtraSpecialNormaliser` searches for elements of the normal subgroup, and can only reach a negative conclusion in certain limited cases. If it cannot reach a conclusion it returns `"unknown"`.

`IsExtraSpecialNormaliser(G)`

Given a matrix group G defined over a finite field, the intrinsic returns `true` if G normalises an extraspecial r-group or 2-group of symplectic type, `false` if G is known not to normalise an extraspecial r-group or a 2-group of symplectic type, or `"unknown"` if it cannot reach a conclusion.

`ExtraSpecialParameters(G)`

Given a matrix group G defined over a finite field that is known to normalise an extraspecial r-group or 2-group of symplectic type, this intrinsic returns a sequence of two integers, r and n, where the extraspecial or symplectic subgroup R normalised by G has order r^n.

`ExtraSpecialGroup(G)`

Given a matrix group G defined over a finite field that is known to normalise an extraspecial r-group or 2-group of symplectic type, this intrinsic returns the extraspecial or symplectic subgroup normalised by G.

`ExtraSpecialNormaliser(G)`

Given a matrix group G defined over a finite field that is known to normalise an extraspecial r-group or 2-group of symplectic type, this intrinsic returns the action of the generators of G on its normal extraspecial or symplectic subgroup as a sequence of matrices, each of degree $2r$, one for each generator of G.

`ExtraSpecialAction(G, g)`

Given a matrix group G defined over a finite field that is known to normalise an extraspecial r-group or 2-group of symplectic type, this intrinsic returns a matrix of degree $2r$ describing the action of element g on the extraspecial or symplectic group normalised by G.

`ExtraSpecialBasis(G)`

Given a matrix group G defined over a finite field, which is the odd prime degree case of G normalising an extraspecial r-group or 2-group of symplectic type, this intrinsic returns the change-of-basis matrix which conjugates the normal extraspecial subgroup into a "nice" representation, generated by a diagonal and a permutation matrix.

Example H60E6

For this example we construct a subgroup G of $\mathrm{GL}(7,8)$ that normalises an extraspecial r-group or 2-group of symplectic type.

```
> F:=GF(8);
> P:=GL(7,F);
> w := PrimitiveElement(F);
> g1:=P![
> w,0,w^2,w^5,0,w^3,w,w,1,w^6,w^3,0,w^4,w,w^2,w^6,w^4,1,w^3,w^3,w^5,
> w^6,w,w^3,1,w^5,0,w^4,1,w^6,w^3,w^6,w^3,w^2,w^2,w^3,w^6,w^6,w^4,1,w^2,w^4,
> w^5,w^4,w^2,w^6,1,w^5,w ];
> g2:=P![w^3,w^4,w^2,w^6,w,w,w^3,w^3,w^4,w,w,w^2,w^3,w^3,w,w^3,w^5,w,1,w^3,w,
> 0,w^2,w^6,w,w^5,1,w,w^6,0,w^3,0,w^4,w,w^5,w^3,w^3,1,w^3,w^5,w^5,w^3,
> w^4,w^6,w,w^6,w^4,w^4,0 ];
> g3:=P![w^5,w^6,w^2,w,w,w^4,w^6,w^6,w^6,w,w^6,w,1,w^3,w,w^6,w^2,w,w^6,w^3,w^6,
> w^2,w^6,w^6,w^3,w,w^6,w^5,0,w^4,w^6,w^6,w,w^2,0,w,w^3,w^5,w^2,w^3,w^4,w^6,
> 0,w^3,w,w^3,w^4,w^3,1];
> gens := [g1,g2,g3];
> G := sub< P | gens >;
> IsExtraSpecialNormaliser(G);
true
```

So G has the desired normaliser property.

```
> ExtraSpecialParameters (G);
[ 7, 3 ]
> N:=ExtraSpecialNormaliser(G);
> N;
[
    [3 4]
    [1 4],
    [4 3]
    [0 2],
    [1 0]
    [0 1]
]
```

60.4.7 Writing Representations over Subfields

The algorithm implemented by these functions is due to Glasby, Leedham-Green and O'Brien [GLGO05]. We also provide access to an earlier algorithm for the non-scalar case developed by Glasby and Howlett [GH97].

`IsOverSmallerField(G : parameters)`

`Scalars`	BoolElt	*Default :* `false`
`Algorithm`	MonStgElt	*Default :* "*GLO*"

Given an absolutely irreducible matrix group G defined over a finite field K, this intrinsic decides whether or not G has an equivalent representation over a subfield of K. If so, it returns `true` and the representation over the smallest possible subfield, otherwise it returns `false`. If the optional argument `Scalars` is `true` then decide whether or G modulo scalars has an equivalent representation over a subfield of K. If the optional argument `Algorithm` is set to `"GH"`, then the non-scalar case uses the original Glasby and Howlett algorithm. The default is the Glasby, Leedham-Green and O'Brien algorithm, specified by `"GLO"`.

`IsOverSmallerField(G, k : parameters)`

`Scalars`	BoolElt	*Default :* `false`
`Algorithm`	MonStgElt	*Default :* "*GLO*"

Given an absolutely irreducible matrix group G defined over a finite field K, and a positive integer k which is a proper divisor of the degree of K, this intrinsic decides whether or not G has an equivalent representation over a proper subfield of K having degree k over the prime field. If so, it returns `true` and the representation over this subfield, else it returns `false`. If the optional argument `Scalars` is `true` then it decides whether or not G modulo scalars has an equivalent representation over a degree k subfield of K. If the optional argument `Algorithm` is set to `"GH"`, then the non-scalar case uses the original Glasby and Howlett algorithm. The default is the Glasby, Leedham-Green and O'Brien algorithm, specified by `"GLO"`.

`SmallerField(G)`

Given an absolutely irreducible matrix group G defined over a finite field K, which can be written over a proper subfield of K (possibly modulo scalars), return the subfield.

`SmallerFieldBasis(G)`

Given an absolutely irreducible matrix group G defined over a finite field K, which can be written over a proper subfield of K (possibly modulo scalars), return the change of basis matrix for G which rewrites G over the smaller field.

`SmallerFieldImage(G, g)`

Given an absolutely irreducible matrix group G defined over a finite field K, which can be written over a proper subfield of K (possibly modulo scalars), return the image of $g \in G$ in the group defined over the subfield.

Example H60E7

We define a subgroup of $\mathrm{GL}(3,8)$ which can be written over $\mathbf{F}_2$.

```
> G := GL (2, GF (3, 2));
> H := GL (2, GF (3, 8));
> K := sub < H | G.1, G.2 >;
> K;
MatrixGroup(2, GF(3^8))
Generators:
    [ $.1^820        0]
    [       0        1]

    [       2        1]
    [       2        0]
> flag, M := IsOverSmallerField (K);
> flag;
true
> M;
MatrixGroup(2, GF(3^2))
Generators:
    [$.1^7 $.1^2]
    [    1     2]

    [$.1^7 $.1^6]
    [$.1^2 $.1^5]
> F := GF(3, 4);
> G := MatrixGroup<2, F | [ F.1^52, F.1^72, F.1^32, 0 ],
>                                 [ 1, 0, F.1^20, 2 ] >;
> flag, X := IsOverSmallerField (G);
> flag;
false
```

We now see if G has an equivalent representation modulo scalars.

```
> flag, X := IsOverSmallerField (G: Scalars := true);
> flag;
true
> X;
MatrixGroup(2, GF(3))
Generators:
    [2 1]
    [1 0]
    [2 1]
    [1 1]
> SmallerField (G);
Finite field of size 3
> SmallerFieldBasis (G);
[F.1^33 F.1^23]
[F.1^43 F.1^63]
```

```
> g := G.1 * G.2^2; g;
[F.1^52 F.1^72]
[F.1^32      0]
> SmallerFieldImage (G, g);
[1 2]
[2 0]
```

`WriteOverSmallerField(G, F)`

Given a group G of $d \times d$ matrices over a finite field E having degree e and a subfield F of E having degree f, write the matrices of G as de/f by de/f matrices over F and return the group and the isomorphism.

Example H60E8

We define the group $\mathrm{GL}(2, 4)$ and then rewrite in over $\mathbf{F}_2$ as a degree 4 matrix group.

```
> G := GL(2, 4);
> H := WriteOverSmallerField(G, GF(2));
> H;
MatrixGroup(4, GF(2))
Generators:
    [0 1 0 0]
    [1 1 0 0]
    [0 0 1 0]
    [0 0 0 1]

    [1 0 1 0]
    [0 1 0 1]
    [1 0 0 0]
    [0 1 0 0]
```

60.4.8 Decompositions with Respect to a Normal Subgroup

`SearchForDecomposition(G, S)`

Given a matrix group G defined over a finite field and a sequence S of elements of G, this intrinsic first constructs the normal closure N of S in G. It then seeks to decide whether or not G, with respect to N, has a decomposition corresponding to one of the categories (ii)–(vi) in the theorem of Aschbacher stated at the beginning of this section. Theoretical details of the algorithms used may be found in Holt, Leedham-Green, O'Brien, and Rees [HLGOR96a].

In summary, it tests for one of the following possibilities:

(ii) G acts semilinearly over an extension field L of K, and N acts linearly over L;

(iii) G acts imprimitively on V and N fixes each block of imprimitivity;

(iv) G preserves a tensor product decomposition $U \otimes W$ of V, where N acts as scalar matrices on U;

(v) N acts absolutely irreducibly on V and is an extraspecial p-group for some prime p, or a 2-group of symplectic type;

(vi) G preserves a tensor-induced decomposition $V = \otimes^m U$ of V for some $m > 1$, where N acts absolutely irreducibly on V and fixes each of the m factors.

If one of the listed decompositions is found, then the function *reports* the type found and returns `true`; if no decomposition is found with respect to N, then the function returns `false`. The answer provided by the function is conclusive for decompositions of types (ii)–(v), but a negative answer for (vi) is not necessarily conclusive.

Each test involves a decomposition of G with respect to the normal subgroup N (which may sometimes be trivial or scalar). In (ii), N is the subgroup of G acting linearly over the extension field irreducibly on V. In (iii), N is the subgroup which fixes each of the subspaces in the imprimitive decomposition of V. In (iv), it is the subgroup acting as scalar matrices on one of the factors in the tensor-product decomposition. In (v), N is already described, and in (vi), it is the subgroup fixing each of the factors in the tensor-induced decomposition (so N itself falls in Category (iv)).

If any one of these decompositions can be found, then it may be possible to obtain an explicit representation of G/N and hence reduce the study of G to a smaller problem. For example, in Category (iii), G/N acts as a permutation group on the subspaces in the imprimitive decomposition of V. Currently only limited facilities are provided to construct G/N.

Information about the progress of the algorithm can be output by setting the verbose flag `SetVerbose ("Smash", 1)`.

60.4.8.1 Accessing the Decomposition Information

The access functions described in the sections on Primitivity Testing, Semilinearity, Tensor Products, Tensor Induction, and Normalisers of extraspecial groups may be used to extract information about decompositions of type (ii), (iii), (iv), (v) and (vi). We illustrate such decompositions below.

Example H60E9

We begin with an example where no decomposition exists.

```
> G := GL(4, 5);
> SearchForDecomposition (G, [G.1]);
Smash: No decomposition found
false
```

The second example is of an imprimitive decomposition.

```
> M := GL (4, 7);
> P := Sym (3);
> G := WreathProduct (M, P);
> SearchForDecomposition (G, [G.1, G.2]);
Smash: G is imprimitive
true
> IsPrimitive (G);
false
> BlocksImage (G);
Permutation group acting on a set of cardinality 3
    Id($)
    Id($)
    (1, 2, 3)
    (1, 2)
```

The third example admits a semilinear decomposition.

```
> P := GL(6,3);
> g1 := P![0,1,0,0,0,0,-1,0,0,0,0,0,
>          0,0,1,0,0,0,0,0,0,1,0,0,0,0,0,0,1,0,0,0,0,0,0,1];
> g2 := P![-1,0,0,0,1,0,0,-1,0,0,0,1,
>          -1,0,0,0,0,0,0,-1,0,0,0,0,0,0,-1,0,0,0,0,0,0,-1,0,0];
> g3 := P![1,0,0,0,0,0,0,-1,0,0,0,0,
>          0,0,1,0,0,0,0,0,0,-1,0,0,0,0,0,0,1,0,0,0,0,0,0,-1];
> G := sub <P | g1, g2, g3 >;
>
> SearchForDecomposition (G, [g1]);
Smash: G is semilinear
true
> IsSemiLinear (G);
true
> DegreeOfFieldExtension (G);
2
```

```
> CentralisingMatrix (G);
[2 2 0 0 0 0]
[1 2 0 0 0 0]
[0 0 2 2 0 0]
[0 0 1 2 0 0]
[0 0 0 0 2 2]
[0 0 0 0 1 2]
> FrobeniusAutomorphisms (G);
[ 1, 1, 3 ]
```

The fourth example admits a tensor product decomposition.

```
> F := GF(5);
> G := GL(5, F);
> H := GL(3, F);
> P := GL(15, F);
> A := MatrixAlgebra (F, 5);
> B := MatrixAlgebra (F, 3);
> g1 := A!G.1; g2 := A!G.2;  g3 := A!Identity(G);
> h1 := B!H.1; h2 := B!H.2; h3 := B!Identity(H);
> w := TensorProduct (g1, h3);
> x := TensorProduct (g2, h3);
> y := TensorProduct (g3, h1);
> z := TensorProduct (g3, h2);
> G := sub < P | w, x, y, z>;
> SearchForDecomposition (G, [G.1, G.2]);
Smash: G is a tensor product
true
> IsTensor (G);
true
> TensorBasis (G);
[1 0 0 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 1 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 0 0 1 0 0 0 0 0]
[4 0 1 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 4 0 1 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 4 0 1 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 0 0 4 0 1]
[0 0 0 0 0 0 0 0 0 4 0 1 0 0 0]
[1 4 4 0 0 0 0 0 0 0 0 0 0 0 0]
[0 0 0 1 4 4 0 0 0 0 0 0 0 0 0]
[0 0 0 0 0 0 1 4 4 0 0 0 0 0 0]
[0 0 0 0 0 0 0 0 0 0 0 0 1 4 4]
[0 0 0 0 0 0 0 0 0 1 4 4 0 0 0]
```

Our fifth example is of a tensor-induced decomposition.

```
> M := GL (3, GF(2));
```

```
> P := Sym (3);
> G := TensorWreathProduct (M, P);
> SearchForDecomposition (G, [G.1]);
Smash: G is tensor induced
true
>
> IsTensorInduced (G);
true
> TensorInducedPermutations (G);
[ Id(P), Id(P), (1, 3, 2), (1, 3) ]
```

Our final example is of a normaliser of a symplectic group.

```
> F := GF(5);
> P := GL(4,F);
> g1 := P![ 1,0,0,0,0,4,0,0,2,0,2,3,3,0,4,3];
> g2 := P![ 4,0,0,1,2,4,4,0,1,0,1,2,0,0,0,1];
> g3 := P![ 4,0,1,1,0,1,0,0,0,1,3,4,0,4,3,2];
> g4 := P![ 2,0,4,3,4,4,2,4,0,1,3,4,4,2,0,1];
> g5 := P![ 1,1,3,4,0,0,3,4,2,0,0,4,3,1,3,4];
> g6 := P![ 2,0,0,0,0,2,0,0,0,0,2,0,0,0,0,2];
> G := sub < P | g1, g2, g3, g4, g5, g6 >;
> SearchForDecomposition (G, [G.4]);

60.5 Constructive Recognition for Simple Groups

For each finite non-abelian simple group S, we designate a specific *standard copy* of S. The standard copy has a designated set of *standard generators*. For example, the standard copy of $\mathrm{Alt}(n)$ is on n points; its standard generators are $(1,2,3)$ and either of $(3,\ldots,n)$ or $(1,2)(3,\ldots,n)$ according to the parity of n. For a projective representation, the standard copy is the quotient of a matrix group by its scalar subgroup. For example, the standard copy of $\mathrm{PSL}(n,q)$ is the quotient of $\mathrm{SL}(n,q)$ by its scalar subgroup.

To compute in a copy G of S, we first construct effective isomorphisms between G and its standard copy. We do this by finding generators in G that correspond to the standard generators of S under an isomorphism. More formally, a *constructive recognition algorithm* for a non-abelian simple group G (possibly with decorations) solves the following problem: construct an isomorphism ϕ from G to a standard copy S of G, such that $\phi(g)$ can be computed efficiently for every $g \in G$. This is done by constructing standard generators in both G and its standard copy S.

A *rewriting algorithm* for G solves the *constructive membership problem*: given $g \in U \geq G = \langle X \rangle$, decide whether or not $g \in G$, and if so express g as an SLP in X. (Here U is the generic overgroup of G, such as $\mathrm{GL}(d,q)$ or $\mathrm{Sym}(n)$.) The rewriting algorithm is used to make the isomorphism between S and G effective. To compute the image of an arbitrary element s of S in G, we first write s as an SLP in the standard generators of S and then evaluate the SLP in the copy of the standard generators in G.

To verify that the homomorphism from S to G is an isomorphism, we can evaluate in G a *standard presentation* for S on its standard generators. If the copy of the standard generators in G satisfy the presentation, then we have proved that we have an isomorphism.

For a detailed discussion of these topics, see [O'B11, LGO09].

`ClassicalStandardGenerators(type, d, q)`

This intrinsic produces the standard generators of Leedham-Green and O'Brien for the quasisimple classical group of specified type in dimension d over field of size q. The type is designated by the argument "type" which must be one of the strings "SL", "Sp", "SU", "Omega", "Omega-", or "Omega+". The standard generators defined a specific copy of a classical group and are defined in [LGO09] and [DLLGO13].

`ClassicalConstructiveRecognition(G : parameters)`

`Case`	MonStgElt	*Default :* "*unknown*"
`Randomiser`	GrpRandProc	*Default :*

The argument G must be a matrix group defined over a finite field such that $G = \langle X \rangle$ is conjugate to a quasisimple classical group in its natural representation in dimension at least 2. The intrinsic constructs a copy $\mathcal{S}$ in G of the generators defined by `StandardGenerators`. If G is quasisimple and classical, then the function returns

`true`, the standard generators $\mathcal{S}$, and SLPs for these in X; otherwise it returns `false`.

The result returned by the intrinsic `ClassicalType (G)` can be supplied using the optional parameter `Case`.

The parameter `Randomiser` allows the user to specify the random process that is be used to construct random elements and the SLPs returned for the standard generators are in the word group of this process. The default value of `Randomiser` is `RandomProcessWithWords(G)`.

The implementations for even and odd characteristic were developed by Heiko Dietrich and Eamonn O'Brien respectively.

`ClassicalChangeOfBasis(G)`

G is a classical group in its natural representation; return a change-of-basis matrix to conjugate the generators returned by `ClassicalStandardGenerators` to those returned by `ClassicalConstructiveRecognition` (G). The latter intrinsic must have been applied to G.

`ClassicalRewrite(G, gens, type, dim, q, g` : *parameters*`)`

`Method` MonStgElt *Default : "choose"*

Let G be a classical group of type `type`, which is one of the strings "SL", "Sp", "SU", "Omega", "Omega-", or "Omega+", with dimension `dim` over the field $\mathbf{F}_q$ generated by `gens` which satisfy `ClassicalStandardPresentation (type, dim, q)`. Further, let g be an element of `Generic`(G).

If $g \in G$, then the function returns `true` and an SLP for g in `gens`; if $g \notin G$ then the function searches for an SLP w such that $g{\cdot}$`Evaluate`$(w, gens)^{-1}$ centralizes G; if it is successful, it returns `false` and w. Otherwise the function returns `false, false`.

The function chooses one of the following methods:

(i) If G is in its natural representation and `gens` is `ClassicalStandardGenerators (type, dim, q)` then Elliot Costi's implementation [Cos09] is used.

(ii) If (i) is not valid, but G is an absolutely irreducible representation in the defining characteristic, then another implementation developed by Csaba Schneider is used. This implementation is based on the description given by Costi [Cos09].

(iii) If neither of (i) and (ii) is valid, then a "black-box" method, independent of the representation of G, developed by Csaba Schneider is used. This case is not yet implemented for orthogonal groups.

The optional parameter `Method` can be used to override the default choice of method. The possible values of `Method` are `CharP` and `BB`.

A description of the algorithm used in the defining characteristic case appears in [Cos09]; a short description of the black-box algorithm appears in [AMPS10]. The code was prepared for distribution by Csaba Schneider.

`ClassicalRewriteNatural(type, CB, g)`

This is a faster specialized verson of the intrinsic `ClassicalRewrite` discussed above; it is designed for classical groups in their **natural representation**.

The argument `type` must be one of the strings "SL", "Sp", "SU", "Omega", "Omega-", or "Omega+". Both `CB` and g are elements of some $\mathrm{GL}(d, q)$.

If g is a member of the group generated by `ClassicalStandardGenerators (type, d, q)`$^{\mathbf{CB}}$ then the function returns `true` and an SLP w such that `Evaluate (w, ClassicalStandardGenerators (type, d, q)`$^{\mathbf{CB}}$`)` $= g$. Otherwise the function returns `false, false`.

This algorithm was developed and implemented by Elliot Costi; the code was prepared for distribution by Csaba Schneider.

`ClassicalStandardPresentation(type, d, q : parameters)`

`Projective` BoolElt *Default :* `false`

Given the specification `type, d, q` of a quasisimple group G, this intrinsic constructs a presentation on the standard generators for G. The string `type` must be one of "SL", "Sp", "SU", "Omega", "Omega-", or "Omega+", while d is the dimension and q is the cardinality of the finite field. The presentations are described in [LGO]. The relations are returned as SLPs together with the parent SLPGroup.

If the parameter `Projective` is set to true, the intrinsic constructs a presentation for the corresponding projective group.

Example H60E10

As our first illustration, we produce standard generators for $\mathrm{SL}(6, 5^3)$:

```
> E := ClassicalStandardGenerators ("SL", 6, 5^3);
> E;
[
    [      0       1       0       0       0       0]
    [      4       0       0       0       0       0]
    [      0       0       1       0       0       0]
    [      0       0       0       1       0       0]
    [      0       0       0       0       1       0]
    [      0       0       0       0       0       1],

    [      0       0       0       0       0       1]
    [      4       0       0       0       0       0]
    [      0       4       0       0       0       0]
    [      0       0       4       0       0       0]
    [      0       0       0       4       0       0]
    [      0       0       0       0       4       0],

    [      1       1       0       0       0       0]
    [      0       1       0       0       0       0]
    [      0       0       1       0       0       0]
```

```
    [      0       0       0       1       0       0]
    [      0       0       0       0       1       0]
    [      0       0       0       0       0       1],

    [    $.1       0       0       0       0       0]
    [      0 $.1^123       0       0       0       0]
    [      0       0       1       0       0       0]
    [      0       0       0       1       0       0]
    [      0       0       0       0       1       0]
    [      0       0       0       0       0       1]
]
```

We now perform constructive recognition on $\mathrm{SL}(6, 5^3)$, and so obtain S, conjugate to E in $\mathrm{GL}(6, 5^3)$. Observe that the change-of-basis matrix returned by `ClassicalChangeOfBasis` performs this conjugation.

```
> G := SL (6, 5^3);
> f, S, W := ClassicalConstructiveRecognition (G);
> f;
true
> CB := ClassicalChangeOfBasis (G);
> E^CB eq S;
true
```

Note that W is list of SLPs expressing S in terms of defining generators of G.

```
> S eq Evaluate (W, [G.i: i in [1..Ngens (G)]]);
true
```

We next express a random element of G as a SLP in S and then check that the standard generators satisfy the standard presentation.

```
> g := Random (G);
> f, w := ClassicalRewriteNatural ("SL", CB, g);
> Evaluate (w, S) eq g;
true
>
> P, R := ClassicalStandardPresentation ("SL", 6, 5^3);
> Set (Evaluate (R, S));
{
    [      1       0       0       0       0       0]
    [      0       1       0       0       0       0]
    [      0       0       1       0       0       0]
    [      0       0       0       1       0       0]
    [      0       0       0       0       1       0]
    [      0       0       0       0       0       1]
}
```

We perform constructive recognition on a random conjugate of $\mathrm{Sp}(10, 3^6)$ and again check that the standard generators satisfy the standard presentation.

```
> G := RandomConjugate (Sp(10, 3^6));
```

```
> f, S, W := ClassicalConstructiveRecognition (G);
> f;
true
```

The return variable W is list of SLPs expressing S in terms of defining generators of G.

```
> S eq Evaluate (W, [G.i: i in [1..Ngens (G)]]);
true
>
> g := Random (G);
> CB := ClassicalChangeOfBasis (G);
> f, w := ClassicalRewriteNatural ("Sp", CB, g);
> Evaluate (w, S) eq g;
true
>
> P, R := ClassicalStandardPresentation ("Sp", 10, 3^6);
> Set (Evaluate (R, S));
{
    [1 0 0 0 0 0 0 0 0 0]
    [0 1 0 0 0 0 0 0 0 0]
    [0 0 1 0 0 0 0 0 0 0]
    [0 0 0 1 0 0 0 0 0 0]
    [0 0 0 0 1 0 0 0 0 0]
    [0 0 0 0 0 1 0 0 0 0]
    [0 0 0 0 0 0 1 0 0 0]
    [0 0 0 0 0 0 0 1 0 0]
    [0 0 0 0 0 0 0 0 1 0]
    [0 0 0 0 0 0 0 0 0 1]
}
```

As another demonstration, we constructively recognise $\Omega^-(16, 2^6)$.

```
> G := RandomConjugate (OmegaMinus (16, 2^6));
> f, S, W := ClassicalConstructiveRecognition (G);
> f;
true
```

A random element of G is expressed as an SLP in S:

```
> g := Random (G);
> CB := ClassicalChangeOfBasis (G);
> f, w := ClassicalRewriteNatural ("Omega-", CB, g);
> Evaluate (w, S) eq g;
true
```

Finally, we illustrate using `ClassicalRewrite` to write an element of a classical group in a non-natural representation as an SLP in its standard generators.

```
> gens := [ExteriorSquare (x) : x in ClassicalStandardGenerators ("Sp", 6, 25)];
> G := sub<Universe (gens) | gens>;
> x := Random (G);
```

```
> f, w := ClassicalRewrite (G, gens, "Sp", 6, 25, x);
> f;
true
> Evaluate (w, gens) eq x;
true
> f, w := ClassicalRewrite (G, gens, "Sp", 6, 25, x : Method := "BB");
> f;
true
> Evaluate (w, gens) eq x;
true
```

60.6 Composition Trees for Matrix Groups

A *composition tree* for a group G can be viewed as a data structure that present a group in terms of its composition factors. The tree is constructed recursively and the data structure facilitates the rewriting of elements of G in terms of different generating sets.

The basic strategy for computing a *composition tree* of a matrix group employs a combination of a constructive version of Aschbacher's theorem [Asc84] and constructive recognition algorithms for finite simple groups. The basic algorithms are described in [LG01, O'B06, O'B11] while some new ideas introduced in [NS06] are incorporated. A detailed account of the entire *CompositionTree* procedure appears in [BHLGO11].

The algorithm to construct a composition tree proceeds as follows. Given a group G, either:

(i) Construct an effective homomorphism $\phi : G \to G_1$, for some group G_1. We call ϕ a *reduction* since G_1 is "smaller" than G in some respect – for example, its degree or field of definition.

(ii) Or deduce that G is cyclic, elementary abelian, or "close" to being non-abelian simple. Now G becomes a *leaf* in the tree.

Assume that Case (i) applies.

1. Now construct a composition tree for G_1.
2. Construct generators for $G_0 := \mathrm{Ker}(\phi)$. This requires a rewriting algorithm for G_1.
3. Construct a composition tree for G_0.
4. Combine the composition trees for G_1 and G_0 into a tree for G.

If $G \leq \mathrm{GL}(d, q)$, then we exploit Aschbacher's theorem [Asc84] in Step (1). This requires algorithms to decide if G lies in a certain Aschbacher class, and to construct the corresponding ϕ. Other homomorphisms, such as the determinant map, may also be used.

The group associated with a leaf need not be simple. It may be cyclic or elementary abelian, a soluble or non-abelian simple primitive permutation group, or an absolutely irreducible matrix group that is simple modulo its centre. The decisions on just which

groups are treated as a leaves are partly dictated by complexity considerations, and partly based on the quality of available algorithms to process a leaf. For example, we observe no practical advantage flowing from refining a cyclic group to its composition factors.

Once a composition tree for $G = \langle X \rangle$ has been constructed, then a second list Y of *nice generators* are stored with G. We call $\langle Y \rangle$ the *nice group*. The intrinsic `CompositionTree` constructs the nice generators Y as SLPs in X. The rewriting algorithm solves rewriting problems on Y and the resulting SLPs can then be rewritten to provide SLPs on X.

The verbose flag `SetVerbose("CompositionTree", n)` with $n = 1, \ldots, 10$ may be used to print increasing levels of information on the progress of the functions.

`CompositionTree(G : parameters)`

`Verify`	BoolElt	*Default :* `false`
`Scalar`	FldFinElt	*Default :* 1
`KernelBatchSize`	RngIntElt	*Default :* 5
`MandarinBatchSize`	RngIntElt	*Default :* 100
`MaxHomFinderFails`	RngIntElt	*Default :* 1
`MaxQuotientOrder`	RngIntElt	*Default :* 10^6
`FastTensorTest`	BoolElt	*Default :* `true`
`MaxBSGSVerifyOrder`	RngIntElt	*Default :* 2000
`AnalysePermGroups`	BoolElt	*Default :* `false`
`KnownLeaf`	BoolElt	*Default :* `false`
`NamingElements`	RngIntElt	*Default :* 200
`UnipotentBatchSize`	RngIntElt	*Default :* 100
`PresentationKernel`	BoolElt	*Default :* `true`

Given a matrix group G defined over a finite field, this intrinsic constructs a composition tree for G and returns the tree.

`Verify`: If `true`, then verify correctness of the tree during construction.

`KernelBatchSize`: The number of normal generators used to construct the kernel of homomorphism.

`MandarinBatchSize`: The number of random elements used to check correctness of the outcome of Monte-Carlo algorithms.

`MaxHomFinderFails`: Assume a negative answer after this many failures of certain Monte Carlo algorithms.

`AnalysePermGroups`: If `false`, then always treat the permutation group as a leaf, and do not analyse its structure.

`NamingElements`: The number of random elements used in calls to `LieType` and `RecogniseClassical`.

`MaxQuotientOrder`: A leaf with larger order will not be fully refined to its composition factors.

`FastTensorTest`: Use only the fast tensor product test.

`MaxBSGSVerifyOrder`: If `RandomSchreier` is used on a leaf and it has order less than `MaxBSGSVerifyOrder`, then `Verify` the calculation.

`PresentationKernel`: Use presentations to obtain kernels, where possible.

`UnipotentBatchSize`: Batch size for the unipotent kernels.

`CompositionTreeFastVerification(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. The intrinsic determines if correctness of the composition tree can be verified at modest cost using presentations. In effect, the intrinsic determines whether presentations on nice generators are known for all the leaves.

`CompositionTreeVerify(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. The intrinsic verifies the correctness of the composition tree by using it to construct a presentation for G. If G satisfies the presentation, then return `true`, and the relators of the presentation as SLPs; otherwise return `false`. The presentation is on the group returned by `CompositionTreeNiceGroup`(G).

`CompositionTreeNiceGroup(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. The intrinsic returns the nice group for G.

`CompositionTreeSLPGroup(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure and the associated nice group H has previously been constructed. The intrinsic returns the word group W for H, and the map from W to H.

`DisplayCompTreeNodes(G :` *parameters*`)`

`NonTrivial`	BoolElt	*Default :* `true`
`Leaves`	BoolElt	*Default :* `false`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic displays information about the nodes in the composition tree for G. The tree is traversed in-order. If parameter `NonTrivial` is `true`, then only non-trivial nodes will be displayed. If parameter `Leaves` is `true` then only leaves will be displayed.

`CompositionTreeNiceToUser(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns the coercion map from SLPs in nice generators of G to SLPs in input user generators of G, as well as the SLPs of the nice generators given in terms the user generators.

`CompositionTreeOrder(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns the order of G.

`CompositionTreeElementToWord(G, g)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. Given an element $g \in G$, return `true` and an SLP for g in the nice generators of G, otherwise return `false`.

`CompositionTreeCBM(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns a change-of-basis matrix that exhibits the Aschbacher reductions of G given by the composition tree.

`CompositionTreeReductionInfo(G, t)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns a string description of the reduction at the internal node t in the composition tree for G, as well as the image and kernel of this reduction.

`CompositionTreeSeries(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns:

1. A normal series of subgroups $1 = G_0 < G_1 < ... < G_k = G$.
2. Maps $G_i \mapsto S_i$, where S_i is the standard copy of G_i/G_{i-1}, where $i \geq 1$. The kernel of this map is G_{i-1}. Observe that S_i may be the standard copy plus scalars Z, and the map is then a homomorphism modulo scalars, so that the kernel is $(G_{i-1}.Z)/Z$.
3. Maps $S_i \mapsto G_i$.
4. Maps $S_i \mapsto$ `WordGroup`(S_i).
5. Boolean flag `true` or `false` to indicate if the series is a true composition series.
6. A sequence of the leaf nodes in the composition tree corresponding to each composition factor. All maps are defined by rules, so `Function` can be applied on them to avoid built-in membership testing.

`CompositionTreeFactorNumber(G, g)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic returns the minimal integer i such that g lies in the ith-term of the normal series returned by `CompositionTreeSeries` for G.

`HasCompositionTree(G)`

Given a matrix group G defined over a finite field, this intrinsic returns `true` if G has a composition tree and `false` otherwise.

`CleanCompositionTree(G)`

The argument G must be a matrix group over a finite field for which a composition tree datastructure has previously been constructed. This intrinsic removes all data related to the composition tree datastructure for G.

Example H60E11

We construct a composition tree for the conformal orthogonal group G of plus type of degree 4 over $\mathbf{F}_{5^2}$.

```
> G := CGOPlus(4, 5^2);
>
> T := CompositionTree(G);
>
> DisplayCompTreeNodes (G: Leaves:=true);
node = 2
parent = 1
depth = 1
scalar = 1
info = leaf, GrpAb, cyclic group, order 12
fast verify = true
----------
node = 4
parent = 3
depth = 2
scalar = 1
info = leaf, GrpAb, cyclic group, order 4
fast verify = true
----------
node = 7
parent = 6
depth = 4
scalar = 12
info = leaf, GrpAb, cyclic group, order 24
fast verify = true
----------
node = 8
parent = 6
depth = 4
scalar = 2
info = leaf, GrpMat, almost simple, <"A", 1, 25>
fast verify = true
----------
node = 9
```

```
parent = 5
depth = 3
scalar = 1
info = leaf, GrpMat, almost simple, <"A", 1, 25>
fast verify = true
----------
```

We now verify correctness of the composition tree. In order to show what is going on we illustrate various pieces of the verification process. We begin by setting up the nice group H for G and its associated SLP group; observe that $H = G$. After checking that verification can be done quickly, we perform the verification.

```
> H := CompositionTreeNiceGroup(G);
> W := CompositionTreeSLPGroup(G);
>
> CompositionTreeFastVerification(G);
true
>
> f, R := CompositionTreeVerify(G);
> #R;
73
```

At this point we have verified correctness. However, we now explicitly evaluate the relations R on the generators of H. This step has already been performed by `CompositionTreeVerify` so it is shown here just for demonstration purposes.

```
> Set(Evaluate(R, [H.i:i in [1..Ngens(H)]]));
{
    [     1      0      0      0]
    [     0      1      0      0]
    [     0      0      1      0]
    [     0      0      0      1]
}
```

Now that we know that the composition tree is correct, we ask for the order of G.

```
> CompositionTreeOrder(G);
11681280000
```

Express the element g of G as a SLP on the generators of the nice group H.

```
> g := Random(G);
> f, w := CompositionTreeElementToWord(G, g);
> Evaluate(w, [H.i:i in [1..Ngens(H)]]) eq g;
true
```

Rewrite the SLP in terms of the user-supplied generators for G.

```
> tau := CompositionTreeNiceToUser(G);
> tau;
```

```
Mapping from: GrpSLP: W to SLPGroup(5)
```

Images of elements of W under *tau* lie in `WordGroup`(G).

```
> v := tau(w);
> Evaluate (v, [G.i : i in [1..Ngens(G)]]) eq g;
true
```

Test a random element of the generic group for G for membership. (The generic group will be the general linear group $\mathrm{GL}(4, 5^2)$.)

```
> x := Random(Generic(G));
> f, w := CompositionTreeElementToWord(G, x);
> f;
false
```

Finally, we construct a normal series for G and locate a random element within this series.

```
> CS, _, _, _, flag := CompositionTreeSeries(G);
> "Series is composition series? ", flag;
Series is composition series?  true
> "Length is ", #CS;
Length is  10
>
> g := Random(G);
> CompositionTreeFactorNumber(G, g);
10
```

Example H60E12

In this example, we choose a maximal subgroup of the linear group $SL(10, 2^8)$ and compute its composition tree.

```
> X := ClassicalMaximals ("L", 10, 2^8);
> G := X[1];
>
> T := CompositionTree (G);
>
> DisplayCompTreeNodes (G: Leaves:=true, NonTrivial:=true);
node = 6
parent = 5
depth = 5
scalar = 1
info = leaf, GrpAb, cyclic group, order 255
fast verify = true
----------
node = 9
parent = 8
depth = 5
scalar = 1
info = leaf, GrpMat, almost simple, <"A", 8, 256>
```

```
fast verify = true
----------
node = 13
parent = 12
depth = 3
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 15
parent = 14
depth = 4
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 17
parent = 16
depth = 5
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 19
parent = 18
depth = 6
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 21
parent = 20
depth = 7
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 23
parent = 22
depth = 8
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 25
parent = 24
depth = 9
scalar = 1
```

```
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 27
parent = 26
depth = 10
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
node = 29
parent = 28
depth = 11
scalar = 1
info = leaf, GrpPC, abelian group, order 256
fast verify = true
----------
```

We now set up the nice group H for G and its associated SLP group; observe that $H = G$.

```
> H := CompositionTreeNiceGroup(G);
> "# of generators of H is ", Ngens(H);
# of generators of H is  77
> W := CompositionTreeSLPGroup(G);
```

After checking that correctness of the composition tree can be verified quickly, we perform verification.

```
> CompositionTreeFastVerification(G);
true
> f, R := CompositionTreeVerify(G);
> #R;
3028
```

Evaluate the relations on the generators of H.

```
> Set (Evaluate (R, [H.i:i in [1..Ngens (H)]]));
{
    [1 0 0 0 0 0 0 0 0 0]
    [0 1 0 0 0 0 0 0 0 0]
    [0 0 1 0 0 0 0 0 0 0]
    [0 0 0 1 0 0 0 0 0 0]
    [0 0 0 0 1 0 0 0 0 0]
    [0 0 0 0 0 1 0 0 0 0]
    [0 0 0 0 0 0 1 0 0 0]
    [0 0 0 0 0 0 0 1 0 0]
    [0 0 0 0 0 0 0 0 1 0]
    [0 0 0 0 0 0 0 0 0 1]
```

```
}
```

Express the element g of G as a SLP on the generators of the nice group H. Then rewrite the SLP in terms of user generators for G.

```
> g := Random (G);
> f, w := CompositionTreeElementToWord (G, g);
> Evaluate (w, [H.i:i in [1..Ngens (H)]]) eq g;
true
>
> tau := CompositionTreeNiceToUser (G);
> tau;
Mapping from: GrpSLP: W to SLPGroup(4)
>
> v := tau (w);
> Evaluate (v, [G.i : i in [1..Ngens (G)]]) eq g;
true
```

Next test a random element of the generic group of G for membership of G.

```
> x := Random (Generic (G));
> f, w := CompositionTreeElementToWord (G, x);
> f;
false
```

Finally, we construct a normal series for G.

```
> CS, _, _, _, flag := CompositionTreeSeries (G);
> "Series is composition series? ", flag;
Series is composition series?  true
> "Length is ", #CS;
Length is  78
```

60.7 The LMG functions

The LMG (large matrix group) functions are designed to provide a user-friendly interface to the `CompositionTree` package, and thereby enable the user to carry out a limited range of structural calculations in a matrix group that is too large for the use of BSGS methods.

By default, these methods have a small probability of failing or even of returning incorrect results. For most examples, at the cost of some extra time, the user can ensure that the computed results are verified as correct by calling `LMGInitialise` with the `Verify` flag on the group G before calling any of the other functions. (Once `CompositionTree` or any of the LMG functions has been called on a group, further calls of `LMGInitialise` will have no effect.)

Let G be a matrix group over a finite field. On the first call of any of the LMG functions on G, MAGMA decides whether it will use BSGS or Composition Tree based methods on G. It does this by carrying out a quick calculation to decide whether any of the basic orbit lengths would be larger than a constant `LMGSchreierBound`, which is

set to 40000 by default, but can be changed by the user. If all basic orbit lengths are at most `LMGSchreierBound`, then BSGS methods are used on G, and the LMG functions are executed using the corresponding standard MAGMA functions. Otherwise, Composition Tree methods are used, starting with a call of `CompositionTree`(G).

Composition Tree methods are also used if the user calls `CompositionTree` on the group before using th LMG functions, or if the user calls `LMGInitialize` with the `Al` option set to `"CompositionTree"`.

`SetVerbose("LMG", n)` with $n = 1, 2$ or 3 will provide increasing levels of information on the progress of the functions.

`SetLMGSchreierBound(n)`

Set the constant `LMGSchreierBound` to n.

`LMGInitialize(G : parameters)`

`LMGInitialise(G : parameters)`

`Al`	MONSTGELT	*Default :* ""
`Verify`	BOOLELT	*Default :* `false`
`RandomSchreierBound`	RNGINTELT	*Default :* `LMGSchreierBound`

It is not normally necessary to call this function but, by setting the optional parameters, it can be used to initialise G for LMG computations with a different value of `LMGSchreierBound` or, by setting `Al` to be `"CompositionTree"` (or `"CT"` or `"RandomSchreier"` (or `"RS"`), to force the use of either Composition Tree or BSGS methods on G.

If the `Verify` flag is set, then an attempt will be made to verify the correctness of the computed BSGS or Composition Tree. This will make the initialisation process slower, and for some groups the increased memory requirements will make verification impractical. In that case, a warning message is displayed.

`LMGOrder(G)`

Given a matrix group G defined over a finite field, this intrinsic returns the order of G.

`LMGFactoredOrder(G)`

Given a matrix group G defined over a finite field, this intrinsic returns the factored order of G.

`LMGIsIn(G, x)`

Given a matrix group G defined over a finite field $\mathbf{F}_{n,q}$ of G, the intrinsic returns `true` if x is in G and `false` otherwise.

`LMGIsSubgroup(G, H)`

Given a matrix group G defined over a finite field $\mathbf{F}_{n,q}$ of G, the intrinsic returns `true` if $H \leq G$ and `false` otherwise.

`LMGEqual(G, H)`

Given a matrix groups G and H belonging to a common overgroup $\mathrm{GL}(n, q)$, the intrinsic returns `true` if G and H are equal and `false` otherwise.

`LMGIndex(G, H)`

Given a matrix group G defined over a finite field, and a subgroup H of G, the intrinsic returns the index of H in G.

`LMGIsNormal(G, H)`

Given a matrix group G defined over a finite field, and a subgroup H of G, the intrinsic returns `true` if H is normal in G and `false` otherwise.

`LMGNormalClosure(G, H)`

Given a matrix group G defined over a finite field, and a subgroup H of G, the intrinsic returns the normal closure of H in G.

`LMGDerivedGroup(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the derived subgroup of G.

`LMGCommutatorSubgroup(G, H)`

Let g and H be subgroups of $\mathrm{GL}(n, q)$. This intrinsic returns the commutator subgroup of G and H as a subgroup of $\mathrm{GL}(n, q)$.

`LMGIsSoluble(G)`
`LMGIsSolvable(G)`

Given a matrix group G defined over a finite field, the intrinsic returns `true` if G is soluble and `false` otherwise.

`LMGIsNilpotent(G)`

Given a matrix group G defined over a finite field, the intrinsic returns `true` if G is nilpotent and `false` otherwise.

`LMGCompositionSeries(G)`

Given a matrix group G defined over a finite field, the intrinsic returns a composition series for G.

`LMGCompositionFactors(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the composition factors of G. The Handbook entry for `CompositionFactors(G)` of a finite group gives a detailed description of how to interpret the returned sequence.

`LMGChiefSeries(G)`

Given a matrix group G defined over a finite field, the intrinsic returns a chief series for G.

`LMGChiefFactors(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the chief factors G. The Handbook entry for `ChiefFactors(G)` of a finite group gives a detailed description of how to interpret the returned sequence.

`LMGUnipotentRadical(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the unipotent radical U of the matrix group G. A group P of type `GrpPC` and an isomorphism $U \to P$ are also returned.

`LMGSolubleRadical(G)`
`LMGSolvableRadical(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the soluble radical S of G. A group P of type `GrpPC` and an isomorphism $S \to P$ are also returned.

`LMGFittingSubgroup(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the Fitting subgroup S of G. A group P of type `GrpPC` and an isomorphism $S \to P$ are also returned.

`LMGCentre(G)`
`LMGCenter(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the centre of G.

`LMGSylow(G,p)`

Given a matrix group G defined over a finite field, the intrinsic returns a Sylow p-subgroup of G.

`LMGSocleStar(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the inverse image in G of the socle of G/S, where S is the soluble radical of G.

`LMGSocleStarFactors(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the simple direct factors of `LMGSocleStar(G)`/`LMGSolubleRadical(G)`, which may be represented projectively for large classical groups. A list of maps from the factors to G is also returned.

`LMGSocleStarAction(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the map ϕ representing the conjugation action of G on the simple direct factors of `LMGSocleStar(G)`/`LMGSolubleRadical(G)`. The image and kernel of ϕ are also returned.

`LMGSocleStarActionKernel(G)`

Given a matrix group G defined over a finite field, this intrinsic returns three values. The first is the kernel of the conjugation action of G on the simple direct factors of `LMGSocleStar(G)`/`LMGSolubleRadical(G)`. A group P of type `GrpPC` isomorphic to `LMGSocleStarActionKernel(G)`/`LMGSocleStar(G)` and the epimorphism $G \to P$ are also returned.

`LMGSocleStarQuotient(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the quotient group `G`/`LMGSocleStar(G)` represented as a permutation group, with associated epimorphism and kernel.

Example H60E13

We apply the LMG functions to a maximal subgroup of $\mathrm{SL}(12, 5)$.

```
> SetVerbose("LMG", 1);
> C := ClassicalMaximals("L", 12, 5);
> G := C[4];
> LMGFactoredOrder(G);
RandomSchreierBound is 40000
Using CompositionTree on this group
Composition tree computed
Composition series has length 40
Order of group is:  27845944957511377275508129969239234924316406250000000000000\
0000000000000000000
[ <2, 32>, <3, 7>, <5, 66>, <7, 1>, <11, 1>, <13, 3>, <31, 3>, <71, 1>, <313,
1>, <19531, 1> ]
> LMGChiefFactors(G);
Classifying composition factors
Defined PCGroup of solvable radical
Computed PCGroup of SocleKernel/SocleStar
    G
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  A(3, 5)                = L(4, 5)
    *
    |  A(7, 5)                = L(8, 5)
    *
```

```
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(5) (32 copies)
    1
> D := LMGDerivedGroup(G);
RandomSchreierBound is 40000
Using CompositionTree on this group
Composition tree computed
Composition series has length 38
Order of group is:  6961486239377844318877032492309808731079101562500000000000\
0000000000000000000
> LMGIndex(G, D);
4
> SetVerbose("LMG", 0);
> LMGEqual( LMGDerivedGroup(D), D );
true
> S := LMGSolubleRadical(G);
> LMGFactoredOrder(S);
[ <2, 4>, <5, 32> ]
> LMGIsSoluble(G);
false
> LMGIsSoluble(S);
true
> LMGIsNilpotent(S);
false
> #LMGCentre(G);
4
> #LMGCentre(S);
4
```

We carelessly used the standard Magma Order function in the above two commands, but it did not matter, because it was small. We will be more careful next time!

```
> F := LMGFittingSubgroup(G);
> LMGFactoredOrder( LMGCentre(F) );
[ <2, 2>, <5, 32> ]
> P := LMGSylow(G, 5);
> LMGFactoredOrder(P);
[ <5, 66> ]
> LMGEqual( D, LMGNormalClosure(G,P) );
true
> facs, maps := LMGSocleStarFactors(G);
> #facs;
```

```
2
> LMGChiefFactors(facs[1]);
    G
    |  A(7, 5)                = L(8, 5)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
```

Note that, for large classical groups, the socle-star factors are represented projectively.

```
> I := sub< Generic(G) | [ facs[2].i @ maps[2] : i in [1..Ngens(facs[2])] ] >;
> LMGChiefFactors( LMGNormalClosure(G, I) );
    G
    |  A(3, 5)                = L(4, 5)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *

    *
    |  Cyclic(5) (4 copies)
    *
    |  Cyclic(5) (4 copies)
    1
```

The remaining functions in this section will work only if a permutation representation can be computed for G/L, where L is the soluble radical of G. Apart from `LMGRadicalQuotient` itself, they all operate by solving the problem first in G/L and then lifting the solution through elementary abelian layers of L. Results are returned using the same formats as for other types of finite groups.

`LMGRadicalQuotient(G)`

Given a matrix group G defined over a finite field, the intrinsic returns a permutation group P isomorphic to G/L, where L is the soluble radical of G. An epimorphism $G \to P$ and its kernel L are also returned.

Of course, this will only work if G/L has such a representation of sufficiently small degree. This function is called implicitly as a first step in all of the remaining functions in this section.

`LMGCentraliser(G, g)`

`LMGCentralizer(G, g)`

Given a matrix group G defined over a finite field, the intrinsic returns the centraliser in the matrix group G of $g \in G$.

`LMGIsConjugate(G, g, h)`

Given a matrix group G defined over a finite field, the intrinsic returns `true` if the elements g, h in G are conjugate. If so, a conjugating element will also be returned.

`LMGClasses(G)`

`LMGConjugacyClasses(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the conjugacy classes of G.

`LMGNormaliser(G, H)`

`LMGNormalizer(G, H)`

Given a matrix group G defined over a finite field, and a subgroup H of G, the intrinsic returns the normaliser of H in G.

`LMGIsConjugate(G, H, K)`

Given a matrix group G defined over a finite field, and subgroups H and K of G, the intrinsic returns `true` if the subgroups H and K are conjugate in G. If so, a conjugating element will also be returned.

`LMGMaximalSubgroups(G)`

Given a matrix group G defined over a finite field, the intrinsic returns the maximal subgroups of G.

60.8 Unipotent Matrix Groups

The *power-conjugate presentation* is a very efficient way of representing a unipotent group; see Chapter 63 for more information. In this section we describe a number of functions for finding such a *PC-presentation* for a unipotent matrix group defined over a finite field.

The algorithm used is a straightforward echelonisation-like procedure.

`UnipotentMatrixGroup(G)`

Given a matrix group G defined over a finite field, the intrinsic constructs a known unipotent matrix group from G. Note that MAGMA does not at this stage check that G is in fact unipotent.

`WordMap(G)`

Given a unipotent matrix group G defined over a finite field, the intrinsic constructs the *word map* for G. The word map is a map from G to the group of straight-line programs on n generators, where n is the number of generators of G. More information on SLP-groups may be found in Chapter 76.

Example H60E14

We construct a unipotent matrix group, and use the word map.

```
> G := MatrixGroup<4, GF(5) | [1,1,0,0, 0,1,0,0, 0,0,1,0, 0,0,0,1],
>       [1,-1,0,0, 0,1,1,0, 0,0,1,0, 0,0,0,1]>;
> G;
MatrixGroup(4, GF(5))
Generators:
    [1 1 0 0]
    [0 1 0 0]
    [0 0 1 0]
    [0 0 0 1]

    [1 4 0 0]
    [0 1 1 0]
    [0 0 1 0]
    [0 0 0 1]
> IsUnipotent(G);
true
>
> G := UnipotentMatrixGroup(G);
> g := GL(4,5)![1,4,4,0, 0,1,3,0, 0,0,1,0, 0,0,0,1];
> g in G;
true
> phi := WordMap(G);
> phi;
Mapping from: GL(4, GF(5)) to SLPGroup(2) given by a rule [no inverse]
>
> assert g in G;
```

```
> wg := phi(g); wg;
function(G)
    w6 := G.1^4; w1 := G.1^-4; w2 := G.2 * w1; w7 := w2^3; w8 := w6 *
    w7; w3 := G.1^-1; w4 := G.1^w2; w5 := w3 * w4; w9 := w5^2; w10 :=
    w8 * w9; return w10;
end function
> Evaluate(wg, G);
[1 4 4 0]
[0 1 3 0]
[0 0 1 0]
[0 0 0 1]
> Evaluate(wg, G) eq g;
true
```

`PCPresentation(G)`

Given a unipotent matrix group G defined over a finite field, the intrinsic constructs a PC-presentation for G. It returns a finite soluble group H as first return value, a map from G to H as the second value, and a map from H to G as the third.

`Order(G)`
`#G`
`FactoredOrder(G)`

Given a unipotent matrix group G defined over a finite field, this intrinsic returns the order of G as an integer or as a factored integer (depending upon the choice of intrinsic). It is faster than the standard matrix group order intrinsic because of the use of the PC-presentation of G.

`g in G`

Given a matrix g and a unipotent matrix group G defined over a finite field, the intrinsic returns `true` if g is an element of G, and `false` otherwise. It is faster than the standard matrix group membership intrinsic because of the use of the PC-presentation of G.

Example H60E15

We construct the PC-presentation of some Sylow subgroup and demonstrate the use of the `FactoredOrder` function.

```
> G := UnipotentMatrixGroup(ClassicalSylow(GL(9,7), 7));
> H,phi,psi := PCPresentation(G);
> phi;
Mapping from: GrpMatUnip: G to GrpPC: H given by a rule [no inverse]
> psi;
Mapping from: GrpPC: H to GrpMatUnip: G
> phi(G.2);
```

```
H.9
> psi(H.3);
[1 0 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0]
[0 0 1 1 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0]
[0 0 0 0 1 0 0 0 0]
[0 0 0 0 0 1 0 0 0]
[0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 0 1]
> FactoredOrder(G);
[ <7, 36> ]
```

61 MATRIX GROUPS OVER INFINITE FIELDS

Chapter 61
MATRIX GROUPS OVER INFINITE FIELDS

61.1 Overview

In this chapter we provide algorithms for computing with a group G given by a finite set $S = \{g_1, \ldots, g_r\}$ of invertible $n \times n$ matrices over an infinite field K. The algorithms are based on special techniques developed for computing in this class of groups ([DF08, DF09, DFO09, DEF09, DFO12, DFO11]), which rely on properties of finitely generated linear groups.

The group G is defined over the subring R of K generated by the entries of the matrices $g_i, {g_i}^{-1}$, $1 \leq i \leq r$. If ρ is an ideal of R, then it induces a congruence homomorphism from $GL(n, R)$ onto $GL(n, R/\rho)$, which replaces every entry of an element in S by its image in R/ρ. Our techniques depend on the construction of a congruence homomorphism with the property that all torsion elements of its kernel G_ρ (called a congruence subgroup) are unipotent. The existence of a normal subgroup of finite index in G with such a property was proved by Selberg and Wehrfritz. One advantage of the congruence homomorphism techniques is that they replace the ground domain by a domain that is more convenient for computing. In particular, if the ideal ρ is maximal, then we get a reduction to a finite field R/ρ. For more details on the method see [DF08, Section 3].

In this chapter we provide three sets of functions based on the above techniques.

(a) Functions which test finiteness of matrix groups over a wide range of infinite domains. These functions are an implementation of algorithms developed in [DF09, DFO09, DFO12]. Together with other currently available algorithms for deciding finiteness, they enable testing finiteness of a finitely generated linear group over an arbitrary field (subject to special representation of input data). Additionally, if a group is found to be finite, then we can construct an isomorphic copy over a finite field, and use that for further structural investigation of the group.

(b) Functions for testing various properties of infinite matrix groups. These functions test whether G is soluble-by-finite or soluble, nilpotent-by-finite or nilpotent, abelian-by-finite, or central-by-finite. In effect, they provide access to the first publicly available implementations of algorithms to decide the "Tits alternative" for a linear group. If G is soluble-by-finite we can test whether it is completely reducible. These functions are an implementation of algorithms developed in [DFO11].

(c) Functions for testing nilpotency and computing with nilpotent matrix groups. These functions are an implementation of algorithms developed in [DF08], which in turn are based on an implementation of algorithms in [DF06] for computing with nilpotent matrix groups over finite fields. The functions may also be used for investigating the structure of nilpotent matrix groups. In particular, special algorithms have been developed for deciding finiteness of nilpotent matrix groups. Functions are also available to decide irreducibility and primitivity for finite nilpotent matrix groups over number fields and function fields

in zero characteristic; these algorithms, developed and implemented by Tobias Rossmann, are described in [Ros10, Ros11].

Since G is finitely generated, it is defined over a finitely generated subfield of K. Hence, the main fields to be considered are finite degree extensions of $F(x_1, \ldots, x_m)$, where the $x_1, \ldots, x_m$ are algebraically independent indeterminates, $m \geq 0$, and the coefficient field F is an number field or a finite field.

For a recent survey of work in the area of computing with matrix groups over infinite fields, we refer to [DEF09].

Verbose output for these functions can be obtained with `SetVerbose ("Infinite", 1);`

61.2 Construction of Congruence Homomorphisms

In this section, K is a finite degree extension of $F(x_1, \ldots, x_m)$, where F is Q, a number field, or a finite field. Also $m \geq 0$ if $charF = 0$, and $m > 0$ otherwise.

`CongruenceImage(G : parameters)`

`Virtual`	BoolElt	*Default :* `false`
`Prime`	RngIntElt	*Default :* 3
`Limit`	RngIntElt	*Default :* 10
`ExtDegree`	RngIntElt	*Default :* 1

If G is a finitely generated subgroup of $\mathrm{GL}(n, K)$, then G has a normal subgroup N whose torsion elements are unipotent; so N is torsion-free if K has characteristic 0.

This function constructs a *congruence homomorphism* from G into $\mathrm{GL}(n, \mathbf{F}_q)$ for some prime power q; its kernel is N. If $charK$ is positive, then $\mathbf{F}_q$ has the same characteristic.

For a detailed description of the congruence homomorphisms see [DFO12, Section 3]. The function returns the congruence image H, the congruence homomorphism, and the list of images of generators of G.

If the optional parameter `Virtual` is set to `true` then the congruence homomorphism satisfies additional properties [DFO11]. In particular it can be used to test whether G satisfies the "virtual" properties described in Section 61.4.

The optional parameter `Prime` applies if K has characteristic 0: if `Prime` is positive, then it is a lower bound for the characteristic of the congruence image; if it is 0 then the function returns a congruence image defined over a field of characteristic 0.

The optional parameter `Limit` applies to groups defined over (rational) function fields. If $charK > 0$, then we consider extensions of F to degree `Limit` only; otherwise we examine tuples in the ring of integers mod `Limit`.

The optional parameter `ExtDegree` applies to groups defined over (algebraic) function fields of positive characteristic: we construct a congruence image over an extension of (at least) this degree of coefficient field.

61.3 Testing Finiteness

In this section, K is a finite degree extension of the field $F(x_1, \ldots, x_m)$, where F is Q, a number field, or a finite field. Also $m \geq 0$ if $charF = 0$, and $m > 0$ otherwise.

`IsFinite(G : parameters)`

`NumberRandom`	RngIntElt	*Default :* 10
`Presentation`	MonStgElt	*Default :* "*CT*"
`Small`	RngIntElt	*Default :* 10^5
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Algebra`	BoolElt	*Default :* `true`
`Nilpotent`	BoolElt	*Default :* `false`
`UseCongruence`	BoolElt	*Default :* `false`
`DetermineOrder`	BoolElt	*Default :* `false`
`Prime`	RngIntElt	*Default :* 3

Let G be a finitely generated subgroup of $\mathrm{GL}(n, K)$. If G is finite then the function returns `true`, otherwise `false`. The function is an implementation of algorithms from [DFO12, DF09, DFO09, DF08].

The algorithm first tests whether `NumberRandom` random elements of G have finite order.

If the optional parameter `Algebra` is `true` and K is a function field of characteristic zero (resp. positive characteristic), then we use the "algebra algorithm" of [DF09] (resp. [DFO09]) to decide finiteness.

Otherwise, we prove that G is finite by first constructing a congruence homomorphism, then a presentation for the congruence image, and finally evaluates its relations to obtain normal generators for the congruence kernel. If $charK = 0$, then the kernel should be trivial, otherwise the kernel is unipotent.

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

If K is Q or a number field and `UseCongruence` is `true`, then use congruence homomorphism machinery to decide; otherwise use default algorithm.

If G is known to be nilpotent then by setting the optional parameter `Nilpotent` to `true`, the function will call a special procedure for testing finiteness of nilpotent groups (see [DF08, Section 4.3]).

If the optional parameter `DetermineOrder` is set to `true`, and G is finite, then the function returns the order of G. This may sometimes be more expensive than deciding finiteness.

The optional parameter `Prime` applies if K has characteristic 0: if `Prime` is positive, then it is a lower bound for the characteristic of the congruence image; if it is 0 then the function constructs a congruence image defined over a field of characteristic 0.

`IsomorphicCopy(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`Small`	RngIntElt	*Default :* 10^5
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Verify`	BoolElt	*Default :* `false`
`Algebra`	BoolElt	*Default :* `false`
`StartDegree`	RngIntElt	*Default :* 1
`EndDegree`	RngIntElt	*Default :* 5
`CompletelyReducible`	BoolElt	*Default :* `false`

The input is a finite subgroup G of $\mathrm{GL}(n, K)$. If the function succeeds, then it returns `true` and an isomorphic copy of G in $\mathrm{GL}(n, \mathbf{F}_q)$ where q is a prime power; otherwise it returns `false`. A description of the method used is in [DFO12, Section 4.3]. If $charK$ is positive, then $\mathbf{F}_q$ has the same characteristic. Note that the function always succeeds if K has zero characteristic.

If the optional parameter `Algebra` is `true` and K is a function field of characteristic zero (resp. positive characteristic), then we use the "algebra algorithm" of [DF09] (resp. [DFO09]) to construct an isomorphic copy.

Otherwise we prove that a congruence homomorphism is an isomorphism by constructing a presentation for the congruence image and evaluating its relations to obtain normal generators for the congruence kernel.

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

If the optional parameter `Verify` is set to `true` then we first check whether G is finite.

If the characteristic of the coefficient field F is positive, then we investigate extensions of F in the range `StartDegree` ... `EndDegree`.

If the optional parameter `CompletelyReducible` is set to `true` then we use a more efficient algorithm to construct the isomorphic copy.

`Order(G : parameters)`

`Verify`	BoolElt	*Default :* `false`
`UseCongruence`	BoolElt	*Default :* `false`

Given a finite subgroup G of $\mathrm{GL}(n, K)$, the function returns the order of G by applying `IsomorphicCopy` to G.

If the optional parameter `Verify` is set to `true`, then we first check that G is finite.

If K is Q or a number field and `UseCongruence` is `true`, then use congruence homomorphism machinery to decide; otherwise use default algorithm.

61.4 Deciding Virtual Properties of Linear Groups

In this section, K is a finite degree extension of $F(x_1, \ldots, x_m)$, where F is Q, a number field, or a finite field. Also $m \geq 0$ if $charF = 0$, and $m > 0$ otherwise.

We describe algorithms to decide various "virtual" properties of a finitely generated linear group over an infinite field. Details of the algorithms can be found in [DFO11].

`IsSolubleByFinite(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5

This function takes as input a finitely generated matrix group G over K, and tests whether G is soluble-by-finite. If so, it returns `true`, otherwise `false`. Note that currently the function is valid only for $p > n$ if K has characteristic $p > 0$.

The algorithm first constructs a congruence homomorphism, then a presentation for the congruence image, and finally evaluates its relations to obtain normal generators for the congruence kernel. For further details, see [DFO11, Section 3.2].

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

IsPolycyclicByFinite(G : *parameters*)

Presentation	MonStgElt	*Default :* "*CT*"
OrderLimit	RngIntElt	*Default :* 10^{12}
Small	RngIntElt	*Default :* 10^5

This function takes as input a finitely generated matrix group G over Z, and tests whether G is polycyclic-by-finite. If so, it returns `true`, otherwise `false`. See [DFO11, Section 3.2] for details.

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

IsNilpotentByFinite(G : *parameters*)

Presentation	MonStgElt	*Default :* "*CT*"
OrderLimit	RngIntElt	*Default :* 10^{12}
Small	RngIntElt	*Default :* 10^5

This function takes as input a finitely generated matrix group G over K, and tests whether G is nilpotent-by-finite. If so, it returns `true`, otherwise `false`. Here K must currently be Q, a number field, or an (algebraic) function field with a single indeterminate.

The algorithm first constructs a congruence homomorphism, then a presentation for the congruence image, and finally evaluates its relations to obtain normal generators for the congruence kernel. Further details of the algorithm can be found in [DFO11, Section 5.2].

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

`IsAbelianByFinite(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5

This function takes as input a finitely generated matrix group G over K, and tests whether G is abelian-by-finite. If so, it returns `true`, otherwise `false`. As before, K must currently be Q, a number field, or an (algebraic) function field with a single indeterminate.

The algorithm first constructs a congruence homomorphism, then a presentation for the congruence image, and finally evaluates its relations to obtain normal generators for the congruence kernel. Further details of the algorithm can be found in [DFO11, Section 5.2].

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

`IsCentralByFinite(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5
`CompletelyReducible`	BoolElt	*Default :* `false`

This function takes as input a finitely generated matrix group G over a field K, and tests whether G is central-by-finite. If so, it returns `true`, otherwise `false`. Here K is (a finite degree extension of) $F(x_1, \ldots, x_m)$, where F is Q or a number field.

The algorithm first constructs a congruence homomorphism, then a presentation for the congruence image, and finally evaluates its relations to obtain normal generators for the congruence kernel. Further details of the algorithm can be found in [DFO11, Section 5.3].

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional

argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

If the optional parameter `CompletelyReducible` is set to `true` then we use a more efficient algorithm to test whether G is central-by-finite.

61.5 Other Properties of Linear Groups

In this section, K is a finite degree extension of $F(x_1, \ldots, x_m)$, where F is Q, a number field, or a finite field, and $m \geq 0$.

`IsCompletelyReducible(G : parameters)`

`SolubleByFinite`	BoolElt	*Default :* `false`
`NilpotentByFinite`	BoolElt	*Default :* `false`
`AbelianByFinite`	BoolElt	*Default :* `false`
`Nilpotent`	BoolElt	*Default :* `false`
`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5

This function takes as input a finitely generated matrix group G over K, and tests whether G is completely reducible. If so, it returns `true`, otherwise `false`.

The algorithm used is described in [DFO11, Section 4]. It applies only if G is soluble-by-finite, nilpotent-by-finite, or abelian-by-finite. Hence one (and only one) of the four optional arguments `SolubleByFinite, NilpotentByFinite, AbelianByFinite, Nilpotent` must be true. In particular, if `Nilpotent` is set to be true, then a more efficient algorithm (from [DF08]) is used.

In positive characteristic p, if p divides the order of the congruence image of G then currently the algorithm cannot decide complete reducibility of G.

The optional parameter `Presentation` is used to dictate how the presentation is constructed. If its value is "CT", then we use the presentation provided by `CompositionTreeVerify`. If its value is "PC" and the image is soluble, then we use a PC-presentation provided by `LMGSolubleRadical`. If its value is "FP" then we use the presentation provided by `FPGroup` or `FPGroupStrong`. If the order of the congruence image is less than the value of the optional argument `Small`, then we use `FPGroup` to construct the presentation; if it is less than the value of the optional argument `OrderLimit`, then we use `FPGroupStrong` to construct the presentation; otherwise we use the presentation provided by `CompositionTreeVerify`.

`IsUnipotent(G)`

This function takes as input a finitely generated matrix group G defined over an exact field F, and tests whether G is unipotent, i.e., whether it is conjugate in $\mathrm{GL}(n, F)$ to a group of upper unitriangular matrices. If G is unipotent then the function returns `true` and a change-of-basis matrix $c \in \mathrm{GL}(n, F)$ such that G^c is upper unitriangular, otherwise `false`. See [DF06, Section 2.1] for details of the algorithm.

`IsNilpotent(G)`

Let G be a finitely generated subgroup of $\mathrm{GL}(n, K)$. This function returns `true` if G is nilpotent; otherwise it returns `false`. If K is finite then the function is an implementation of the algorithm of [DF06]. If K is infinite then the function is similar to the algorithm in [DF08], and is based on the construction of a homomorphic image H of G via `CongruenceImage`.

`IsSoluble(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5
`UseCongruence`	BoolElt	*Default :* `false`

Let G be a finitely generated subgroup of $\mathrm{GL}(n, K)$. This function returns `true` if G is soluble; otherwise it returns `false`. If K is infinite and has characteristic $p > 0$, then the algorithm is applicable only for $p > n$. For details see [DFO11, Section 3.2].

If K is Q or a number field and `UseCongruence` is `true`, then use congruence homomorphism machinery to decide; otherwise use default algorithm.

The other optional arguments are those described above for `IsSolubleByFinite`.

`IsPolycyclic(G : parameters)`

`Presentation`	MonStgElt	*Default :* "*CT*"
`OrderLimit`	RngIntElt	*Default :* 10^{12}
`Small`	RngIntElt	*Default :* 10^5

This function takes as input a finite matrix group G over Z, and tests whether G is polycyclic. If so, it returns `true`, otherwise `false`.

The optional arguments are those described above for `IsSolubleByFinite`.

`HasFiniteOrder (g : parameters)`

`UseCongruence`	BoolElt	*Default :* `false`

Let g be an invertible matrix defined over Z, Q, a number field, a function field, or an algebraic function field.

If g has finite order, then return `true` and, if known, a multiplicative upper bound for the order of g; else return `false`.

If g is defined over Z, Q, or a number field and `UseCongruence` is `true`, then use congruence homomorphism machinery to decide; otherwise use default algorithm.

61.6 Other Functions for Nilpotent Matrix Groups

`SylowSystem(G : parameters)`

`Verify` BoolElt *Default :* `false`

Given a nilpotent matrix group G over a finite field, this function constructs one Sylow p-subgroup for each prime p dividing $|G|$ using the algorithm of [DF06]. If the optional parameter `Verify` is set to `true`, then we first verify that G is nilpotent.

The next two functions were developed and implemented by Tobias Rossmann.

`IsIrreducibleFiniteNilpotent(G : parameters)`

`DecideOnly` BoolElt *Default :* `false`

`Verify` BoolElt *Default :* `false`

Let G be a finite nilpotent matrix group over K, where K is a number field or a rational function field over a number field. The function returns `true` if G is irreducible or `false` and a proper submodule of `GModule(G)`. The construction of a submodule can be suppressed by setting `DecideOnly` to `true`. If the optional parameter `Verify` is set to `true`, then the function checks if G is nilpotent and finite. The algorithm used for irreducibility testing is described in [Ros10a].

`IsPrimitiveFiniteNilpotent(G : parameters)`

`DecideOnly` BoolElt *Default :* `false`

`Verify` BoolElt *Default :* `false`

Let G be an irreducible finite nilpotent matrix group over K, where K is a number field or a rational function field over a number field. The function returns `true` if G is primitive, or `false` and a system of imprimitivity for G given as a sequence of subspaces of `RSpace(G)`. The construction of a system of imprimitivity can be suppressed by setting `DecideOnly` to `true`. If the optional parameter `Verify` is set to `true`, then the function checks if G is nilpotent and finite. The algorithm used for primitivity testing is described in [Ros10b].

61.7 Examples

Example H61E1

```
> Q := Rationals ();
> F<t>:= RationalFunctionField (Q);
> M:= MatrixAlgebra (F, 3);
> a:= M![-1, 2*t^2, -2*t^4 - 2*t^3 - 2*t^2, 0, 1, 0, 0, 0, 1];
> b:= M![1, 0, 0, 1/t^2, -1, (2*t^3 - 1)/(t - 1), 0, 0, 1];
> c:= M![t, -t^3 + t^2, t^5 - t^2 - t, t^2, -t^4, (t^8 - t^5 + 1)/
> (t^2 - t), (t - 1)/t, -t^2 + t, t^4 - t];
> G:= sub<GL(3,F)|a,b,c>;

62 MATRIX GROUPS OVER Q AND Z

Chapter 62
MATRIX GROUPS OVER Q AND Z

62.1 Overview

In addition to the functionality explained in Chapter 61 and the functions that are available for all finite (matrix) groups, MAGMA can also compute normalizers and centralizers of a finite integral matrix group G in $\mathrm{GL}_n(\mathbf{Z})$ as well as decide conjugacy in $\mathrm{GL}_n(\mathbf{Z})$ and $\mathrm{GL}_n(\mathbf{Q})$.

These algorithms are based on the sublattice machinery (see Section 31.3.5) and the enumeration of G-perfect forms. They are explained in [OPS98, Opg01]. The algorithms perform very well, as long as the space of G-invariant symmetric forms has small dimension (say less than 15) and the index of the groups in their Bravais groups is not too large.

The databases of maximal finite irreducible rational, integral, symplectic and quaternionic matrix groups are explained in Chapter 66.

62.2 Invariant Forms

Let G be a finite matrix group $G < \mathrm{GL}_n(\mathbf{Q})$. A matrix $F \in M_n(\mathbf{Q})$ is G-invariant if $gFg^{tr} = F$ for all $g \in G$.

`PositiveDefiniteForm(G)`

For a finite integral or rational matrix group G, return a positive definite symmetric G-invariant form.

`InvariantForms(G)`
`SymmetricForms(G)`
`AntisymmetricForms(G)`

For an integral or rational matrix group G, return a basis for the space of G-linear forms or for the subspace of (anti-) symmetric forms respectively.

The first form returned by `InvariantForms` and `SymmetricForms` will be positive definite.

`InvariantForms(G, n)`
`SymmetricForms(G, n)`
`AntisymmetricForms(G, n)`

For an integral or rational matrix group G, return a sequence consisting of $n \geq 0$ G-invariant (symmetric or antisymmetric) bilinear forms for G.

`NumberOfInvariantForms(G)`

`NumberOfSymmetricForms(G)`

`NumberOfAntisymmetricForms(G)`

For an integral or rational matrix group G or a G-lattice L, return the dimension of the space of (symmetric or anti-symmetric) invariant bilinear forms for G.

The algorithm uses a modular method which is much faster than the actual computation of the forms.

62.3 Endomorphisms

`EndomorphismRing(G)`

For an integral or rational matrix group G, return the endomorphism ring (i.e. the commuting algebra) of G as a subalgebra of $M_n(\mathbf{Z})$ or $M_n(\mathbf{Q})$ respectively.

`CentreOfEndomorphismRing(G)`

`CentreOfEndomorphismAlgebra(G)`

For an integral or rational matrix group G, return the center of the endomorphism ring (i.e. the commuting algebra) of G as a subalgebra of $M_n(\mathbf{Z})$ or $M_n(\mathbf{Q})$ respectively.

`DimensionOfEndomorphismRing(G)`

Return the dimension of the endomorphism ring of an integral or rational matrix group G by a modular method.

`DimensionOfCentreOfEndomorphismRing(G)`

Return the dimension of the centre of the endomorphism ring of an integral or rational matrix group G by a modular method.

`Endomorphisms(G, n)`

For an integral or rational matrix group G, return a sequence containing n independent endomorphisms of G. n must be in the range $[0..d]$, where d is the dimension of the endomorphism ring of G.

`CentralEndomorphisms(G, n)`

For an integral or rational matrix group G, return a sequence containing n independent central endomorphisms of G. n must be in the range $[0..d]$, where d is the dimension of the centre of the endomorphism ring of G.

62.4 New Groups From Others

`BravaisGroup(G)`

For a finite integral matrix group G, compute its Bravais group which is the integral group fixing all symmetric bilinear forms fixed by G.

`IntegralGroup(G)`

Return the action of the finite rational matrix group G on an invariant lattice as an integral matrix group, thus giving an equivalent integral group H, together with the transformation matrix T from the standard lattice to the invariant lattice. Thus $H = T \cdot G \cdot T^{-1}$.

62.5 Perfect Forms and Normalizers

`PerfectForms(G)`

`Limit` RngIntElt *Default :* ∞

A positive definite symmetric G-invariant form F is called G-perfect if for every nonzero symmetric G-invariant form F' there exists some shortest vector x of F such that $F'x^{tr}x$ has nonzero trace.

The normalizer of the Bravais group of G in $\mathrm{GL}_n(\mathbf{Z})$ acts on the set of integral G-perfect forms whose entries have GCD 1 and the number of orbits is finite. This function returns a sequence of representatives of these orbits.

If `Limit` is set to a positive integer m, then the algorithm stops after m orbits have been enumerated.

`NormalizerGLZ(G)`

`CentralizerGLZ(G)`

`IsBravais` BoolElt *Default :* `false`

Given a finite subgroup G of $\mathrm{GL}_n(\mathbf{Z})$, returns the normalizer or centralizer of G in $\mathrm{GL}_n(\mathbf{Z})$.

If G is know to be equal to its Bravais group, one can set `IsBravais` to `true` to speed up the computation.

The algorithm employed is a variation of Opgenorth's normalizer algorithm [Opg01].

62.6 Conjugacy

`ZClasses(G)`

`Homogeneously` BoolElt *Default :* `false`

Given a finite integral or rational matrix group G, its $\mathrm{GL}_n(\mathbf{Q})$-conjugacy class splits into finitely many $\mathrm{GL}(n, \mathbf{Z})$-conjugacy classes. Representatives of these classes are constructed as the action of G on some G-invariant sublattices. More precisely, the $\mathrm{GL}(n, \mathbf{Z})$-conjugacy classes are in bijection with the orbits of G-invariant lattices under the normalizer N of G in $\mathrm{GL}(n, \mathbf{Q})$.

A G-lattice L' belongs to a G-lattice L if $L = \sum_i L'e_i$ where $e_1, \ldots, e_r$ denote the central idempotents of the endomorphism ring of G. Further, L is called *homogeneously decomposable* if L belongs to itself.

The algorithm will first compute representatives $L_1, \ldots, L_k$ of the orbits of homogeneously decomposable G-lattices under the action of N.

In a second step, it will then compute the G-lattices $L_{i,j}$ belonging to L_i up to the action of N.

The second return value will then consist of a sequence of k sequences $T_1, \ldots, T_k$. The first element $T_i[1]$ is the basis matrix of L_i, the following entries are basis matrices of the lattices $L_{i,j}$.

The first return value is a sequence of integral matrix groups describing the action of G on the lattices $L_{1,1}, L_{1,2}, \ldots$. Hence these groups correspond to the $\mathrm{GL}_n(\mathbf{Z})$-conjugacy classes of G.

If `Homogeneously` is set to `true`, the function will only compute the homogeneously decomposable lattices $L_1, \ldots, L_k$ and the corresponding matrix groups. (If G is reducible, this option is much faster, but will not yield all conjugacy classes / orbits of lattices.)

`IsGLZConjugate(G, H)`

Tests whether the finite integral matrix groups G and H are conjugate in $\mathrm{GL}_n(\mathbf{Z})$. If so, a matrix x such that $G^x = H$ is also returned.

`IsBravaisEquivalent(G, H)`

Given two finite integral matrix groups G and H, tests whether their Bravais groups $B(G)$ and $B(H)$ are conjugate in $\mathrm{GL}_n(\mathbf{Z})$. If so, a matrix x such that $B(G)^x = B(H)$ is also returned.

Note that this function does not need to compute the Bravais groups and hence it is faster than calling `IsGLZConjugate` on the Bravais groups directly.

If G and H are known to be Bravais groups, this function is usually more efficient than calling `IsGLZConjugate`.

`IsGLQConjugate(G, H)`

`Al` MonStgElt *Default :*

Tests whether the finite rational matrix groups G and H are conjugate in $\mathrm{GL}_n(\mathbf{Q})$. If so, a matrix x such that $G^x = H$ is also returned.

There are currently two algorithms available. If the optional parameter `Al` equals `"Aut"`, Magma will use the `GModule`-machinery together with the outer automorphism group of H. If `Al` is set to `"ZClasses"`, Magma splits the $\mathrm{GL}(n, \mathbf{Q})$-conjugacy class of H into $\mathrm{GL}_n(\mathbf{Z})$-conjugacy classes and then decides whether an integral copy of G lies in one of these classes by several calls to `IsGLZConjugate`.

If `Al` is not provided, a sensible choice is made by the system.

62.7 Conjugacy Tests for Matrices

Given two $n \times n$ matrices A and B with rational or integral entries, Magma can test whether A is conjugate to B in $\mathrm{GL}_n(Z)$.

Currently, the implementation is limited to the cases where A, B have finite order or where $n = 2$. This limitation will be removed in future versions.

`IsGLZConjugate(A, B)`

`IsSLZConjugate(A, B)`

Tests whether two rational or integral matrices A and B are conjugate in $\mathrm{GL}_n(\mathbf{Z})$ or $\mathrm{SL}_n(\mathbf{Z})$. If so, a matrix x such that $A^x = B$ is also returned.

`CentralizerGLZ(A)`

Given a rational or integral matrix A, this function returns its centralizer in $\mathrm{GL}_n(\mathbf{Z})$. The current implementation is limited to the cases where either A has finite order or A is a 2×2 matrix.

62.8 Examples

Example H62E1

We split the $\mathrm{GL}_3(\mathbf{Q})$-conjugacy class of the following faithful representation of the dihedral group with 12 elements.

```
> G := MatrixGroup< 3, Integers() |
>  [ 1, -1, 0, 0, -1, 0, 0, 0, 1 ],
>  [ 1, -1, 0, 1, 0, 0, 0, 0, -1 ] >;
> Z, T:= ZClasses(G);
> #Z;
3
> < #t : t in T >;
```

```
<1, 2>
```

So there are 2 classes of homogeneously decomposable lattices represented by `T[1,1]` and `T[2,1]`. The third lattice `T[2,2]` belongs to `T[2,1]` as we check.

```
> Q := Rationals();
> GQ := ChangeRing(G, Q);
> Ids := CentralIdempotents(EndomorphismRing(GQ));
> L := VerticalJoin([ Matrix(Integers(), T[2,2] * i) : i in Ids]);
> Image(L) eq Image(Matrix(Integers(), T[2,1]));
true
```

Finally, we check that the 3 $\mathrm{GL}_3(\mathbf{Z})$-conjugacy classes stored in `Z` correspond to the 3 lattices in `T`.

```
> TT := &cat T;
> [ GQ eq ChangeRing(Z[i], Q)^(GL(3, Q) ! TT[i]) : i in [1..#Z] ];
[ true, true, true ]
```

Example H62E2

We test that the automorphism groups of the lattices B_8 and D_8 are conjugate in $\mathrm{GL}_8(\mathbf{Q})$ but not in $\mathrm{GL}_8(\mathbf{Z})$.

```
> G := AutomorphismGroup( Lattice("B", 8) );
> H := AutomorphismGroup( Lattice("D", 8) );
> ok, x := IsGLQConjugate(G, H); ok, x;
true
[ 1 -1  0  0  0  0  0  0]
[ 1 -1 -2  0  0  0  0  0]
[-1  1  2  2  2  2  2  2]
[ 1  1  0  0  0  0  0  0]
[-1  1  2  2  2  2  2  0]
[ 1 -1 -2 -2 -2  0  0  0]
[-1  1  2  2  2  2  0  0]
[-1  1  2  2  0  0  0  0]
> Determinant(x);
-128
> IsGLZConjugate(G,H);
false
```

Example H62E3

Let C be the companion matrix of the fifth cyclotomic polyomial. We find a unimodular matrix that induces the automorphism $C -> C^2$.

```
> C:= CompanionMatrix(CyclotomicPolynomial(5));
> ok, h:= IsGLZConjugate(C, C^2); ok;
true
> C^2 eq h^-1 * C * h;
```

```
true
```

We now check by hand that this automorphism cannot be realized by a matrix of determiant 1.

```
> Determinant(h);
-1
> G:= CentralizerGLZ(C);
> [ Determinant(g) : g in Generators(G) ];
[1, 1, 1]
```

Of course, we could also just ask:

```
> IsSLZConjugate(C, C^2);
false
```

63 FINITE SOLUBLE GROUPS

Chapter 63
FINITE SOLUBLE GROUPS

63.1 Introduction

Any finite soluble group has a subnormal series with cyclic factors. Such a series gives rise to various polycyclic presentations. These polycyclic presentations are useful because the word problem in such presentations can be solved in an algorithmic fashion. In MAGMA, we use the specific form called a *power-conjugate presentation (pc-presentation)*, which is described below. The MAGMA category of groups represented by a power-conjugate presentation (pc-groups for short) is called `GrpPC`.

This chapter describes how to use polycyclic presentations to compute with p-groups and other finite soluble groups in MAGMA. While most functions apply to any soluble group, a small number of functions specific to p-groups are identified in the text.

Over the past two decades a considerable body of efficient algorithms has been developed for computing with soluble groups defined in terms of pc-presentations. It is recommended that the `GrpPC` representation of a soluble group be used whenever intensive calculation with that group is necessary.

63.1.1 Power-Conjugate Presentations

Let G be a finite soluble group. A presentation for G of the form

$$< a_1, \ldots, a_n \mid a_j^{p_j} = w_{jj}, \quad 1 \leq j \leq n, \quad a_j^{a_i} = w_{ij}, \quad 1 \leq i < j \leq n >$$

where

(i) p_j is the least prime such that $a_j^{p_j} \in < a_{j+1}, \ldots, a_n >$ for $j < n$, and $a_j^{p_j}$ is the identity for $j = n$, and

(ii) w_{ij} is a word in the generators $a_{i+1}, \ldots, a_n$, will be called a *power-conjugate presentation (pc-presentation)* for G. The generators of G corresponding to $a_1, \ldots, a_n$ in this presentation are known as a *power-conjugate generating sequence (pc-generators)* for G.

It is easy to show that every finite soluble group possesses a pc-presentation. If such a presentation satisfies a certain additional condition (the *consistency condition*) then every element a of G can be written uniquely in the *normal form*

$$a_1^{\alpha_1} \ldots a_n^{\alpha_n}, 0 \leq \alpha_i < p_i \quad \text{for } i = 1, \ldots, n.$$

Given such a pc-presentation for G there exists an algorithm (the *collection algorithm*), which given an arbitrary word in the pc-generators $a_1, \ldots, a_n$, will determine the corresponding normal word. In particular, collection can be used to compute the normal word which is equal to the product of two given normal words, thus implementing the group multiplication.

63.2 Creation of a Group

A user can create a GrpPC representation of a finite soluble group in a variety of ways. There are several built-in construction functions for creating standard examples such as cyclic or dihedral groups. For greater flexibility, it is possible to define a group directly from a power-commutator presentation. One can also build new groups out of old groups using standard constructions such as direct product. Finally, there are several conversion functions which will automatically compute a pc-presentation for an existing soluble group in some other category (such as permutation group or matrix group). We will start with the first two styles of construction and describe the remaining two in later sections.

In each case, regardless of how the group was originally defined, MAGMA will store the group internally as a pc-presentation and will display the pc-presentation whenever the group is printed. Normally when printing a pc-presentation, trivial conjugate relations are omitted. In the case of a p-group, then trivial power relations (those indicating that a generator has order p) are also omitted. The one exception to this policy is in the case of elementary abelian p-groups (which would have no relations displayed under the above policies). In the elementary abelian case, MAGMA will display the power relations, even though they are trivial.

63.2.1 Construction Functions

The simplest method of producing a pc-presentation for a group is to use one of the built-in construction functions. By specifying the category GrpPC as the first parameter of each function, we produce the desired representation.

It is also possible to obtain a pc-presentation for many small soluble groups by using the function SmallGroup described in Chapter 66.

`CyclicGroup(GrpPC, n)`

The cyclic group of order n as a pc-group.

`AbelianGroup(GrpPC, Q)`

Construct the abelian group defined by the sequence $Q = [n_1, \ldots, n_r]$ of positive integers as a pc-group. The function returns the abelian group which is the direct product of the cyclic groups $C_{n_1} \times C_{n_2} \times \cdots \times C_{n_r}$.

`DihedralGroup(GrpPC, n)`

The dihedral group of order $2 * n$ as a pc-group.

`ExtraSpecialGroup(GrpPC, p, n : parameters)`

Given a small prime p and a small positive integer n, construct an extra-special group G of order p^{2n+1} in the category GrpPC. The isomorphism type of G may be selected using the parameter Type.

Type MONSTGELT *Default :* "+"

Possible values for this parameter are "+" (default) and "−".

If `Type` is set to "+", the function returns, for $p = 2$, the central product of n copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p.

If `Type` is set to "−", the function returns for $p = 2$ the central product of a quaternion group of order 8 and $n - 1$ copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p^2.

Example H63E1

A pc-representation for the cyclic group C_{12} can be computed as follows.

```
> G := CyclicGroup(GrpPC, 12);
```

We can then check various properties of G.

```
> Order(G);
12
> IsAbelian(G);
true
> IsSimple(G);
false
```

If we simply print G, we will see the presentation which MAGMA has generated for this group.

```
> G;
GrpPC : G of order 12 = 2^2 * 3
PC-Relations:
    G.1^2 = G.2,
    G.2^2 = G.3,
    G.3^3 = Id(G)
```

Or, we could build a slightly different group.

```
> H := AbelianGroup(GrpPC, [2,2,3]);
> Order(H);
12
> IsCyclic(H);
false
```

63.2.2 Definition by Presentation

While the standard construction functions are convenient, most groups cannot be defined in that way. Complete flexibility in defining a soluble group can be obtained by directly specifying the group's pc-presentation.

One uses a power-conjugate presentation to define a soluble group by means of the `PolycyclicGroup` constructor, or the `quo` constructor for finitely presented groups.

`PolycyclicGroup< x1, ..., xn | R : parameters >`

`Check`	BOOLELT	*Default :* `true`
`ExponentLimit`	RNGINTELT	*Default :* 20
`Class`	MONSTGELT	*Default :*

Construct the soluble group G defined by the power-conjugate presentation $< x_1, \ldots, x_n \mid R >$.

The construct $x_1, \ldots, x_n$ defines names for the generators of G that are local to the constructor, i.e. they are used when writing down the relations to the right of the bar. However, no assignment of *values* to these variables is made. If the user wants to refer to the generators by these (or other) names, then the *generators assignment* construct must be used on the left hand side of an assignment statement.

The construct R denotes a list of pc-relations. Thus, an element of R must be one of:

(a) A *power relation* $a_j^{p_j} = w_{jj}$, $1 \leq j \leq n$, where w_{jj} is 1 or a word in generators $a_{j+1}, \ldots, a_n$ for $j < n$, and $w_{jj} = 1$ for $j = n$, and p_j a prime.

(b) A *conjugate relation* $a_j^{a_i} = w_{ij}$, $1 \leq i < j \leq n$, where w_{ij} is a word in the generators $a_{i+1}, \ldots, a_n$.

(c) A *power* $a_j^{p_j}$, $1 \leq j \leq n$ and p_j a prime, which is treated as the *power relation* $a_j^{p_j} = Id(F)$.

(d) A set of (a) – (c).

(e) A sequence of (a) – (c).

Note the following points:

(i) A power relation must be present for each generator a_i, $i = 1, \ldots, n$;

(ii) Conjugate relations involving commuting generators (i.e. of the form $y^x = y$) may be omitted;

(iii) The words w_{ij} must be in normal form.

In addition, one can alternatively specify a power-commutator presentation using commutator relations rather than conjugate relations.

(b') A *commutator relation* $(a_j, a_i) = w_{ij}$, $1 \leq i < j \leq n$, where w_{ij} is a word in the generators $a_{i+1}, \ldots, a_n$. However, commutators and conjugates cannot be mixed in a single presentation.

A map f from the free group of rank n to G is returned as well.

The parameters `Check` and `ExponentLimit` may be used. `Check` indicates whether or not the presentation is checked for consistency. `ExponentLimit` determines the amount of space that will be used by the group to speed calculations. Given `ExponentLimit := e`, the group will precompute and store normal words for appropriate products $a^i * b^j$ where a and b are generators and i and j are in the range 1 to e.

If the construction of an object in the category `GrpPC` fails because R is not a valid power-conjugate presentation, an attempt is made to construct a group in the

category GrpGPC (cf. Chapter 72). This feature can be turned off by setting the parameter Class to "GrpPC"; an invalid power-conjugate presentation then causes a runtime error. Since, by default, the constructor always returns a group in the category GrpPC if possible, this is the only effect of setting the parameter Class to "GrpPC".

quo< GrpPC : F | R : *parameters* >

Check	BoolElt	*Default :* true
ExponentLimit	RngIntElt	*Default :* 20

Given a free group F of rank n with generating set X, and a collection R of pc-relations on X, construct the soluble group G defined by the power-conjugate presentation $< X|R >$.

The construct R denotes a list of pc-relations. The syntax and semantics for the relations clause is identical to that appearing in the PolycyclicGroup-construct.

This constructor returns a pc-group because the category GrpPC is stated. If no category were stated, it would return an fp-group.

The parameters Check and ExponentLimit may be used as described in the PolycyclicGroup-construct.

The natural homomorphism, $F \to G$, is also returned.

Example H63E2

Consider the group of order 80 defined by the presentation

$$< a, b, c, d, e \mid a^2 = c, b^2, c^2 = e, d^5, e^2, b^a = b * e, c^a = c, c^b = c,$$
$$d^a = d^2, d^b = d, d^c = d^4, e^a = e, e^b = e, e^c = e, e^d = e > .$$

Giving the relations in the form of a list, this presentation would be specified as follows:

```
> G<a,b,c,d,e> := PolycyclicGroup<a, b, c, d, e |
>  a^2 = c, b^2, c^2 = e, d^5, e^2,
>  b^a = b*e, d^a = d^2, d^c = d^4 >;
```

Starting from a free group and giving the relations in the form of a set of relations, this presentation would be specified as follows:

```
> F<a,b,c,d,e> := FreeGroup(5);
> rels := { a^2 = c, b^2 = Id(F), c^2 = e, d^5 = Id(F), e^2 = Id(F),
>  b^a = b*e, d^a = d^2, d^c = d^4 };
> G<a,b,c,d,e> := quo< GrpPC : F | rels >;
```

Notice that here we have redefined the variables $a, \ldots, e$ to be the pc-generators in G. Thus, when G is printed, Magma displays the following presentation:

```
> G;
GrpPC : G of order 80 = 2^4 * 5
PC-Relations:
    a^2 = c,
```

```
    b^2 = Id(G),
    c^2 = e,
    d^5 = Id(G),
    e^2 = Id(G),
    b^a = b * e,
    d^a = d^2,
    d^c = d^4
> Order(G);
80
> IsAbelian(G);
false
```

63.2.3 Possibly Inconsistent Presentations

The `PolycyclicGroup` and `quo` constructors accept a parameter `Check` which enables the user to suppress the automatic consistency checking for input presentations. This is primarily intended to be used when it is certain that the input presentation is consistent, in order to save time. For instance, the presentation may have been generated from some other reliable program, or even from an earlier MAGMA session. This parameter should be used with care, since all of the MAGMA functions assume that every `GrpPC` group is consistent. The user will encounter numerous bizarre results if an attempt is made to compute with an inconsistent presentation.

On occasion, a user may wish to "try out" a series of pc-presentations, some of which may not be consistent. The `Check` parameter can be used, along with the function `IsConsistent`, to test a presentation for consistency.

`IsConsistent(G)`

Returns `true` if G has a consistent presentation, `false` otherwise.

Example H63E3

The following example demonstrates generating a family of presentations, and then checking consistency. Of course, it is easy to predict the outcome in this simple example.

```
> F := FreeGroup(2);
> for p in [n: n in [3..10] | IsPrime(n)] do
>   r := [F.1^3=Id(F), F.2^p=Id(F), F.2^F.1=F.2^2];
>   G := quo<GrpPC: F | r: Check:=false>;
>   if IsConsistent(G) then
>     print "For p=",p," the group is consistent.";
>   else
>     print "For p=",p," the group is inconsistent.";
>   end if;
> end for;
For p= 3  the group is inconsistent.
For p= 5  the group is inconsistent.
```

```
For p= 7  the group is consistent.
```

63.3 Basic Group Properties

63.3.1 Infrastructure

The functions described here provide access to basic information stored for a pc-group G.

`G . i`

The i-th pc-generator for G. A negative subscript indicates that the inverse of the generator is to be created. $G.0$ is `Identity(G)`.

`Generators(G)`

A set containing the defining generators for G. If G is a p-group, this is guaranteed to be a minimal set of generators. For non-p-groups, this will be the set of pc-generators.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for G.

`PCGenerators(G)`

An indexed set containing the pc-generators for G.

`NumberOfPCGenerators(G)`

`NPCGenerators(G)`

`NPCgens(G)`

The number of pc-generators for G.

`PCPrimes(G)`

A sequence $[p_1, \ldots, p_n]$ containing the primes associated with the pc-generators of G. The i-th term of the sequence contains the prime associated with generator a_i of G for $i = 1, \ldots, n$.

63.3.2 Numerical Invariants

MAGMA has built-in functions to compute the order and exponent of a group.

`Order(G)`
`#G`

The order of the group G, returned as an ordinary integer.

`FactoredOrder(G)`

The factored order of the group G.

`Exponent(G)`

The exponent of the group G.

63.3.3 Predicates

MAGMA has built-in functions to check standard group properties.

`IsAbelian(G)`

Returns `true` if the group G is abelian, `false` otherwise.

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise.

`IsNilpotent(G)`

Returns `true` if the group G is nilpotent, `false` otherwise.

`IsPerfect(G)`

Returns `true` if the group G is perfect, `false` otherwise. A soluble group G is perfect only if it is trivial.

`IsSimple(G)`

Returns `true` if the group G is simple, `false` otherwise.

`IsSoluble(G)`
`IsSolvable(G)`

Returns `true` if the group G is soluble, `false` otherwise. It always returns the value `true` for a pc-group.

`IsTrivial(G)`

Returns `true` if the group G has order 1, `false` otherwise.

`IsSpecial(G)`

Given a p-group G, return `true` if G is special, `false` otherwise.

`IsExtraSpecial(G)`

Given a p-group G, return `true` if G is extra-special, `false` otherwise e.

Example H63E4

We use a presentation to define an extraspecial 3-group of exponent 9.

```
> E := PolycyclicGroup<a1,a2,b1,b2,z|a1^3,a2^3,b1^3=z,b2^3=z,
>   z^3,b1^a1=b1*z,b2^a2=b2*z>;
```

The sequence of base, exponent pairs from `FactoredOrder` shows us that the group has order 3^5.

```
> FactoredOrder(E);
[ <3, 5> ]
> Exponent(E);
9
```

As well as with the `Order` function, one can get the size of a group by using the `#` shorthand.

```
> D3 := DihedralGroup(GrpPC, 3);
> #D3;
6
> IsNilpotent(D3);
false
```

63.4 Homomorphisms

Arbitrary homomorphisms can be defined between pc-groups by using the `hom<>` constructor. For pc-groups, this constructor has features not generally available for user-defined homomorphisms. In addition to defining the map by giving images for the pc-generators, a homomorphism can be defined by giving images for any generating set of the domain. MAGMA will verify that the specified images define a homomorphism and will compute the kernel and inverse images for the defined map. Note that the value returned for an inverse image of an element is simply one element from the preimage, not the complete coset.

`hom< G -> H | L >`

`Check` BOOLELT *Default :* `true`

Construct a homomorphism $\phi : G \to H$ defined by the images specified by the list L.

The list L must be one of the following:

(a) a list, set, or sequence of 2-tuples $< g_i, h_i >$ (order not important);

(b) a list, set, or sequence of arrow pairs $g_i -> h_i$ (order not important);

(c) a list or sequence of images $h_1, \ldots, h_n$ (order is important).

The elements g_i and h_i must be elements of G and H, respectively, in each case. For the cases (a) and (b), the elements g_i must generate G and the homomorphism will satisfy $\phi(g_i) = h_i$. For case (c), n must be the number of pc-generators of G and the g_i are implicitly defined to be the pc-generators.

The parameter `Check` can be set to false in order to turn off the check that the map defined is a homomorphism. This should only be done when one is certain that the map is a homomorphism, since later results will most likely be incorrect if it is not.

`IsHomomorphism(G, H, L)`

This is a conditional form of the `hom`-constructor. The argument L must be a set or sequence of pairs (as in case (a) of the `hom`-constructor), or a sequence of images in H for the pc-generators of G (as in case (c) of the `hom`-constructor). If the specified images define a homomorphism, the value true and the resulting map are returned. Otherwise, false is returned.

`IdentityHomomorphism(G)`

The identity map from G to G.

`Kernel(f)`

Given a homomorphism f from one pc-group to another, return the kernel of f. This will be a pc-group which is a subgroup of the domain of f.

`Homomorphisms(G, H)`

Given finite *abelian* groups G and H, return a sequence containing all elements of $\mathrm{Hom}(G, H)$. The elements are returned as actual (MAGMA map type) homomorphisms. Note that this function simply uses `Hom`, transferring each element of the returned group to the actual MAGMA map type homomorphism.

Example H63E5

Let G be a pc-representation of the symmetric group S_4, and N be $O_2(G)$.

```
> G := PCGroup(Sym(4));
> G;
GrpPC : G of order 24 = 2^3 * 3
PC-Relations:
    G.1^2 = Id(G),
    G.2^3 = Id(G),
    G.3^2 = Id(G),
    G.4^2 = Id(G),
    G.2^G.1 = G.2^2,
    G.3^G.1 = G.3 * G.4,
    G.3^G.2 = G.4,
    G.4^G.2 = G.3 * G.4
> N := pCore(G,2);
> Order(N);
```

```
4
```

Let us define H to be a complement of N in G.

```
> H := sub<G|G.1*G.4,G.2*G.4>;
> Order(H);
6
> H meet N;
GrpPC of order 1
PC-Relations:
```

We now wish to define the projection homomorphism from G to H. This will map each element of N to the identity and each element of H to itself. We can define the map directly using these properties.

```
> pairs := [];
> for n in Generators(N) do
>   pairs cat:= [<G!n,Id(H)>];
> end for;
> for h in Generators(H) do
>   pairs cat:= [<G!h, h>];
> end for;
> proj := hom<G -> H|pairs>;
> proj;
Mapping from: GrpPC: G to GrpPC: H
> proj(G.1);
H.1
> proj(N);
GrpPC of order 1
PC-Relations:
```

We can also compute inverse images and can verify that N is the kernel of the map. Note that the preimage of a single element is just one element from the preimage, not the complete coset. Of course, one can use the kernel to compute the full coset if desired.

```
> y := (H.1)@@proj;
> y;
G.1
> Kernel(proj) eq N;
true
> {y*k: k in Kernel(proj)};
{ G.1 * G.3 * G.4, G.1 * G.4, G.1, G.1 * G.3 }
```

63.5 New Groups from Existing

`DirectProduct(G, H)`

The direct product K of the pc-groups G and H. The second argument returned is a sequence containing the inclusion maps $I_G : G \to K$ and $I_H : H \to K$. The third argument returned is a sequence containing the projection maps $P_G : K \to G$ and $P_H : K \to H$. Furthermore, the (user-) presentation of K is arranged so that the first pc-generators correspond to those of G and the remaining generators correspond to those of H.

`DirectProduct(Q)`

The direct product of pc-groups in the non-empty sequence Q, and the inclusion and projection maps.

`Extension(G, H, f)`

The split extension K of the pc-group G by the pc-group H, where the action of H on G is given by the homomorphism $\phi : H \to \mathrm{Aut}(G)$ specified by f. The extension K will have a normal subgroup $G^\sim$ isomorphic to G, while the quotient group $K/G^\sim$ is isomorphic to H.

The homomorphism ϕ is given by the sequence of maps f. Suppose that the pc-generators for H are $h_1, \ldots, h_s$. The i-th entry of f defines the action of h_i on G. That is, $f[i](x) = h_i^{-1} \cdot x \cdot h_i$, for $x \in G$.

`Extension(M, H)`

The split extension K of the G-module M by the pc-group H. We use the action of H on M to define the action of H on an elementary abelian p-group of order p^d where M is a d-dimensional module over $GF(p)$, p prime.

`Extension(G, H, f, t)`

The non-split extension K of the pc-group G by the pc-group H, where the action of H on G is given by the homomorphism $\phi : H \to \mathrm{Aut}(G)$ and the tails for H are given as the set of tuples t. The extension K will have a normal subgroup $G^\sim$ isomorphic to G, while the quotient group $K/G^\sim$ is isomorphic to H.

The homomorphism ϕ is given by the sequence of maps f. Suppose that the pc-generators for H are $h_1, \ldots, h_s$. The i-th entry of f defines the action of h_i on G. That is, $f[i](x) = h_i^{-1} \cdot x \cdot h_i$, for $x \in G$.

The specification of t involves giving the relations $h_j^{-1} h_i h_j = w_{ij}$, where w_{ij} is a word in K for $1 \le j < i \le s$. For $i = j$, we need the relation ${h_i}^{p_i} = w_{ii}$, where w_{ii} is a word in K for $1 \le i \le s$. Each w_{ij} is the RHS of the relation from H with the tail x_{ij}. The tails are given by the sequence t in the order $t = [x_{11}, x_{21}, x_{22}, x_{31}, \ldots, x_{ss}]$. Alternatively, t can be given as a set of tuples $< i, j, x_{ij} >$ for non-trivial x_{ij}.

Note that if $x_{ij} =$`Id(G)`, for $1 \le i \le s$ and $1 \le j \le i$, then K will just be the split extension of G and H.

`Extension(M, H, t)`

The non-split extension K of the G-module M by the pc-group H. We use the action of H on M to define the action of H on an elementary abelian p-group of order p^d where M is a d-dimensional module over $GF(p)$, p prime.

The specification of t is similar to that for t in the preceding description.

`IsExtension(G, H, f)`

`IsExtension(M, H)`

`IsExtension(G, H, f, t)`

`IsExtension(M, H, t)`

For each `Extension` variation, there is a corresponding function `IsExtension` which attempts to construct the specified group and returns a boolean value indicating whether or not the construction succeeded. If the construction succeeds, the extension group is also returned.

The `Extension` functions will generate a runtime error if the specified construction is not legal. The `IsExtension` function allows the user to detect this error condition and continue.

`WreathProduct(G, H)`

The wreath product of the pc-groups G and H, where the regular permutation representation of H is used to define the action.

`WreathProduct(G, H, f)`

The wreath product of the pc-groups G and H where the action of H is given by f, which may be either a homomorphism from H into a permutation group P or a sequence of permutations defining a homomorphism from H into P. If f is a sequence, the homomorphism $\phi : H \to P$ is defined by $H.i \to f[i]$ for $i = 1, \ldots, s$.

Example H63E6

To demonstrate some of the versions of `Extension` we first build a split extension of a cyclic group of order 4 acting on an elementary abelian group of order 9.

```
> C4 := CyclicGroup(GrpPC,4);
> E9 := AbelianGroup(GrpPC,[3,3]);
> f1 := hom<E9->E9|[E9.1*E9.2^2, E9.1^2*E9.2^2]>;
> f2 := hom<E9->E9|[E9.1^2,E9.2^2]>;
> G := Extension(E9,C4,[f1,f2]);
> G;
GrpPC : G of order 36 = 2^2 * 3^2
PC-Relations:
    G.1^2 = G.2,
    G.2^2 = Id(G),
    G.3^3 = Id(G),
    G.4^3 = Id(G),
```

```
    G.3^G.1 = G.3 * G.4^2,
    G.3^G.2 = G.3^2,
    G.4^G.1 = G.3^2 * G.4^2,
    G.4^G.2 = G.4^2
```

Then, we define a module for this group and use it to build a nonsplit extension.

```
> MR := MatrixRing(GF(3),2);
> m1 := MR![1,1,1,2];
> m2 := MR![2,0,0,2];
> V := GModule(G,[m1,m2,Id(MR),Id(MR)]);
> IsIrreducible(V);
true
> v0 := V!0;
> tails := [v0,v0,v0,v0,V![1,0],V![2,0],V![1,2],V![0,2],v0,V![0,1]];
> H := Extension(V,G,tails);
> H;
GrpPC : H of order 324 = 2^2 * 3^4
PC-Relations:
    H.1^2 = H.2,
    H.2^2 = Id(H),
    H.3^3 = H.5^2,
    H.4^3 = H.6,
    H.5^3 = Id(H),
    H.6^3 = Id(H),
    H.3^H.1 = H.3 * H.4^2,
    H.3^H.2 = H.3^2 * H.5,
    H.4^H.1 = H.3^2 * H.4^2 * H.5 * H.6^2,
    H.4^H.2 = H.4^2 * H.6^2,
    H.5^H.1 = H.5 * H.6,
    H.5^H.2 = H.5^2,
    H.6^H.1 = H.5 * H.6^2,
    H.6^H.2 = H.6^2
```

Notice that the relations of H involving the first four generators are those of G with the specified tails appended. We are then ready to compute various properties of H.

```
> [N`order:N in NormalSubgroups(H)];
[ 1, 9, 81, 162, 324 ]
```

Example H63E7

In this example we verify an example of Cossey and Hawkes in [CH00]. The paper shows that the largest size of a conjugacy class in an abelian by nilpotent finite group is at least as large as the product of the largest class sizes for the Sylow subgroups. The example is a group having derived length 3 in which this fails.
We start with a dihedral group of order 10 acting on a cyclic group of order 8.

```
> E := DihedralGroup(GrpPC,5);
```

```
> A := CyclicGroup(GrpPC,8);
```

Define an action of E on A and create the split extension.

```
> f1 := hom<A->A|A.1->(A.1)^-1>;
> f2 := hom<A->A|A.1->A.1>;
> H := Extension(A, E, [f1, f2]);
```

Then construct a certain H-module...

```
> QH := SylowSubgroup(H,2);
> t := TrivialModule(QH, FiniteField(5));
> B := Induction(t, H);
```

...and form the split extension of H acting on that module.

```
> G := Extension(B, H);
> print G;
GrpPC : G of order 250000 = 2^4 * 5^6
PC-Relations:
    G.1^2 = Id(G),
    G.2^5 = Id(G),
    G.3^2 = G.4,
    G.4^2 = G.5,
    G.5^2 = Id(G),
    G.6^5 = Id(G),
    G.7^5 = Id(G),
    G.8^5 = Id(G),
    G.9^5 = Id(G),
    G.10^5 = Id(G),
    G.2^G.1 = G.2^4,
    G.3^G.1 = G.3 * G.4 * G.5,
    G.4^G.1 = G.4 * G.5,
    G.6^G.2 = G.10,
    G.7^G.1 = G.10,
    G.7^G.2 = G.6,
    G.8^G.1 = G.9,
    G.8^G.2 = G.7,
    G.9^G.1 = G.8,
    G.9^G.2 = G.8,
    G.10^G.1 = G.7,
    G.10^G.2 = G.9
> print DerivedLength(G);
3
```

Now check the relevant class sizes.

```
> P := SylowSubgroup(G,5);
> Q := SylowSubgroup(G,2);
> print  Maximum({x[2]:x in Classes(G)});
1250
```

```
> print  Maximum({x[2]:x in Classes(P)});
625
> print  Maximum({x[2]:x in Classes(Q)});
4
```

Note that 1250 is less than the product 625*4.

63.6 Elements

Elements of a pc-group are written in terms of the generators. The pc-generators of a group G can always be written as `G.1`, `G.2`, ... Any variables naming the generators, either assigned during the definition of the group, or later using standard assignment statements, can also be used to express the generators. An arbitrary element can be written as a word in the generators using the various element operations.

63.6.1 Definition of Elements

A *word* is defined inductively as follows:

(i) A generator is a word;

(ii) The expression (u) is a word, where u is a word;

(iii) The product $u * v$ of the words u and v is a word;

(iv) The conjugate u^v of the word u by the word v is a word (u^v expands into the word $v^{-1} * u * v$);

(v) The power of a word u^n, where u is a word and n is an integer, is a word;

(vi) The commutator (u, v) of the words u and v is a word ((u, v) expands into the word $u^{-1} * v^{-1} * u * v$).

A group element is always printed by MAGMA as a normal word in the pc-generators of its parent group.

It is also possible to create an element of a group G from its exponent vector. That is, the sequence $[e_1, e_2, \ldots, e_n]$ corresponds to the element $G.1^{e_1} * G.2^{e_2} * \cdots * G.n^{e_n}$. The coercion operator `!` is used to convert the sequence to the element.

`G ! Q`

Given the pc-group G and a sequence Q of length n, containing the distinct positive integers α_i, $0 \leq \alpha_i < p_i$ for $i = 1, \ldots, n$, construct the element x of G given by

$$x = a_1^{\alpha_1} \ldots a_n^{\alpha_n}, \quad 0 \leq \alpha_i < p_i \quad \text{for } i = 1, \ldots, n.$$

`ElementToSequence(x)`

`Eltseq(x)`

Given an element x belonging to the pc-group G, where

$$x = a_1^{\alpha_1} \ldots a_n^{\alpha_n}, \quad 0 \leq \alpha_i < p_i \quad \text{for } i = 1, \ldots, n,$$

return the sequence Q of n integers defined by $Q[i] = \alpha_i$, for $i = 1, \ldots, n$.

Identity(G)

Id(G)

G ! 1

Construct the identity element of the pc-group G.

Example H63E8

Given a pc-group, we can define elements as words in the generators or as more general expressions.

```
> G := PolycyclicGroup<a,b,c|a^3,b^2,c^2,b^a=c,c^a=b*c>;
> G;
GrpPC : G of order 12 = 2^2 * 3
PC-Relations:
    G.1^3 = Id(G),
    G.2^2 = Id(G),
    G.3^2 = Id(G),
    G.2^G.1 = G.3,
    G.3^G.1 = G.2 * G.3
> x := G.1^2*G.3;
> x;
G.1^2 * G.3
> x^2;
G.1 * G.2 * G.3
> x^3;
Id(G)
```

MAGMA will print the element in normal form even if it is not entered that way.

```
> G.2*G.1;
G.1 * G.3
```

When coercing a sequence into a group element, the sequence is always interpreted as an exponent vector for a normal word.

```
> y := G![0,1,1];
> y;
G.2 * G.3
> x*y;
G.1^2 * G.2
> y*x;
G.1^2
> (x,y);
G.2
```

An element can also be converted into a sequence.

```
> x^y;
G.1^2 * G.2 * G.3
> Eltseq(x^y);
[ 2, 1, 1 ]
```

63.6.2 Arithmetic Operations on Elements

New elements can be computed from existing elements using standard operations.

`g * h`

Product of the element g and the element h, where g and h belong to some common subgroup G of a pc-group U. If g and h are given as elements belonging to the same proper subgroup G of U, then the result will be returned as an element of G; if g and h are given as elements belonging to distinct subgroups H and K of U, then the product is returned as an element of G, where G is the smallest subgroup of U known to contain both elements.

`g *:= h`

Replace g with the product of element g and element h.

`g ^ n`

The n-th power of the element g, where n is a positive or negative integer.

`g ^:= n`

Replace g with the n-th power of the element g.

`g / h`

Quotient of the element g by the element h, i.e. the element $g * h^{-1}$. Here g and h must belong to some common subgroup G of a pc-group U. The rules for determining the parent group of g/h are the same as for $g * h$.

`g /:= h`

Replace g with the quotient of the element g by the element h.

`g ^ h`

Conjugate of the element g by the element h, i.e. the element $h^{-1} * g * h$. Here g and h must belong to some common subgroup G of a pc-group U. The rules for determining the parent group of g^h are the same as for $g * h$.

`g ^:= h`

Replace g with the conjugate of the element g by the element h.

`(g1, ..., gn)`

Given the n words $g_1, \ldots, g_n$ belonging to some common subgroup G of a pc-group U, return the commutator. If $g_1, \ldots, g_n$ are given as elements belonging to the same proper subgroup G of U, then the result will be returned as an element of G; if $g_1, \ldots, g_n$ are given as elements belonging to distinct subgroups of U, then the product is returned as an element of G, where G is the smallest subgroup of U known to contain all elements. Commutators are *left-normed*, so that they are evaluated from left to right.

63.6.3 Properties of Elements

`Order(x)`

Order of the element x.

`Parent(x)`

The parent group G of the element x.

63.6.4 Predicates for Elements

Elements in the same group can be compared using `eq` and `ne`.

`g eq h`

Given elements g and h belonging to a common pc-group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given elements g and h belonging to a common pc-group, return `true` if g and h are distinct elements, `false` otherwise.

`IsIdentity(g)`
`IsId(g)`

Returns `true` if g is the identity element, `false` otherwise.

`IsConjugate(G, g, h)`

Given a group G and elements g and h belonging to G, return the value `true` if g and h are conjugate in G. The function also returns a second value in the event that the elements are conjugate: an element z such that $g^z = h$.

Example H63E9

We check if one element commutes with another.

```
> G<a,b,c> := PolycyclicGroup<a,b,c|a^3,b^2,c^2,b^a=c,c^a=b*c>;
> b^a eq b;
false
```

The same information can also be obtained by checking the commutator.

```
> IsIdentity((b,a));
false
```

If we assign the result of `IsConjugate` to a single variable, it will store the boolean result.

```
> r := IsConjugate(G, c, b);
> r;
```

```
true
```

If we simply print `IsConjugate`, the boolean value and the conjugating element (if any) are displayed. On the other hand, using the multiple assignment, we can capture both of those values.

```
> IsConjugate(G, c, b);
true a^2
> r, x := IsConjugate(G, c, b);
> x, r;
a^2 true
> c^x;
b
```

63.6.5 Set Operations

These functions allow one to work with the set of elements of G, possibly without much knowledge of the structure of G.

`NumberingMap(G)`

A bijective mapping from the group G onto the set of integers $\{1...|G|\}$. The actual mapping depends upon the current presentation for G.

`Random(G)`

An element, randomly chosen, from the group G. This function uses an entirely different procedure than that used by `RandomProcess` (see below). A group element is chosen with uniform probability by generating (pseudo-)random integers in the proper range to form a legal exponent vector for G. The corresponding element is returned. This is an extremely efficient process and is the recommended method for producing random elements of a pc-group.

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 20

Create a process to generate randomly chosen elements from the group G. The process uses an 'expansion' procedure to construct a set of elements corresponding to fairly long words in the generators of G. At all times, N elements are stored where N is the maximum of the specified value for `Slots` and `Ngens`$(G) + 1$. Initially, these are simply the generators of G and products of pairs of generators of G. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses an element x stored by the process and returns it, replacing x with the product of x and another random element (multiplied on the left or the right). Setting `Scramble := m` causes m such operations to be performed initially.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the finite group G, construct a random element of G by forming a random product over the expanded generating set constructed when the process was created.

`Representative(G)`

`Rep(G)`

A representative element of G. For a pc-group, this always returns the identity element.

Example H63E10

The `NumberingMap` function assigns a number to each group element.

```
> G := DihedralGroup(GrpPC,4);
> num_map := NumberingMap(G);
> for x in G do
>   print x,"->",num_map(x);
> end for;
Id(G) -> 1
G.3 -> 2
G.2 -> 3
G.2 * G.3 -> 4
G.1 -> 5
G.1 * G.3 -> 6
G.1 * G.2 -> 7
G.1 * G.2 * G.3 -> 8
```

The inverse map can be used to obtain the group element corresponding to a particular number.

```
> 6 @@ num_map;
G.1 * G.3
```

The `Random` function is sometimes useful to create a statistical profile of a group. To demonstrate, we take two groups of order 3^6 from the `SmallGroup` database.

```
> G1 := SmallGroup(3^6, 60);
> G2 := SmallGroup(3^6, 392);
```

We want to build a histogram of element orders for each group. Since these are 3-groups, each order will be a power of 3 and we use `Ilog` to get the exponent of the order. First, we define a short function to compute the histogram.

```
> function hist(G, trials)
>   // Given a 3-group G, of exponent <= 3^5,
>   // return a sequence whose ith term is the
>   // number of elements of order p^(i-1) out
>   // of trials randomly chosen elements.
>   table := [0,0,0,0,0,0];
>   for i := 1 to trials do
```

```
>     x := Random(G);
>     n := Ilog(3, Order(x));
>     table[n+1] +:= 1;
>   end for;
>   return table;
> end function;
```

Now, we use this function to compute order distributions for 100 elements in each group.

```
> t1 := hist(G1,100);
> t1;
[ 0, 0, 5, 28, 67, 0 ]
> t2 := hist(G2,100);
> t2;
[ 0, 5, 5, 25, 65, 0 ]
```

We can even display them with simple character graphics.

```
> for e in t1 do print ":","@"^e; end for;
:
:
: @@@@@
: @@@@@@@@@@@@@@@@@@@@@@@@@@@@
: @@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@
:
> for e in t1 do print ":","@"^e; end for;
:
: @@@@@
: @@@@@
: @@@@@@@@@@@@@@@@@@@@@@@@@
: @@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@
:
```

Example H63E11

Given the subgroups H and K of G, construct the set product of the groups H and K.

```
> set_product := func<G, H, K | { G | x * y : x in H, y in K }>;
```

Given a subgroup H of the pc-group G, construct H as a set of elements of G.

```
> elements := func<G, H | { G | x : x in H }>;
```

63.7 Conjugacy

`Class(H, g)`

`Conjugates(H, g)`

`g ^ H`

Given a group H and an element g belonging to a group K such that H and K are subgroups of some covering group, this function returns the set of conjugates of g under the action of H. If $H = K$, the function returns the conjugacy class of g in H.

`ConjugacyClasses(G)`

`Classes(G)`

Construct a set of representatives for the conjugacy classes of G. The classes are returned as a sequence of tuples containing the order of the elements in the class, the class length and a representative element for the class. For non-p-groups, the classes are computed using the homomorphism principle down a series with elementary abelian factors and orbit-stabilizer in each quotient. See [MN89] for details. For p-groups an algorithm based on linear algebra developed by Charles Leedham-Green is used.

`ClassMap(G)`

The class map $M : G \to \{1, \ldots, n\}$ for the group G, where n is the number of conjugacy classes of G.

`ClassRepresentative(G, x)`

The designated representative for the conjugacy class of G containing the element x (relative to existing conjugacy classes).

`IsConjugate(G, g, h)`

Given a group G and elements g and h belonging to G, return the value true if g and h are conjugate in G. The function also returns a second value in the event that the elements are conjugate: an element z which conjugates g into h.

`NumberOfClasses(G)`

`Nclasses(G)`

The number of conjugacy classes of elements of the group G.

`PowerMap(G)`

The power map M associated with the conjugacy classes of G. The map M describes where the elements of the conjugacy classes of G move under powers. That is, $< c, n >@M$ returns the class number where class c moves under the power n. The value of c must be in the range $[1 \ldots$`Nclasses(G)`$]$.

$M : \{1 \ldots n\} \times \mathbf{Z} \to \{1 \ldots n\}$

Example H63E12

Let G be a pc-representation of SL(2,3). We can compute the conjugacy classes of G. Notice that the conjugacy class object has a special printing routine, but you can still access individual entries.

```
> G := PCGroup(SpecialLinearGroup(2,GF(3)));
> G;
GrpPC : G of order 24 = 2^3 * 3
PC-Relations:
    G.1^3 = Id(G),
    G.2^2 = G.4,
    G.3^2 = G.4,
    G.4^2 = Id(G),
    G.2^G.1 = G.3 * G.4,
    G.3^G.1 = G.2 * G.3 * G.4,
    G.3^G.2 = G.3 * G.4
> Nclasses(G);
7
> cc := Classes(G);
> cc;
Conjugacy Classes of group G
----------------------------
[1]     Order 1       Length 1
        Rep Id(G)
[2]     Order 2       Length 1
        Rep G.4
[3]     Order 3       Length 4
        Rep G.1
[4]     Order 3       Length 4
        Rep G.1^2
[5]     Order 4       Length 6
        Rep G.2
[6]     Order 6       Length 4
        Rep G.1 * G.4
[7]     Order 6       Length 4
        Rep G.1^2 * G.4
> cc[3];
<3, 4, G.1>
> x := cc[3][3];
> Class(G,x);
{ G.1 * G.2 * G.3 * G.4, G.1 * G.2 * G.4, G.1, G.1 * G.3 }
7
>
```

We can use the `ClassMap` function to compute class multiplication constants (structure constants for the center of the group algebra). For example, we compute the decomposition of class 3 times class 5.

```
> cm := ClassMap(G);
```

```
> cm(G.1);
3
> i := 3; j := 5;
> t := [0: c in cc];
> for x in Class(G,cc[i][3]), y in Class(G,cc[j][3]) do
>   t[cm(x*y)] +:= 1;
> end for;
> t;
[ 0, 0, 12, 0, 0, 12, 0 ]
```

To get the actual structure constants, we need to divide each entry in `t` by the corresponding class size.

```
> [ t[i]/cc[i][2]: i in [1..#t] ];
[ 0, 0, 3, 0, 0, 3, 0 ]
```

63.8 Subgroups

Subgroups of pc-groups are treated as independent pc-groups in their own right, with the subgroup relationship maintained in internal data structures. Thus, a subgroup has generators and a pc-presentation and one can apply any of the functions described earlier for groups. Furthermore, there are a variety of functions and operations specifically involving subgroups.

63.8.1 Definition of Subgroups by Generators

The most flexible method of defining a subgroup is to list generators or normal generators for the subgroup.

`sub< G | L >`

Construct the subgroup H of the pc-group G generated by the elements specified by the terms of the *generator list* L.

A term $L[i]$ of the generator list may consist of any of the following objects:

(a) An element liftable to G (in particular, any element of G);

(b) A subgroup of G;

(c) A set or sequence of (a), or (b).

The collection of words and groups specified by the list must all belong to the group G and H will be constructed as a subgroup of G.

The subgroup H is defined to be generated by the words specified directly by terms $L[i]$ together with the stored generating words for any groups specified by terms of $L[i]$. MAGMA will compute a set of pc-generators for H and, if H is a p-group, a minimal generating set.

The inclusion map from H to G is returned as well.

`ncl< G | L >`

Construct the subgroup N of the pc-group G as the normal closure of the subgroup generated by the elements specified by the terms of the *generator list* L.

The possible forms of a term $L[i]$ of the generator list are the same as for the `sub`-constructor.

The inclusion map from N to G is returned as well.

Example H63E13

We define G to be Z_5 wr Z_3 and then create two subgroups. Notice that the `ncl`-constructor builds a larger subgroup in this case.

```
> G<a,b,c,d> := PolycyclicGroup<a,b,c,d| a^3, b^5, c^5, d^5,
>   b^a = c, c^a = d, d^a = b>;
> H := sub<G| b,c>;
> Order(H);
25
> IsAbelian(H);
true
> IsNormal(G, H);
false
> N := ncl<G| b,c>;
> IsNormal(G, N);
true
> Order(N);
125
```

63.8.2 Membership and Coercion

There are several functions and operators which allow one to take advantage of the subgroup relationship to rewrite elements from one presentation to another. That is, if x is an element of H which is a subgroup of G, then x has a representation as a normal word in the pc-generators of H, but also has a representation as a (different) normal word in the pc-generators of G. The coercion operator and inclusion map allow one to compute one of these words based on the other, thus shifting where we view the element in question.

MAGMA keeps track of the various relationships between subgroups in a group. Thus, if H is a subgroup of K which is a subgroup of G, then H can also be considered a subgroup G. Similarly, in situations involving elements of two groups, A and B, MAGMA will often try to find a *covering group* C which contains both of A and B. In this case, the elements may be automatically coerced into the covering group.

`g in G`

Given an element g and a group G, return `true` if g is an element of G, `false` otherwise. In order for this comparison to make sense, both g and G must be contained in some covering group.

`g notin G`

Given an element g and a group G, return `true` if g is not an element of G, `false` otherwise. In order for this comparison to make sense, both g and G must be contained in some covering group.

`G ! g`

Given an element g belonging to some subgroup H of the group G, rewrite g as an element of G.

`H ! g`

Given an element g belonging to the group G, and given a subgroup H of G containing g, rewrite g as an element of H.

`K ! g`

Given an element g belonging to the group H, and a group K, such that H and K are subgroups of a covering group G, and both H and K contain g, rewrite g as an element of K.

Example H63E14

We create two subgroups of a dihedral group.

```
> G := DihedralGroup(GrpPC, 10);
> C := sub<G| G.2>;
> H := sub<G| G.1, G.3>;
> H.1 in C;
false
> H.2 in C;
true
> Parent(H.1);
GrpPC : H of order 10 = 2 * 5
PC-Relations:
    H.1^2 = Id(H),
    H.2^5 = Id(H),
    H.2^H.1 = H.2^4
> G!(H.1);
G.1
```

MAGMA will compute appropriate covering groups as needed.

```
> H.1*C.1;
G.1 * G.2 * G.3^2
> x := (H.1, C.2);
> x;
G.3^2
> H!x;
H.2^2
> C!x;
```

```
C.2^2
> C!(H.2);
C.2
```

63.8.3 Inclusion and Equality

`S subset G`

Given an group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is not a subset of G, `false` otherwise.

`H subset G`

Given groups G and H, subgroups of some covering group, return `true` if H is a subgroup of G, `false` otherwise.

`H notsubset G`

Given groups G and H, subgroups of some covering group, return `true` if H is not a subgroup of G, `false` otherwise.

`G eq H`

Given groups G and H, subgroups of some covering group, return `true` if G and H are the same group, `false` otherwise.

`G ne H`

Given groups G and H, subgroups of some covering group, return `true` if G and H are distinct groups, `false` otherwise.

`InclusionMap(G, H)`

The map from the subgroup H of G to G.

63.8.4 Standard Subgroup Constructions

The operators and functions which construct a subgroup of a pc-group always return the subgroup as a pc-group.

```
H ^ g
```

```
Conjugate(H, g)
```

Construct the conjugate $g^{-1} * H * g$ of the group H under the action of the element g. The group H and the element g must belong to a common group.

```
H meet K
```

The intersection of groups H and K. The algorithm used for non-p-groups is described in [GS90].

```
H meet:= K
```

Replace H with the intersection of groups H and K.

```
CommutatorSubgroup(G, H, K)
```

```
CommutatorSubgroup(H, K)
```

Construct the commutator subgroup of groups H and K, where H and K are subgroups of a common group G.

```
Centralizer(G, g)
```

```
Centraliser(G, g)
```

The centralizer of the element g in the group G.

```
Centralizer(G, H)
```

```
Centraliser(G, H)
```

The centralizer of the subgroup H in the group G.

```
Core(G, H)
```

The maximal normal subgroup of G that is contained in the subgroup H of G.

```
H ^ G
```

```
NormalClosure(G, H)
```

The normal closure of the subgroup H in the group G.

```
Normalizer(G, H)
```

```
Normaliser(G, H)
```

The normalizer of the subgroup H of the group G. The algorithm used for non-p-groups is described in [GS90].

Example H63E15

We'll consider various subgroups of a direct product of a cyclic group of order 6 and dihedral group of order 10.

```
> G := DirectProduct(CyclicGroup(GrpPC,6), DihedralGroup(GrpPC,5));
> x := G.3;
> C := Centralizer(G,x);
> C;
GrpPC : C of order 12 = 2^2 * 3
PC-Relations:
    C.1^2 = Id(C),
    C.2^2 = Id(C),
    C.3^3 = Id(C)
> H := sub<G|G.2,G.4>;
> Order(H);
15
```

We can compute the intersection using the `meet` operator.

```
> K := H meet C;
> K;
GrpPC : K of order 3
PC-Relations:
    K.1^3 = Id(K)
```

To get the join of two subgroups, we simply use the `sub`-constructor.

```
> J := sub<G|H, C>;
> J eq G;
true
```

63.8.5 Properties of Subgroups

`Index(G, H)`

The index of the subgroup H in the group G, returned as an ordinary integer.

`FactoredIndex(G, H)`

The factored index of the subgroup H in the group G.

63.8.6 Predicates for Subgroups

`IsCentral(G, H)`

Returns `true` if the subgroup H of the group G lies in the centre of G, `false` otherwise.

`IsConjugate(G, H, K)`

Given a group G and subgroups H and K belonging to G, return the value `true` if H and K are conjugate in G. The function returns a second value in the event that the subgroups are conjugate: an element z which conjugates H into K.

`IsMaximal(G, H)`

Returns `true` if the subgroup H of the group G is a maximal subgroup of G, `false` otherwise.

`IsNormal(G, H)`

Returns `true` if the subgroup H of the group G is a normal subgroup of G, `false` otherwise.

`IsSelfNormalizing(G, H)`

Returns `true` if the subgroup H of the group G is self-normalizing in G, `false` otherwise.

`IsSubnormal(G, H)`

Returns `true` if the subgroup H of the group G is subnormal in G, `false` otherwise.

Example H63E16

```
> G := PCGroup(Sym(4));
> G;
GrpPC : G of order 24 = 2^3 * 3
PC-Relations:
    G.1^2 = Id(G),
    G.2^3 = Id(G),
    G.3^2 = Id(G),
    G.4^2 = Id(G),
    G.2^G.1 = G.2^2,
    G.3^G.1 = G.3 * G.4,
    G.3^G.2 = G.4,
    G.4^G.2 = G.3 * G.4
> U := sub<G|G.4>;
> IsNormal(G,U);
false
> IsSubnormal(G,U);
```

```
true
```

Now, we try to construct a subnormal chain by taking normalizers.

```
> N1 := Normalizer(G,U);
> Index(G,N1);
3
> N2 := Normalizer(G,N1);
> Index(G,N2);
3
> N1 eq N2;
true
```

We're stuck. However, we can work our way down with `NormalClosure`.

```
> M1 := NormalClosure(G,U);
> U subset M1;
true
> M1 subset U;
false
> M2 := NormalClosure(M1,U);
> M2 eq U;
true
```

Now, we work inside the Sylow 2-subgroup and look for complements of the cyclic group of order 4 by brute force.

```
> S := Sylow(G,2);
> S;
GrpPC : S of order 8 = 2^3
PC-Relations:
    S.2^S.1 = S.2 * S.3
> T := sub<S|S.1*S.2>;
> list := [];
> for x in S do
>   if (Order(x) ne 2) or (x in T) then
>     continue;
>   end if;
>   Append(~list, sub<S|x>);
> end for;
> #list;
4
> for i in [1..3], j in [i+1..4] do
>   print i,j,IsConjugate(S,list[i],list[j]);
> end for;
1 2 true S.1
1 3 false
1 4 false
2 3 false
2 4 false
```

```
3 4 true S.2
```

We see that T has two conjugacy classes of complements.

63.8.7 Hall π-Subgroups and Sylow Systems

The functions given here all assume that G is a soluble group having order $p_1^{e_1}p_2^{e_2}\cdots p_k^{e_k}$.

`ComplementBasis(G)`

A complement basis of the soluble group G. This is a sequence of k subgroups of G, where the i-th subgroup has order $p_1^{e_1}\ldots p_{i-1}^{e_{i-1}}p_{i+1}^{e_{i+1}}\ldots p_k^{e_k}$, i.e. the complements of the k Sylow subgroups of G.

`HallSubgroup(G, S)`

The Hall π-subgroup of G, where π is defined by S. The argument S may be a set of primes, a single prime, or the negation of a single prime. If $S = -p$, then the Hall p'-subgroup of G is returned.

`pCore(G, S)`

The core of the Hall π-subgroup, where π is defined by the argument S, which has the same interpretation as for `HallSubgroup`.

`SylowBasis(G)`

A Sylow basis for the soluble group G. This is a sequence of k subgroups of G, having orders $p_1^{e_1},\ldots,p_k^{e_k}$, i.e. the k Sylow subgroups of G.

`SylowSubgroup(G, p)`

`Sylow(G, p)`

A Sylow p-subgroup for the group G.

`SystemNormalizer(G)`

`SystemNormaliser(G)`

The system normalizer for the group G. The system normalizer of the complement basis $\Sigma = \{H_1, ..., H_k\}$ is defined to be the intersection of the normalizers in G of each H_i, ie. $N(\Sigma) = \cap_{i=1}^{k} N_G(H_i)$. The algorithm used is derived directly from the definition.

Example H63E17

Given the group $D_3 \wr D_5$, we can construct the Hall 2-subgroup as follows:

```
> H := DihedralGroup(GrpPerm, 5);
> G := WreathProduct(DihedralGroup(GrpPC, 3), DihedralGroup(GrpPC, 5),
>         [H.2, H.1]);
> H2 := HallSubgroup(G, 2);
> Order(H2);
64
```

The Hall $2'$-subgroup of the same group is constructed as follows:

```
> H35 := HallSubgroup(G, -2);
> Order(H35);
1215
```

63.8.8 Conjugacy Classes of Subgroups

MAGMA has functions for computing the subgroups of a group that return the subgroups either as a list of conjugacy class representatives as or as a poset. Details of these functions may be found in Chapter 57. Here we mention the basic functions for convenience.

`SubgroupClasses(G)`

`Subgroups(G)`

Conjugacy class representatives for all subgroups of G. The algorithm was developed by M. Slattery and is essentially that of [Hul99] without the action of automorphisms.

`AbelianSubgroups(G)`

`CyclicSubgroups(G)`

`ElementaryAbelianSubgroups(G)`

`NilpotentSubgroups(G)`

Conjugacy class representatives for all subgroups of the indicated type in G. The algorithm used is essentially that of [Hul99] without the action of automorphisms. Appropriate filters are applied to select the desired groups at each successive quotient in the computation.

`MaximalSubgroups(G)`

A sequence of conjugacy class representatives for the maximal subgroups of G. The algorithm, developed by Charles Leedham-Green, relies on computing a special presentation for G.

`SubgroupLattice(G)`

The lattice of conjugacy classes of subgroups of G.

`BurnsideMatrix(G)`

The Burnside matrix corresponding to the lattice of subgroups of G.

`DisplayBurnsideMatrix(G)`

Pretty-print the Burnside matrix corresponding to the lattice of subgroups of G.

Example H63E18

To show a bit about subgroup classes, we look at the direct product of C_3 and D_3. First we list out the normal subgroups of G.

```
> G := DirectProduct(CyclicGroup(GrpPC,3),
>                    DihedralGroup(GrpPC,3));
> ns := NormalSubgroups(G);
> ns;
Conjugacy classes of subgroups
------------------------------
[1]     Order 1            Length 1
        GrpPC of order 1
        PC-Relations:
[2]     Order 3            Length 1
        GrpPC of order 3
        PC-Relations:
            $.1^3 = Id($)
[3]     Order 3            Length 1
        GrpPC of order 3
        PC-Relations:
            $.1^3 = Id($)
[4]     Order 6            Length 1
        GrpPC of order 6 = 2 * 3
        PC-Relations:
            $.1^2 = Id($),
            $.2^3 = Id($),
            $.2^$.1 = $.2^2
[5]     Order 9            Length 1
        GrpPC of order 9 = 3^2
        PC-Relations:
            $.1^3 = Id($),
            $.2^3 = Id($)
[6]     Order 18           Length 1
        GrpPC of order 18 = 2 * 3^2
        PC-Relations:
            $.1^2 = Id($),
            $.2^3 = Id($),
            $.3^3 = Id($),
```

```
            $.3^$.1 = $.3^2
```

The normal subgroups sequence has a special printing routine. Each entry in the sequence is actually a record.

```
> ns[2];
rec<recformat<order, length, subgroup, presentation> |
 order := 3, length := 1, subgroup := GrpPC of order 3
PC-Relations:
    $.1^3 = Id($)>
```

We extract the two normal subgroups of order 3. Each of them turn out to have one conjugacy class of complements in G. However, one of the complements is normal and the other is not.

```
> N1 := ns[2]`subgroup;
> N2 := ns[3]`subgroup;
> c1 := Complements(G,N1);
> c1;
[
    GrpPC of order 6 = 2 * 3
    PC-Relations:
        $.1^2 = Id($),
        $.2^3 = Id($),
        $.2^$.1 = $.2^2
]
> c2 := Complements(G,N2);
> c2;
[
    GrpPC of order 6 = 2 * 3
    PC-Relations:
        $.1^2 = Id($),
        $.2^3 = Id($)
]
> Index(G,Normalizer(G,c1[1]));
1
> Index(G,Normalizer(G,c2[1]));
3
```

We can look at the full list of classes of subgroups of G to see that there are three classes of non-normal subgroups as well as the normal subgroups. There are two non-normal subgroups of order 3 in addition to $N1$ and $N2$.

```
> Subgroups(G);
Conjugacy classes of subgroups
------------------------------
[ 1]    Order 1            Length 1
        GrpPC of order 1
        PC-Relations:
[ 2]    Order 2            Length 3
        GrpPC of order 2
        PC-Relations:
```

```
          $.1^2 = Id($)
[ 3]    Order 3           Length 1
        GrpPC of order 3
        PC-Relations:
          $.1^3 = Id($)
[ 4]    Order 3           Length 1
        GrpPC of order 3
        PC-Relations:
          $.1^3 = Id($)
[ 5]    Order 3           Length 2
        GrpPC of order 3
        PC-Relations:
          $.1^3 = Id($)
[ 6]    Order 6           Length 1
        GrpPC of order 6 = 2 * 3
        PC-Relations:
          $.1^2 = Id($),
          $.2^3 = Id($),
          $.2^$.1 = $.2^2
[ 7]    Order 6           Length 3
        GrpPC of order 6 = 2 * 3
        PC-Relations:
          $.1^2 = Id($),
          $.2^3 = Id($)
[ 8]    Order 9           Length 1
        GrpPC of order 9 = 3^2
        PC-Relations:
          $.1^3 = Id($),
          $.2^3 = Id($)
[ 9]    Order 18          Length 1
        GrpPC of order 18 = 2 * 3^2
        PC-Relations:
          $.1^2 = Id($),
          $.2^3 = Id($),
          $.3^3 = Id($),
          $.3^$.1 = $.3^2
```

63.9 Quotient Groups

63.9.1 Construction of Quotient Groups

One of the strengths of representing groups with polycyclic or power-conjugate presentations is that arbitrary quotient groups can be computed. Given (generators for) a normal subgroup of a pc-group, MAGMA will compute a pc-presentation for the quotient and the corresponding canonical homomorphism.

The `pQuotient` function, which can be used to find a prime-power quotient of a finitely-presented group, can also be used to compute quotients of pc-groups.

`quo< G | L >`

Construct the quotient Q of the pc-group G by the normal subgroup N, where N is the smallest normal subgroup of G containing the elements specified by the terms of the *generator list* L.

The possible forms of a term $L[i]$ of the generator list are the same as for the `sub`-constructor.

The quotient group Q and the corresponding natural homomorphism $f : G \to Q$ are returned.

`G / N`

Given a normal subgroup N of the pc-group G, construct the quotient of G by N.

Example H63E19

We will compute $O_{3',3}(G)$, where G is a pc-representation of the symmetric group S_4. The subgroup is defined by $O_{3',3}(G)/O_{3'}(G) = O_3(G/O_{3'}(G))$.

```
> G := PCGroup(Sym(4));
> N := pCore(G,-3);
> Q,f := quo<G|N>;
> Q;
GrpPC : Q of order 6 = 2 * 3
PC-Relations:
    Q.1^2 = Id(Q),
    Q.2^3 = Id(Q),
    Q.2^Q.1 = Q.2^2
> S := pCore(Q,3);
> H := S @@ f;
> H;
GrpPC : H of order 12 = 2^2 * 3
PC-Relations:
    H.1^3 = Id(H),
    H.2^2 = Id(H),
    H.3^2 = Id(H),
    H.2^H.1 = H.2 * H.3,
    H.3^H.1 = H.2
```

63.9.2 Abelian and p-Quotients

A number of standard quotients may be constructed.

`AbelianQuotient(G)`

The maximal abelian quotient G/G' of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism $\pi : G \to G/G'$ is returned as second value.

`AbelianQuotientInvariants(G)`

`AQInvariants(G)`

A sequence of integers giving the abelian invariants of the maximal abelian quotient of G.

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient Q of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism $\pi : G \to Q$ is returned as second value.

`pQuotient(G, p, c : parameters)`

`Workspace`	RngIntElt	*Default :* 5000000
`Metabelian`	BoolElt	*Default :* `false`
`Exponent`	RngIntElt	*Default :* 0
`Print`	RngIntElt	*Default :* 0

Given a pc-group G, a prime p, and a positive integer c, this function constructs a consistent power-conjugate presentation for the largest p-quotient P of G having lower exponent-p class at most c. If c is given as zero, then the limit 127 is placed on the class.

The function also returns the natural homomorphism π from G to P, a sequence S describing the definitions of the pc-generators of P and a flag indicating whether P is the maximal p-quotient of G.

The k-th element of S is a sequence of two integers, describing the definition of the k-th pc-generator $P.k$ of P as follows.

- If $S[k] = [0, r]$, then $P.k$ is defined via the image of $G.r$ under π.
- If $S[k] = [r, 0]$, then $P.k$ is defined via the power relation for $P.r$.
- If $S[k] = [r, s]$, then $P.k$ is defined via the conjugate relation involving $P.r^{P.s}$.

63.10 Normal Subgroups and Subgroup Series

63.10.1 Characteristic Subgroups

`Centre(G)`
`Center(G)`

The centre of the group G.

`CommutatorSubgroup(G)`
`DerivedSubgroup(G)`
`DerivedGroup(G)`

The derived subgroup of the group G.

`FittingSubgroup(G)`
`FittingGroup(G)`

The Fitting subgroup of the group G.

`FrattiniSubgroup(G)`

The Frattini subgroup of the group G.

`Hypercentre(G)`
`Hypercenter(G)`

The hypercentre of the group G, i.e. the stationary term in the upper central series for G.

`MinimalNormalSubgroups(G)`

A sequence containing all minimal normal subgroups of G.

`pCore(G, S)`

The maximal normal π-subgroup of G, $O_\pi(G)$, where π is defined by S. The argument S may be a set of primes, a single prime, or the negation of a single prime. If $S = -p$, then $O_{p'}(G)$ is returned.

`Socle(G)`

The socle of G.

63.10.2 Subgroup Series

`AbelianBasis(G)`

Given an abelian group G, return sequences B and I such that order$(B[i]) = I[i]$ and $\langle B \rangle = G$ and the terms of I give the types of each p-primary component of G.

`AbelianInvariants(G)`

`Invariants(G)`

The abelian invariants of the abelian group G as a sequence of integers.

`ChiefSeries(G)`

A chief series for the group G. The series is returned as a sequence of subgroups of G.

`CompositionSeries(G)`

A composition series for the group G. The series is returned as a sequence of subgroups of G. The i-th term of the composition series has a presentation given by the generators $G.i$ through $G.$`NPCgens`(G) and relations involving those generators only.

`CompositionFactors(G)`

A sequence of integer tuples that describe the composition factors, ordered according to some composition series for the group G. Since each factor will be a cyclic group of prime order, the tuples will each be of the form $< 19, 0, q >$ representing the cyclic group of order q. The sequence has a custom print routine.

`CompositionSeries(G, i)`

The $i+1$-th entry of the composition series for the group G. Its presentation is given by the generators $G.(i+1)$ through $G.m$, where m is the number of pc-generators of G and relations involving these generators only.

`DerivedSeries(G)`

The derived series of the group G. The series is returned as a sequence of subgroups.

`DerivedLength(G)`

The derived length of the group G.

`ElementaryAbelianSeries(G)`

An elementary abelian series is a chain of normal subgroups with the property that the quotient of each pair of successive terms in the series is elementary abelian. The elementary abelian series for the group G is returned as a sequence of subgroups.

`ElementaryAbelianSeriesCanonical(G)`

Gives a similar result to using `ElementaryAbelianSeries`, except the series returned depends only on the isomorphism type of the group, and consists of characteristic subgroups. This function may be slower than `ElementaryAbelianSeries`.

`LowerCentralSeries(G)`

The lower central series for the group G. The series is returned as a sequence of subgroups.

`NilpotencyClass(G)`

If G is nilpotent, return the nilpotence class of G. Otherwise, -1 is returned.

`pCentralSeries(G, p)`

The p-central series for G, where p is a prime dividing $|G|$. The series is returned as a sequence of subgroups. The p-central series $P_1 \triangleright P_2 \triangleright \cdots \triangleright P_i$ of a soluble group G is defined inductively as follows:

$P_1 = G$,

$P_{i+1} = (G, P_i)P_i^p$, for $i > 0$.

`SubnormalSeries(G, H)`

Given a group G and a subgroup H of G, return a sequence of subgroups commencing with G and terminating with H, such that each subgroup is normal in the previous one. If H is not subnormal in G, the empty sequence is returned.

`UpperCentralSeries(G)`

The upper central series of G. The series is returned as a sequence of subgroups.

Example H63E20

The elementary abelian series of the group $D_3 \wr D_5$ has terms of the following orders:

```
> H := DihedralGroup(GrpPerm, 5);
> G := WreathProduct(DihedralGroup(GrpPC, 3), DihedralGroup(GrpPC, 5),
>       [H.2, H.1]);
> EAS := ElementaryAbelianSeries(G);
> for i := 1 to #EAS do
>    print FactoredOrder(EAS[i]);
> end for;
    [ <2, 6>, <3, 5>, <5, 1> ]
    [ <2, 4>, <3, 5>, <5, 1> ]
    [ <2, 4>, <3, 5> ]
    [ <3, 5> ]
    []
```

Hence the elementary abelian factors can be seen to have sizes 2^2, 5, 2^4, and 3^5, reading from top to bottom.

63.10.3 Series for p-groups

The following functions are only defined for a pc-group which is a p-group.

`Agemo(G, i)`

Given a p-group G, return the characteristic subgroup of G generated by the elements x^{p^i}, $x \in G$, where i is a positive integer.

`Omega(G, i)`

Given a p-group G, return the characteristic subgroup of G generated by the elements of order dividing p^i, where i is a positive integer.

`JenningsSeries(G)`

Given a p-group G, return the Jennings series for G. The series is returned as a sequence of subgroups. The Jennings series $J_1 \triangleright J_2 \triangleright \cdots \triangleright J_i \cdots$ of a p-group G is defined inductively as follows:

$J_1 = G$,

$J_{i+1} =< (J_i, G), J_k^p >$, with $k = \lceil (i+1)/p \rceil$, $i > 0$.

`pClass(G)`

The lower exponent-p class of the p-group G.

`pRanks(G)`

A sequence whose i-th entry is the number of pc-generators for the lower exponent-p class i quotient of the p-group G.

63.10.4 Normal Subgroups and Complements

`NormalSubgroups(G)`

The collection of all normal subgroups of G returned as a sequence.

`NormalLattice(G)`

The lattice of normal subgroups of G.

`MinimalNormalSubgroup(G)`

An elementary abelian minimal normal subgroup of the soluble group G.

`MinimalNormalSubgroup(G, N)`

Given a non-trivial, normal subgroup N of G, return an elementary abelian minimal normal subgroup of G contained in N.

`Complements(G, N)`

Given a normal subgroup N of G, return conjugacy class representatives of all complements of N in G. This function implements the first cohomology computation described in [CNW90].

`NormalComplements(G, N)`

Given a normal subgroup N of G, return all normal complements of N in G. This function implements the first cohomology computation described in [CNW90].

`NormalComplements(G, H, N)`

Given a normal subgroup N of G, and a normal subgroup H of G containing N, return all complements of N in H which are normal in G. This function implements the first cohomology computation described in [CNW90].

Example H63E21

We define the direct product of an extraspecial group of order 3^3 and D_3 and let N be the first factor of this product. Inside the Sylow 3-subgroup, we see that N has 11 classes of complements, three of which are normal.

```
> A := ExtraSpecialGroup(GrpPC,3,1);
> B := DihedralGroup(GrpPC,3);
> G,f,p := DirectProduct(A,B);
> N := f[1](A);
> S3 := Sylow(G,3);
> cS := Complements(S3,N);
> [Index(S3,Normalizer(S3,t)):t in cS];
[ 1, 1, 1, 3, 3, 3, 3, 3, 3, 3, 3 ]
```

We can compute only the normal complements by using `NormalComplements`.

```
> ncS := NormalComplements(S3,N);
> #ncS;
3
```

We can check that precisely one of these three complements is actually normal in G.

```
> [IsNormal(G,t):t in ncS];
[ true, false, false ]
```

Since N has a G-normal complement in $S3$, we must have $S3$ normal in G. We can verify this. Using the three-parameter version of `NormalComplements` we can directly compute the G-normal complements of N in $S3$.

```
> IsNormal(G,S3);
true
> ncG := NormalComplements(G,S3,N);
> #ncG;
1
> #NormalComplements(G,N);
```

```
1
```

63.11 Cosets

63.11.1 Coset Tables and Transversals

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a group G and a subgroup H of G, this function returns

(a) An indexed set of elements T of G forming a right transversal for G over H; and

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and g in G, ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

`CosetTable(G, H)`

Given a group G and a subgroup H of G of index r, return a mapping $M : \langle\{1..r\}, G\rangle \to \{1..r\}$ describing the action of G on the (right) cosets of H.

`Transversal(G, H, K)`

An indexed set of representatives for the double cosets HuK in G, and the corresponding transversal mapping. The algorithm used is described in [Sla01].

`ShortCosets(p, H, G)`

Computes a set of representatives for the transversal of G modulo H of all cosets that contain p. This computation does not do a full transversal of G modulo H and may therefore be used even if the index of $(G : H)$ is very large.

63.11.2 Action on a Coset Space

`CosetAction(G, H)`

Given a subgroup H of the group G, construct the permutation representation of G given by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The natural homomorphism $f : G \to L$;

(b) The induced group L;

(c) The kernel K of the action (a subgroup of G).

`CosetImage(G, H)`

Given a subgroup H of the group G, construct the image L of G given by the action of G on the set of (right) cosets of H in G. L is returned as a permutation group.

`CosetKernel(G, H)`

Given a subgroup H of the group G, construct the kernel of the action of G on the set of (right) cosets of H in G.

63.12 Automorphism Group

63.12.1 General Soluble Group

In the case of a soluble non-p-group there are two algorithms available. By default, a lifting-based algorithm developed by M. Smith [Smi94] and extended by Smith and Slattery to use second cohomology is used. Alternatively, there is also an algorithm developed by D. Howden [How12], which uses the automorphism group of a Sylow p-subgroup of G to construct the automorphism group of G.

63.12.1.1 Lifting Algorithm

The automorphism group is computed step-by-step considering a series of factors of G by terms of a characteristic series

$$G = G_1 > G_2 > \cdots > G_k > 1$$

such that G_i/G_{i+1} is elementary abelian for each i. We compute the automorphism group $\mathrm{Aut}(G/G_2) \cong \mathrm{GL}(d, p)$ for some integer d and prime p, and then lift through each of the elementary abelian layers $G/G_3, \ldots, G/G_{k-1}$, finally arriving at $\mathrm{Aut}(G/G_k) = \mathrm{Aut}(G)$.

A group of type `GrpAuto` is returned. Details of the computation can be seen by setting the verbose flag `AutomorphismGroup` to `true`, and the characteristic series is available as the attribute `CharacteristicSeries` on the returned group.

In addition to the usual properties of `GrpAuto` (such as `Order`, `Ngens`, etc.), two special fields, `GenWeights` and `WeightSubgroupOrders`, are provided for automorphism groups of (non p-group) pc-groups. These each relate to weight subgroups of the automorphism group. Let i be the largest subscript such that the automorphism acts trivially on G/G_i. Then the automorphism is said to have weight $2i + 1$ if it acts non-trivially on G_i/G_{i+1}, and weight $2i + 2$ if it acts trivially on G_i/G_{i+1}. Note that there are no automorphisms of weight 2. The automorphisms of weight greater than or equal to a given value form a normal subgroup of A.

`AutomorphismGroup(G)`

Given a soluble group G presented by a pc-presentation, this function returns the automorphism group of G as a group of type `GrpAuto`.

`HasAttribute(A, "GenWeights")`

If the attribute `GenWeights` is defined for A then the function returns `true`, and a sequence of integers. This integer sequence indicates where each generator lies in the normal series of A corresponding to the action of the group on G (as described at the beginning of the section). If the attribute is not set then the sequence is unassigned. The function call `AutomorphismGroup(G)`, where G has type `GrpPC`, always returns an automorphism group with this attribute set. In this case the sequence may also be obtained by the short form `A‘GenWeights`.

```
HasAttribute(A, "WeightSubgroupOrders")
```

If the attribute `WeightSubgroupOrders` is defined for A then the function returns `true`, and a sequence of integers. This sequence of integers gives the orders for the normal series of weight subgroups described at the beginning of the section. If the attribute is not set then the sequence is unassigned. The function call `AutomorphismGroup(G)`, where G has type `GrpPC`, always returns an automorphism group with this attribute set. In this case the sequence may also be obtained by the short form `A‘WeightSubgroupOrders`.

Example H63E22

An example using `AutomorphismGroup` and some related features. We build a group based on the structure of a finite field (multiplicative group acting on the additive group) and then compute its automorphism group. First, we set up the field.

```
> E := GF(2);
> F := GF(8);
> V,phi := VectorSpace(F,E);
> d := Dimension(V);
> x := PrimitiveElement(F);
```

Then, define a pc-group to act and define the action based on the multiplication in the field. Compute the matrix by mapping the vectors back to the field, multiplying by x, and then recording the result.

```
> C := CyclicGroup(GrpPC,Order(x));
> MR := MatrixRing(E, d);
> s := [];
> for i := 1 to d do
>  y := ((V.i)@@phi)*x;
>  s cat:= Eltseq(y);
> end for;
```

Turn the sequence of image components into a matrix and use the matrix to create a C-module. Then use that module to create the split extension.

```
> t := MR!s;
> M := GModule(C,[t]);
> G := Extension(M,C);
> G;
GrpPC : G of order 56 = 2^3 * 7
PC-Relations:
    G.1^7 = Id(G),
    G.2^2 = Id(G),
    G.3^2 = Id(G),
    G.4^2 = Id(G),
    G.2^G.1 = G.3,
    G.3^G.1 = G.4,
```

```
    G.4^G.1 = G.2 * G.3
```

Then we can compute the automorphism group of G.

```
> A := AutomorphismGroup(G);
> A;
A group of automorphisms of GrpPC : G
Generators:
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1^2
        G.2 |--> G.3 * G.4
        G.3 |--> G.2 * G.4
        G.4 |--> G.3
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1
        G.2 |--> G.2 * G.3
        G.3 |--> G.3 * G.4
        G.4 |--> G.2 * G.3 * G.4
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1 * G.2 * G.3
        G.2 |--> G.2
        G.3 |--> G.3
        G.4 |--> G.4
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1 * G.3 * G.4
        G.2 |--> G.2
        G.3 |--> G.3
        G.4 |--> G.4
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1 * G.4
        G.2 |--> G.2
        G.3 |--> G.3
        G.4 |--> G.4
> [Order(x):x in Generators(A)];
[ 3, 2, 7, 2, 2 ]
```

Next, we can use the automorphisms to create an extension of G.

```
> b := A.1;
> Order(b);
3
> tau := hom<G->G|[b(G.i):i in [1..NPCgens(G)]]>;
> D := CyclicGroup(GrpPC,Order(b));
> K := Extension(G,D,[tau]);
> K;
GrpPC : K of order 168 = 2^3 * 3 * 7
PC-Relations:
    K.1^3 = Id(K),
    K.2^7 = Id(K),
    K.3^2 = Id(K),
```

```
    K.4^2 = Id(K),
    K.5^2 = Id(K),
    K.2^K.1 = K.2^2,
    K.3^K.1 = K.4 * K.5,
    K.3^K.2 = K.4,
    K.4^K.1 = K.3 * K.5,
    K.4^K.2 = K.5,
    K.5^K.1 = K.4,
    K.5^K.2 = K.3 * K.4
> #Classes(K);
8
```

Finally, we examine information about the weight subgroups. We list only the orders of the terms of the characteristic series in G in order to save space.

```
> [Order(H): H in A‘CharacteristicSeries];
[ 56, 8, 1 ]
> A‘GenWeights;
[ 1, 3, 4, 4, 4 ]
> A‘WeightSubgroupOrders;
[ 168, 56, 56, 8 ]
```

63.12.1.2 Lifting from the Automorphism Group of a Sylow p-subgroup

The algorithm developed by D. Howden [How12] follows a different strategy to the Smith-Slattery lifting approach. Given a soluble group G, the algorithm determines a suitable Sylow p-subgroup P of G, and uses the automorphism group of P (using the algorithm for p-groups detailed below) to construct the automorphism group of G.

In cases where the automorphism group is soluble, the algorithm automatically constructs a pc-representation for it. Solublility of the returned group can then be tested via the `IsSoluble` intrinsic. The pc-representation obtained using the `PCGroup` intrinsic, and pc-generators (as automorphism maps) via the `PCGenerators` intrinsic.

In some cases where the automorphism group is not soluble, the algorithm will construct a permutation representation during its construction.

A group of type `GrpAuto` is returned. Details of the computation can be seen by setting the verbose flag `AutomorphismGroupSolubleGroup` to 1.

A variation of this algorithm can be used for isomorphism testing.

`AutomorphismGroupSolubleGroup(G: parameters)`

Given a soluble group G presented by a pc-presentation, this function returns the automorphism group of G as a group of type GrpAuto.

p [RngIntElt] *Default :* 1;

A prime p dividing the order of G. The automorphism group of the Sylow p-subgroup is then used to construct the automorphism group of G. If the p-core of G is trivial

then an error is given. The default value of $p = 1$ indicates that the algorithm should take p to be the prime giving the largest Sylow p-subgroup of G.

`IsIsomorphicSolubleGroup(G, H: parameters)`

Returns `true` if the soluble groups G, H presented by pc-presentations, are isomorphic, and `false` otherwise. Where the groups are isomorphic, a mapping $G \to H$ is also returned.

`p` [RngIntElt] *Default :* 1;

A prime p dividing the order of G (assuming that the orders of G and H are the same). The algorithm then tests Sylow p-subgroups of G and H for isomorphism and attempts to extend these isomorphisms to an isomorphism $G \to H$. If the p-cores of G and H are trivial then an error is given. The default value of $p = 1$ indicates that the algorithm should take p to be the prime giving the largest Sylow p-subgroup of G.

Example H63E23

An example using `AutomorphismGroupSolubleGroup` and some related features. We use a group from the `solgps` library.

```
> load solgps;
> G := G10();
> FactoredOrder(G);
[ <2, 18>, <7, 4> ]
> time A := AutomorphismGroupSolubleGroup(G);
Time: 18.220
> time R_A, phi_A := PCGroup(A);
Time: 0.000
> FactoredOrder(R_A);
[ <2, 20>, <3, 2>, <7, 6> ]
```

63.12.2 p-group

For a description of the algorithm used to construct the automorphism group of a p-group, see [ELGO02].

While it is difficult to state very firm guidelines for the performance of the algorithm, our experience suggests that it has most difficulty in constructing automorphism groups of p-groups of "large" Frattini rank (say rank larger than about 6) and p-class 2. If the group has larger p-class, then it usually has more characteristic structure and the algorithm exploits this. The *order* of a group is *not* a useful guide to the difficulty of the computation.

`SetVerbose ("AutomorphismGroup", 1)` provides information on the progress of the algorithm.

`AutomorphismGroup(G: parameters)`

The group G is a p-group described by a pc-presentation. The function returns the automorphism group of G as a group of type `GrpAuto`.

`CharacteristicSubgroups`

[GrpPC] *Default :* [];

A list of known characteristic subgroups of G; these may improve the efficiency of the construction. Note that the algorithm simply accepts that the supplied subgroups are fixed under the action of the automorphism group; it does *not* verify that they are in fact characteristic.

Example H63E24

```
> G := SmallGroup (64, 78);
> A := AutomorphismGroup (G);
> #A;
1024
> A.1;
    Automorphism of GrpPC : G which maps:
        G.1 |--> G.1
        G.2 |--> G.2
        G.3 |--> G.1 * G.3
        G.4 |--> G.4
        G.5 |--> G.5
        G.6 |--> G.4 * G.6
> Order (A.1);
4
> a := A.1^2; [a (G.i): i in [1..6]];
[ G.1, G.2, G.3 * G.5, G.4, G.5, G.6 ]
```

`OrderAutomorphismGroupAbelianPGroup(A)`

Order of automorphism group of abelian p-group G where $A = [a_1, a_2, \ldots]$ and $G = C_{a_1} \times C_{a_2} \times \ldots$.

Example H63E25

Subgroups of $C_4 \times C_8 \times C_{64}$.

```
> NumberOfSubgroupsAbelianPGroup ([4, 8, 64]);
[ 7, 35, 91, 139, 171, 171, 139, 91, 35, 7, 1 ]
```

Hence, for example, there are 7 subgroups of order 2 and 139 subgroups of order 2^4.

```
> OrderAutomorphismGroupAbelianPGroup ([4, 8, 64]);
4194304
```

63.12.3 Isomorphism and Standard Presentations

The `pQuotient` command returns a power-conjugate presentation for a given p-group but this presentation depends on the user-supplied description of the group. The Standard Presentation algorithm computes a "canonical" presentation for the p-group, which is independent of the user-supplied description. For a description of this algorithm, see [O'B94].

The canonical or *standard* presentation of a given p-group is the power-conjugate presentation obtained when a description of the group is computed using the default implementation of the p-group generation algorithm.

Hence, two groups in the same isomorphism class have identical standard presentations. Given two p-groups, if their standard presentations are identical, then the groups are isomorphic, otherwise they are not. Hence to decide whether two groups are isomorphic, we can first construct the standard presentation of each using the `StandardPresentation` function and then compare these presentations using the `IsIdenticalPresentation` function.

While it is difficult to state very firm guidelines for the performance of the algorithm, our experience suggests that the difficulty of deciding isomorphism between p-groups is governed by their Frattini rank and is most practical for p-groups of rank at most 5. The *order* of a group is *not* a useful guide to the difficulty of the computation.

`SetVerbose ("Standard", 1)` will provide information on the progress of the algorithm.

`StandardPresentation(G)`

`StandardPresentation(G:` *parameters*`)`

The group G is a p-group presented by an arbitrary pc-presentation. The group H defined by its standard presentation is returned together with a map from G to H.

`StartClass` RngIntElt *Default :* 1

If `StartClass` is k, then use `pQuotient` to construct the class $k-1$ p-quotient of G and standardize the presentation only from class k onwards.

`IsIdenticalPresentation(G, H)`

Returns `true` if G and H have identical presentations, `false` otherwise.

`IsIsomorphic(G, H)`

The function returns `true` if the p-groups G and H are isomorphic, `false` otherwise. It constructs their standard presentations class by class, and checks for equality. If they are isomorphic, it also returns an isomorphism from G to H.

Example H63E26

In the next two examples, we investigate whether particular p-quotients of fp-groups are isomorphic.

```
> F<x, y, t> := FreeGroup(3);
```

```
> G := quo< F | x*y^2*x^-1=y^-2, y*x^2*y^-1=x^-2, x^2=t^2, y^2=(t^-1*x)^2,
>                       t*(x*y)^2=(x*y)^2*t >;
> Q1 := pQuotient(G, 2, 3: Print := 1);
Lower exponent-2 central series for G
Group: G to lower exponent-2 central class 1 has order 2^3
Group: G to lower exponent-2 central class 2 has order 2^7
Group: G to lower exponent-2 central class 3 has order 2^11
> H := quo< F | x*y^2*x^-1=y^-2, y*x^2*y^-1=x^-2, x^2=t^2*(x*y)^2,
>                       y^2=(t^-1*x)^2, t*(x*y)^2=(x*y)^2*t >;
> Q2 := pQuotient(H, 2, 3: Print := 1);
Lower exponent-2 central series for H
Group: H to lower exponent-2 central class 1 has order 2^3
Group: H to lower exponent-2 central class 2 has order 2^7
Group: H to lower exponent-2 central class 3 has order 2^11
```

Now check whether the class 3 2-quotients are isomorphic.

```
> IsIsomorphic(Q1, Q2);
false
```

In the next example, we construct an explicit isomorphism between two 5-groups.

```
> F<a, b> := Group<a, b | a^5, b^5, (a * b * a)^5 = (b, a, b) >;
> G := pQuotient (F, 5, 6 : Print := 1);
Lower exponent-5 central series for F
Group: F to lower exponent-5 central class 1 has order 5^2
Group: F to lower exponent-5 central class 2 has order 5^3
Group: F to lower exponent-5 central class 3 has order 5^4
Group: F to lower exponent-5 central class 4 has order 5^5
Group: F to lower exponent-5 central class 5 has order 5^7
Group: F to lower exponent-5 central class 6 has order 5^8
> G;
GrpPC : G of order 390625 = 5^8
PC-Relations:
G.2^G.1 = G.2 * G.3,
G.3^G.1 = G.3 * G.4,
G.3^G.2 = G.3 * G.6 * G.7^4 * G.8^4,
G.4^G.1 = G.4 * G.5,
G.4^G.2 = G.4 * G.7 * G.8,
G.4^G.3 = G.4 * G.7^4 * G.8,
G.5^G.1 = G.5 * G.6,
G.5^G.2 = G.5 * G.7,
G.5^G.3 = G.5 * G.8^2,
G.6^G.2 = G.6 * G.8,
G.7^G.1 = G.7 * G.8^3
> K<a, b> := Group<a, b | a^5, b^5, (b * a * b)^5 = (b, a, b) >;
> H := pQuotient (K, 5, 6 : Print := 1);
Lower exponent-5 central series for K
Group: K to lower exponent-5 central class 1 has order 5^2
Group: K to lower exponent-5 central class 2 has order 5^3
```

```
Group: K to lower exponent-5 central class 3 has order 5^4
Group: K to lower exponent-5 central class 4 has order 5^5
Group: K to lower exponent-5 central class 5 has order 5^7
Group: K to lower exponent-5 central class 6 has order 5^8
> H;
GrpPC : H of order 390625 = 5^8
PC-Relations:
H.2^H.1 = H.2 * H.3,
H.3^H.1 = H.3 * H.4,
H.3^H.2 = H.3 * H.6^2 * H.7^2 * H.8^2,
H.4^H.1 = H.4 * H.5,
H.4^H.2 = H.4 * H.7,
H.4^H.3 = H.4 * H.7^4 * H.8,
H.5^H.1 = H.5 * H.6,
H.5^H.2 = H.5 * H.7,
H.5^H.3 = H.5 * H.8^2,
H.6^H.2 = H.6 * H.8,
H.7^H.1 = H.7 * H.8^3
> flag, phi := IsIsomorphic (G, H);
> flag;
true
> for g in PCGenerators (G) do print g, "--->", phi (g); end for;
G.1 ---> H.1
G.2 ---> H.2^3 * H.4^3 * H.5^3 * H.6^2 * H.7^4 * H.8^3
G.3 ---> H.3^3 * H.5^3 * H.6^4 * H.8^3
G.4 ---> H.4^3 * H.6^3 * H.7^2 * H.8^3
G.5 ---> H.5^3 * H.8
G.6 ---> H.6^3
G.7 ---> H.7^4
G.8 ---> H.8^4
```

The functions `IsIsomorphic` and `StandardPresentation` are expensive. Here we have a list of groups and we want to find any isomorphisms among the collection. Rather than repeatedly applying `IsIsomorphic`, we first construct and store standard presentations for each group in the sequence, and then quickly compare these using `IsIdenticalPresentation`.

```
> F<a, b> := FreeGroup (2);
> p := 7;
> Q := [];
> for k := 1 to p - 1 do
>       G := quo< F | a^p = (b, a, a), b^p = a^(k*p), (b, a, b)>;
>       H := pQuotient (G, p, 10);
>       Q[k] := StandardPresentation (H);
> end for;
```

Now run over the list of standard presentations and check for equality.

```
> for i in [2..p - 1] do
>    for j in [1.. i - 1] do
>       if IsIdenticalPresentation (Q[i], Q[j]) then
```

```
>          print "Standard Presentations  ", i, " and ", j, " are identical";
>       end if;
>    end for;
> end for;
Standard Presentations   2  and  1  are identical
Standard Presentations   4  and  1  are identical
Standard Presentations   4  and  2  are identical
Standard Presentations   5  and  3  are identical
Standard Presentations   6  and  3  are identical
Standard Presentations   6  and  5  are identical
```

63.13 Generating p-groups

The p-central series of a group G is the descending sequence of subgroups

$$G = P_0(G) \geq \ldots \geq P_{i-1}(G) \geq P_i(G) \geq \ldots \geq$$

where $P_i(G) = [P_{i-1}(G), G]P_{i-1}(G)^p$ for $i \geq 1$.

If $P_c(G) = 1$ and c is the smallest such integer then G has *p-class c*. A group with p-class c is nilpotent and has nilpotency class at most c.

Let G be a finite p-group with Frattini rank d and class c. A group H is a *descendant* of G if H has Frattini rank d and the quotient $H/P_c(H)$ is isomorphic to G. A group is an *immediate descendant* of G if it is a descendant of G and has class $c+1$.

The p-group generation algorithm allows the construction of (immediate) descendants of a p-group. For a description of this algorithm, see [New77, O'B90].

`SetVerbose ("GeneratepGroups", 1)` will provide information on the progress of the algorithm.

`GeneratepGroups (p, d, c : parameters)`

Generate all d-generator p-class at most c p-groups.

`Exponent` RngIntElt *Default :* 0

All groups constructed satisfy the supplied exponent.

`OrderBound` RngIntElt *Default :* 0

Given `OrderBound := n`, all groups constructed have order at most p^n.

`StepSizes` [RngIntElt] *Default :* []

Construct descendants of order $p^{(n+s)}$ of a group of order p^n only for s in `StepSizes`.

`All` BoolElt *Default :* `true`

If `true`, return all groups. Otherwise, return only the capable groups (those which have descendants).

`Descendants(G : parameters)`

`Descendants(G, c : parameters)`

Construct descendants of G having p-class at most c; if c is not supplied, it is assumed to be one larger than the p-class of G. This function supports the same variable arguments as `GeneratepGroups`.

Example H63E27

```
> G := DihedralGroup(GrpPC, 16);
> T := Descendants (G, 8);
> #T;
12
> H := T[5];
> H;
GrpPC : H of order 128 = 2^7
PC-Relations:
    H.1^2 = H.7,
    H.2^2 = H.3 * H.4,
    H.3^2 = H.4 * H.5,
    H.4^2 = H.5 * H.6,
    H.5^2 = H.6 * H.7,
    H.6^2 = H.7,
    H.2^H.1 = H.2 * H.3,
    H.3^H.1 = H.3 * H.4,
    H.4^H.1 = H.4 * H.5,
    H.5^H.1 = H.5 * H.6,
    H.6^H.1 = H.6 * H.7
```

Example H63E28

What is the soluble length of a 2-generator group of exponent 4? We construct the 2-generator 2-groups having exponent 4.

```
> T := GeneratepGroups(2, 2, 10: Exponent := 4);
> "The number of 2-generator exponent 4 groups is ", # T;
The number of 2-generator exponent 4 groups is  26
```

What are their soluble lengths?

```
> for i := 1 to #T do
>       "Group ", i, " has soluble length ", DerivedLength (T[i]);
> end for;
Group  1  has soluble length  1
Group  2  has soluble length  2
Group  3  has soluble length  2
Group  4  has soluble length  1
Group  5  has soluble length  2
Group  6  has soluble length  2
```

```
Group  7  has soluble length  2
Group  8  has soluble length  2
Group  9  has soluble length  2
Group  10  has soluble length  2
Group  11  has soluble length  2
Group  12  has soluble length  2
Group  13  has soluble length  2
Group  14  has soluble length  2
Group  15  has soluble length  2
Group  16  has soluble length  2
Group  17  has soluble length  2
Group  18  has soluble length  2
Group  19  has soluble length  2
Group  20  has soluble length  2
Group  21  has soluble length  3
Group  22  has soluble length  3
Group  23  has soluble length  3
Group  24  has soluble length  3
Group  25  has soluble length  3
Group  26  has soluble length  3
```

Example H63E29

Can we find all 2-generator 3-groups of abundance zero? Such groups have order at most 3^5. First, we define a function which checks the number of conjugacy classes of a group (to determine abundance).

```
> IsGoodGroup := function(G, k)
>
>    ncl := # Classes(G);
>
>    O := FactoredOrder(G);
>    p := O[1][1];
>    m := O[1][2];
>    n := Floor(m / 2);
>    e := m - n * 2;
>    Desired := n * (p^2 - 1) + p^e + k * (p - 1) * (p^2 - 1);
>
>    return (Desired eq ncl);
>
> end function;
```

Then, we generate the potential candidates and check each.

```
> a := GeneratepGroups (3, 2, 4 : OrderBound := 5);
> #a;
42
>
> for i := 1 to #a do
```

```
>        G := a[i];
>        if IsGoodGroup(G, 0) then
>           "Group ", i, " of order ", Order(G), " has abundance 0";
>        end if;
> end for;
Group  1  of order  9  has abundance 0
Group  3  of order  27  has abundance 0
Group  4  of order  27  has abundance 0
Group  11  of order  81  has abundance 0
Group  12  of order  81  has abundance 0
Group  13  of order  81  has abundance 0
Group  14  of order  81  has abundance 0
Group  40  of order  243  has abundance 0
Group  41  of order  243  has abundance 0
Group  42  of order  243  has abundance 0
```

`ClassTwo(p, d :` *parameters*`)`

`ClassTwo(p, d, Step :` *parameters*`)`

`ClassTwo(p, d, s :` *parameters*`)`

Count the d-generator p-groups of p-class 2. If s or *Step* is supplied, then count only those of order $p^{(d+s)}$ or $p^{(d+m)}$ for $m \in Step$. In the first two invocations, the sequence returns a sequence of length $\binom{d}{2}$, whose m-th entry is the number of groups of $p^{(d+m)}$. (Some additional entries may be deduced on the basis of duality.) The last invocation returns the number of groups of $p^{(d+s)}$. For details of the algorithm used see [EO99].

`Exponent` RngIntElt *Default :* 0

If `Exponent` is `true`, count those groups which have exponent p. The directive `SetVerbose ("ClassTwo", 1)` will provide information on the progress of the algorithm.

Example H63E30

Count the number of 3-generator p-class 2 5-groups.

```
> ClassTwo(5, 3);
[ 4, 19, 42, 19, 4, 1 ]
```

For example, the number of 3-generator 5-groups of order 5^6 and p-class 2 is precisely 42.
Count the number of 4-generator p-class 2 5-groups of order 5^7.

```
> ClassTwo(5, 4, 3);
6598
```

63.14 Representation Theory

Chapter 91 on characters describes many functions for computing with partial character tables or individual characters.

`CharacterDegrees(G)`

`CharacterDegrees(G, z, p)`

Given a finite pc-group G, return the sequence $[\langle d_1, c_1\rangle, \langle d_2, c_2\rangle, \ldots]$, where c_i is the number of irreducible characters of G having degree d_i. For details of the algorithm see Conlon [Con90b].

The second form requires z to be a central element of G and p to be a prime or zero. The sequence returned enumerates the number of absolutely irreducible characters of G in characteristic p, lying over some faithful linear character of $\langle z\rangle$.

`CharacterDegrees(G)`

Given a finite p-group G, return the sequence $[\langle d_1, c_1\rangle, \langle d_2, c_2\rangle, \ldots]$, where c_i is the number of irreducible characters of G having degree d_i. For details of the algorithm see [Sla86].

`CharacterDegreesPGroup(G)`

Given a finite p-group G, return the sequence $[C_0, C_1, \ldots]$, where C_i is the number of irreducible characters of G having degree p^i. For details of the algorithm see [Sla86].

`CharacterTable(G:` *parameters*`)`

Construct the table of ordinary irreducible characters for the group G.

`Al` MonStgElt *Default :* "*Default*"

This parameter controls the algorithm used. The string `"DS"` forces use of the Dixon-Schneider algorithm. The string `"IR"` forces the use of Unger's induction/reduction algorithm [Ung06]. The `"Default"` algorithm is to use Dixon-Schneider for groups of order ≤ 5000 and Unger's algorithm for larger groups. This may change in future.

`DSSizeLimit` RngIntElt *Default :* 10^4

When the default algorithm is selected, a positive value n for `DSSizeLimit` means that before using Unger's algorithm, the full character space is split by some passes of Dixon-Schneider, restricted to using class matrices corresponding to conjugacy classes with size at most n.

`CharacterTableConlon(G)`

Given a finite p-group G, return the character table of G. The algorithm is due to Conlon, as described in [Con90].

`GModule(G, M)`

The G-module for the action of G on the vector space defined by the matrix ring M.

`GModule(G, A)`

A KG-module M corresponding to the action of the group G on the elementary abelian subgroup A of G is constructed. The map from A to the vector space underlying M is also returned.

`GModule(G, A, B)`

A KG-module M corresponding to the action of the group G on the elementary abelian section A/B of G is constructed. The map from A to the vector space underlying M is also returned.

`AbsolutelyIrreducibleRepresentationsSchur(G, k:` *parameters*`)`

`AbsolutelyIrreducibleModulesSchur(G, k:` *parameters*`)`

Compute the absolutely irreducible representations of the group G over appropriate extensions or sub-fields of the given field k. The representations returned are inequivalent and consist of all distinct representations, subject to the conditions imposed. The field k may be a finite field, the rationals or a cyclotomic field. In the case when k is a finite field, the Glasby-Howlett algorithm is used to determine the minimal field over which a representation may be realised. If k has characteristic 0, the field over which a representation is realised may not be minimal.

The representations are found using Schur's method of climbing the composition series for G defined by the pc-presentation. If the argument i is given then the algorithm will calculate only representations of the ith subgroup of the composition series.

The "Representations" function returns a list of homomorphisms $\rho : G \to GL(n, K)$, where K is a field compatible with k. The "Modules" version returns an equivalent list of G-modules.

`Process` BoolElt *Default :* `true`

If the parameter `Process` is set true then the list is a list of pairs comprising an integer and a representation. This list or any sublist of it is a suitable value for the argument L in the last versions of the function, and in this case only the representations in L will be extended up the series. This allows the user to inspect the representations produced along the way and cull any that are uninteresting.

`GaloisAction` MonStgElt *Default :* "Yes"

Possible values are `"Yes"`, `"No"` and `"Relative"` The default is `"Yes"` for intermediate levels and `"No"` for the whole group. The value `"Yes"` means that it only lists one representation from each orbit of the action of the absolute Galois group $Gal(K/\text{primefield}(K))$. Setting this parameter to `"No"` turns this reduction off (thus listing all inequivalent representations), while setting it to `"Relative"` uses the group $Gal(K/k)$.

MaxDimension RngIntElt *Default :*

Restrict the representations to those of dimension $\leq$ MaxDimension. Default is no restriction.

ExactDimension SetEnum *Default :*

If ExactDimension is assigned a set S of positive integers, attention is restricted to representations having dimensions lying in the set S. The default is equivalent to taking the set of all positive integers.

If both MaxDimension and ExactDimension are assigned values, then representations having dimensions that are either bounded by MaxDimension or contained in ExactDimension are produced.

IrreducibleRepresentationsSchur(G, k: *parameters*)

IrreducibleModulesSchur(G, k: *parameters*)

Compute irreducible representations of G over the given field k. All arguments and parameters are as for the absolutely irreducible case.

The computation proceeds by first computing the absolutely irreducible representations subject to the given parameters, then rewriting over the field k, with a consequent change of dimension of the representation.

Example H63E31

We compute representations of the dihedral group of order 20.

```
> G := DihedralGroup(GrpPC, 10);
> FactoredOrder(G);
[ <2, 2>, <5, 1> ]
```

First some modular representations with characteristic 2.

```
> r := IrreducibleModulesSchur(G, GF(2));
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 4 over GF(2)
*]
> r := AbsolutelyIrreducibleModulesSchur(G, GF(2));
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 2 over GF(2^2),
    GModule of dimension 2 over GF(2^2)
*]
> r := AbsolutelyIrreducibleModulesSchur(G, GF(2) : GaloisAction:="Yes");
> r;
[*
    GModule of dimension 1 over GF(2),
    GModule of dimension 2 over GF(2^2)
```

```
*]
```

The irreducible representation of dimension 4 is not absolutely irreducible, as over $GF(4)$ it splits into two Galois-equivalent representations.
Getting irreducible representations over the complex field presents no problem, despite not being able to use the complex field as an argument to the function call. We could specify the field to be the cyclotomic field with degree equal to Exponent(G), but it is preferable to ask for absolutely irreducible representations over the rationals.

```
> r := AbsolutelyIrreducibleRepresentationsSchur(G, Rationals());
> r;
[*
    Mapping from: GrpPC: G to GL(1, RationalField()),
    Mapping from: GrpPC: G to GL(1, RationalField()),
    Mapping from: GrpPC: G to GL(1, RationalField()),
    Mapping from: GrpPC: G to GL(1, RationalField()),
    Mapping from: GrpPC: G to GL(2, CyclotomicField(5)),
    Mapping from: GrpPC: G to GL(2, CyclotomicField(5)),
    Mapping from: GrpPC: G to GL(2, CyclotomicField(5)),
    Mapping from: GrpPC: G to GL(2, CyclotomicField(5))
*]
> r[6](G.2);
[zeta_5^3        0]
[       0 zeta_5^2]
```

63.15 Central Extensions

We now describe functions to construct $H^2(G, U)$ for a finite soluble group G and finite abelian group U (a trivial G-module). We also present functions to construct central extensions of U by G.

Denote by $Z^2(G, U)$ the abelian group of all cocycles from G to U, under pointwise multiplication. The values $\psi(g, h)$ of $\psi \in Z^2(G, U)$ may be represented as a "cocyclic matrix" with entries in U.

If $\phi : G \to U$ is a set map with $\phi(1_G) = 1_U$, then there is a coboundary $\partial\phi \in Z^2(G, U)$ defined by $\partial\phi(g, h) = \phi(g)\phi(h)\phi(gh)^{-1}$. The group of all coboundaries from G to U is denoted $B^2(G, U)$, and we have $H^2(G, U) = Z^2(G, U)/B^2(G, U)$. Then $H^2(G, U) = I \times T$, where I is the (faithful) image of $\mathrm{Ext}(G/G', U) \leq H^2(G/G', U)$ under inflation, and T is the (faithful) image of $\mathrm{Hom}(H_2(G), U)$ under a certain transgression homomorphism. Here we provide functions which construct representatives for the elements in a generating set for each of these two factors.

For details of the theory and the algorithm used, see [FO00].

`SetVerbose ("Cocycle", 1)` will provide additional information on the calculations in the functions.

`ExtGenerators(G, U)`

Given a soluble group G and an abelian group U (both defined by pc-presentations) the function returns a sequence of tuples describing generators for $\mathrm{Ext}(G/G', U)$ as cocyclic matrices; the first entry in each tuple is a representative of a generator, the second is the order of the coset of the representative in $H^2(G, U)$.

`HomGenerators(G, U)`

Given a soluble group G and an abelian group U (both defined by pc-presentations) the function returns a sequence of tuples describing generators for $\mathrm{Hom}(H_2(G), U)$ as cocyclic matrices; the first entry in each tuple is a representative of a generator, the second is the order of the coset of the representative in $H^2(G, U)$.

`ElementSequence(G)`

For a soluble group G, the function returns an indexed set of elements of G listed in the order used by `ExtGenerators` and `HomGenerators`.

`RepresentativeCocycles(G, U, Ext, Hom)`

Let G be a soluble group G and U be an abelian group both defined by pc-presentations. Let Ext and Hom be the values returned by calling `ExtGenerators` and `HomGenerators` respectively. The function `RepresentativeCocycles` returns a complete and irredundant set of representatives for the elements of $H^2(G, U)$ as cocyclic matrices.

`CentralExtension(G, U, A)`

Let G be a soluble group G and U be an abelian group, both defined by pc-presentations. Further, let A be a cocyclic matrix (as determined by the function `RepresentativeCocycles`). Then, this function returns the central extension of U by G determined by the cocyclic matrix A.

`CentralExtensions(G, U, Q)`

If G is a soluble group G and U is an abelian group, both defined by pc-presentations, and Q is a sequence of cocyclic matrices (as determined by the function `RepresentativeCocycles`), this function returns the corresponding sequence of central extension of U by G determined by the sequence of cocyclic matrices A. Note that the central extensions thereby constructed need not be mutually non-isomorphic.

`CentralExtensionProcess(G, U)`

Given a soluble group G and an abelian group U (both defined by pc-presentations) the function creates a process P for central extensions of U by G. Note that the list of central extensions constructed by this process will contain all isomorphism types but the extensions need not be mutually non-isomorphic.

`NextExtension(~P)`

Given a central extension process P, construct the next central extension determined by P.

`IsEmpty(P)`

Return `true` if all central extensions determined by the process P have been constructed; otherwise return `false`.

Example H63E32

We compute the abelian invariants of $H^2(D_4, C_2)$.

```
> G := DihedralGroup(GrpPC, 4);
> U := AbelianGroup(GrpPC, [2]);
>
> Ext := ExtGenerators(G, U);
> Ext[1];
    <[Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) Id(U) Id(U) Id(U) U.1 U.1 U.1 U.1]
    [Id(U) Id(U) Id(U) Id(U) U.1 U.1 U.1 U.1]
    [Id(U) Id(U) Id(U) Id(U) U.1 U.1 U.1 U.1]
    [Id(U) Id(U) Id(U) Id(U) U.1 U.1 U.1 U.1], 2>,
>
> Hom := HomGenerators(G, U);
> Hom;
[
    <[Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) U.1 U.1 Id(U) Id(U) U.1 U.1 Id(U)]
    [Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U) Id(U)]
    [Id(U) U.1 U.1 Id(U) Id(U) U.1 U.1 Id(U)]
    [Id(U) Id(U) Id(U) U.1 Id(U) U.1 U.1 U.1]
    [Id(U) U.1 Id(U) Id(U) U.1 U.1 Id(U) U.1]
    [Id(U) Id(U) Id(U) U.1 Id(U) U.1 U.1 U.1]
    [Id(U) U.1 Id(U) Id(U) U.1 U.1 Id(U) U.1], 2>
]
>
> AbelianInvariants(Ext, Hom);
[ 2, 2, 2 ]
```

We now compute the central extension of U by G determined by a single cocyclic matrix.

```
> A := RepresentativeCocycles(G, U, Ext, Hom);
> E := CentralExtension(G, U, A[2]);
> E;
GrpPC : E of order 16 = 2^4
PC-Relations:
```

```
    E.1^2 = E.4,
    E.2^2 = E.3 * E.4,
    E.2^E.1 = E.2 * E.3
```

Alternatively we can build all central extensions of U by G.

```
> E := CentralExtensions(G, U, A);
> "Number of extensions is ", #E;
Number of extensions is  8
```

Next, we provide an example of using the central extension process. Firstly, we create the groups and initialize the process.

```
> G := SmallGroup(12, 5);
> U := AbelianGroup(GrpPC, [2, 3]);
> P := CentralExtensionProcess(G, U);
```

Now we run over the central extensions and count conjugacy classes.

```
> C := [];
> while IsEmpty(P) eq false do
>    NextExtension(~P, ~E);
>    Append(~C, #Classes (E));
> end while;
> "# conjugacy classes is ", C;
# conjugacy classes is  [ 45, 72, 45, 72, 45, 72, 45, 72, 45, 72, 45,
72, 45, 72, 45, 72, 45, 72, 45, 72, 45, 72, 45, 72 ]
```

63.16 Transfer Between Group Categories

63.16.1 Transfer to GrpPC

The `PolycyclicGroup`-constructor allows complete flexibility in defining a pc-group. However, it is often more convenient to have MAGMA compute a pc-presentation based on some other description of the group. The `PCGroup` function will produce a pc-presentation for a finite group in various categories such as `GrpPerm` and `GrpMat`. Converting from a `GrpFP` group is trickier, since the original group need not be finite. There are two functions provided to produce pc-presentations for certain quotients of finitely-presented groups. The `pQuotient` function constructs a pc-presentation for the largest p-group quotient having specified lower exponent-p class. Similarly, `SolubleQuotient` will compute the largest soluble quotient subject to certain restrictions. Each of these functions also provides a homomorphism (isomorphism in the case of `PCGroup`) from the original group to the new pc-group. More information on each of the two quotient functions can be found in Chapter 71.

`PCGroup(G)`

A `GrpPC` representation of the group G and the isomorphism.

`pQuotient( F, p, c : parameters)`

`Workspace`	RngIntElt	*Default :* 1000000
`Metabelian`	BoolElt	*Default :* `false`
`Exponent`	RngIntElt	*Default :* 0
`Print`	RngIntElt	*Default :* 0

Given a finitely presented group F, a prime p, and a positive integer c, this function constructs a consistent power-conjugate presentation for the largest p-quotient H of F having lower exponent-p class at most c). If c is given as zero, then the limit 127 is placed on the class. The function returns both the p-quotient H defined by a pc-presentation and the homomorphism from F to H.

`SolubleQuotient(G)`

`SolvableQuotient(G)`

A `GrpPC` representation P of the largest solvable quotient of G and the homomorphism $\phi : G \to P$.

Example H63E33

We use `PCGroup` to produce a pc-presentation for a matrix group.

```
> GL := GeneralLinearGroup(4,GF(3));
> S3 := Sylow(GL,3);
> P := PCGroup(S3);
> P;
GrpPC : P of order 729 = 3^6
PC-Relations:
    P.2^P.1 = P.2 * P.4^2,
    P.3^P.1 = P.3 * P.5^2,
    P.3^P.2 = P.3 * P.6^2,
    P.5^P.2 = P.4 * P.5,
    P.6^P.1 = P.4 * P.6
```

63.16.2 Transfer from GrpPC

Given a pc-group, it is straight-forward to convert it to a GrpFP or GrpGPC representation by using the appropriate transfer function. If one wishes to have a permutation representation of the group, this requires more cleverness. The `CosetAction` function can be used to compute the permutation representation of a group on a subgroup. If the subgroup is chosen to have trivial core, then the permutation group obtained will be isomorphic to the original group.

`AbelianGroup(G)`

Given an abelian pc-group G, return a `GrpAb` group H isomorphic to G and an isomorphism $\phi : G \to H$.

FPGroup(G)

A GrpFP representation F of G and the isomorphism from G to F.

GPCGroup(G)

A GrpGPC representation F of G and the isomorphism from G to F.

Example H63E34

Take one of the groups of order $2^6 * 3^2$.

```
> G := SmallGroup(576, 4123);
> G;
GrpPC : G of order 576 = 2^6 * 3^2
PC-Relations:
    G.1^2 = Id(G),
    G.2^2 = Id(G),
    G.3^2 = G.5,
    G.4^3 = Id(G),
    G.5^2 = G.7,
    G.6^2 = G.7,
    G.7^2 = Id(G),
    G.8^3 = Id(G),
    G.2^G.1 = G.2 * G.6,
    G.6^G.1 = G.6 * G.7,
    G.6^G.2 = G.6 * G.7,
    G.8^G.1 = G.8^2
```

Since G is small, we can search for a minimum degree permutation presentation by brute force. First we build a set containing all the subgroups.

```
> SL := Subgroups(G);
> T := {X`subgroup: X in SL};
> #T;
243
```

Then, we select those subgroups with trivial core, and find one with the smallest index.

```
> TrivCore := {H:H in T| #Core(G,H) eq 1};
> mdeg := Min({Index(G,H):H in TrivCore});
> Good := {H: H in TrivCore| Index(G,H) eq mdeg};
> #Good;
3
> H := Rep(Good);
```

We then use CosetAction to construct the permutation representation on the cosets of H.

```
> f,P,K := CosetAction(G,H);
> #K;
1
> IsPrimitive(P);
false
```

63.17 More About Presentations

Each pc-group can have up to three pc-presentations associated with it. If the user specifies a consistent presentation in the `PolycyclicGroup`-constructor, then this presentation (the "user" presentation) will be used for all printing and interpretation of element input. If the specified presentation is inconsistent, a runtime error is generated.

Internally, MAGMA uses a "conditioned" presentation for computation. The composition series associated with this presentation is guaranteed to refine a normal series with elementary abelian factors. If G is a p-group, then the composition series is guaranteed to be a central series and the first d pc-generators are a minimal set of generators for the group. Hence, their images generate the Frattini factor group. If the user presentation satisfies these conditions, then it is used as the conditioned presentation. Otherwise, a separate presentation is computed automatically.

Several algorithms rely on a "special" presentation for the group. This presentation exhibits Hall π-subgroups and a characteristic series with elementary abelian factors. When needed, such a presentation is computed and elements are automatically translated between presentations.

The "compact" presentation is not a presentation used in computation. Rather it provides an efficient means to input and output large pc-groups. This is especially useful for stored collections of groups (libraries or databases).

63.17.1 Conditioned Presentations

MAGMA will compute a pc-presentation which will be used for internal computation, but the user's presentation will be used for all input and output. The recommended way to access the conditioned internal presentation is via the intrinsic `ConditionedGroup`.

63.17.1.1 Structure Operations

`ConditionedGroup(G)`

The internally used, conditioned presentation of the pc-group G. The returned group is recorded as a subgroup of G in the relationship tables, so coercion can be used to move between presentations.

`IsConditioned(G)`

Reutrns `true` if G uses the user presentation as the internal presentation, `false` otherwise.

63.17.1.2 Element Operations

`LeadingTerm(x)`

Given an element x of a pc-group G with n pc-generators and a conditioned presentation, where x is of the form $a_1^{\alpha_1} \dots a_n^{\alpha_n}$, return $a_i^{\alpha_i}$ for the smallest i such that $\alpha_i > 0$. If x is the identity of G, then the identity is returned.

`LeadingGenerator(x)`

Given an element x of a pc-group G with n pc-generators and a conditioned presentation, where x is of the form $a_1^{\alpha_1} \dots a_n^{\alpha_n}$, return a_i for the smallest i such that $\alpha_i > 0$. If x is the identity of G, then the identity is returned.

`LeadingExponent(x)`

Given an element x of a pc-group G with n pc-generators and a conditioned presentation, where x is of the form $a_1^{\alpha_1} \dots a_n^{\alpha_n}$, return α_i for the smallest i such that $\alpha_i > 0$. If x is the identity of G, then 0 is returned.

`Depth(x)`

Given an element x of a pc-group G with n pc-generators and a conditioned presentation, where x is of the form $a_1^{\alpha_1} \dots a_n^{\alpha_n}$, return the smallest i such that $\alpha_i > 0$. If x is the identity of G, then 0 is returned.

`PCClass(x)`

`WeightClass(x)`

The weight class of the element x. The `WeightClass` of an arbitrary element of a pc-group G is defined to be k if $x \in G_{\delta_{k-1}}$ and $x \notin G_{\delta_k}$. If x is the identity of G, then `WeightClass` returns $n + 1$.

63.17.2 Special Presentations

A special presentation is one which has several properties described by C. R. Leedham-Green:

(1) The composition series defined by the pc-generators refines the LG-series. The LG-series is a characteristic series which refines the nilpotent series. Within each nilpotent section, it refines the series of successive Frattini factors. Factors of successive terms in the LG-series are elementary abelian p-groups, with p increasing through each Frattini factor.

(2) The presentation exhibits a Sylow system. By this we mean that if π is a set of primes, then the pc-generators whose corresponding prime lies in π will generate a Hall π-subgroup.

(3) The presentation exhibits "head splittings". These are certain complements in factors of the group as follows: If N is a term of the nilpotent series of G, M the next term (so N/M is a maximal nilpotent factor of N), and F/M is the Frattini subgroup of N/M, then it is possible to show that N/F has a complement in G/F. We say the presentation exhibits this complement (or "splitting") if the pc-generators of G which are not in N generate a complement for N mod F.

Several algorithms rely on having a special presentation for the given group. In these cases, MAGMA will automatically compute a special presentation. However, if the user wishes to have a special presentation as the user presentation for a group, the function

`SpecialPresentation` can be used. This is typically used when implementing new algorithms which rely on the properties of a special presentation. The other functions allow one to identify specific characteristics of a special presentation. They are not defined for arbitrary presentations.

`SpecialPresentation(G)`

Returns a new group H which is defined by a special presentation. H is in fact a subgroup of G (equal to G) and so one can use the coercion operator (!) to translate elements between the two presentations. Furthermore, any subgroup of H is automatically a subgroup of G. For instance, if one computed the center Z of H (using some algorithm relying on the special presentation), Z would be a subgroup of G, and would be the center of G.

`SpecialWeights(G)`

A sequence of triples of integers is returned, with one triple corresponding to each pc-generator. The first integer in a triple gives the number of the nilpotent section containing the generator, the second gives the number of the square-free exponent abelian section of that nilpotent section containing it, and the third gives the number of the elementary abelian p-group layer that contains the generator. The prime for the generator is not included in the triple (see `PCPrimes`).

`NilpotentLength(G)`

The number of nilpotent factors in the nilpotent series.

`NilpotentBoundary(G,i)`

The subscript of the last generator in the ith nilpotent section, where i lies between 1 and `NilpotentLength(G)`.

`MinorLength(G,i)`

The number of minor sections (Frattini factors) in the ith nilpotent section of G.

`MinorBoundary(G,i,j)`

The subscript of the last generator in the jth minor section of the ith nilpotent section, where j lies between 1 and `MinorLength(G,i)`.

`LayerLength(G,i,j)`

The number of elementary abelian p-group layers in the jth minor section of the ith nilpotent section of G.

`LayerBoundary(G,i,j,k)`

The subscript of the last generator in the kth elementary abelian p-group layer of the jth minor section of the ith nilpotent section, where k lies between 1 and `LayerLength(G,i,j)`.

Example H63E35

We show how user presentations and special presentations can differ. If we define a wreath product using `PolycyclicGroup`, the given presentation becomes the user presentation, but this is not a special presentation for the group.

```
> T := PolycyclicGroup<a,b,c,d|a^3,b^3,c^3,d^3,
>                          b^a=c, c^a=d, d^a=b>;
> T;
GrpPC : T of order 81 = 3^4
PC-Relations:
    T.2^T.1 = T.3,
    T.3^T.1 = T.4,
    T.4^T.1 = T.2
> S := SpecialPresentation(T);
> S;
GrpPC : S of order 81 = 3^4
PC-Relations:
    S.2^S.1 = S.2 * S.3^2 * S.4,
    S.3^S.1 = S.3 * S.4^2
```

Here we build another wreath product and construct a special presentation.

```
> C6 := CyclicGroup(GrpPC,6);
> C2 := CyclicGroup(GrpPC,2);
> G := WreathProduct(C2,C6);
> G;
GrpPC : G of order 384 = 2^7 * 3
PC-Relations:
    G.1^2 = G.2,
    G.2^3 = Id(G),
    G.3^2 = Id(G),
    G.4^2 = Id(G),
    G.5^2 = Id(G),
    G.6^2 = Id(G),
    G.7^2 = Id(G),
    G.8^2 = Id(G),
    G.3^G.1 = G.8,
    G.3^G.2 = G.5,
    G.4^G.1 = G.6,
    G.4^G.2 = G.3,
    G.5^G.1 = G.7,
    G.5^G.2 = G.4,
    G.6^G.1 = G.3,
    G.6^G.2 = G.8,
    G.7^G.1 = G.4,
    G.7^G.2 = G.6,
    G.8^G.1 = G.5,
    G.8^G.2 = G.7
> H := SpecialPresentation(G);
```

```
> H;
GrpPC : H of order 384 = 2^7 * 3
PC-Relations:
    H.1^2 = Id(H),
    H.2^2 = Id(H),
    H.3^3 = Id(H),
    H.4^2 = Id(H),
    H.5^2 = Id(H),
    H.6^2 = Id(H),
    H.7^2 = Id(H),
    H.8^2 = Id(H),
    H.2^H.1 = H.2 * H.4,
    H.5^H.3 = H.6,
    H.6^H.3 = H.5 * H.6,
    H.7^H.1 = H.6 * H.7,
    H.7^H.3 = H.8,
    H.8^H.1 = H.5 * H.6 * H.8,
    H.8^H.3 = H.7 * H.8
```

We can coerce between the presentations.

```
> G!(H.2), H!(G.2);
G.6 * G.7 * G.8 H.3
```

Look at some specific features of the presentation.

```
> SpecialWeights(H);
[ <1, 1, 1>, <1, 1, 1>, <1, 1, 2>, <1, 2, 1>, <2, 1, 1>, <2, 1, 1>, <2, 1, 1>,
<2, 1, 1> ]
> MinorLength(H,1);
2
> MinorBoundary(H,1,1);
3
```

63.17.3 CompactPresentation

When the MAGMA parser reads in large group presentations of the form

```
S4 := PolycyclicGroup< a, b, c, d | a^2 = 1, b^3 = 1, c^2 = 1,
       d^2 = 1, b^a = b^2, c^a = c * d, c^b = c * d, d^b = c >;
```

a large amount of memory and time is used to build all of the expressions involved in the statement. This time is most noticeable when loading in large libraries of MAGMA code containing many large presentations. The following intrinsics provide a way to avoid this overhead.

`CompactPresentation(G)`

Given a pc-group G, return a sequence of integers that contains the information needed to define the group's presentation.

PCGroup(Q : *parameters*)

Check	BoolElt	*Default :* false
ExponentLimit	RngIntElt	*Default :* 20

Return a group G in category GrpPC, whose presentation is provided by the integer sequence Q. Constructing the group from the integer sequence has very low overhead in the parser. The time taken to construct the group is less when the presentation is conditioned.

The parameter Check indicates whether or not the presentation is checked for consistency. Leaving the Check parameter set to false speeds the construction of the group, but will be disastrous if the sequence Q does not represent a consistent pc-presentation.

Parameter ExponentLimit determines the amount of space that will be used by the group to speed calculations. Given ExponentLimit := e, the group will store the products $a^i * b^j$ where a and b are generators and i and j are in the range 1 to e.

Example H63E36

If the user wants to store the definition of a group in a library, the following may be done.

```
> S4 := PolycyclicGroup< a, b, c, d | a^2 = 1, b^3 = 1, c^2 = 1, d^2 = 1,
>  b^a = b^2, c^a = c * d, c^b = c * d, d^b = c >;
> Q := CompactPresentation( S4 );
> Q;
[ 4, -2, -3, -2, 2, 33, 218, 114, 55 ]
```

The library code would then be

```
> Make:=func< | PCGroup(\[4, 2, 3, 2, 2, 33, 218, 114, 55] : Check := false) >;
```

Note the use of a literal sequence here — see Chapter 10.

63.18 Optimizing Magma Code

63.18.1 PowerGroup

If the user is working with enumerated sets of pc-groups that are all subgroups of a common over-group G, then the following optimization is strongly recommended. Define the set to have the universe PowerGroup(G). For any subgroup H of G, we can find a canonical form for the generators of H. This allows us to have a very good hashing function for the subgroups.

Example H63E37

The following example illustrates the optimization.

```
> G := ExtraSpecialGroup( GrpPC, 3, 3 );
> P := PowerGroup(G);
> time s1 := {  P | sub< G | Random(G), Random(G) > : x in { 1..500}  };
Time: 1.140
> time s2 := { Parent(G) | sub< G | Random(G), Random(G) > : x in { 1..500}  };
Time: 9.769
```

64 BLACK-BOX GROUPS

Chapter 64
BLACK-BOX GROUPS

64.1 Introduction

This Chapter describes the category of black-box groups (BB-groups). The name in MAGMA for the category of BB-groups is `GrpBB`.

64.2 Construction of an SLP-Group and its Elements

64.2.1 Structure Constructors

Magma's black-box groups are built on Magma's other group types. The basic constructor takes a group and returns a corresponding black-box group. The element set of the black-box group is essentially the same as the element set of the original group, and the group operations are inherited from the original group.

`NaturalBlackBoxGroup(H)`

Construct the natural black-box group from the concrete group H.

64.2.2 Construction of an Element

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity element for the BB-group G.

64.3 Arithmetic with Elements

`u * v`

Construct the product of elements u and v of the BB-group G.

`u ^ m`

Given an integer m and u, an element of BB-group G, return the element of G corresponding to the m-th power of u.

`u ^ v`

Given u and v, elements of BB-group G, return the element of G corresponding to the conjugate of u by v, i.e. $v^{-1} * u * v$.

`(u, v)`

Commutator of the elements u and v, i.e. the element $u^{-1} * v^{-1} * u * v$. Here u and v must belong to the same BB-group G.

64.3.1 Accessing the Defining Generators

The functions described here provide access to basic information stored for a BB-group G.

`G . i`

The i-th generator for G.

`Generators(G)`

A set containing the generators for G.

`NumberOfGenerators(G)`
`Ngens(G)`

The number of generators for B.

64.4 Operations on Elements

64.4.1 Equality and Comparison

`u eq v`

Returns `true` if and only if the underlying concrete group elements for u and v are equal.

`u ne v`

Returns `true` if and only if the underlying concrete group elements for u and v are not equal.

64.4.2 Attributes of Elements

`Parent(u)`

The parent group G of the element u.

`UnderlyingElement(u)`

The concrete group element corresponding to the BB-group element u.

`Order(u)`

The order of the underlying concrete group element of u.

Example H64E1

The following function takes a black box group isomorphic to M_{24} and finds standard generators. It is taken from the ATLAS of Finite Group Representations page on M_{24}.

```
> m24_standard := function(B)
> repeat a := PseudoRandom(B); until Order(a) eq 10;
> a := a ^ 5;
> repeat b := PseudoRandom(B); until Order(b) eq 15;
> b := b ^ 5;
> repeat b := b ^ PseudoRandom(B); ab := a*b;
> until Order(ab) eq 23;
> x := ab*(ab^2*b)^2*ab*b;
> if Order(x) eq 5 then b := b^-1; end if;
> return a,b;
> end function;
```

We take a group which must be M_{24} and find these generators.

```
> G := PermutationGroup<24 |
> [ 20, 4, 10, 3, 15, 9, 7, 1, 11, 22, 21, 19, 8, 2, 24, 5,
> 12, 18, 13, 16, 14, 23, 6, 17 ],
> [ 12, 18, 3, 2, 7, 11, 5, 21, 19, 22, 23, 1, 14, 17, 10,
> 8, 4, 13, 24, 20, 9, 15, 6, 16 ]>;
> #G;
244823040
> Transitivity(G);
5
> B := NaturalBlackBoxGroup(G);
> a,b := m24_standard(B); a,b;
GrpBBElt (1, 16)(2, 22)(3, 14)(4, 15)(5, 11)(6, 24)(7,
10)(8, 18)(9, 19)(12, 17)(13, 20)(21, 23)
GrpBBElt (1, 14, 17)(2, 18, 13)(5, 16, 20)(7, 22, 9)(8, 24,
15)(19, 23, 21)
```

The printing of the GrpBBElts shows the underlying concrete group elements. These may be extracted using the `UnderlyingElement` intrinsic for use within G.

64.5 Set-Theoretic Operations

64.5.1 Membership and Equality

`g in G`

Return true if and only if G is the parent group of g or the parent group of g is a subgroup of G.

64.5.2 Set Operations

`PseudoRandom(G)`

Return a pseudo-random element of the BB-group G. The method used is product-replacement with accumulator.

`Rep(G)`

A representative element of G.

64.5.3 Coercions Between Related Groups

`G ! g`

Given an element g belonging to a subgroup of the BB-group G, rewrite g as an element of G.

65 ALMOST SIMPLE GROUPS

Chapter 65
ALMOST SIMPLE GROUPS

65.1 Introduction

65.1.1 Overview

This chapter describes a set of tools for working with finite almost-simple groups (AS-groups). In the program for computing with non-soluble finite groups, the goal is to reduce the solution of many problems concerning a non-soluble group G to that of solving the same problem for the non-abelian simple composition factors of G. We are concerned with very specific types of computation with AS-groups.

The techniques described in this chapter are under development and are very incomplete in their coverage. The material falls roughly into two main categories.

(a) Functions which try to identify a particular group S known to be almost simple with a standard copy T of that AS-group. In addition, if such an isomorphism is found, it is often desirable to explicitly construct it so that questions concerning S can be answered by mapping them into the "standard" group T. Hence the recognition functions are divided into those which perform *non-constructive recognition* (they assert the existence of an isomorphism between S and T) and those that perform *constructive recognition* (an explicit isomorphism between S and T is returned).

(b) Functions which allow the user to determine information about an AS-group. These functions are usually implemented separately for each family of simple groups. Thus, for each family of simple groups our goal is to provide machinery for constructing key properties of any group T in that family in the context of a standard representation of the group. Using the isomorphism constructed in (a), this information can then be transferred back to the user's group S. Examples of such information include, information about element conjugacy, maximal subgroups, and Sylow p-subgroups.

The functions described in this chapter do not assume that a BSGS-representation can be constructed available. Thus, the techniques described here apply to groups possibly having both much larger order and/or much larger dimension than those that can be handled with the techniques of Chapters 58 and 59.

65.2 Creating Finite Groups of Lie Type

Several functions are provided which construct various classical groups and other groups of Lie type. The effect of these functions is to define the group in terms of a set of generating matrices.

As shown by Chevalley, for each simple Lie algebra L over the complex field and for each finite field $\mathbf{F}_q$ there is an associated matrix group $L(q)$. In general, these groups are perfect but not simple. To obtain the simple group, it is necessary to form the quotient by the centre. Similarly, as Steinberg, Ree and others have shown, if the associated Coxeter graph has an automorphism, of order t say, then there will be a 'twisted' version ${}^tL(q)$ of $L(q)$.

Generators for the series A, C, ^{2}A and ^{2}B are described in [Tay87]. Generators for the series B, D and ^{2}D are as given by Rylands and Taylor [RT98]. Generators for the exceptional groups of Lie type are described by Howlett, Rylands and Taylor in [HRT01].

65.2.1 Generic Creation Function

`ChevalleyGroup(X, n, K:` *parameters*`)`

`ChevalleyGroup(X, n, q:` *parameters*`)`

`Irreducible` BoolElt *Default :* `false`

Construct a matrix group over the field K (or over $\mathbf{F}_q$) which has the adjoint Chevalley group of Lie series `X` and Lie rank n as the quotient modulo scalar matrices. In most cases the group returned is the universal Chevalley group $X_n(q)$; however, for series `B`, `D` and `2D` the universal group is the spin group and the matrix group returned by `ChevalleyGroup` is $\Omega(2n+1,q)$, $\Omega^+(2n,q)$ or $\Omega^-(2n,q)$.

For the twisted groups the meaning of the parameter q is consistent with the (abbreviated) notation in the 'Atlas of Finite Groups' and in the monograph series 'The Classification of the Finite Simple Groups' by Gorenstein, Lyons and Solomon. For a Chevalley group of rank n and type X with an automorphism of order t the Atlas defines the *twisted Chevalley group* ${}^tX_n(q,q^t)$ to be the set of elements of $X_n(q^t)$ fixed by the quotient of the twisting automorphism and the field automorphism induced by $x \mapsto x^q$ of $\mathbf{F}_{q^t}$. In the Atlas the abbreviated notation for the twisted group is ${}^tX_n(q)$ but in Carter [Car72] it is ${}^tX_n(q^t)$. The first signature of the intrinsic expects the field $\mathbf{F}_{q^t}$ but the second signature expects the parameter q.

For example, for the series `"2A"`, the group ${}^2A_n(q)$ is $\mathrm{SU}(n+1,q)$ but, in the first form of the signature, K must be the field $\mathbf{F}_{q^2}$. Similarly the first form of the signature for the groups ${}^3D_4(q)$ and ${}^2E_6(q)$ requires the fields $\mathbf{F}_{q^3}$ and $\mathbf{F}_{q^2}$, respectively.

The possible series and the groups returned are:

`"A"` : $n \geq 0$, $A_n(q)$, the special linear group $\mathrm{SL}(n+1,q)$.

`"B"` : $n \geq 1$, $B_n(q)$, the orthogonal group $\Omega(2n+1,q)$.

`"C"` : $n \geq 1$, $C_n(q)$, the symplectic group $\mathrm{Sp}(2n,q)$.

`"D"` : $n \geq 1$, $D_n(q)$, the orthogonal group $\Omega^+(2n, q)$.

`"E"` : $n \in \{6, 7, 8\}$, the exceptional groups $E_n(q)$. $E_6(q)$ is represented as a matrix group of degree 27. It is simple unless $q \equiv 1 \bmod 3$, in which case its centre has order 3. $E_7(q)$ is represented as a matrix group of degree 56. It is simple unless $q \equiv 1 \bmod 2$, in which case its centre has order 2. $E_8(q)$ is represented as a matrix group of degree 248.

`"F"` : $n = 4$, the exceptional group $F_4(q)$ represented as a matrix group of degree 26. If $q = 3^k$ then this representation is reducible. An irreducible representation is not yet available.

`"G"` : $n = 2$, the exceptional group $G_2(q)$ represented as a matrix group of degree 7. If $q = 2^k$ then this representation is reducible. An irreducible representation of degree 6 can be obtained by setting the parameter `Irreducible := true`.

`"2A"` : $n \geq 1$, $K = \mathbf{F}_{q^2}$, the special unitary group ${}^2A_n(q) = \mathrm{SU}(n+1, q)$.

`"2B"` : $n = 2$, $K = \mathbf{F}_q$, $q = 2^{2k+1}$, the Suzuki group ${}^2B_2(q) = \mathrm{Sz}(q)$.

`"2D"` : $n \geq 1$, $K = \mathbf{F}_q$, ${}^2D_n(q)$, the orthogonal group $\Omega^-(2n, q)$.

`"3D"` : $n = 4$, $K = \mathbf{F}_{q^3}$, the exceptional group ${}^3D_4(q)$.

`"2E"` : $n = 6$, $K = \mathbf{F}_{q^2}$, the exceptional group ${}^2E_6(q)$.

`"2F"` : $n = 4$, $K = \mathbf{F}_q$, $q = 2^{2k+1}$, the Ree group ${}^2F_4(q)$, simple except when $q = 2$ when the derived group is simple and is returned by the function `TitsGroup`.

`"2G"` : $n = 2$, $K = \mathbf{F}_q$, $q = 3^{2k+1}$, the Ree group ${}^2G_2(q)$, simple except when $q = 3$.

65.2.2 The Orders of the Chevalley Groups

`ChevalleyOrderPolynomial(type, n: parameters)`

The orders of the universal Chevalley groups $X_n(q)$ and ${}^tX_n(q)$ are polynomials in q. For the twisted groups of types ${}^2A_n$, ${}^3D_4$ and ${}^2E_6$ the parameter q is the order of the fixed field of the Frobenius automorphism.

Other versions of Chevalley groups are quotients of universal Chevalley groups modulo a subgroup of the centre.

`FactoredChevalleyGroupOrder(type, n, F: parameters)`

`FactoredChevalleyGroupOrder(type, n, q: parameters)`

`Proof`	BoolElt	*Default :* `true`
`Version`	MonStgElt	*Default :* "*Default*"

`ChevalleyGroupOrder(type, n, F: parameters)`

`ChevalleyGroupOrder(type, n, q: parameters)`

`Version` MonStgElt *Default : "Default"*

The (factored) order of the Chevalley group of a given type and rank over the field F (or $\mathbf{F}_q$). The default is the order of the group returned by `ChevalleyGroup`, which except for types B_n, D_n and ${}^2D_n$ is the universal group. The orders of the universal and adjoint Chevalley group can be obtained by setting the parameter `Version` to `Universal` or `Adjoint`. In the factored version the value of `Proof` is passed to the Magma's factorisation function (q.v.).

65.2.3 Classical Groups

Magma offers several functions to construct the classical groups. For most of these functions, it is possible to specify the particular group by giving one of the following combinations of arguments:

(i) The degree n and the coefficient field K of the desired matrix group;

(ii) The degree n of the desired matrix group and a prime power q which relates the group to the appropriate Lie algebra. With the exception of the unitary groups (which will be defined over $\mathbf{F}_{q^2}$), the resulting group will be defined over $\mathbf{F}_q$; or,

(iii) A full vector space $V = K^n$ on which the desired matrix group should act naturally.

65.2.3.1 Linear Groups

`GeneralLinearGroup(n, q)`

`GeneralLinearGroup(n, K)`

`GeneralLinearGroup(V)`

`GL(n, q)`

`GL(n, K)`

`GL(V)`

Here n is a positive integer, q is the power of a prime, K is a finite field $\mathbf{F}_q$, and V is an n-dimensional vector space over K. This function constructs the general linear group $\mathrm{GL}(n, q)$ (resp. $\mathrm{GL}(n, K)$, $\mathrm{GL}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `GL`.

`SpecialLinearGroup(n, q)`

`SpecialLinearGroup(n, K)`

`SpecialLinearGroup(V)`

`SL(n, q)`

`SL(n, K)`

`SL(V)`

Here n is a positive integer, q is the power of a prime, K is a finite field $\mathbf{F}_q$, and V is an n-dimensional vector space over K. This function constructs the special linear group $\mathrm{GL}(n, q)$ (resp. $\mathrm{GL}(n, K)$, $\mathrm{GL}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `SL`.

```
AffineGeneralLinearGroup(GrpMat, n, q)
AffineGeneralLinearGroup(GrpMat, n, K)
AffineGeneralLinearGroup(GrpMat, V)
AGL(GrpMat, V)
```

Here n is a positive integer greater than or equal to 2, q is the power of a prime, K is a finite field $\mathbf{F}_q$, and V is an n-dimensional vector space over K. This function constructs the affine general linear group $\mathrm{AGL}(n, q)$ (resp. $\mathrm{AGL}(n, K)$, $\mathrm{AGL}(V)$) as a subgroup of $\mathrm{GL}(n+1, K)$. If the category name `GrpMat` is omitted the affine group will be returned as a permutation group. The intrinsic name may be abbreviated to `AGL`.

```
AffineSpecialLinearGroup(GrpMat, n, q)
AffineSpecialLinearGroup(GrpMat, n, K)
AffineSpecialLinearGroup(GrpMat, V)
ASL(GrpMat, V)
```

Here n is a positive integer greater than or equal to 2, q is the power of a prime, K is a finite field $\mathbf{F}_q$, and V is an n-dimensional vector space over K. This function constructs the affine special linear group $\mathrm{ASL}(n, q)$ (resp. $\mathrm{ASL}(n, K)$, $\mathrm{ASL}(V)$) as a subgroup of $\mathrm{SL}(n+1, K)$. If the category name `GrpMat` is omitted, the affine group will be returned as a permutation group. The intrinsic name may be abbreviated to `ASL`.

65.2.3.2 Unitary Groups

```
ConformalUnitaryGroup(n, q)
ConformalUnitaryGroup(n, K)
ConformalUnitaryGroup(V)
CU(n, q)
CU(n, K)
CU(V)
```

Here $n \geq 2$ is a positive integer, q is the power of a prime, K is the finite field $\mathbf{F}_{q^2}$, and V is the n-dimensional vector space over K. This function constructs the conformal unitary group $\mathrm{CU}(n, q)$ (resp. $\mathrm{CU}(n, K)$, $\mathrm{CU}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `CU`. A conformal unitary group is the group that preserves a unitary form up to a constant.

```
GeneralUnitaryGroup(n, q)
GeneralUnitaryGroup(n, K)
GeneralUnitaryGroup(V)
GU(n, q)
GU(n, K)
GU(V)
```

Here $n \geq 2$ is a positive integer, q is the power of a prime, K is the finite field $\mathbf{F}_{q^2}$, and V is the n-dimensional vector space over K. This function constructs the general unitary group $\mathrm{GU}(n, q)$ (resp. $\mathrm{GU}(n, K)$, $\mathrm{GU}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `GU`.

```
SpecialUnitaryGroup(n, q)
SpecialUnitaryGroup(n, K)
SpecialUnitaryGroup(V)
SU(n, q)
SU(n, K)
SU(V)
```

Here n is an integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_{q^2}$, and V is the n-dimensional vector space over K. This function constructs the special unitary group $\mathrm{SU}(n, q)$ (resp. $\mathrm{SU}(n, K)$, $\mathrm{SU}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `SU`.

65.2.3.3 Symplectic Groups

```
ConformalSymplecticGroup(n, q)
ConformalSymplecticGroup(n, K)
ConformalSymplecticGroup(V)
CSp(n, q)
CSp(n, K)
CSp(V)
```

Here n is an even integer greater than or equal to 4, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the conformal symplectic group $\mathrm{CSp}(n, q)$ (resp. $\mathrm{CSp}(n, K)$, $\mathrm{CSp}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `CSp`. A conformal symplectic group is the group that preserves a symplectic form up to a constant.

```
SymplecticGroup(n, q)
SymplecticGroup(n, K)
SymplecticGroup(V)
Sp(n, q)
Sp(n, K)
Sp(V)
```

Here n is an even integer greater than or equal to 4, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the symplectic group $\mathrm{Sp}(n, q)$ (resp. $\mathrm{Sp}(n, K)$, $\mathrm{Sp}(V)$) in terms of two generating matrices. The intrinsic name may be abbreviated to `Sp`.

65.2.3.4 Orthogonal and Spin Groups

```
ConformalOrthogonalGroup(n, q)
ConformalOrthogonalGroup(n, K)
ConformalOrthogonalGroup(V)
CO(n, q)
CO(n, K)
CO(V)
```

Here n is an odd integer greater than or equal to 3, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the conformal orthogonal group $\mathrm{CO}(n, q)$ (resp. $\mathrm{CO}(n, K)$, $\mathrm{CO}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `CO`.

```
GeneralOrthogonalGroup(n, q)
GeneralOrthogonalGroup(n, K)
GeneralOrthogonalGroup(V)
GO(n, q)
GO(n, K)
GO(V)
```

Here n is an odd integer greater than or equal to 3, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the general orthogonal group $\mathrm{GO}(n, q)$ (resp. $\mathrm{GO}(n, K)$, $\mathrm{GO}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `GO`.

```
SpecialOrthogonalGroup(n, q)
SpecialOrthogonalGroup(n, K)
```

```
SpecialOrthogonalGroup(V)
SO(n, q)
SO(n, K)
SO(V)
```

Here n is an odd integer greater than or equal to 3, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the special orthogonal group $\mathrm{SO}(n, q)$ (resp. $\mathrm{SO}(n, K)$, $\mathrm{SO}(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `SO`.

```
ConformalOrthogonalGroupPlus(n, q)
ConformalOrthogonalGroupPlus(n, K)
ConformalOrthogonalGroupPlus(V)
COPlus(n, q)
COPlus(n, K)
COPlus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the conformal orthogonal group $\mathrm{CO}^+(n, q)$ (resp. $\mathrm{CO}^+(n, K)$, $\mathrm{CO}^+(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `COPlus`.

```
GeneralOrthogonalGroupPlus(n, q)
GeneralOrthogonalGroupPlus(n, K)
GeneralOrthogonalGroupPlus(V)
GOPlus(n, q)
GOPlus(n, K)
GOPlus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the general orthogonal group $\mathrm{GO}^+(n, q)$ (resp. $\mathrm{GO}^+(n, K)$, $\mathrm{GO}^+(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `GOPlus`.

```
SpecialOrthogonalGroupPlus(n, q)
SpecialOrthogonalGroupPlus(n, K)
SpecialOrthogonalGroupPlus(V)
SOPlus(n, q)
SOPlus(n, K)
SOPlus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the special orthogonal group $\mathrm{SO}^+(n,q)$ (resp. $\mathrm{SO}^+(n,K)$, $\mathrm{SO}^+(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `SOPlus`.

```
ConformalOrthogonalGroupMinus(n, q)
ConformalOrthogonalGroupMinus(n, K)
ConformalOrthogonalGroupMinus(V)
COMinus(n, q)
COMinus(n, K)
COMinus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the conformal orthogonal group $\mathrm{CO}^-(n,q)$ (resp. $\mathrm{CO}^-(n,K)$, $\mathrm{CO}^-(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `COMinus`.

```
GeneralOrthogonalGroupMinus(n, q)
GeneralOrthogonalGroupMinus(n, K)
GeneralOrthogonalGroupMinus(V)
GOMinus(n, q)
GOMinus(n, K)
GOMinus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the general orthogonal group $\mathrm{GO}^-(n,q)$ (resp. $\mathrm{GO}^-(n,K)$, $\mathrm{GO}^-(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `GOMinus`.

```
SpecialOrthogonalGroupMinus(n, q)
SpecialOrthogonalGroupMinus(n, K)
SpecialOrthogonalGroupMinus(V)
SOMinus(n, q)
SOMinus(n, K)
SOMinus(V)
```

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the special orthogonal group $\mathrm{SO}^-(n,q)$ (resp. $\mathrm{SO}^-(n,K)$, $\mathrm{SO}^-(V)$) in terms of generating matrices. The intrinsic name may be abbreviated to `SOMinus`.

```
Omega(n, q)
```

`Omega(n, K)`

`Omega(V)`

Here n is an odd integer greater than or equal to 3, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the orthogonal group $\Omega(n, K)$ (resp. $\Omega(n, K)$, $\Omega(V)$) in terms of two generating matrices. The group $\Omega(n, K)$ is the kernel of the spinor norm map on $\mathrm{SO}(n, K)$).

`OmegaPlus(n, q)`

`OmegaPlus(n, K)`

`OmegaPlus(V)`

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the orthogonal group $\Omega^+(n, q)$ (resp. $\Omega^+(n, K)$, $\Omega^+(V)$) in terms of two generating matrices. The group $\Omega^+(n, K)$ is the kernel of the spinor norm map on $\mathrm{SO}^+(n, K)$.

`OmegaMinus(n, q)`

`OmegaMinus(n, K)`

`OmegaMinus(V)`

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the orthogonal group $\Omega^-(n, q)$ (resp. $\Omega^-(n, K)$, $\Omega^-(V)$) in terms of two generating matrices. The group $\Omega^-(n, K)$ is the kernel of the spinor norm map on $\mathrm{SO}^-(n, K)$.

`Spin(n, q)`

`Spin(n, K)`

`Spin(V)`

Here n is an odd integer greater than or equal to 1, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the spin group $\mathrm{Spin}(n, K)$ (resp. $\mathrm{Spin}(n, K)$, $\mathrm{Spin}(V)$).

`SpinPlus(n, q)`

`SpinPlus(n, K)`

`SpinPlus(V)`

Here n is an even integer greater than or equal to 2, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the spin group $\mathrm{Spin}^+(n, K)$ (resp. $\mathrm{Spin}^+(n, K)$, $\mathrm{Spin}^+(V)$).

```
SpinMinus(n, q)
SpinMinus(n, K)
SpinMinus(V)
```

Here n is an even integer greater than or equal to 4, q is the power of a prime, K is the finite field $\mathbf{F}_q$, and V is the n-dimensional vector space over K. This function constructs the spin group $\mathrm{Spin}^-(n, K)$ (resp. $\mathrm{Spin}^-(n, K)$, $\mathrm{Spin}^-(V)$).

65.2.4 Exceptional Groups

65.2.4.1 Suzuki Groups

The Suzuki groups are specified slightly differently, as the degree of the group is always four. Thus for this family of groups, the possible combinations of arguments are:

(i) A finite field $K = \mathbf{F}_{2^{2m+1}}$, over which the resulting matrix group is defined;

(ii) An integer $q = 2^{2m+1}$, corresponding to the field $K = \mathbf{F}_q$ over which the resulting matrix group is defined; or,

(iii) A vector space $V = K^4$ where $K = \mathbf{F}_{2^{2m+1}}$ on which the resulting matrix group acts naturally. which the resulting

```
SuzukiGroup(q)
SuzukiGroup(K)
SuzukiGroup(V)
```

Here q is a prime power of the form 2^{2n+1}, K is the finite field $\mathbf{F}_q$, and V is the 4-dimensional vector space over K. This function constructs the Suzuki simple group $\mathrm{Sz}(q)$ (resp. $\mathrm{Sz}(K)$, $\mathrm{Sz}(V)$) in terms of two generating matrices. The intrinsic name may be abbreviated to `Sz`.

Example H65E1

We create the 10-dimensional symplectic group over $\mathbf{F}_8$:

```
> F<u> := FiniteField(8);
> G := SymplecticGroup(10, F);
> G;
MatrixGroup(10, GF(2, 3))
Generators:
[  u   0   0   0   0   0   0   0   0   0]
[  0   1   0   0   0   0   0   0   0   0]
[  0   0   1   0   0   0   0   0   0   0]
[  0   0   0   1   0   0   0   0   0   0]
[  0   0   0   0   u   0   0   0   0   0]
[  0   0   0   0   0   u   0   0   0   0]
[  0   0   0   0   0   0   1   0   0   0]
[  0   0   0   0   0   0   0   1   0   0]
```

```
[  0   0   0   0   0   0   0   0   1   0]
[  0   0   0   0   0   0   0   0   0 u^6]

[0 0 0 1 1 1 0 0 0 0]
[1 0 0 0 0 0 0 0 0 0]
[0 1 0 0 0 0 0 0 0 0]
[0 0 1 0 0 0 0 0 0 0]
[0 0 0 1 0 0 0 0 0 0]
[0 0 0 0 1 0 1 0 0 0]
[0 0 0 0 0 0 0 1 0 0]
[0 0 0 0 0 0 0 0 1 0]
[0 0 0 0 0 0 0 0 0 1]
[0 0 0 0 1 0 0 0 0 0]
```

Example H65E2

We create the Suzuki group over $\mathbf{F}_{128}$:

```
> F<w> := FiniteField(128);
> V := VectorSpace(F, 4);
> S := SuzukiGroup(V);
> S;
MatrixGroup(4, GF(2, 7))
Generators:
[0 0 0 1]
[0 0 1 0]
[0 1 0 0]
[1 0 0 0]

[  w^8     0     0     0]
[    0 w^120     0     0]
[    0     0   w^7     0]
[    0     0     0 w^119]

[   1    0    0    0]
[ w^8    1    0    0]
[   0    w    1    0]
[w^17  w^9  w^8    1]
> Order(S);
34093383680
> FactoredOrder(S);
[ <2, 14>, <5, 1>, <29, 1>, <113, 1>, <127, 1> ]
```

65.2.4.2 Small Ree Groups

The Ree groups (${}^2G_2(q)$) are given in an irreducible matrix representation of degree seven. The possible combinations of arguments are:

(i) A finite field $K = \mathbf{F}_{3^{2m+1}}$ with $m > 0$, over which the matrix group is defined.

(ii) An integer $q = 3^{2m+1}$ with $m > 0$, corresponding to the field $K = \mathbf{F}_q$ over which the group is defined; or,

(iii) A vector space $V = K^7$ where $K = \mathbf{F}_{3^{2m+1}}$ with $m > 0$, on which the matrix group acts naturally.

```
ReeGroup(q)
ReeGroup(K)
ReeGroup(V)
```

Here q is a prime power of the form $q = 3^{2m+1}$ with $m > 0$, K is the finite field $\mathbf{F}_q$, and V is the 7-dimensional vector space over K. This function constructs the Ree group ${}^2G_2(q)$ (resp. ${}^2G_2(K)$, ${}^2G_2(V)$) in terms of standard generating matrices. The intrinsic name may be abbreviated to `Ree`.

65.2.4.3 Large Ree Groups

The Ree groups (${}^2F_4(q)$) are given in an irreducible matrix representation of degree twenty-six. The possible combinations of arguments are:

(i) A finite field $K = \mathbf{F}_{2^{2m+1}}$ with $m > 0$, over which the matrix group is defined.

(ii) An integer $q = 2^{2m+1}$ with $m > 0$, corresponding to the field $K = \mathbf{F}_q$ over which the group is defined; or,

(iii) A vector space $V = K^{26}$ where $K = \mathbf{F}_{2^{2m+1}}$ with $m > 0$, on which the matrix group acts naturally.

```
LargeReeGroup(q)
LargeReeGroup(K)
LargeReeGroup(V)
```

Here q is a prime power of the form $q = 2^{2m+1}$ with $m > 0$, K is the finite field $\mathbf{F}_q$, and V is the 26-dimensional vector space over K. This function constructs the Ree group ${}^2F_4(q)$ (resp. ${}^2F_4(K)$, ${}^2F_4(V)$) in terms of standard generating matrices. The intrinsic name may be abbreviated to `LargeRee`.

65.3 Group Recognition

65.3.1 Constructive Recognition of Alternating Groups

`RecogniseAlternatingOrSymmetric(G, n)`

Constructive recognition of the group G, which will succeed with probability $\geq 1-e^5$ if G is isomorphic to either the alternating or symmetric group of degree $n > 11$. The method is that of Beals *et al* [BLGN$^+$03], implemented by Colva Roney-Dougal.

The return values start with a flag indicating success or failure. If the algorithm was successful, then there are three more return values: a flag which is true when G is symmetric and false when alternating, and two programs. The first program takes an element x of an overgroup of G and produces a boolean to indicate whether $x \in G$ and a permutation representing x in the natural action of S_n (if such a permutation exists). The second taking a permutation to the corresponding element of G. The programs define mutually inverse group isomorphisms, implemented as MAGMA functions.

Example H65E3

We give an example of `RecogniseAlternatingOrSymmetric` in use.

```
> a:= AlternatingGroup(13);
> h:= Stabiliser(a, {1,2});
> k:= CosetImage(a, h);
> Degree(k);
78
> worked, is_sym, bb_to_perm, perm_to_bb:=
> RecogniseAlternatingOrSymmetric(k, 13);
> worked;
true
> is_sym;
false
> x:= Sym(78)!(1, 35, 16, 28, 14, 26, 69, 5, 74)(2, 54,
> 67, 18, 51, 63, 6, 50, 77)(3, 33, 78, 12, 34, 29, 19, 15, 73)
> (4, 52, 61, 24, 49, 60, 68, 38, 64)(7, 20, 71, 17,
> 32, 11, 72, 8, 36)(9, 76, 47, 31, 56, 62, 13, 53, 59)
> (10, 70, 57, 23, 37, 22, 21, 27, 25)(30, 45, 46, 43, 42,
> 44, 40, 41, 75)(39, 55, 65)(48, 66, 58);
> x in k;
true;
> in_k, perm_image:= bb_to_perm(x);
> in_k;
true
> perm_image;
(1, 2, 3)(4, 7, 12, 6, 10, 11, 13, 9, 8)
> perm_to_bb(perm_image) eq x;
true
```

`RecogniseSymmetric(G, n: parameters)`

`maxtries`	RngIntElt	*Default :* $100n + 5000$
`Extension`	BoolElt	*Default :* `false`

The group G should be known to be isomorphic to the symmetric group S_n for some $n \geq 8$. The Bratus-Pak algorithm [BP00] (implemented by Derek Holt) is used to define an isomorphism between G and S_n. If successful, return `true`, homomorphism from G to S_n, homomorphism from S_n to G, the map from G to its word group and the map from the word group to G.

If the optional parameter `Extension` is set, then the group G should be known to be isomorphic either to S_n or to a perfect central extension $2.S_n$. In that case, the first two maps returned will be a homomorphism from G to S_n and a map from S_n to G that induces a homomorphism onto $G/Z(G)$. The sixth value returned will be `true`, if $G \cong 2.S_n$ and `false`, if $G \cong 2.A_n$.

If unsuccessful, `false` is returned. This will always occur if the input group is not isomorphic to S_n (or $2.S_n$ when `Extension` is set) with $n \geq 8$, and may occur occasionally even when G is isomorphic to S_n. The optional parameter `maxtries` (default $100n + 5000$) can be used to control the number of random elements chosen before giving up.

`SymmetricElementToWord (G, g)`

If g is an element of G which has been constructively recognised to be isomorphic to S_n (or $2.S_n$), then return `true` and element of word group for G which evaluates to g. Otherwise return `false`. This facilitates membership testing in G.

`RecogniseAlternating(G, n: parameters)`

`maxtries`	RngIntElt	*Default :* $100n + 5000$
`Extension`	BoolElt	*Default :* `false`

The group G should be known to be isomorphic to the alternating group A_n for some $n \geq 9$. The Bratus-Pak algorithm [BP00] (implemented by Derek Holt) is used to define an isomorphism between G and A_n. If successful, return `true`, homomorphism from G to A_n, homomorphism from A_n to G, the map from G to its word group and the map from the word group to G.

If the optional parameter `Extension` is set, then the group G should be known to be isomorphic either to A_n or to a perfect central extension $2.A_n$. In that case, the first two maps returned will be a homomorphism from G to A_n and a map from A_n to G that induces a homomorphism onto $G/Z(G)$. The sixth value returned will be `true`, if $G \cong 2.A_n$ and `false`, if $G \cong 2.A_n$.

If unsuccessful, `false` is returned. This will always occur if the input group is not isomorphic to A_n (or $2.A_n$ when `Extension` is set) with $n \geq 9$, and may occur occasionally even when G is isomorphic to A_n. The optional parameter tt maxtries (default $100n + 5000$) can be used to control the number of random elements chosen before giving up.

`AlternatingElementToWord (G, g)`

If g is an element of G which has been constructively recognised to be isomorphic to A_n (or $2.A_n$), then return `true` and element of word group for G which evaluates to g. Otherwise return `false`. This facilitates membership testing in G.

`GuessAltsymDegree(G: parameters)`

`maxtries`	RngIntElt	*Default :* 5000
`Extension`	BoolElt	*Default :* `false`

The group G should be believed to be isomorphic to S_n or A_n for some $n > 6$, or to $2.S_n$ or $2.A_n$ if the optional parameter `Extension` is set. This function attempts to determine n and whether G is symmetric or alternating. It does this by sampling orders of elements. It returns either `false`, if it is unable to make a decision after sampling `maxtries` elements (default 5000), or `true`, *type* and n, where *type* is "Symmetric" or "Alternating", and n is the degree. If G is not isomorphic to S_n or A_n (or $2.S_n$ or $2.A_n$ when `Extension` is set) for $n > 6$, then the output is meaningless - there is no guarantee that `false` will be returned. There is also a small probability of a wrong result or `false` being returned even when G is S_n or A_n with $n > 6$. This function was written by Derek Holt.

Example H65E4

For a group G which is believed to be isomorphic to S_n or A_n for some unknown value of $n > 6$, the function `GuessAltsymDegree` can be used to try to guess n, and then `RecogniseSymmetric` or `RecogniseAlternating` can be used to confirm the guess.

```
> G:= sub< GL(10,5) |
> PermutationMatrix(GF(5),Sym(10)![2,3,4,5,6,7,8,9,1,10]),
> PermutationMatrix(GF(5),Sym(10)![1,3,4,5,6,7,8,9,10,2]) >;
> GuessAltsymDegree(G);
true Alternating 10
> flag, m1, m2, m3, m4  := RecogniseAlternating(G,10);
> flag;
true
> x:=Random(G); Order(x);
8
> m1(x);
(1, 2, 4, 9, 10, 8, 6, 3)(5, 7)
> m2(m1(x)) eq x;
true
> m4(m3(x)) eq x;
true
> flag, w := AlternatingElementToWord(G,x);
> flag;
true
> m4(w) eq x;
true
```

```
> y := Random(Generic(G));
> flag, w := AlternatingElementToWord(G,y);
> flag;
false
> flag, m1, m2, m3, m4 := RecogniseAlternating(G,11);
> flag;
false
> flag, m1, m2, m3, m4 := RecogniseSymmetric(G,10);
> flag;
false
```

The nature of the `GuessAltsymDegree` function is that it assumes that its input is either an alternating or symmetric group and then tries to guess which one and the degree. As such, it is almost always correct when the input is an alternating or symmetric group, but will often return a bad guess when the input group is not of this form, as in the following example.

```
> GuessAltsymDegree(Sym(50));
true Symmetric 50
> GuessAltsymDegree(Alt(73));
true Alternating 73
> GuessAltsymDegree(PSL(5,5));
true Alternating 82
```

65.3.2 Determining the Type of a Finite Group of Lie Type

Given a finite quasisimple group of Lie type in any representation, the functions in this section apply probabilistic algorithms to determine its defining characteristic and type as a Lie group.

`LieCharacteristic(G : parameters)`

`NumberRandom`	RngIntElt	*Default :* 100
`Verify`	BoolElt	*Default :* `true`

Given a finite quasisimple permutation or matrix group G which is of Lie type, determine its defining characteristic. The Monte Carlo algorithm implemented by this function is that of Liebeck and O'Brien [LO07]. Since it is Monte Carlo, there is a small probability of error. The number of random elements considered is `NumberRandom`. If `Verify` is `true`, then we first verify that G is perfect by applying `IsProbablyPerfect`.

Example H65E5

```
> F := GF (4);
> w := PrimitiveElement (F);
> a := [
> 0,w^3,0,0,0,
> w^3,0,0,0,0,
```

```
> 0,0,0,w^3,0,
> 0,0,w^3,0,0,
> w^2,w^2,w^3,w^3,w^3];
> b := [
> 0,0,w^3,0,0,
> w^1,w^2,w^2,0,0,
> w^2,w^1,w^2,0,0,
> 0,0,0,0,w^3,
> w^2,w^2,w^2,w^3,w^3];
> G := sub <GL(5, F) | a, b>;
> LieCharacteristic(G);
11
```

`LieType(G, p : parameters)`

`LieType(G, p : parameters)`

`NumberRandom` RngIntElt *Default :* 100

If the matrix or permutation group G is nearly simple, and its non-abelian composition factor is isomorphic to a group of Lie type in characteristic p, then this function returns `true` and its standard Chevalley name. Otherwise it returns `false`.

The algorithm is that of Babai, Kantor, Pálfy and Seress [BKPS02]; this implementation was developed by Malle and O'Brien. Since it is Monte Carlo, there is a small probability of error. The number of random elements considered is `NumberRandom`.

The standard name is a tuple that defines the isomorphism type of the composition factor. It is similar to that employed by `CompositionFactors`, described in the Permutation Groups chapter.

If the composition factor is a group of Lie type, then the tuple is $< s, n, q >$ and it defines the adjoint Chevalley group of Lie series s and Lie rank n over $GF(q)$. The tuple entries are valid arguments for `ChevalleyGroup`.

If the composition factor is an alternating group, and so lies in family 17, then the tuple is $< 17, n, 0 >$ and it defines the alternating group of degree n.

If the composition factor is a sporadic group and so lies in family 18, then the tuple is $< 18, n, s >$; the string s is its standard Atlas name and n is the number of the group in family 18.

`SimpleGroupName(G : parameters)`

`SimpleGroupName(G : parameters)`

`NumberRandom` RngIntElt *Default :* 100

If the matrix or permutation group G is nearly simple, this function returns `true` and a list of possible names for its non-abelian simple composition factor; otherwise it returns `false`. Since it is Monte Carlo, there is a small probability of error.

The number of random elements considered is `NumberRandom`. The list of standard names follows the convention described above.

The algorithm and implementation were developed by Malle and O'Brien; it uses `LieType` and `LieCharacteristic`.

Example H65E6

We create the classical group $\Omega(7,5)$ in its natural representation and apply `SimpleGroupName` to it.

```
> SetSeed(1);
> G := Omega(7, 5);
> flag, name := SimpleGroupName(G);
> name;
[* <B, 3, 5> *]
```

We create a certain 5-dimensional matrix group over $GF(3)$ and determine which simple group it is.

```
> F := GF(3);
> P := GL(5,F);
> gens := [
> P![2,1,2,1,2,2,0,0,0,2,0,2,0,0,0,0,1,2,0,1,1,0,2,2,1],
> P![2,1,0,2,1,1,2,0,2,2,1,1,2,1,1,0,2,0,1,1,1,1,2,2,2]];
> G := sub <P | gens>;
> flag, name := SimpleGroupName(G);
> flag;
true
> name;
[* <18, 1, M11> *]
```

¿ /* naming an alternating group */

```
> G := MatrixGroup<4, GF(2) |
>    [ 0, 0, 1, 0, 0, 0, 0, 1, 1, 0, 0, 0, 0, 1, 0, 0 ],
>    [ 0, 1, 0, 1, 1, 1, 1, 1, 0, 0, 1, 1, 0, 0, 1, 0 ] >;
> flag, name := SimpleGroupName(G);
> flag;
true
> /* this is A5 */
> name;
[* <17, 5, 0> *]
> /* naming a classical group */
> F := GF(7^2);
> P := GL (6,F);
> w := PrimitiveElement (F);
> gens := [
> P![w^12,w^36,  0,  5,  2,  0,w^44,w^36,  0,  6,  2,  0,
> w^42,w^42,w^28,w^22,w^22,  3,  4,  3,  0,w^36,w^12,  0,
> 2,  3,  0,w^20,w^12,  0,w^14,w^14,  1,w^18,w^18, w^4],
```

```
>
> P![w^38,w^26,w^25,w^21, w^9,  3,w^21,w^45,w^33, w^4,w^28,
> 2,  6,  4, w^1, w^7,w^15,  4,  1,w^36,w^35, w^5,w^41,  5,
> w^31, w^7,w^43,w^36,w^12,  1,w^34,w^42,w^11,w^39,w^47,  2]
> ];
> G := sub <P | gens>;
> flag, name := LieType(G, 5);
> flag;
true
> name;
<A, 1, 5>
> /* so this is SL(2, 5) */
```

65.3.3 Classical Forms

Let G be an absolutely irreducible subgroup of $\mathrm{GL}(d, q)$. The following functions compute symplectic, unitary and orthogonal forms of the underlying vector space V left invariant by the action of G.

A *bilinear* form is a bilinear function κ from $V \times V \to F$. It is G-invariant modulo scalars if for each $g \in G$ there is a $\mu_g \in F$ such that $\kappa(vg, wg) = \mu_g \kappa(v, w)$ for all $v, w \in V$.

Now suppose that $a \mapsto \bar{a}$ is an automorphism of F of order 2. A *sesquilinear* form is a biadditive function κ from $V \times V \to F$ such that $\kappa(au, bv) = a\bar{b}\kappa(u, v)$ for all $u, v \in V$ and $a, b \in F$. It is G-invariant modulo scalars if for each $g \in G$ there is a $\mu_g \in F$ such that $\kappa(vg, wg) = \mu_g \kappa(v, w)$ for all $v, w \in V$.

A quadratic form is a function $\chi : V \to F$ such that

(1) $\chi(av) = a^2\chi(v)$ for all $a \in F$, $v \in V$; and

(2) the form κ, defined by $\kappa(u, v) = \chi(u + v) - \chi(u) - \chi(v)$ for all $u, v \in V$, is bilinear.

It is G-invariant if for each $g \in G$, $\chi(vg) = \chi(v)$ for all $v \in V$. It is G-invariant modulo scalars if for each $g \in G$ there is a $\mu_g \in F$ such that $\chi(vg) = \mu_g \chi(v)$ for all $v \in V$.

A bilinear form which is G-invariant (modulo scalars) is represented by a matrix B such that $g * B * g^{tr} = \mu_g B$ for all $g \in G$ and is unique up to multiplication by an element of F. Assume F has an automorphism $a \mapsto \bar{a}$ of order 2; a sesquilinear form is a matrix B such that $g * B * \bar{g}^{tr} = \mu_g B$ for all $g \in G$ and is unique up to multiplication by an element of F (where $\bar{g}$ denotes the matrix obtained from g by replacing each entry g_{ij} by $\bar{g_{ij}}$). A quadratic form is represented by an upper triangular matrix Q such that the matrix $g * Q * g^{tr}$, normalized into an upper triangular matrix, equals $\mu_g Q$.

The functions below will exit with an error message if the input group G is reducible. They may also exit with error if G is not absolutely irreducible, or if `Scalars` is `true` and the derived subgroup $[G, G]$ of G is not absolutely irreducible. They may however sometimes succeed in finding a fixed form when G is irreducible but not absolutely irreducible.

`ClassicalForms(G: parameters)`

`Scalars` BoolElt *Default :* `false`

Given as input a matrix group G acting absolutely irreducibly on the underlying vector space V over the field F, `ClassicalForms` will try to find a classical form which is G-invariant or prove that no such form exists. If the optional argument `Scalars` is `true` then it will look for a form which is G-invariant modulo scalars. When `Scalars` is `true`, it is only guaranteed to succeed when $[G, G]$ acts absolutely irreducibly on V. If it finds a fixed form, then it will stop and will not look for alternative fixed forms of different types.

The classical forms are: *symplectic* (non-degenerate, alternating bilinear), *unitary* (non-degenerate sesquilinear) or *orthogonal* (a *symmetric bilinear form* and a *quadratic* form).

The function `ClassicalForms` returns a record `forms` which contains the components `formType`, `sign`, `bilinearForm`, `sesquilinearForm`, `quadraticForm` and `scalars`. Depending on the entry `formType` the record components are set to indicate:

`"unknown"` : it is not known whether G fixes a classical form.

`"linear"` : it is known that G does not fix a classical form modulo scalars.

`"symplectic"` : G fixes a symplectic form modulo scalars. The matrix of the form is stored in `bilinearForm` and the scalars for each generator of G are stored in `scalars`. In characteristic two this also implies that no quadratic form is fixed.

`"unitary"` : G fixes a unitary form (modulo scalars). The matrix of the form is stored in `sesquilinearForm`. The scalars for each generator of G are stored in `scalars`.

`"orthogonalcircle"` :

`"orthogonalplus"` :

`"orthogonalminus"` : G fixes an orthogonal form modulo scalars. The matrix of the bilinear form is stored in `bilinearForm` and the corresponding quadratic form in `quadraticForm`. The scalars for each generator of G are stored in `scalars`. In the orthogonal case, `sign` is set to 0, 1, or -1 when `formType` is `"orthogonalcircle"`, `"orthogonalplus"`, or `"orthogonalminus"`, respectively.

`SymplecticForm(G: parameters)`

`Scalars` BoolElt *Default :* `false`

If the absolutely irreducible group G preserves a symplectic form (modulo scalars if the optional argument `Scalars` is `true`), this function returns `true` and the matrix of the form. If it is known that G does not preserve such a form it returns `false`.

If it cannot decide (perhaps because the group does not act absolutely irreducibly), then it exits with an error message. If `Scalars` is `true`, then the list of scalars for the generators of G is also returned.

`SymmetricBilinearForm(G: parameters)`

`Scalars` BoolElt *Default :* `false`

If the absolutely irreducible group G preserves an orthogonal form (modulo scalars if the optional argument `Scalars` is `true`), then this function returns `true`, the matrix of the symmetric bilinear form, and the type of the form (as in `ClassicalForms`). If it is known that G does not preserve such a form, it returns `false`. If it cannot decide, then it exits with an error message. If `Scalars` is `true`, then the list of scalars for the generators of G is also returned.

`QuadraticForm(G)`

`Scalars` BoolElt *Default :* `false`

If the absolutely irreducible group G preserves a quadratic form (modulo scalars if the optional argument `Scalars` is `true`), this function returns `true`, the matrix of the form in upper triangular form, and the type of the form (as in `ClassicalForms`). If it is known that G does not preserve such a form it returns `false`. If it cannot decide, then it exits with an error message. If `Scalars` is `true`, then the list of scalars for the generators of G is also returned.

`UnitaryForm(G)`

`Scalars` BoolElt *Default :* `false`

If the absolutely irreducible group G preserves a unitary form (non-degenerate sesquilinear) (modulo scalars if the optional argument `Scalars` is `true`), then this function returns `true` and the matrix of the form. If it is known that G does not preserve such a form, it returns false. If it cannot decide, then it exits with an error message. If `Scalars` is `true`, then the list of scalars for the generators of G is also returned.

`FormType(G)`

`Scalars` BoolElt *Default :* `false`

If the absolutely irreducible group G preserves a classical form (modulo scalars if the optional argument `Scalars` is `true`), this function returns its type (see `ClassicalForms`). Otherwise it returns `"unknown"`.

Example H65E7

```
> G := Omega( 9, 11 );
> ClassicalForms( G );
rec<recformat<bilinearForm, quadraticForm, sesquilinearForm, bilinFlag,
sesquiFlag, scalars, formType, bc, n> | bilinearForm :=
[ 0  0  0  0  0  0  0  0  1]
[ 0  0  0  0  0  0  0  1  0]
[ 0  0  0  0  0  0  1  0  0]
[ 0  0  0  0  0  1  0  0  0]
[ 0  0  0  0  6  0  0  0  0]
[ 0  0  0  1  0  0  0  0  0]
[ 0  0  1  0  0  0  0  0  0]
[ 0  1  0  0  0  0  0  0  0]
[ 1  0  0  0  0  0  0  0  0],
quadraticForm :=
[ 0  0  0  0  0  0  0  0  1]
[ 0  0  0  0  0  0  0  1  0]
[ 0  0  0  0  0  0  1  0  0]
[ 0  0  0  0  0  1  0  0  0]
[ 0  0  0  0  3  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0],
sesquilinearForm := false, bilinFlag := true,  sesquiFlag := false,
scalars := [ 1, 1 ], formType := orthogonalcircle, sign := 0>
> FormType( G );
orthogonalcircle
> SymplecticForm( G );
false
```

`TransformForm(form, type)`

Return a matrix m such that G^m lies in the classical group returned by the MAGMA function `GU`, `Sp`, or `GO(Plus/Minus)`. The argument *form* should be a classical form of type *type* fixed by an absolutely irreducible subgroup G of $GL(d, q)$. It should be the bilinear or sesquilinear form fixed by G, except when G is orthogonal in characteristic 2, in which case it should be the quadratic form. The argument *type* should be as in the `formType` component of the record returned by `ClassicalForms`; i.e. one of `"symplectic"`, `"unitary"`, `"orthogonalcircle"`, `"orthogonalplus"`, or `"orthogonalminus"`.

`TransformForm(G)`

`Scalars`	BoolElt	*Default :* `false`

This function calls `ClassicalForms` to find a form fixed by the absolutely irreducible subgroup G of $GL(d, q)$. If `Scalars` is `true`, then `ClassicalForms` is called with `Scalars` set to `true`, so that a form fixed module scalars is found. If a form $form$ of type *type* is fixed, then it returns `TransformForm(form, type)`. Otherwise it returns `false`.

`SpinorNorm(g, form)`

The spinor norm of g with respect to the given form . $form$ must be the matrix of an orthogonal form (ie, it must be symmetric and nonsingular), and g an element of the general orthogonal group `GO(Plus/Minus)` fixing that form. Note that the form is ignored in even characteristic, since the spinor norm of g is just equal to the rank modulo 2 of $g - I$ in that case.

65.3.4 Recognizing Classical Groups in their Natural Representation

Let G be an irreducible subgroup of $\mathrm{GL}(d, q)$. The following algorithm is designed to test whether G contains the corresponding classical group Ω and is contained in Δ. Here Ω and Δ are defined as follows:

Case "linear": $\Delta = \mathrm{GL}(d, q)$, $\Omega = \mathrm{SL}(d, q)$

Case "symplectic": $\Delta = \mathrm{GSp}(d, q)$, $\Omega = \mathrm{Sp}(d, q)$

Case "orthogonalplus": $\Delta = \mathrm{GO}^+(d, q)$, $\Omega = \Omega^+(d, q)$

Case "orthogonalminus": $\Delta = \mathrm{GO}^-(d, q)$, $\Omega = \Omega^-(d, q)$

Case "orthogonalcircle":$\Delta = \mathrm{GO}^\circ(d, q)$, $\Omega = \Omega^\circ(d, q)$

Case "unitary": $\Delta = \mathrm{GU}(d, q)$, $\Omega = \mathrm{SU}(d, q)$

`RecognizeClassical( G : parameters)`

`Case`	MonStgElt	*Default :* "*unknown*"
`NumberOfElements`	RngIntElt	*Default :* 25
Verbose	`Classical`	*Maximum :* 3

`RecognizeClassical` takes as input a group G, which is a subgroup of $\mathrm{GL}(d, q)$.

The parameter `Case` is one of `"linear"`, `"symplectic"`, `"orthogonalplus"`, `"orthogonalminus"`, `"orthogonalcircle"`, `"unitary"` or `"unknown"`; if `Case` is supplied, then the algorithm seeks to decide for this case only.

The parameter `NumberOfElements` is the number of random elements selected from G during the execution of the algorithm.

The output of `RecognizeClassical` is either `true`, `false` or `"Does not apply"`. If the algorithm returns `true`, then we know with certainty that G contains Ω and is contained in Δ. Note that the proof of correctness of the algorithm depends on the finite simple group classification. If it returns `false` then either G does not contain

Ω, or G is not contained in Δ, or G is not irreducible, or there is a small chance that G is contained in Δ and contains Ω. More precisely, if the irreducible group G is contained in Δ and really does contain Ω then the probability with which the algorithm returns `false` is less than ε, where ε is a real number between 0 and 1. The smaller the value of ε, the larger `NumberOfElements` must be. If the algorithm returns `"Does not apply"` then it is not applicable to the given group.

If `"Classical"` is set to verbose then, where `RecognizeClassical` returns `true`, it also prints the statement "Proved that the group contains a classical group of type *case* in n random selections", where n is the number of selections needed. If it returns `false`, it prints a statement giving some indication of why the algorithm reached this conclusion.

Theoretical details of the algorithms used may be found in Niemeyer & Praeger [NP97][NP98][NP99] and Praeger [Pra99]. Its approach is based on the SL-recognition algorithm (Neumann & Praeger, [NP92]).This implementation also uses algorithms described in Celler & Leedham-Green [CLG97a][CLG97b] and Celler et al. [CLGM$^+$95].

For small fields ($q < 2^{16}$), the cost of this implementation for a given value of `NumberOfElements` is $O(d^3 \log d)$ bit operations.

`IsLinearGroup(G)`

This function tests whether the subgroup G of $\mathrm{GL}(d, q)$ contains $\mathrm{SL}(d, q)$. If the function can establish this fact, it returns `true` and otherwise `false`. Hence, if `IsLinearGroup` returns `false`, there is a small chance that G nevertheless contains $\mathrm{SL}(d, q)$. See `RecognizeClassical` for more details.

`IsSymplecticGroup(G)`

This function tests whether the subgroup G of $\mathrm{GSp}(d, q)$ contains $\mathrm{Sp}(d, q)$. If the function can establish this fact, it returns `true` and otherwise `false`. Hence, if `IsSymplecticGroup` returns `false`, there is a small chance that G nevertheless contains $\mathrm{Sp}(d, q)$. See `RecognizeClassical` for more details.

`IsOrthogonalGroup(G)`

This function tests whether the subgroup G of $\mathrm{GO}^\epsilon(d, q)$ contains $\Omega^\epsilon(d, q)$. If the function can establish this fact, it returns `true` and otherwise `false`. Hence, if `IsOrthogonalGroup` returns `false`, there is a small chance that G nevertheless contains $\Omega^\epsilon(d, q)$. See `RecognizeClassical` for more details.

`IsUnitaryGroup(G)`

This function tests whether the subgroup G of $\mathrm{GU}(d, q)$ contains $\mathrm{SU}(d, q)$. If the function can establish this fact, it returns `true` and otherwise `false`.

`ClassicalType(G)`

If G is known to be a classical subgroup of $\mathrm{GL}(d, q)$ this function returns the appropriate classical type as a string, i.e. `"linear"`, `"symplectic"`, `"orthogonalplus"`, `"orthogonalminus"`, `"orthogonalcircle"`, or `"unitary"`. Otherwise the function returns `false`.

Example H65E8

```
> G := SU (60, 9);
> SetVerbose( "Classical", true );
> RecognizeClassical( G );
true
> IsLinearGroup( G );
false
> IsUnitaryGroup( G );
true
> IsSymplecticGroup( G );
false
> IsOrthogonalGroup( G );
false
> ClassicalType( G );
unitary
> G := Sp (462, 3);
> time RecognizeClassical( G );
true
Time: 7.630
```

65.3.5 Constructive Recognition of Linear Groups

The functions in this section recognise whether of not a given group G is a specified linear group T. If it is, then an isomorphism between G and T is returned.

`RecognizeSL2(G)`

`RecognizeSL2(G)`

`RecognizeSL2(G, q)`

`RecognizeSL2(G, q)`

If G, a matrix or permutation group, is isomorphic, possibly modulo scalars, to $(P)SL(2, q)$, then homomorphisms between G and $(P)SL(2, q)$ are constructed. The function returns a homomorphism from G to $(P)SL(2, q)$, a homomorphism from $(P)SL(2, q)$ to G, the map from G to its word group, and the map from the word group to G.

If q, the cardinality of the defining field for G, is known, it *should* be supplied. Otherwise, the function `SL2Characteristic` is used to determine q; if q is large, this calculation may be **expensive**.

SL2ElementToWord(G, g)

SL2ElementToWord(G, g)

If g is an element of the matrix or permutation group G which has been constructively recognised to have central quotient isomorphic to $PSL(2, q)$, then return `true` and element of word group for G which evaluates to g, else `false`. This facilitates membership testing in G.

SL2Characteristic(G : *parameters*)

SL2Characteristic(G : *parameters*)

NumberRandom	RngIntElt	*Default :* 100
Verify	BoolElt	*Default :* `true`

Subject to the *assumption* that the group G has central quotient $(P)SL(2, q)$, determine its characteristic and field size. The Monte Carlo algorithm implemented by this function is that of Liebeck and O'Brien [LO07]. Since it is Monte Carlo, there is a small probability of error. The number of random elements considered is `NumberRandom`. If `Verify` is `true`, then we first verify that G is perfect by applying `IsProbablyPerfect`.

The constructive recognition algorithms for $SL(2, q)$ were developed by Conder, Leedham-Green and O'Brien [CLGO06]. The algorithm used for other representations was developed by Brooksbank and O'Brien.

Example H65E9

Our first example uses $G = \mathrm{SL}(2, 3^2)$ in its natural representation. We first recognise the group and then express a random matrix of G as a word in the generators of G.

```
> G := SL(2, 3^2);
> flag, phi, tau, gamma, delta := RecogniseSL2(G, 3^2);
> g := G![1, 2, 0, 1];
> w := gamma(g);
> delta(w) eq g;
true
```

Example H65E10

We now consider a representation of a 2-dimensional linear group inside $GL(6, \mathbf{F}_{57})$.

```
> K<w> := GF(5, 7);
> G :=
> MatrixGroup<6, GF(5, 7) |
> [w^19035, w^14713, w^50617, w^14957, w^51504, w^48397, w^16317, w^3829,
>  w^35189, w^2473, w^19497, w^77192, w^46480, w^6772, w^29577, w^61815,
>  w^54313, w^16757, w^43765, w^64406, w^58788, w^30789, w^13579, w^66728,
>  w^7733, w^45434, w^42411, w^61613, w^12905, w^6889, w^50116, w^16117,
>  w^56717, w^25226, w^49940, w^36836 ],
```

```
> [w^63955, w^40568, w^45004, w^11642, w^39536, w^11836, w^52594, w^71166,
>  w^47015, w^74450, w^32373, w^37021, w^76381, w^18155, w^57943, w^31194,
>  w^62524, w^65864, w^11868, w^76867, w^26483, w^41335, w^64856, w^41125,
>  w^43990, w^40104, w^24842, w^3153, w^23777, w^60024, w^14454, w^68648,
>  w^43403, w^26710, w^39779, w^22074 ] >;
>
> flag, phi, tau, gamma, delta := RecogniseSL2(G, 5^7);
> phi;
Mapping from: GrpMat: G to SL(2, GF(5, 7)) given by a rule [no inverse]
> g := Random(G);
> h := phi (g);
> h;
[w^40430   w^970]
[ w^5607 w^11606]
> k := tau(h);
> w := gamma(k);
> m := delta(w);
```

Recall that we are working modulo scalars.

```
> IsScalar(m * g^-1);
true
> H := SL(2, 5^7);
> h := H![1,1,0,1];
> g := tau(h);
> Order(g);
5
```

We now test a random element of $GL(6, \mathbf{F}_{57})$ for membership of our group.

```
> g := Random(GL(6, 5^7));
> SL2ElementToWord(G, g);
false
```

`RecogniseSL3(G)`

`RecogniseSL3(G, q : parameters)`

`Verify` BoolElt *Default :* `true`

If $G \leq GL(d, F)$, is isomorphic, possibly modulo scalars, to $(P)SL(3, q)$, then construct homomorphisms between G and $(P)SL(3, q)$. Return homomorphism from G to $(P)SL(3, q)$, homomorphism from $(P)SL(3, q)$ to G, the map from G to its word group and the map from the word group to G.

If q, the cardinality of the defining field for G, is known, it *should* be supplied. Otherwise, it is computed using the functions `LieCharacteristic` and `LieType`.

If `Verify` is `false`, then assume G is isomorphic, possibly modulo scalars, to $(P)SL(3, q)$.

`SL3ElementToWord (G, g)`

If g is an element of G which has been constructively recognised to have central quotient isomorphic to $PSL(3, q)$, then return `true` and element of word group for G which evaluates to g, else `false`. This facilitates membership testing in G.

The constructive recognition algorithms for $SL(3, q)$ were developed by Lübeck, Magaard, and O'Brien [LMO07]. Its current implementation, which is part of the `CompositionTree` package, was developed by Bäärnhielm and O'Brien.

Example H65E11

We create $SL(3, 5^4)$ in its natural representation and recognise it. We then form its symmetric square and apply the recognition machinery to that.

```
> G := SL(3, 5^4);
> flag, phi, tau, gamma, delta := RecogniseSL3(G);
> w := PrimitiveElement (GF(5^4));
> g := GL(3, 5^4)! [1,2,1,0,w,1,0,0,w^-1];
> w := gamma (g);
> delta (w) eq g;
true
> G := ActionGroup(SymmetricSquare(GModule(G)));
> flag, phi, tau, gamma, delta := RecogniseSL3(G);
> phi;
Mapping from: GL(6, GF(5, 4)) to SL(3, GF(5, 4)) given by a rule [no inverse]
> g := Random(G);
> h := phi(g);
> h;
[$.1^40430   $.1^970]
[ $.1^5607 $.1^11606]
> k := tau(h);
> w := gamma(k);
> m := delta(w);
```

Recall that we are working modulo scalars. We conclude by testing whether a random element of $GL(6, 5^4)$ is contained in our group.

```
> IsScalar(m * g^-1);
true
> g := Random(GL(6, 5^4));
> SL3ElementToWord(G, g);
false
```

`RecogniseSL(G, d, q)`

`RecognizeSL(G, d, q)`

Use the Kantor-Seress algorithm to try to find an isomorphism between the finite group G (regarded as a black-box group) and $\mathrm{SL}(d, q)$ or $\mathrm{PSL}(d, q)$. The first return value indicates whether the attempt was successful. If so, then the second and third return values are mutually inverse homomorphisms (modulo scalars if $G \cong \mathrm{PSL}(d, q)$) from G to $\mathrm{SL}(d, q)$ and from $\mathrm{SL}(d, q)$ to G.
Warning: This function often returns `false` even when G is isomorphic to $\mathrm{SL}(d, q)$ or $\mathrm{PSL}(d, q)$, so it should be called repeatedly until it returns `true`!

65.3.6 Constructive Recognition of Symplectic Groups

`RecogniseSpOdd(G, d, q)`

`RecognizeSpOdd(G, d, q)`

Use the Kantor-Seress algorithm to try to find an isomorphism between the finite group G (regarded as a black-box group) and $\mathrm{Sp}(d, q)$ or $\mathrm{PSp}(d, q)$ for odd q. The first return value indicates whether the attempt was successful. If so, then the second and third return values are mutually inverse homomorphisms (modulo scalars if $G \cong \mathrm{PSp}(d, q)$) from G to $\mathrm{Sp}(d, q)$ and from $\mathrm{Sp}(d, q)$ to G.
Warning: This function often returns `false` even when G is isomorphic to $\mathrm{Sp}(d, q)$ or $\mathrm{PSp}(d, q)$, so it should be called repeatedly until it returns `true`!

`RecogniseSp4Even(G, q)`

`RecognizeSp4Even(G, q)`

Use an algorithm of Peter Brooksbank to try to find an isomorphism between the finite group G (regarded as a black-box group) and $\mathrm{Sp}(4, q)$ for even q. The first return value indicates whether the attempt was successful. If so, then the second and third return values are mutually inverse homomorphisms from G to $\mathrm{Sp}(d, q)$ and from $\mathrm{Sp}(d, q)$ to G. The third and fourth return values are mutually inverse homomorphisms from G to the word group W of G and from W to G.

65.3.7 Constructive Recognition of Unitary Groups

`RecogniseSU3(G, d, q)`

`RecognizeSU3(G, d, q)`

Use an algorithm of Peter Brooksbank to try to find an isomorphism between the finite group G (regarded as a black-box group) and $\mathrm{SU}(3, q)$ or $\mathrm{PSU}(3, q)$ for $q > 2$. The first return value indicates whether the attempt was successful. If so, then the second and third return values are mutually inverse homomorphisms (modulo scalars if $G \cong \mathrm{PSU}(3, q)$) from G to $\mathrm{SU}(3, q)$ and from $\mathrm{SU}(3, q)$ to G. The third and fourth return values are mutually inverse homomorphisms from G to the word group W of G and from W to G.

`RecogniseSU4(G, d, q)`

`RecognizeSU4(G, d, q)`

Use an algorithm of Peter Brooksbank to try to find an isomorphism between the finite group G (regarded as a black-box group) and $\mathrm{SU}(4,q)$ or $\mathrm{PSU}(4,q)$. The first return value indicates whether the attempt was successful. If so, then the second and third return values are mutually inverse homomorphisms (modulo scalars if $G \cong \mathrm{PSU}(4,q)$) from G to $\mathrm{SU}(4,q)$ and from $\mathrm{SU}(4,q)$ to G. The third and fourth return values are mutually inverse homomorphisms from G to the word group W of G and from W to G.

65.3.8 Constructive Recognition of $\mathrm{SL}(d,q)$ in Low Degree

Let $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$ with $q = p^f$, where V is the natural H-module. Let H act on an irreducible $\mathbf{F}_q$-module W of dimension at most d^2. Magaard, O'Brien & Seress [MOAS08] describe algorithms which, given as input the irreducible representation of H on W, construct a d-dimensional projective representation of H. Their implementations, prepared by Eamonn O'Brien, are described below.

`RecogniseSymmetricSquare (G)`

G is symmetric square representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$ and $d \geq 4$. Reconstruct H; if successful, then return `true` and H, otherwise `false`.

`SymmetricSquarePreimage (G, g)`

G is symmetric square representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$; return preimage of g in H.

`RecogniseAlternatingSquare (G)`

G is alternating square representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$ and $d \geq 3$. Reconstruct H; if successful, then return `true` and H, otherwise `false`.

`AlternatingSquarePreimage (G, g)`

G is alternating square representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$; return preimage of g in H.

`RecogniseAdjoint (G)`

G is adjoint representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$ and $d \geq 3$. Reconstruct H; if successful, then return `true` and H, otherwise `false`.

`AdjointPreimage (G, g)`

G is adjoint representation of H, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$; return preimage of g in H.

`RecogniseDelta (G)`

G is absolutely irreducible representation of $H \otimes H^{p^e}$, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$ and $d \geq 4$. Reconstruct H; if successful, then return `true` and H, otherwise `false`.

`DeltaPreimage (G, g)`

G is absolutely irreducible representation of $H \otimes H^{(}p^e)$, where $\mathrm{SL}(d,q) \leq H \leq \mathrm{GL}(d,q)$; return preimage of g in H.

Example H65E12

```
> G := SL(4, 3^2);
> G := SL(4, 9);
> M := GModule (G);
> M := SymmetricPower (M, 2);
> G := MatrixGroup (M);
> G := RandomConjugate (G);
> f, H := RecogniseSymmetricSquare (G);
> f;
true
> H;
MatrixGroup(4, GF(3^2))
Generators:
    [    0     1     0     0]
    [    0     0     0     1]
    [$.1^6     2     2   $.1]
    [    2   $.1     0   $.1]
    [    0     0     1     0]
    [$.1^2 $.1^7     1 $.1^6]
    [    1     2 $.1^6 $.1^6]
    [  $.1     0 $.1^7     0]
> g := Random (G);
>  h := SymmetricSquarePreimage (G, g);
> h;
[$.1^6     0     0 $.1^2]
[$.1^6     0 $.1^3     0]
[$.1^2 $.1^5     2   $.1]
[    0 $.1^3 $.1^5   $.1]
```

65.3.9 Constructive Recognition of Suzuki Groups

65.3.9.1 Introduction

A description of the functionality for constructive recognition and constructive membership testing of the Suzuki groups $\mathrm{Sz}(q)$, with $q = 2^{2m+1}$ for some $m > 0$ follows.

The main intrinsics of the package are `RecogniseSz(G)` which performs constructive recognition of $G \cong \mathrm{Sz}(q)$, `SzElementToWord(G, g)` which returns a `GrpSLPElt` for g in the generators of G, and `IsSuzukiGroup(G)` which is a non-constructive test for isomorphism between G and $\mathrm{Sz}(q)$.

Informative printing can be obtained using one of a number of verbose flags:

`SuzukiGeneral`, for the general routines.

`SuzukiStandard`, for the routines related to the standard copy.

`SuzukiConjugate`, for the routines related to conjugation.

`SuzukiTensor`, for the routines related to tensor decomposition.

`SuzukiMembership`, for the routines related to membership testing.

`SuzukiCrossChar`, for the routines related to cross-characteristic representations.

`SuzukiTrick`, for the routines related to the double coset trick.

`SuzukiNewTrick`, for the routines related to the stabiliser trick.

For each of the flags, the verbose level takes any value up to 10, with higher values resulting in more output.

65.3.9.2 Recognition Functions

`IsSuzukiGroup(G)`

Given a matrix group G, this function determines (non-constructively) whether or not G is isomorphic to $\mathrm{Sz}(q)$. The corresponding finite field cardinality q is also returned.

If the group G is defined over a field of odd characteristic or has degree greater than 4, the Monte Carlo algorithm of `LieType` is used. If G has degree 4 and is over a field of characteristic 2, then a fast Las Vegas algorithm is used, described in [Bää06a].

`RecogniseSz(G : parameters)`

`RecognizeSz(G : parameters)`

`Verify`	BoolElt	*Default :* `true`
`FieldSize`	RngIntElt	*Default :*
`Optimise`	BoolElt	*Default :* `false`

Let G be a group that is absolutely irreducible and is defined over a minimal field. This function constructively recognises G as a Suzuki group. If G is isomorphic to $\mathrm{Sz}(q)$, where q is the size of the defining field of G, then return:

Isomorphism from G to $\mathrm{Sz}(q)$.

Isomorphism from $\mathrm{Sz}(q)$ to G.

Map from G to the word group of G.

Map from the word group of G to G.

The isomorphisms are composed of maps that are defined by rules, so `Function` should be used on each component to avoid unnecessary built-in membership testing. The word group is the `GrpSLP` group which is the parent of the elements returned by `SzElementToWord`. In general this is not the same as `WordGroup(G)`, but is created from it using `AddRedundantGenerators`.

If `Verify` is true, then it is checked if G is isomorphic to $\mathrm{Sz}(q)$, using `IsSuzukiGroup`. In that case, `FieldSize` must be set to the correct value of q. Constructive recognition of 2.Sz(8) is also handled.

If `Optimise` is true, then the third map returns element in an optimised word group (using `AddRedundantGenerators`). Then each invocation of the map will be faster, but the initialisation will take longer.

The algorithms used for constructive recognition are described in [Bää06a] and [Bää05].

`SzElementToWord(G, g)`

If G has been constructively recognised as a Suzuki group, and if g is an element of G, then return `true` and a `GrpSLPElt` from the word group of G which evaluates to g, else return `false`.

This facilitates membership testing in G.

`SzPresentation(q)`

If $q = 2^{2m+1}$ for some $m > 0$, return a short presentation of $\mathrm{Sz}(q)$ on the MAGMA standard generators, i.e. the generators returned by the `Sz` intrinsic.

`SatisfiesSzPresentation(G)`

G is constructively recognised as $\mathrm{Sz}(q)$ for some q. Verify that it satisfies a presentation for this group.

`SuzukiIrreducibleRepresentation(F, twists :` *parameters*`)`

`CheckInput` BOOLELT *Default :* `true`

Let F be a finite field of cardinality $q = 2^{2m+1}$ for some $m > 0$, and let *twists* be a sequence of n distinct integers in the range $[0 \dots 2m]$. The function returns an absolutely irreducible representation of $\mathrm{Sz}(q)$ having dimension 4^n, being a tensor product of twisted powers of the copy returned by the `Sz` intrinsic, where the twists are given by the input sequence.

If `CheckInput` is true, then it is verified that F and *twists* satisfy the above requirements. Otherwise this is not checked.

Example H65E13

We illustrate the basic facilities starting with a random conjugate of the standard version of the Suzuki group $Sz(32)$. We first perform non-constructive recognition.

```
> G := Sz(32);
> G ^:= Random(Generic(G));
> flag, q := SuzukiRecognition(G);
> flag, q eq 32;
true true
```

The next step is to perform constructive recognition. The explicit isomorphisms will be the values of `iso` and `inv`.

```
> flag, iso, inv, g2slp, slp2g := RecognizeSz(G);
> flag;
true
> iso, inv;
Mapping from: GrpMat: G to MatrixGroup(4, GF(2^5)) given by a rule [no inverse]
Mapping from: MatrixGroup(4, GF(2^5)) to GrpMat: G given by a rule [no inverse]
```

We now experiment with membership testing. We use Function to avoid MAGMA's built-in membership testing but in doing so, we may not obtain the shortest possible SLP.

```
> w := Function(g2slp)(G.1);
> #w;
284
```

The algorithm is probabilistic, so different executions will most likely give different results.

```
> ww := Function(g2slp)(G.1);
> w eq ww;
false
```

Note that the resulting SLPs are from a word group that is not the word group W corresponding to the defining generators of G. However, they can be coerced into W.

```
> W := WordGroup(G);
> NumberOfGenerators(Parent(w)), NumberOfGenerators(W);
7 3
> flag, ww := IsCoercible(W, w);
> flag;
true
> slp2g(w) eq Evaluate(ww, UserGenerators(G));
true
```

So there are two ways to get the element back. An alternative is to use the intrinsic `SzElementToWord`, which is better if the elements are not known to lie in the group.

```
> flag, ww := SzElementToWord(G, G.1);
> flag, slp2g(w) eq slp2g(ww);
```

```
true true
```

We take an element just outside the group.

```
> H := Sp(4, 32);
> flag, ww := SzElementToWord(G, H.1);
> flag;
false
> // in this case we will not get an SLP
> ww := Function(g2slp)(H.1);
> ww;
false
> SatisfiesSzPresentation(G);
true
```

Example H65E14

As a variation we apply the machinery to $2.Sz(8)$. We demonstrate constructive recognition and constructive membership testing.

```
> A := ATLASGroup("2Sz8");
> reps := MatRepKeys(A);
> G := MatrixGroup(reps[3]);
> Degree(G), CoefficientRing(G);
40 Finite field of size 7
> flag, iso, inv, g2slp, slp2g := RecognizeSz(G);
> flag;
true
> R := RandomProcess(G);
> g := Random(R);
> w := Function(g2slp)(g);
> slp2g(w) eq g;
true
```

Example H65E15

For the next example we consider a case where the dimension is large. We construct the Suzuki group in a 64-dimensional matrix representation and then take a random conjugate and also rewrite is over a smaller field.

```
> F := GF(2, 9);
> twists := [0, 3, 6];
> G := SuzukiIrreducibleRepresentation(F, twists);
> Degree(G), IsAbsolutelyIrreducible(G);
64 true
> G ^:= Random(Generic(G));
> flag, GG := IsOverSmallerField(G);
> flag, CoefficientRing(GG);
```

```
true Finite field of size 2^3
```

Non-constructive recognition is harder in this case and will give us the defining field size. Constructive recognition will decompose the tensor product.

```
> time SuzukiRecognition(GG);
true 512
Time: 2.330
> time flag, iso, inv, g2slp, slp2g := RecogniseSz(GG);
Time: 4.800
> iso;
Mapping from: GrpMat: GG to MatrixGroup(4, GF(2^9)) given by a rule [no inverse]
```

Constructive membership is again easy

```
> R := RandomProcess(GG);
> g := Random(R);
> time w := Function(g2slp)(g);
Time: 0.020
> // but SLP evaluation is harder in large dimensions
> time slp2g(w) eq g;
true
Time: 0.370
> time SatisfiesSzPresentation(GG);
true
Time: 10.930
```

Example H65E16

The final example will be in cross characteristic. We build a representation of $Sz(8)$ in cross characteristic.

```
> G := Sz(8);
> _, P := SuzukiPermutationRepresentation(G);
> // for example over GF(9)
> M := PermutationModule(P, GF(3, 2));
> factors := CompositionFactors(M);
> exists(m64){f : f in factors | Dimension(f) eq 64};
true
> m64;
GModule m64 of dimension 64 over GF(3^2)
> H := ActionGroup(m64);
> IsAbsolutelyIrreducible(H);
true
> flag, G := IsOverSmallerField(H);
> Degree(G), CoefficientRing(G);
64 Finite field of size 3
```

We actually end up with a group in characteristic 3.

```
> time flag, iso, inv, g2slp, slp2g := RecogniseSz(G);
```

```
Time: 3.490
> iso;
Mapping from: GrpMat: G to MatrixGroup(4, GF(2^3)) given by a rule [no inverse]
> R := RandomProcess(G);
> g := Random(R);
> time w := Function(g2slp)(g);
Time: 0.010
> time slp2g(w) eq g;
true
Time: 0.110
> time SatisfiesSzPresentation(G);
true
Time: 0.330
```

65.3.10 Constructive Recognition of Small Ree Groups

65.3.10.1 Introduction

This machinery provides functionality for constructive recognition and constructive membership testing of the small Ree groups ${}^2\mathrm{G}_2(q) = \mathrm{Ree}(q)$, with $q = 3^{2m+1}$ for some $m > 0$.

The important intrinsics are `RecogniseRee` which performs constructive recognition of $G \cong \mathrm{Ree}(q)$, `ReeElementToWord` which returns a `GrpSLPElt` for g in the generators of G, and `IsReeGroup` which is a non-constructive test for isomorphism between G and $\mathrm{Ree}(q)$.

There are a few verbose flags used in the package.

`ReeGeneral`, for the general routines.

`ReeStandard`, for the routines related to the standard copy.

`ReeConjugate`, for the routines related to conjugation.

`ReeTensor`, for the routines related to tensor decomposition.

`ReeMembership`, for the routines related to membership testing.

`ReeCrossChar`, for the routines related to cross-characteristic representations.

`ReeTrick`, for the routines related to the stabiliser trick.

`ReeInvolution`, for the routines related to involution centralisers.

`ReeSymSquare`, for the routines related to symmetric square decomposition.

All the flags can be set to values up to 10, with higher values resulting in more output.

65.3.10.2 Recognition Functions

`RecogniseRee(G : parameters)`

`RecognizeRee(G : parameters)`

`Verify`	BoolElt	*Default :* `true`
`FieldSize`	RngIntElt	*Default :*
`Optimise`	BoolElt	*Default :* `false`

G is absolutely irreducible and defined over minimal field. Constructively recognise G as a Ree group. If G is isomorphic to Ree(q) where q is the size of the defining field of G, then return:

Isomorphism from G to Ree(q).

Isomorphism from Ree(q) to G.

Map from G to the word group of G.

Map from the word group of G to G.

The isomorphisms are composed of maps that are defined by rules, so `Function` should be used on each component to avoid unnecessary built-in membership testing.

The word group is the `GrpSLP` which is the parent of the elements returned by `ReeElementToWord`. In general this is not the same as `WordGroup(G)`, but is created from it using `AddRedundantGenerators`.

If `Verify` is true, then it is checked that G is isomorphic to Ree(q), using `IsReeGroup`, otherwise this is not checked. In that case, `FieldSize` must be set to the correct value of q.

If `Optimise` is true, then the third map returns element in an optimised word group (using `AddRedundantGenerators`). Then each invocation of the map will be faster, but the initialisation will take longer.

The algorithms for constructive recognition are those of [Bää06b].

`ReeElementToWord(G, g)`

If G has been constructively recognised as a Ree group, and if g is an element of G, then return `true` and a `GrpSLPElt` from the word group of G which evaluates to g, else return `false`.

This facilitates membership testing in G.

`IsReeGroup(G)`

Determine (non-constructively) if G is isomorphic to Ree(q). The corresponding q is also returned.

If G is over a field of characteristic not 3 or has degree greater than 7, the Monte Carlo algorithm of `LieType` is used. If G has degree 7 and is over a field of characteristic 3, then a fast Las Vegas algorithm is used.

`ReeIrreducibleRepresentation(F, twists : parameters)`

`CheckInput` BoolElt *Default :* `true`

The finite field F must have size $q = 3^{2m+1}$ for some $m > 0$, and *twists* should be a sequence of n distinct pairs of integers (i, j) where i is 7 or 27 and j in the range $[0 \dots 2m]$.

Return an absolutely irreducible representation of $\mathrm{Ree}(q)$, a tensor product of twisted powers of the representation of dimension 7 or 27, where the twists are given by the input sequence.

If `CheckInput` is `true`, then it is verified that F and *twists* satisfy the above requirements. Otherwise this is not checked.

Example H65E17

Our first example shows off the recognition machinery for the Ree group defined over $\mathbf{F}_{27}$.

```
> SetSeed(1);
> F := GF(3, 3);
> G := ReeGroup(F);
> G ^:= Random(Generic(G));
> flag, q := ReeRecognition(G);
> flag, q eq #F;
true true
> flag, iso, inv, g2slp, slp2g := RecognizeRee(G);
> flag;
true
> iso, inv;
Mapping from: GrpMat: G to MatrixGroup(7, GF(3^3)) given by a rule [no inverse]
Mapping from: MatrixGroup(7, GF(3^3)) to GrpMat: G given by a rule [no inverse]
```

We now experiment with membership testing. As the algorithm is probabilistic, different executions will most likely give different results.

```
> w := Function(g2slp)(G.1);
> #w;
342
> ww := Function(g2slp)(G.1);
> w eq ww;
false
```

The resulting SLPs are from another word group but can be coerced into W.

```
> W := WordGroup(G);
> NumberOfGenerators(Parent(w)), NumberOfGenerators(W);
7 3
> flag, ww := IsCoercible(W, w);
> flag;
true
> // so there are two ways to get the element back
> slp2g(w) eq Evaluate(ww, UserGenerators(G));
```

```
true
```

If the elements are not known to lie in the group, a better alternative is to use the intrinsic `ReeElementToWord`. We take a generator of $\Omega(7, F)$ as an example of an element not lying in $G_2(27)$.

```
> flag, ww := ReeElementToWord(G, G.1);
> flag, slp2g(w) eq slp2g(ww);
true true
> H := Omega(7, #F);
> flag, ww := ReeElementToWord(G, H.1);
> flag;
false
> ww := Function(g2slp)(H.1);
> ww;
false
```

65.3.11 Constructive Recognition of Large Ree Groups

65.3.11.1 Introduction

This machinery provides functionality for constructive recognition and constructive membership testing of the large Ree groups ${}^2\mathrm{F}_4(q) = \mathrm{LargeRee}(q)$, with $q = 2^{2m+1}$ for some $m > 0$.

The important intrinsics are `RecogniseLargeRee` which performs constructive recognition of $G \cong \mathrm{LargeRee}(q)$, `LargeReeElementToWord` which returns a `GrpSLPElt` for g in the generators of G, and `IsLargeReeGroup` which is a non-constructive test for isomorphism between G and $\mathrm{LargeRee}(q)$.

There are a few verbose flags used in the package.

`LargeReeGeneral`, for the general routines.

`LargeReeStandard`, for the routines related to the standard copy.

`LargeReeConjugate`, for the routines related to conjugation.

`LargeReeRyba`, for the routines related to membership testing.

`LargeReeTrick`, for the routines related to the stabiliser trick.

`LargeReeInvolution`, for the routines related to involution centralisers.

All the flags can be set to values up to 10, with higher values resulting in more output.

65.3.11.2 Recognition Functions

`RecogniseLargeRee(G : parameters)`

`RecognizeLargeRee(G : parameters)`

`Verify`	BoolElt	*Default :* `true`
`FieldSize`	RngIntElt	*Default :*
`Optimise`	BoolElt	*Default :* `false`

G is absolutely irreducible and defined over minimal field. Constructively recognise G as a Large Ree group. If G is isomorphic to LargeRee(q) where q is the size of the defining field of G, then return:

Isomorphism from G to LargeRee(q).

Isomorphism from LargeRee(q) to G.

Map from G to the word group of G.

Map from the word group of G to G.

The isomorphisms are composed of maps that are defined by rules, so `Function` should be used on each component to avoid unnecessary built-in membership testing.

The word group is the `GrpSLP` which is the parent of the elements returned by `LargeReeElementToWord`. In general this is not the same as `WordGroup(G)`, but is created from it using `AddRedundantGenerators`.

If `Verify` is true, then it is checked that G is isomorphic to LargeRee(q), using `IsLargeRee`, otherwise this is not checked. In that case, `FieldSize` must be set to the correct value of q.

If `Optimise` is true, then the third map returns element in an optimised word group (using `AddRedundantGenerators`). Then each invocation of the map will be faster, but the initialisation will take longer.

`LargeReeElementToWord(G, g)`

If G has been constructively recognised as a Large Ree group, and if g is an element of G, then return `true` and a `GrpSLPElt` from the word group of G which evaluates to g, else return `false`.

This facilitates membership testing in G.

`IsLargeReeGroup(G)`

Determine (non-constructively) if G is isomorphic to LargeRee(q). The corresponding q is also returned.

If G is over a field of characteristic not 2 or has degree greater than 26, the Monte Carlo algorithm of `LieType` is used. If G has degree 26 and is over a field of characteristic 2, then a fast Las Vegas algorithm is used.

65.4 Properties of Finite Groups Of Lie Type

65.4.1 Maximal Subgroups of the Classical Groups

The `ClassicalMaximals` function, written by Derek Holt and Colva Roney-Dougal, returns a list of the maximal subgroups of the classical quasisimple groups in their natural representations, as returned by the MAGMA functions `SL, Sp, SU, Omega, OmegaPlus, OmegaMinus`. The list should be complete for dimensions up to 12 apart from a few omissions in $\Omega^+(8,q)$ which will be rectified in the near future.

There are also options to return the normalisers of these subgroups in various groups, such as $\mathrm{GL}(n,q)$, $\mathrm{GU}(n,q)$, that lie between the quasisimple group and its normaliser in the general linear group. These should be sufficient to enable the skilled user to determine the maximal subgroups of any group lying between the quasisimple groups and its normaliser.

According to the theorem of Aschbacher [Asc84] discussed earlier in this chapter, the maximal subgroups of a quasisimple classical group over a finite field lie in (at least) one of nine categories, which were listed in the Aschbacher Reduction section.

The subgroups in the first eight of these categories are said to be of *geometric type* and can be described in a uniform fashion. This description is the topic of the book [KL90]. They are returned in all dimensions by `ClassicalMaximals`. There is no such uniform description of the subgroups in the ninth class, which have to be classified separately in each dimension. The lists in the papers [HM01], [HM02] and [LÖ1] contain sufficient information in theory to compute these subgroups up to dimension 250, but currently this has been carried out only up to dimension 12.

`ClassicalMaximals(type, d, q : parameters)`

`classes`	SETENUM	*Default :* $\{1 \ldots 9\}$
`all`	BOOLELT	*Default :* `true`
`special`	BOOLELT	*Default :* `true`
`general`	BOOLELT	*Default :* `true`
`normaliser`	BOOLELT	*Default :* `true`
`novelties`	BOOLELT	*Default :* `false`

Return a list of representatives of the conjugacy classes of maximal subgroups of the quasisimple group of the specified type in dimension d over the field of order q. The string *type* must be one of `L, S, U, O, O+, O-`.

If the optional parameter `classes` is set to a proper subset of $\{1 \ldots 9\}$, then only the subgroups lying in the corresponding Aschbacher categories will be returned.

If the option `all` is set `false`, then representatives of the conjugacy classes under the action of the full automorphism group of the simple classical group will be returned: so this option will usually result in fewer subgroups in the returned list!

The option `special` only has effect for types `O, O+, O-`. When this is set to `true`, the normalisers of the subgroups in the appropriate group $\mathrm{SO}(d,q)$, $\mathrm{SO}^+(d,q)$ or $\mathrm{SO}^-(d,q)$ will be returned.

If the option `general` is set to `true`, then the normalisers of the subgroups in the appropriate group $\mathrm{GL}(d,q)$, $\mathrm{GU}(d,q)$, $\mathrm{GO}(d,q)$, $\mathrm{GO}^+(d,q)$ or $\mathrm{GO}^-(d,q)$ will be returned. (This option has not effect for type `S`.)

If the option `normaliser` is set to `true`, then the normalisers of the subgroups in the full normaliser of the quasisimple group in the general linear group (i.e. the group preserving the relevant form modulo scalars) will be returned. (For type `L` this has the same effect as setting *general* to `true`.)

If the option `novelties` is set `true`, then the intersections with the quasisimple group of any novelty maximal subgroups of any groups lying between the simple group and its full automorphism group will be returned. Use this option with caution, because the results are not guaranteed to be reliable!

65.4.2 Maximal Subgroups of the Exceptional Groups

Here follows some intrinsics for creating and conjugating maximal subgroups of Suzuki and Ree groups. The flags `SuzukiMaximals` and `ReeMaximals` may be used to produce verbose output.

`SuzukiMaximalSubgroups(G)`

If G has been constructively recognised as a Suzuki group, return a sequence of representatives of the maximal subgroups of G. Also returns sequences of `GrpSLPElt` of the generators of the subgroups, from the word group of G.

`SuzukiMaximalSubgroupsConjugacy(G, R, S)`

If G has been constructively recognised as a Suzuki group and if R and S are conjugate maximal subgroups of G, then return an element g of G that conjugates R to S. A `GrpSLPElt` from the word group of G, that evaluates to g, is also returned.

`ReeMaximalSubgroups(G)`

If G has been constructively recognised as a Ree group, return a sequence of representatives of the maximal subgroups of G. Also returns sequences of `GrpSLPElt` of the generators of the subgroups, from the word group of G.

`ReeMaximalSubgroupsConjugacy(G, R, S)`

If G has been constructively recognised as a Ree group and if R and S are conjugate maximal subgroups of G, then return an element g of G that conjugates R to S. A `GrpSLPElt` from the word group of G, that evaluates to g, is also returned. This is not implemented if R, S are Frobenius groups.

65.4.3 Sylow Subgroups of the Classical Groups

The MAGMA ClassicalSylow package written by Mark Stather provides functionality for constructing and conjugating the Sylow p-subgroups of the classical groups over finite fields in their natural representation, for any prime p. The classical groups may be created in MAGMA using the `GL, SL, Sp, GO, GOPlus, GOMinus, SO, SOPlus, SOMinus, Omega, OmegaPlus, OmegaMinus, GU, SU` intrinsics.

This package makes use of code to compute the classical form fixed by a group written by Derek Holt, and code to conjugate classical forms written by Colva Roney-Dougal.

The algorithms in this package are described in [Sta], which in turn makes use of the descriptions of the Sylow subgroups of the classical groups given in [Wei55], [CF64], [R. R57] and [Car72]. The conjugation algorithms make use of only the Meataxe, Smash, basic linear algebra and the solution of norm equations over finite fields.

`ClassicalSylow(G,p)`

The argument G must be a classical group in its natural representation, up to conjugation, with the exception of $GO(2m+1, 2^e)$. More precisely, it must be a conjugate of a group returned by one of the intrinsics `GL, SL, Sp, GO, GOPlus, GOMinus, SO, SOPlus, SOMinus, Omega, OmegaPlus, OmegaMinus, GU, SU`. p must be a prime number. The intrinsic returns a Sylow p-subgroup of G as a matrix group.

`ClassicalSylowConjugation(G,P,S)`

The argument G must be a classical group in its natural representation, up to conjugation, with the exception of $GO(2m+1, 2^e)$. More precisely, it must be a conjugate of a group returned by one of the intrinsics `GL, SL, Sp, GO, GOPlus, GOMinus, SO, SOPlus, SOMinus, Omega, OmegaPlus, OmegaMinus, GU, SU`. The groups P and S must be Sylow p-subgroups of G. The intrinsic returns an element $g \in G$ with $P^g = S$.

`ClassicalSylowNormaliser(G,P)`

In this case G must the full classical group in its natural representation, up to conjugation, with the exception of $GO(2m + 1, 2^e)$. More precisely, it must be a conjugate of a group returned by one of the intrinsics `GL, Sp, GO, GOPlus, GOMinus, GU`. The subgroup P must be a Sylow p-subgroup of G. The intrinsic returns the normaliser of P in G.

`ClassicalSylowToPC(G,P)`

The argument G must be a classical group in its natural representation, up to conjugation, with the exception of $GO(2m+1, 2^e)$. More precisely, it must be a conjugate of a group returned by one of the intrinsics `GL, SL, Sp, GO, GOPlus, GOMinus, SO, SOPlus, SOMinus, Omega, OmegaPlus, OmegaMinus, GU, SU`. The group P must be a Sylow p-subgroup of G. The intrinsic returns a PC group Q isomorphic to P, and also an isomorphism from P to Q and an isomorphism from Q to P.

Example H65E18

We construct a Sylow 7-subgroup P of $G = Sp(28, 17^2)$, take a random conjugate S of P and then find a conjugating element g that takes P to S.

```
> SetSeed(1);
> G := Sp(28,17^2);
> time P := ClassicalSylow(G,7);
Time: 0.080
> S := P^Random(G);
> time g := ClassicalSylowConjugation(G,P,S);
Time: 0.400
```

We next compute the normaliser of P in G.

```
> time N := ClassicalSylowNormaliser(G,P);
Time: 0.310
> // and a PC presentation of P
> time Pc, PtoPc, PctoP := ClassicalSylowToPC(G,P);
Time: 0.200
> Pc;
GrpPC : Pc of order 2401 = 7^4
PC-Relations:
    Pc.1^7 = Id(Pc),
    Pc.2^7 = Id(Pc),
    Pc.3^7 = Id(Pc),
    Pc.4^7 = Id(Pc)
> // We get inverse isomorphisms PtoPc and PctoP
> g := Random(P);
> PctoP(PtoPc(g)) eq g;
true
> x := Random(Pc);
> PtoPc(PctoP(x)) eq x;
true
```

65.4.4 Sylow Subgroups of Exceptional Groups

The flags `SuzukiSylow` and `ReeSylow` may be used to produce verbose output.

`SuzukiSylow(G, p)`

If G has been constructively recognised as a Suzuki group, and if p is a prime number, return a random Sylow p-subgroup S of G.

Also returns a list of `GrpSLPElt` from the word group of G, of the generators of S. If p does not divide $|G|$, then the trivial subgroup is returned.

`SuzukiSylowConjugacy(G, R, S, p)`

If G has been constructively recognised as a Suzuki group, if p is a prime number and if R and S are Sylow p-subgroups of G, then return an element g of G that conjugates R to S. A `GrpSLPElt` from the word group of G, that evaluates to g, is also returned.

Example H65E19

We demonstrate finding a conjugating element for Sylow subgroup in an example over a large field.

```
> q := 2^121;
> G := Sz(q);
> G ^:= Random(Generic(G));
> G := DerivedGroupMonteCarlo(G);
> NumberOfGenerators(G);
19
```

Non-constructive recognition is now a bit harder.

```
> time SuzukiRecognition(G);
true 26584559915698317458076141205606891 52
Time: 0.190
> time flag, iso, inv, g2slp, slp2g := RecogniseSz(G);
Time: 22.810
```

However, after this, each call to constructive membership testing is then easy.

```
> R := RandomProcess(G);
> g := Random(R);
> time w := Function(g2slp)(g);
Time: 0.060
> // evaluating SLPs always takes some time
> time slp2g(w) eq g;
true
Time: 1.250
```

We now create some Sylow subgroups and find conjugating elements.

```
> p := Random([x[1] : x in Factorization(q - 1)]);
> time R := SuzukiSylow(G, p);
Time: 1.370
> time S := SuzukiSylow(G, p);
Time: 1.310
> // that was easy, as is conjugating them
> time g, slp := SuzukiSylowConjugacy(G, R, S, p);
Time: 1.340
> slp2g(slp) eq g;
true
> #R, NumberOfGenerators(R);
23 1
```

```
> time R := SuzukiSylow(G, 2);
Time: 164.020
> time S := SuzukiSylow(G, 2);
Time: 171.740
> NumberOfGenerators(R), #R;
121 706738825911353731833319000297167406330993558750247583248642480517047910 4
> time g, slp := SuzukiSylowConjugacy(G, R, S, 2);
Time: 1.650
```

Creating the Sylow 2-subgroup is hard since they have so many generators. One the other hand, finding a conjugating element is relatively easy.

`ReeSylow(G, p)`

If G has been constructively recognised as a Ree group, and if p is a prime number, return a random Sylow p-subgroup S of G.

Also returns a list of `GrpSLPElt` from the word group of G, of the generators of S. If p does not divide $|G|$, then the trivial subgroup is returned.

`ReeSylowConjugacy(G, R, S, p)`

If G has been constructively recognised as $\mathrm{Ree}(q)$, if p is a prime number and if R and S are Sylow p-subgroups of G, then return an element g of G that conjugates R to S, and a `GrpSLPElt` from the word group of G, that evaluates to g, is also returned.

Currently, this is not implemented for odd p that divide $q^3 + 1$.

`LargeReeSylow(G, p)`

If G has been constructively recognised as a Large Ree group, and if p is a prime number, return a random Sylow p-subgroup S of G.

Also returns a list of `GrpSLPElt` from the word group of G, of the generators of S. If p does not divide $|G|$, then the trivial subgroup is returned.

Currently, this is not implemented for p that divide $q + 1$.

Example H65E20

Starting with the Ree group over the field $\mathbf{F}_{3^{3_1}}$, we construct Sylow p-subgroups for different primes p.

```
> m := 7;
> F := GF(3, 2 * m + 1);
> q := #F;
> q;
14348907
> G := ReeGroup(F);
> G ^:= Random(Generic(G));
> G := DerivedGroupMonteCarlo(G);
> NumberOfGenerators(G);
```

```
19
> ReeRecognition(G);
true 14348907
> flag, iso, inv, g2slp, slp2g := RecogniseRee(G);
> R := RandomProcess(G);
> g := Random(R);
> w := Function(g2slp)(g);
> slp2g(w) eq g;
true
```

We first create two Sylow p-subgroups of prime order and find a conjugating element. Note that 4561 divides the order of G exactly once and also divides $q - 1$.

```
> p := 4561;
> R := ReeSylow(G, p);
> S := ReeSylow(G, p);
> g, slp := ReeSylowConjugacy(G, R, S, p);
```

Thus $R^g = S$. In this case we also automatically get an SLP for the conjugating element.

```
> slp2g(slp) eq g;
true
> #R, NumberOfGenerators(R);
4561 1
```

Sylow 3-subgroups are harder: they have order 3^{45} and hence a considerable number of generators.

```
> time R := ReeSylow(G, 3);
Time: 3.730
> S := ReeSylow(G, 3);
> NumberOfGenerators(R), #R;
15 2954312706550833698643
> time g, slp := ReeSylowConjugacy(G, R, S, 3);
Time: 0.300
```

65.4.5 Conjugacy of Subgroups of the Classical Groups

`IsGLConjugate(H, K)`

Given H and K, both subgroups of the same general linear group $G = GL(n, q)$, return the value `true` if H and K are conjugate in G. The function returns a second value in the event that the subgroups are conjugate: an element z which conjugates H into K. The algorithm is described in Roney-Dougal [RD04].

65.4.6 Conjugacy of Elements of the Exceptional Groups

The flags `SuzukiElements` and `ReeElements` may be used to produce verbose output.

`SzConjugacyClasses(G)`

If G has been constructively recognised as a Suzuki group, return a list of conjugacy classes, using the same format as the `ConjugacyClasses` intrinsic.

`SzClassRepresentative(G, g)`

If G has been constructively recognised as a Suzuki group, and g is an element of G, return the conjugacy class representative h of g, such that h is in the list returned by `SzConjugacyClasses`. Also returns c in G such that $g^c = h$.

`SzIsConjugate(G, g, h)`

If G has been constructively recognised as a Suzuki group, and g and h are elements of G, determine if g is conjugate to h. If so, return `true` and an element c such that $g^c = h$, otherwise return `false`.

`SzClassMap(G)`

If G has been constructively recognised as a Suzuki group, return its class map, as in the `ClassMap` intrinsic.

`ReeConjugacyClasses(G)`

If G has been constructively recognised as a Ree group, return a list of conjugacy classes, using the same format as the `ConjugacyClasses` intrinsic.

65.4.7 Irreducible Subgroups of the General Linear Group

`IrreducibleSubgroups(n, q)`

Return the list of conjugacy classes of irreducible subgroups of $GL(n, q)$ where q is a prime power. At present, the dimension n is restricted to 2. The list is complete for characteristic at least 5. The algorithm is based on the classification of Flannery and O'Brien [FO05].

`IrreducibleSolubleSubgroups(n, q)`

Return the list of conjugacy classes of soluble irreducible subgroups of $GL(n, q)$ where q is a prime power. At present, the dimension n is restricted to 2 or 3. The list is complete for characteristic at least 5. The algorithm is based on the classification of Flannery and O'Brien [FO05].

Example H65E21

```
> L := IrreducibleSubgroups(2, 19^5);
> #[x : x in L | IsAbelian (x)];
552
```

```
> L := IrreducibleSolubleSubgroups(2, 97^2);
> #L;
10617
> L[7];
MatrixGroup(3, GF(97^2))
Generators:
    [$.1^8775 $.1^2037 $.1^6016]
    [$.1^6017 $.1^6705 $.1^7812]
    [$.1^7813 $.1^2817   $.1^33]
```

65.5 Atlas Data for the Sporadic Groups

Most of the functions described here use data derived from the Web Atlas. The data has been prepared for inclusion in MAGMA by Michael Downward and Eamonn O'Brien. It maintains Atlas names, conventions and orderings.

All of these functions, except `GoodBasePoints`, accept as input matrix or permutation groups. The algorithm underpinning `GoodBasePoints` due to O'Brien & Wilson [OW05].

`StandardGenerators(G, str : parameters)`

`Projective`	BOOLELT	*Default :* `false`
`AutomorphismGroup`	BOOLELT	*Default :* `false`

Construct standard generators for small quasisimple or sporadic group G having name *str*; words in SLP group defined on the defining generators of G are also obtained for the standard generators.

If G is sporadic and `AutomorphismGroup` is `true`, assume G is automorphism group of group having name *str*.

If standard generators found, return `true` and sequences of generators and corresponding words, else `false`.

Note: A return value of `false` only means that the algorithm's random search for standard generators did not succeed within the number of tries allowed. If the user is sure the group G matches the name *str*, then they should try the function again.

If G is absolutely irreducible matrix group and `Projective` is `true`, then construct standard generators possibly modulo centre of G.

This function currently works for all sporadic simple groups and all quasisimple groups for which the simple quotient has order at most 2×10^8. If you call it with an invalid value of *str*, then it will print out a list of all valid values.

`IsomorphismToStandardCopy(G, str : parameters)`

`Projective`	BoolElt	*Default :* `false`
`AutomorphismGroup`	BoolElt	*Default :* `false`

Use the StandardGenerators function to construct a (possibly projective) isomorphism from G to a standard copy of G. Options as for StandardGenerators. The first returned value indicates whether the call of StandardGenerators was successful.

`StandardPresentation(G, str : parameters)`

`Projective`	BoolElt	*Default :* `false`
`Generators`	SeqEnum	*Default :* []
`AutomorphismGroup`	BoolElt	*Default :* `false`

Return `true` if standard presentation is satisfied by generators of sporadic group G having name *str*, else `false`.

If `AutomorphismGroup` is `true`, assume G is automorphism group of sporadic group having name *str*.

Standard generators may be supplied as `Generators`, otherwise defining generators are assumed to be standard.

If G is absolutely irreducible matrix group and `Projective` is `true`, then verify presentation modulo centre of G.

`MaximalSubgroups(G, str : parameters)`

`Projective`	BoolElt	*Default :* `false`
`Generators`	SeqEnum	*Default :* []
`AutomorphismGroup`	BoolElt	*Default :* `false`

Construct **some** maximal subgroups for sporadic group G having name *str*. If `AutomorphismGroup` is `true`, assume G is automorphism group of sporadic group having name *str* and construct **some** of its maximal subgroups.

If standard generators supplied as `Generators` or found for G then return `true` and list of subgroups, else return `false`.

If G is absolutely irreducible matrix group and `Projective` is `true`, then construct standard generators and so subgroups possibly modulo centre of G.

`Subgroups(G, str : parameters)`

`Projective`	BoolElt	*Default :* `false`
`Generators`	SeqEnum	*Default :* []

Construct certain subgroups for sporadic group G having name *str*. If standard generators supplied as `Generators` or found for G then return `true` and list of subgroups, else return `false`.

If G is absolutely irreducible matrix group and `Projective` is `true`, then construct standard generators possibly modulo centre of G.

`GoodBasePoints(G, str : parameters)`

`Projective`	BoolElt	*Default :* `false`
`Generators`	SeqEnum	*Default :* []

If standard generators supplied as `Generators` or found for sporadic group G having name *str*, then return `true` and list of base points for G, else return `false`.

If G is absolutely irreducible and `Projective` is `true`, then standard generators are possibly modulo centre of G, and base points are correspondingly adjusted.

`SubgroupsData(str)`

Display stored subgroup data for sporadic group having name *str*.

`MaximalSubgroupsData (str : parameters)`

`AutomorphismGroup`	BoolElt	*Default :* `false`

Display stored data for some maximal subgroups of sporadic group having name *str*. If `AutomorphismGroup` is `true`, then display stored data for some maximal subgroups of automorphism group of sporadic group.

Example H65E22

The machinery is illustrated in the case of the sporadic Janko group J_1.

```
> G :=
> MatrixGroup<7, GF(11) |
> [ 9, 1, 1, 3, 1, 3, 3, 1, 1, 3, 1, 3, 3, 9, 1, 3, 1, 3, 3, 9, 1, 3, 1, 3,
>  3, 9, 1, 1, 1, 3, 3, 9, 1, 1, 3, 3, 3, 9, 1, 1, 3, 1, 3, 9, 1, 1, 3, 1, 3 ],
> [ 0, 1, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 10, 0, 0, 0, 0, 0, 0,

66 DATABASES OF GROUPS

Chapter 66
DATABASES OF GROUPS

66.1 Introduction

This chapter describes the use of the various databases of groups that form part of MAGMA. The available databases are as follows:

Small Groups: This database is constructed by Hans Ulrich Besche, Bettina Eick and Eamonn O'Brien [BE99a, BEO01, BE99b, O'B90, BE01, O'B91, MNVL04, OVL05, DE05], contains the following groups:

- All groups of order up to 2000, excluding the groups of order 1024.
- The groups whose order is the product of at most 3 primes.
- The groups of order dividing p^6 for p a prime.
- The groups of order $q^n p$, where q^n is a prime-power dividing 2^8, 3^6, 5^5 or 7^4 and p is a prime different to q.
- The groups of square-free order. For a different mechanism for accessing the p-groups in this collection, see Section 66.3, specifically the functions `SearchPGroups` and `CountPGroups`. These functions also access groups of order p^7.

p-groups: MAGMA contains the means to construct all p-groups of order p^n where $n \leq 7$. The data used in the constructions was supplied by Hans Ulrich Besche, Bettina Eick, Eamonn O'Brien, Mike Newman and Michael Vaughan-Lee [BE99a, BEO01, BE99b, O'B90, BE01, O'B91, MNVL04, OVL05].

Metacyclic p-groups: MAGMA is able to construct all metacyclic groups of order p^n. This machinery was developed by Mike Newman, Eamonn O'Brien, and Michael Vaughan-Lee.

Perfect Groups: This database contains all perfect groups up to order 50000, and many classes of perfect groups up to order one million. Each group is defined by means of a finite presentation. Further information is also provided which allows the construction of permutation representations. This database was constructed by Derek Holt and Willem Plesken [HP89].

Almost Simple Groups: This database contains information about every group G, where $S \leq G \leq \mathrm{Aut}(S)$ and S is a simple group of order less than 16000000, or S is one of M_{24}, HS, J_3, McL, $Sz(32)$ or $L_6(2)$.

Transitive Permutation Groups: This database is a MAGMA version of the database of transitive permutation groups constructed by Alexander Hulpke [Hul05] (for degree up to 30) and Cannon and Holt [CH08]. It contains all transitive permutation groups having degree up to 32.

Primitive Permutation Groups: This is a database containing all primitive permutation groups having degree less than 4095 as determined by Sims (for degree ≤ 50), Roney-Dougal and Unger [RDU03] (for degree < 1000), Roney-Dougal [RD05] (for degree < 2500), and Coutts, Quick and Roney-Dougal [CQRD11] (for degree < 4096).

Rational Maximal Matrix Groups: This contains the rational maximal finite matrix groups and their invariant forms, for small dimensions (up to 31) as determined by Gabi Nebe and Willem Plesken [NP95, Neb96]. Each entry can be accessed either as a matrix group or as a lattice.

Quaternionic Matrix Groups: A database of the finite absolutely irreducible subgroups of $\mathrm{GL}_n(\mathcal{D})$ where $\mathcal{D}$ is a definite quaternion algebra whose centre has degree d over $\mathbf{Q}$ and $nd \leq 10$. Each entry can be accessed either as a matrix group or as a lattice. The database was constructed by Gabi Nebe [Neb98].

Irreducible Matrix Groups: A database of the irreducible subgroups of $\mathrm{GL}_n(p)$, p prime, $n \geq 1$ and $p^n < 2500$. The groups were determined by Colva Roney-Dougal and William Unger [RDU03] (for $p^n < 1000$) and Roney-Dougal [RD05].

Soluble Irreducible Groups: This database contains one representative of each conjugacy class of irreducible soluble subgroups of $\mathrm{GL}(n, p)$, p prime, for $n > 1$ and $p^n < 256$. It was constructed by Mark Short [Sho92].

ATLAS Groups: This database contains representations of nearly simple groups, as in the Birmingham ATLAS of Finite Group Representations. The data was supplied by Rob Wilson.

66.2 Database of Small Groups

Magma includes the Small Groups Library prepared by Besche, Eick and O'Brien. For a description of the algorithms used to generate these groups, details on the data structures used and applications we refer to [BE99a, BEO01, BE99b, O'B90, BE01, O'B91, MNVL04] and the references therein.

The Small Groups Library contains the following groups.

- All groups of order up to 2000, excluding the groups of order 1024.
- The groups whose order is a product of at most 3 primes.
- The groups of order dividing p^6 for p a prime.
- The groups of order $q^n p$, where q^n is a prime-power dividing 2^8, 3^6, 5^5 or 7^4 and p is a prime different to q.

The descriptions of the groups of order p^4, p^5, p^6 for $p > 3$ were contributed by Boris Girnat, Robert McKibbin, M.F. Newman, E.A. O'Brien, and M.R. Vaughan-Lee.

The Magma version of this library uses the same internal data format as the implementation available in GAP. In particular, the numbering of the groups of a given order in both packages is the same.

For a different mechanism for accessing the p-groups in this collection, see the 66.3 section, specifically the functions `SearchPGroups` and `CountPGroups`. These functions also access the groups of order p^7 (contributed by O'Brien and Vaughan-Lee).

66.2.1 Basic Small Group Functions

Many of the functions in this section have an optional parameter `Search`. It can be used to limit the small group search to soluble (`Search := "Soluble"`) or insoluble (`Search := "Insoluble"`) groups. The default is `Search := "All"`, which allows all groups to be considered.

When a group is extracted from the database, it is returned as a `GrpPC` if it is soluble, or as a `GrpPerm` if it is insoluble.

When using the small groups database for an extended search, it is advisable to open the database using the function `SmallGroupDatabase`, which opens the database and returns a reference to it. This reference can then be passed as first argument to most of the functions described below, and will save that function from opening and closing the database for itself. Doing so will reduce the number of file operations when a lot of use is made of the database. When the database is no longer needed, it can be closed using the `delete` statement.

```
SmallGroupDatabase()
OpenSmallGroupDatabase()
```

Open the small groups database (for extended search) and return a reference to it. This reference may be passed to other functions so that they do fewer file operations.

```
delete D
```

Close the small groups database `D` and free the resources associated with its use.

```
SmallGroupDatabaseLimit()
SmallGroupDatabaseLimit(D)
```

The limiting order up to which all groups (except those of order 1024) are stored in the database of small groups, that is, currently 2000.

```
IsInSmallGroupDatabase(o)
IsInSmallGroupDatabase(D, o)
```

Return `true` if the groups of order o are contained in the database and `false` otherwise. This function can be used to check whether o is a legitimate argument for other functions described in this section, avoiding runtime errors in user written loops or functions.

```
NumberOfSmallGroups(o)
NumberOfSmallGroups(D, o)
```

Given a positive integer o, return the number of groups of order o in the database. If the groups of order o are not contained in the database, 0 is returned. This function can be used to check whether a pair o, n defines a group contained in the small groups database, that is, whether it is a legitimate argument for other functions described in this section, avoiding runtime errors in user written loops or functions.

`SmallGroup(o, n)`
`SmallGroup(D, o, n)`
`Group(D, o, n)`

Given a positive integer o, such that the groups of order o are contained in the small groups library, and a positive integer n, return the n-th group of order o in the database. If the groups of order o are not contained in the database or if n exceeds the number of groups of order o in the database, an error is reported. The function `NumberOfSmallGroups` can be used to check whether the arguments are valid.

`SmallGroup(o:` *parameters*`)`
`SmallGroup(D, o:` *parameters*`)`

`Search` MonStgElt *Default : "All"*

Given a positive integer o, such that the groups of order o are contained in the small groups library, return the first group of order o in the database meeting the search criterion set by the parameter `Search`. If the groups of order o are not contained in the database, an error is reported. The function `IsInSmallGroupDatabase` can be used to check whether o is a valid argument for this function.

`SmallGroup(o, f:` *parameters*`)`
`SmallGroup(D, o, f:` *parameters*`)`

`Search` MonStgElt *Default : "All"*

Given a positive integer o such that the groups of order o are contained in the small groups library and a predicate f (as a function or intrinsic), return the first group of order o in the database meeting the search criterion set by the parameter `Search`, which satisfies f.

`IsSoluble(D, o, n)`
`IsSolvable(D, o, n)`
`SmallGroupIsSoluble(o, n)`
`SmallGroupIsSoluble(D, o, n)`
`SmallGroupIsSolvable(o, n)`
`SmallGroupIsSolvable(D, o, n)`

Return `true` iff `SmallGroup(o, n)` is soluble. This function does not load the group. If the group specified by the arguments does not exist in the database, an error is reported. The function `NumberOfSmallGroups` can be used to check whether the arguments are valid.

`SmallGroupIsInsoluble(o, n)`
`SmallGroupIsInsoluble(D, o, n)`
`SmallGroupIsInsolvable(o, n)`
`SmallGroupIsInsolvable(D, o, n)`

Return `true` iff `SmallGroup(o, n)` is insoluble. This function does not load the group. If the group specified by the arguments does not exist in the database, an error is reported. The function `NumberOfSmallGroups` can be used to check whether the arguments are valid.

`SmallGroup(o, f:` *parameters*`)`
`SmallGroup(S, f:` *parameters*`)`
`SmallGroup(D, o, f:` *parameters*`)`
`SmallGroup(D, S, f:` *parameters*`)`

`Search` MonStgElt *Default :* "*All*"

Given a sequence S of orders or a single order o contained in the database and a predicate f (as a function or intrinsic), return the first group with order in S or equal to o, respectively, which meets the search criterion set by the parameter `Search` and satisfies f.

`SmallGroups(o:` *parameters*`)`
`SmallGroups(D, o:` *parameters*`)`

`Search` MonStgElt *Default :* "*All*"
`Warning` BoolElt *Default :* `true`

Given an order o contained in the database, return a list of all groups of order o, meeting the search criterion set by the parameter `Search`. Some orders will produce a very large sequence of groups – in such cases a warning will be printed unless the user specifies `Warning := false`.

`SmallGroups(S:` *parameters*`)`
`SmallGroups(D, S:` *parameters*`)`

`Search` MonStgElt *Default :* "*All*"
`Warning` BoolElt *Default :* `true`

Given a sequence S of orders contained in the database, return a list of all groups with order in S, meeting the search criterion set by the parameter `Search`. The resulting sequence may be very long – in such cases a warning will be printed unless the user specifies `Warning := false`.

`SmallGroups(o, f: parameters)`

`SmallGroups(D, o, f: parameters)`

`Search` MonStgElt *Default : "All"*

Given an order o contained in the database and a predicate (function or intrinsic) f, return a list containing all groups G of order o, meeting the search criterion set by the parameter `Search` and satisfying `f(G) eq true`.

`SmallGroups(S, f: parameters)`

`SmallGroups(D, S, f: parameters)`

`Search` MonStgElt *Default : "All"*

Given a sequence S of orders contained in the database and a predicate (function or intrinsic) f, return a list containing all groups G with order in S, meeting the search criterion set by the parameter `Search` and satisfying `f(G) eq true`.

Example H66E1

(1) We find the non-abelian groups of order 27.

```
> list := SmallGroups(27, func<x|not IsAbelian(x)> );
> list;
[*
GrpPC of order 27 = 3^3
PC-Relations:
  $.2^$.1 = $.2 * $.3,

GrpPC of order 27 = 3^3
PC-Relations:
  $.1^3 = $.3,
  $.2^$.1 = $.2 * $.3
*]
```

(2) We get the first group in the database with derived length greater than 2.

```
> G := SmallGroup([1..100], func<x|DerivedLength(x) gt 2>);
> G;
GrpPC of order 24 = 2^3 * 3
PC-Relations:
  G.1^3 = Id(G),
  G.2^2 = G.4,
  G.3^2 = G.4,
  G.4^2 = Id(G),
  G.2^G.1 = G.3,
  G.3^G.1 = G.2 * G.3,
```

```
  G.3^G.2 = G.3 * G.4
```

(3) Now for a list of the insoluble groups of order 240. The insoluble groups in the database are returned as permutation groups.

```
> list := SmallGroups(240:Search:="Insoluble");
> #list;
8
> list[7];
Permutation group acting on a set of cardinality 7
  (1, 2, 3, 4)
  (1, 5, 2, 4, 3)(6, 7)
```

(4) The groups of order $2432 = 2^7 \cdot 19$ should be contained in the small groups database. We check this using the function IsInSmallGroupDatabase...

```
> IsInSmallGroupDatabase(2432);
true
```

... and determine the number of groups of order 2432.

```
> NumberOfSmallGroups(2432);
19324
```

(5) We find all groups of order 7^6 with cyclic centre of order 7^2.

```
> f := function (G)
>   Z := Centre (G);
>   return IsCyclic (Z) and #Z eq 7^2;
> end function;
> P := SmallGroups(7^6, f);
> #P;
30
> NumberOfSmallGroups(7^6);
860
```

66.2.2 Processes

A small group process enables iteration over all groups of specified orders satisfying a given predicate, without having to create and store all such groups together.

A small group process is created via the function `SmallGroupProcess` (in various forms). The standard process functions `IsEmpty`, `Current`, `CurrentLabel` and `Advance` can then be applied to the process.

The functions used to create a small group process all have a parameter `Search` attached to them. It can be used to limit the small group search to soluble (`Search := "Soluble"`) or insoluble (`Search := "Insoluble"`) groups. The default is `Search := "All"`, which allows all groups to be considered.

The `Process` functions described below do not have a variant with the database as first argument, as each process opens the database for an extended search automatically.

`SmallGroupProcess(o: parameters)`

`Search` MonStgElt *Default :* "*All*"

Given an order o contained in the small groups database, return a small group process which will iterate though all groups of order o meeting the search criterion set by the parameter `Search`.

`SmallGroupProcess(S: parameters)`

`Search` MonStgElt *Default :* "*All*"

Given a sequence S of orders contained in the small groups database, return a small group process which will iterate though all groups with order in the sequence S meeting the search criterion set by the parameter `Search`.

`SmallGroupProcess(o, f: parameters)`

`Search` MonStgElt *Default :* "*All*"

Given an order o contained in the small groups database and a predicate f (as function or intrinsic), return a small group process which will iterate though all groups of order o, which meet the search criterion set by the parameter `Search` and satisfy the predicate f.

`SmallGroupProcess(S, f: parameters)`

`Search` MonStgElt *Default :* "*All*"

Given a sequence S of orders contained in the small groups database and a predicate f (as function or intrinsic), return a small group process which will iterate though all groups with order in the sequence S, which meet the search criterion set by the parameter `Search` and satisfy the predicate f.

`IsEmpty(p)`

Returns `true` if the process p has passed its last group.

`Current(p)`

Return the current group of the process p.

`CurrentLabel(p)`

Return the label of the current group of the process p. That is, return o and n such that the current group is `SmallGroup(o, n)`.

`Advance(~p)`

Move the process p to its next group.

Example H66E2

We use a small group process to look at all the groups of order 128. We find the nilpotency class of each of them.

```
> P := SmallGroupProcess(128);
> count := {* *};
> repeat
>   G := Current(P);
>   Include(~count, NilpotencyClass(G));
>   Advance(~P);
> until IsEmpty(P);
> count;
{* 1^^15, 2^^947, 3^^1137, 4^^197, 5^^29, 6^^3 *}
```

66.2.3 Small Group Identification

The following functions perform the inverse operation to the small group functions described earlier. Given a group G such that a group isomorphic to G is in the database and identification of groups of order $|G|$ is supported, the identification functions return a pair $\langle o, n \rangle$ so that `SmallGroup(o, n)` is isomorphic to G.

Note that identifying a finitely presented group involves the construction of a permutation representation of this group, which may fail. We refer to the description of `IdentifyGroup` in Chapter 70 for details.

`IdentifyGroup(G)`

Locate the pair of integers $\langle o, n \rangle$ so that `SmallGroup(o, n)` is isomorphic to G. If there is no such group in the database or if identification of groups of order $|G|$ is not supported, then an error will result. The function `CanIdentifyGroup` can be used to test whether groups of a certain order can be identified; this may be useful for avoiding runtime errors in user written loops or functions.

`CanIdentifyGroup(o)`

Return `true` if identification of groups of order o in the database is supported. This function can be used to check whether a group is a legitimate argument for the functions `IdentifyGroup` described above, avoiding runtime errors in user written loops or functions.

Example H66E3

We identify a permutation group in the small group database, and get an isomorphic group from the database.

```
> G := DihedralGroup(10);
> G;
Permutation group G acting on a set of cardinality 10
Order = 20 = 2^2 * 5
  (1, 2, 3, 4, 5, 6, 7, 8, 9, 10)
  (1, 10)(2, 9)(3, 8)(4, 7)(5, 6)
> IdentifyGroup(G);
<20, 4>
> H := SmallGroup(20, 4);
> H;
GrpPC : H of order 20 = 2^2 * 5
PC-Relations:
    H.1^2 = Id(H),
    H.2^2 = Id(H),
    H.3^5 = Id(H),
    H.3^H.1 = H.3^4
```

66.2.4 Accessing Internal Data

The following functions provide access to data used internally by the Small Groups Library for representing groups. They are included just for completeness and are intended to be used by experts only. In particular, we do not give a detailed explanation of the (complicated) data format in this manual.

`Data(D, o, n)`

Returns the data from which the group number n of order o in D is constructed. The format and the meaning of the items in the returned list depends on the group indicated by the pair (o, n).

`SmallGroupEncoding(G)`

Given a finite solvable group G in the category GrpPC, return two integers c and o encoding the power conjugate presentation of G.

The second return value is the order of G. The first return value is an integer specifying the power conjugate relations in the presentation of G.

`SmallGroupDecoding(c, o)`

Given two integers c and o encoding a power conjugate presentation G, return G as a group in the category GrpPC.

The second argument is the order of G. The first return value is an integer specifying the power conjugate relations in the presentation G.

Example H66E4

(1) We extract a power conjugate presentation from the database and compute its encoding.

```
> D := SmallGroupDatabase();
> G := SmallGroup(D,1053,51);
> Category(G);
GrpPC
>  SmallGroupEncoding(G);
1002867124873971659396781 73 1053
```

(2) The second group of order 525 in the small groups database is stored as encoded power conjugate presentation.

```
> Data(D,525,2);
[* code, 666501 *]
```

We can create the corresponding group by decoding this information.

```
> G := SmallGroupDecoding(666501, 525);
> G;
GrpPC : G of order 525 = 3 * 5^2 * 7
PC-Relations:
    G.1^3 = Id(G),
    G.2^5 = G.4,
    G.3^7 = Id(G),
    G.4^5 = Id(G)
```

This gives the same presentation as accessing the database in the "usual" way.

```
> SmallGroup(D,525,2);
GrpPC of order 525 = 3 * 5^2 * 7
PC-Relations:
    $.1^3 = Id($),
    $.2^5 = $.4,
    $.3^7 = Id($),
    $.4^5 = Id($)
```

66.3 The p-groups of Order Dividing p^7

Magma contains the means to construct all p-groups of order p^n where $n \leq 7$. This section describes the functions for accessing these constructions. The data used in the constructions was supplied by Hans Ulrich Besche, Bettina Eick, Eamonn O'Brien, Mike Newman and Michael Vaughan-Lee [BE99a, BEO01, BE99b, O'B90, BE01, O'B91, MNVL04, OVL05].

`SearchPGroups(p, n: parameters)`

Produce a sequence of groups of order p^n satisfying the conditions specified by the following parameters. The restrictions on the order are $n \leq 7$ or $p = 2$ and $n \leq 9$.

`Rank` SetEnum *Default :* $\{1, \ldots n\}$

All groups returned will have Frattini quotient rank in `Rank`. This parameter may also be set to a single integer.

`Class` SetEnum *Default :* $\{1, \ldots n\}$

All groups returned will have p-class in `Class`. This parameter may also be set to a single integer.

`Select` Program *Default :* `true`

The parameter must be set to a program returning either `true` or `false` when given a p-group satisfying the above conditions. All groups G returned will then satisfy `Select(G) eq true`.

`Limit` RngIntElt *Default :* 0

If `Limit` is set to a positive number n, then the program may end its search and return when there are at least n groups found.

`CountPGroups(p, n: parameters)`

Count the number of groups of order p^n satisfying the conditions specified by the parameters. The parameters are the same as for `SearchPGroups`, except that the `Limit` parameter is ignored.

Example H66E5

We search the groups of order 19^7 for specific examples. There are, in total, 9380741 groups with this order. We start with a search for those of rank 5, class 3, and exponent 19. Since we do not set the `Limit` parameter, we will get a sequence containing all the examples.

```
> time Q := SearchPGroups(19, 7:Rank := 5, Class := 3,
>    Select := func<G|IsPrime(Exponent(G))> );
Time: 0.050
> #Q;
4
> Q[1];
GrpPC of order 893871739 = 19^7
PC-Relations:
  $.2^$.1 = $.2 * $.6,
```

```
  $.6^$.1 = $.6 * $.7
```

This time we limit the number returned.

```
> time    Q := SearchPGroups(19, 7:Rank := 4, Class := {3,4},
>    Select := func<G|IsPrime(Exponent(G))>, Limit := 5);
Time: 13.090
> #Q;
5
> [pClass(G):G in Q];
[ 3, 3, 3, 3, 3 ]
> time    Q4 := SearchPGroups(19, 7:Rank := 4, Class := 4,
>   Select := func<G|IsPrime(Exponent(G))>, Limit := 5);
Time: 0.150
> #Q4;
6
```

Note that the limit is not always adhered to exactly. We can also count the number of groups with our property.

```
> time CountPGroups(19, 7:Rank := 4, Class := {3,4},
>   Select := func<G|IsPrime(Exponent(G))>);
Time: 334.720
43
> time CountPGroups(19, 7:Rank := 4, Class := 4,
>    Select := func<G|IsPrime(Exponent(G))>);
10
Time: 0.310
```

66.4 Metacyclic p-groups

Magma contains functions for constructing all metacyclic groups of order p^n. It can also decide if a given p-group is metacyclic, construct invariants which distinguish this metacyclic group from all others of this order, and construct a standard presentation for the group.

This section describes the functions for accessing these algorithms. The functions were developed by Mike Newman, Eamonn O'Brien, and Michael Vaughan-Lee.

`MetacyclicPGroups(p, n: parameters)`

Return a list of the metacyclic groups of order p^m, where p is a prime and n is a positive integer.

`PCGroups` BoolElt *Default :* `true`

If `true`, the groups returned are in category GrpPC, otherwise they are in category GrpFP – this will be faster if the groups have large class.

`IsMetacyclicPGroup (P)`

P is a p-group, either pc- or matrix or permutation group; if P is metacyclic, then return `true`, else `false`.

`InvariantsMetacyclicPGroup (P)`

P is a metacyclic p-group, either pc- or matrix or permutation group; return tuple of invariants which uniquely identify metacyclic p-group P. This tuple which contains at least four terms, $\langle r, s, t, n\rangle$ has the following meaning: P has order p^{n+s}; its derived quotient is $C_{p^r} \times C_{p^s}$; its derived group is cyclic of order p^{n-r}; it has exponent p^{n+s-t}.

If $p = 2$, then additional invariants are needed to distinguish among the groups. We record the abelian invariants of the centre of P. If $s = 1$ and the centre of P has order 2, then the 2-group is maximal class and we record whether it is dihedral, quaternion or semidihedral. If $s > 1$ then the group has two cyclic central normal subgroups of order 2^{s-1} whose central quotients are both semidihedral, or dihedral and quaternion. The invariant tuple has length at most 6.

`StandardMetacyclicPGroup (P)`

P is a metacyclic p-group, either pc- or matrix or permutation group; return metacyclic p-group having a canonical pc-presentation which is isomorphic to P. If two metacyclic p-groups have the same canonical presentation, then they are isomorphic.

`NumberOfMetacyclicPGroups (p, n)`

Return number of metacyclic groups of order p^n.

`HasAllPQuotientsMetacyclic (G)`

`HasAllPQuotientsMetacyclic (G, p)`

Return `true` if for all primes p all p-quotients of the finitely-presented group G are metacyclic; otherwise return `false` and a description of the set of primes for which G has non-metacyclic p-quotient.

If a prime p is supplied as a second argument, then the function returns `true` if all p-quotients of G are metacyclic; otherwise it returns `false`.

Example H66E6

```
> X := MetacyclicPGroups (3, 6);
> #X;
11
> X[4];
GrpPC of order 729 = 3^6
PC-Relations:
    $.1^3 = $.3,
    $.2^3 = $.4,
    $.3^3 = $.6,
```

```
    $.4^3 = $.5,
    $.5^3 = $.6,
    $.2^$.1 = $.2 * $.6^2
> H := SmallGroup (729, 59);
> IsMetacyclicPGroup (H);
true
> I := InvariantsMetacyclicPGroup(H);
> I;
<2, 2, 2, 4, [], , >
> S := StandardMetacyclicPGroup (H);
GrpPC : S of order 729 = 3^6
PC-Relations:
    S.1^3 = S.3,
    S.2^3 = S.4,
    S.3^3 = S.6,
    S.4^3 = S.5,
    S.5^3 = S.6,
    S.2^S.1 = S.2 * S.6^2
> /* find this group in list */
> [IsIdenticalPresentation (S, X[i]): i in [1..#X]];
[ false, false, false, true, false, false, false, false, false, false, false ]
> /* so this group is #4 in list */
> NumberOfMetacyclicPGroups (19, 7);
14
> Q := FreeGroup (4);
> G := quo < Q |  Q.2^2, Q.4^3, Q.2 * Q.3 * Q.2 * Q.3^-1, Q.1^9>;
> /* are all p-quotients of G metacyclic? */
> HasAllPQuotientsMetacyclic (G);
false [ 3 ]
> /* the 3-quotient is not metacyclic */
```

66.5 Database of Perfect Groups

MAGMA includes a database of finite perfect groups. This database includes all perfect groups up to order 50000, and many classes of perfect groups up to order one million. Each group is defined by means of a finite presentation. Further information is also provided which allows the construction of permutation representations.

66.5.1 Specifying an Entry of the Database

There are three ways to key a particular entry of the database. Firstly, a single integer i simply denotes the i-th entry of the database. There is no particular ordering in the correspondence.

Secondly, the database stores information to quickly locate perfect groups of a particular order; thus the pair o, i represents the i-th entry of order o.

The third method corresponds to the notation used in Chapter 5.3 of [HP89]. In this book, the expression $Q\#p$ denotes the class of groups that are isomorphic to perfect extensions of p-groups by Q, where p is a prime and Q is a fixed finite perfect group in which the largest normal p-subgroup is assumed to be trivial. Within a class $Q\#p$, an isomorphism type of groups is denoted by an ordered pair of integers $\langle r, n\rangle$, where $r \geq 0$ and $n \geq 0$.

To specify a particular group Q without extension, a (somewhat descriptive) string is given. The set of possible values can be accessed using the function `TopQuotients`. Among these strings, full or partial covering groups of G are named G`C`n where n is the index of G in G`C`n. Also, there are five classes of 3-extensions of groups which are also defined in the database. The names of these base groups are `A5#2<`r, n`>` where (r, n) are $(4, 2), (5, 5), (5, 6), (5, 7)$ or $(6, 7)$. Furthermore, there are some extensions of direct products: these have names of the form G`x`H. The remainder are names of simple groups. The convention with these names is that if they are elements of a family of simple groups with two parameters then the name will be *fam*`(`p_1`, `p_2`)`, while one parameter families will just be the concatenation of the family name and the parameter.

To illustrate the naming conventions, here are some examples: `A5`, `A5C2`, `A5#2<`$5, 5$`>`, `L(2, 59)C2`, `A5xL(2, 11)`. Notice that there is never a space before the `C` denoting a covering group or on either side of the `x` denoting direct product. However, there is always a space after a comma.

To specify a particular group $Q\#p\langle r, n\rangle$ the four values Q, p, r and n should be given. However, it should be noted that in three cases (`A5#2< 5, 1>`, `L(3, 2)#2<3, 1>`, `L(3, 2)#2<3, 2>`), there are *two* versions of `Q#p<`r, n`>` stored in the database. Strictly speaking, then, there is a fifth key value v required in this third method. However, it can be specified by an optional parameter `Variant :=` v (if necessary), and can normally be ignored. The variant forms are isomorphic to the original forms, and are included for compatibility with Holt & Plesken's tables.

66.5.2 Creating the Database

`PerfectGroupDatabase()`

This function returns a database object which contains information about the database. It is required as first argument to the other access functions.

66.5.3 Accessing the Database

`Group(D, i)`
`Group(D, o, i)`
`Group(D, Q)`
`Group(D, Q, p, r, n:` *parameters*`)`

`Variant` RngIntElt *Default :* 1

Returns the specified entry from the database D as a finitely presented group. In addition, it returns a sequence of pairs $\langle [i_1, \ldots, i_n], [H_1, \ldots, H_n] \rangle$, each of which affords an isomorphism onto a permutation group of degree $\sum_{j=1}^{n} i_j$. The subgroup H_j has index i_j in the defined group, and the sum of the permutation representations of the group on the cosets of the H_j's is faithful. For the meanings of the arguments, see Subsection 66.5.1 above.

`IdentificationNumber(D, i)`
`IdentificationNumber(D, o, i)`
`IdentificationNumber(D, Q)`
`IdentificationNumber(D, Q, p, r, n:` *parameters*`)`

`Variant` RngIntElt *Default :* 1

Returns a number which can be used to access the specified entry from the database D using method one. (See Subsection 66.5.1 above).

`NumberOfRepresentations(D, i)`
`NumberOfRepresentations(D, o, i)`
`NumberOfRepresentations(D, Q)`
`NumberOfRepresentations(D, Q, p, r, n:` *parameters*`)`

`Variant` RngIntElt *Default :* 1

Returns the number of ways stored in the database for building a permutation group representation of the specified entry. (See Subsection 66.5.1 above).

`PermutationRepresentation(D, i:` *parameters*`)`
`PermutationRepresentation(D, o, i:` *parameters*`)`
`PermutationRepresentation(D, Q:` *parameters*`)`
`PermutationRepresentation(D, Q, p, r, n:` *parameters*`)`

`Variant` RngIntElt *Default :* 1

Returns the isomorphism from the finitely presented group G specified to a permutation group representation H as well as the groups G and H. (See Subsection 66.5.1 above).

`Representation` RngIntElt *Default :* 1

Selects which of the stored methods of constructing the permutation representation should be used.

`PermutationGroup(D, i: parameters)`

`PermutationGroup(D, o, i: parameters)`

`PermutationGroup(D, Q: parameters)`

`PermutationGroup(D, Q, p, r, n: parameters)`

`Variant` RngIntElt *Default :* 1

Returns the specified entry from the database D as a permutation group. (See Subsection 66.5.1 above).

`Representation` RngIntElt *Default :* 1

Selects which of the stored methods of constructing the permutation representation should be used.

66.5.4 Finding Legal Keys

`#D`

`NumberOfGroups(D)`

Returns the number of entries stored in the database. (See Subsection 66.5.1, method 1, above).

`NumberOfGroups(D, o)`

Returns the number of entries stored in the database of order o. (See Subsection 66.5.1, method 2, above).

`TopQuotients(D)`

Returns the set of strings denoting the fixed perfect groups Q. (See Subsection 66.5.1, method 3, above).

`ExtensionPrimes(D, Q)`

Returns the set of primes p for which a non-trivial p-extension of the group denoted by Q lies in the database. (See Subsection 66.5.1, method 3, above).

`ExtensionExponents(D, Q, p)`

Returns the set of exponents r such that a non-trivial extension of the group denoted by Q by p^r lies in the database. (See Subsection 66.5.1, method 3, above).

`ExtensionNumbers(D, Q, p, r)`

Returns the set of numbers n such that there is a group $Q\#p\langle r, n\rangle$ in the database. (See Subsection 66.5.1, method 3, above).

`ExtensionClasses(D, Q)`

Returns the set of triples $\langle p, r, n\rangle$ such that there is a group $Q\#p\langle r, n\rangle$ in the database. (See Subsection 66.5.1, method 3, above).

Example H66E7

We hunt through the various levels of key-finding functions available to find an extension of L(3,4) in the database.

```
> DB := PerfectGroupDatabase();
> "L(3, 4)" in TopQuotients(DB);
true
> ExtensionPrimes(DB, "L(3, 4)");
{ 2 }
> ExtensionExponents(DB, "L(3, 4)", 2);
{ 1, 2, 3, 4 }
> ExtensionNumbers(DB, "L(3, 4)", 2, 2);
{ 1, 2, 3 }
```

The database contains extensions of L(3,4) by groups of order 2^1, 2^2, 2^3 and 2^4. We will look at one of the 3 extensions by a group of order 4.

```
> G := Group(DB, "L(3, 4)", 2, 2, 3);
> G;
Finitely presented group G on 3 generators
Relations
  a^2 = Id(G)
  b^4 * e^-2 = Id(G)
  a * b * a * b * a * b * a * b * a * b * a * b * a * b * e
  = Id(G)
  a * b^2 * a * b^2 * a * b^2 * a * b^2 * a * b^2 * e^-1 =
  Id(G)
  a^-1 * b^-1 * a * b * a^-1 * b^-1 * a * b * a^-1 * b^-1 *
  a * b * a^-1 * b^-1 * a * b * a^-1 * b^-1 * a * b * e^-2 =
  Id(G)
  a * b * a * b * a * b^3 * a * b * a * b * a * b^3 * a * b
  * a * b * a * b^3 * a * b * a * b * a * b^3 * a * b * a *
  b * a * b^3 * e^-2 = Id(G)
  (a * b * a * b * a * b^2 * a * b^-1)^5 = Id(G)
  (a, e^-1) = Id(G)
  (b, e^-1) = Id(G)
> P := PermutationGroup(DB, "L(3, 4)", 2, 2, 3);
> P;
Permutation group P acting on a set of cardinality 224
Order = 80640 = 2^8 * 3^2 * 5 * 7
> ChiefFactors(P);
    G
    |  A(2, 4)                = L(3, 4)
    *
```

```
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
> #Radical(P);
4
> IsCyclic(Radical(P));
true
> IsCentral(P, Radical(P));
true
```

66.6 Database of Almost-Simple Groups

MAGMA includes a database containing information about almost simple groups G, where $S \leq G \leq \mathrm{Aut}(S)$ and S is a simple group of small order. The G that are included in the database are those associated with S such that $|S|$ is less than 16000000, as well as M_{24}, HS, J_3, McL, $Sz(32)$ and $L_6(2)$.

The information stored here is primarily for use in computing maximal subgroups and automorphism groups. The database was originally conceived by Derek Holt, with a major extension by Volker Gebhardt and sporadic additions by Bill Unger. The implementation is by Bruce Cox.

It is possible to request the i-th entry of the database. Alternatively, and more usefully, one can supply three integers: the order $o1$ of S, the order $o2$ of G and the sum k of the orders of the class representatives of G. The last of these can be expensive to compute; however, knowledge of the classes is helpful to benefit from the information stored in the entry. Of course, if the entry is beyond the range of the database, then it is a wasted computation—the intrinsics `ExistsGroupData` and `NumberOfGroups` are provided to determine from the orders whether this is the case.

66.6.1 The Record Fields

The result returned by the `GroupData` function is a record with a number of fields containing information about the almost simple group and its socle. This information includes information used to compute automorphisms and maximal subgroups of the almost simple group by these MAGMA functions. The following describes these fields. The groups G and S are as above the almost simple group G and its socle, the simple group S. Let A be the full automorphism group of S, and let $F\langle x, y\rangle$ be a free group on two generators, called x and y.

First comes information about S. Each S is two generated, by x and y as above, say.

Field `resname`: A string giving a name to the simple group S. (S is the soluble residual of G).

Field `resorder`: The order of S as an integer.

Field `geninfo`: Information on where to find x and y in S. This is a sequence of two tuples, each with 3 entries. The first gives a generator order, the second the length of its conjugacy class, and the third the probability of picking the right generator given the previous information. The first tuple's order/length information always uniquely defines one conjugacy class of the group S and has probability 1, so x is easy to find.

Field `rels`: A sequence of words in F which, taken together with the generator orders from `geninfo`, form a presentation for S on x and y.

Field `permrep`: A permutation representation of the full automorphism group of S. The first two generators are x and y, followed by outer generators. In what follows the outer generators are called t, u, v.

Field `outimages` A sequence of sequences of words in F. These give the images of x and y under the generators of the outer automorphism group of S.

Field `order`: An integer, the order of G.

Field `inv`: The invariant used to separate non-isomorphic $\langle |S|, |G| \rangle$ possibilities. An integer, it is the sum over the classes of G of the order of the elements in each class.

Field `name`: A name for G as a string.

Field `conjelts`: If G is not normal in the automorphism group, these words are coset representatives of the normaliser of G in A as words in t, u, v.

Field `subgens`: Words in t, u, v that, together with x and y, generate G.

Field `subpres`: A presentation of G/S on `subgens`. Note: If $G = S$ then `subgens` will be the empty sequence, but `subpres` will be the trivial FP-group with one generator.

Field `normgens`: Words in t, u, v that generate the outer automorphism group of G.

Field `normpres`: A presentation of the outer automorphism group of G on `normgens`. Again, if $A = G$ then `normgens` will be the empty sequence, but `normpres` will be the trivial FP-group with one generator.

Field `maxsubints`: A sequence of records describing the intersections of the maximal subgroups of G that do not contain S with S. Each record gives the order of the intersection, its class length in S, generators as words in x and y, and a presentation on these generators.

66.6.2 Creating the Database

`AlmostSimpleGroupDatabase()`

This function returns a database object which contains information about the database.

66.6.3 Accessing the Database

`#D`

Returns the number of entries stored in the database.

`GroupData(D, i)`

`GroupData(D, o1, o2, k)`

Returns the specified entry from the database D as a record. The first form gives the ith entry of the database. The second form gives information on an almost simple group of order $o2$, with socle of order $o1$. The value of k should be as explained in `inv` above.

`ExistsGroupData(D, o1, o2)`

`ExistsGroupData(D, o1, o2, i)`

Returns whether any record exists for a simple group of order $o1$ and a supergroup G of order $o2$ lying within its automorphism group. In the second form an invariant, i as described above, is also supplied, and the result is true if there is a record in the database with the given orders and invariant, and false otherwise. When the result is true, the corresponding record is also returned.

`NumberOfGroups(D, o1, o2)`

Returns the number of records in the database D corresponding to a simple group of order $o1$ and a supergroup G of order $o2$ lying within its automorphism group. The second return value gives the index of the first such record, if there is one. (This is most useful when the first return value is 1.) If the return values are d and f, with $d > 0$, then the corresponding database entries are numbered $f, f+1, \ldots, f+d-1$.

`IdentifyAlmostSimpleGroup(G)`

`IdentifyAlmostSimpleGroup(G)`

Use the information in the database to construct a monomorphism f from the almost simple group G into A, the permutation representation of the full automorphism group of its socle stored in the database. This function will also cope with groups isomorphic to the alternating and symmetric groups of degree up to 50, which are not actually in the database. Note that the conjugacy class of the image of f in A determines G up to isomorphism. The algorithms used to deal with the alternating and symmetric groups not in the database are by Derek Holt, starting from the paper of Bratus & Pak [BP00].

Example H66E8

We query the database on about an almost simple group of order 720.

```
> G := PermutationGroup<10 |
>  [ 7, 9, 5, 2, 1, 8, 10, 4, 6, 3 ],
>  [ 6, 3, 10, 7, 2, 4, 1, 8, 9, 5 ]>;
> #G;
720
> CompositionFactors(G);
    G
    |  Cyclic(2)
    *
    |  Alternating(6)
    1
> #Radical(G);
1
```

There are 3 such groups, so we really do need k to tell them apart.

```
> S := SolubleResidual(G);
> k := &+[c[1]: c in Classes(G)];
> D := AlmostSimpleGroupDatabase();
> R := GroupData(D, #S, #G, k);
> R`name;
M_10
```

The group is identified. Let's see some of the other information in R.

```
> P := R`permrep;
> P;
Permutation group P acting on a set of cardinality 10
  (1, 6)(2, 9)(3, 10)(4, 8)
  (1, 7, 9, 4)(2, 8, 5, 10)
  (3, 5, 9, 6, 7, 4, 8, 10)
  (3, 7)(4, 6)(5, 10)
> #P;
1440
> R`subgens;
[ t * u ]
> SS := sub<P|P.1, P.2>;
> #SS;
360
> GG := sub<P|SS, P.3*P.4>;
> #GG;
720
>R`normgens;
[ t ]
```

The full automorphism group of S has order 1440. The group P is a representation of this automorphism group with first two generators generating a faithful image of S. The image of S,

together with the product of P.3 and P.4, generate a faithful image of G. The outer automorphism group of G is generated by P.3 modulo GG. We can also get a constructive identification as follows.

```
> f, A := IdentifyAlmostSimpleGroup(G);
> f;
Homomorphism of GrpPerm: $, Degree 10, Order 2^4 * 3^2 * 5
into GrpPerm: A, Degree 10 induced by
  (1, 10)(3, 8)(5, 9)(6, 7) |--> (1, 6)(2, 9)(3, 10)(4, 8)
  (1, 7, 2, 8)(3, 10, 4, 5) |--> (1, 7, 9, 4)(2, 8, 5, 10)
  (1, 10, 4, 8)(2, 6, 9, 5) |--> (3, 10, 7, 6)(4, 8, 5, 9)
> A;
Permutation group A acting on a set of cardinality 10
  (1, 6)(2, 9)(3, 10)(4, 8)
  (1, 7, 9, 4)(2, 8, 5, 10)
  (3, 5, 9, 6, 7, 4, 8, 10)
  (3, 7)(4, 6)(5, 10)
```

66.7 Database of Transitive Groups

MAGMA has a database containing all transitive permutation groups having degree up to 32, and one containing all primitive permutation groups with degree less than 4096.

The transitive groups up to degree 15 were determined by Greg Butler and John McKay, the groups having degree in the range 16 to 30 were determined by Alexander Hulpke [Hul05]. John Cannon and Derek Holt [CH08] have determined the transitive groups of degree 32.

66.7.1 Accessing the Databases

`TransitiveGroupDatabaseLimit()`

The limiting degree of the database of transitive groups.

`NumberOfTransitiveGroups(d)`

Given a degree d in the required range, return the number of transitive groups of degree d.

`TransitiveGroup(d, n)`

Given a degree d in the required range and a positive integer n, return the n-th transitive group of degree d. Also returns a string giving a description of the group.

`TransitiveGroupDescription(d, n)`

A string giving a description of the n-th transitive group of degree d.

`TransitiveGroupDescription(G)`

A string giving a description of the transitive group G.

`TransitiveGroup(d)`

Given a degree d in the required range, return the first transitive group of degree d. Also returns a string giving a description of the group.

`TransitiveGroup(d, f)`

Given a degree d in the required range and a predicate f (as a function or intrinsic), return the first transitive group of degree d which satisfies f. Also returns a string giving a description of the group.

`TransitiveGroup(S, f)`

Given a sequence S of degrees and a predicate f (as a function or intrinsic), return the first transitive group with degree in S which satisfies f. Also returns a string giving a description of the group.

`TransitiveGroups(d:` *parameters*`)`

`Warning` BoolElt *Default :* `true`

Return a sequence of all transitive groups of degree d. Some degrees will produce a very large sequence of groups – in such cases a warning will be printed unless the user specifies `Warning := false`.

`TransitiveGroups(S:` *parameters*`)`

`Warning` BoolElt *Default :* `true`

Given a sequence S of degrees, return a sequence of all transitive groups with degree in S. The resulting sequence may be very long – in such cases a warning will be printed unless the user specifies `Warning := false`.

`TransitiveGroups(d, f)`

Given an integer d and a predicate (function or intrinsic) f, return a sequence containing all transitive groups G of degree d satisfying `f(G) eq true`.

`TransitiveGroups(S, f)`

Given a sequence S of degrees and a predicate (function or intrinsic) f, return a sequence containing all transitive groups G with degree in S satisfying `f(G) eq true`.

Example H66E9

We apply some of these functions to the degree 8 case.

```
> NumberOfTransitiveGroups(8);
50
> TransitiveGroup(8, 3);
Permutation group acting on a set of cardinality 8
    (1, 2)(3, 4)(5, 6)(7, 8)
    (1, 4)(2, 3)(5, 8)(6, 7)
    (1, 8)(2, 7)(3, 6)(4, 5)
E(8) = 2[x]2[x]2
> S := TransitiveGroups(8, IsPrimitive);
> #S;
7
> S;
[
    Permutation group acting on a set of cardinality 8
        (1, 8)(2, 3)(4, 5)(6, 7)
        (1, 3)(2, 8)(4, 6)(5, 7)
        (1, 5)(2, 6)(3, 7)(4, 8)
        (1, 2, 6, 3, 4, 5, 7),
    Permutation group acting on a set of cardinality 8
        (1, 8)(2, 3)(4, 5)(6, 7)
        (1, 3)(2, 8)(4, 6)(5, 7)
        (1, 5)(2, 6)(3, 7)(4, 8)
        (1, 2, 6, 3, 4, 5, 7)
        (1, 2, 3)(4, 6, 5),
    Permutation group acting on a set of cardinality 8
        (1, 2, 3, 4, 5, 6, 8)
        (1, 2, 4)(3, 6, 5)
        (1, 6)(2, 3)(4, 5)(7, 8),
    Permutation group acting on a set of cardinality 8
        (1, 2, 3, 4, 5, 6, 8)
        (1, 3, 2, 6, 4, 5)
        (1, 6)(2, 3)(4, 5)(7, 8),
    Permutation group acting on a set of cardinality 8
        (1, 8)(2, 3)(4, 5)(6, 7)
        (1, 3)(2, 8)(4, 6)(5, 7)
        (1, 5)(2, 6)(3, 7)(4, 8)
        (1, 2, 6, 3, 4, 5, 7)
        (1, 2, 3)(4, 6, 5)
        (1, 2)(5, 6),
    Permutation group acting on a set of cardinality 8
        (1, 2)(3, 4, 5, 6, 7, 8)
        (1, 2, 3),
    Permutation group acting on a set of cardinality 8
        (1, 2, 3, 4, 5, 6, 7, 8)
        (1, 2)
```

```
]
```

66.7.2 Processes

A transitive group process enables iteration over all transitive groups of specified degrees satisfying a given predicate, without having to create and store all such groups together.

The intrinsic function `TransitiveGroupProcess` may be used to create a transitive group process in MAGMA. The standard process functions `IsEmpty`, `Current`, `CurrentLabel` and `Advance` can then be applied to the process.

`TransitiveGroupProcess(d)`

Return a group process which will iterate though all transitive groups of degree d.

`TransitiveGroupProcess(S)`

Return a process which will iterate though all transitive groups with degree in the sequence S.

`TransitiveGroupProcess(d, f)`

Return a process which will iterate though all transitive groups with degree d which satisfy the predicate f.

`TransitiveGroupProcess(S, f)`

Return a process which will iterate though all transitive groups with degree in the sequence S which satisfy the predicate f.

`IsEmpty(p)`

Returns `true` if the process p has passed its last group.

`Current(p)`

Return the current group of the process p, as well as a description of the group.

`CurrentLabel(p)`

Return the label of the current group of the process p. That is, return d and n such that the current group is `TransitiveGroup(d, n)`.

`Advance(~p)`

Move the process p to its next group.

Example H66E10

The use of processes is illustrated by the following code, in which the orders of all transitive groups of degree 5 are listed.

```
> p := TransitiveGroupProcess(5);
> while not IsEmpty(p) do
>     CurrentLabel(p), #Current(p);
>     Advance(~p);
> end while;
5 1 5
5 2 10
5 3 20
5 4 60
5 5 120
```

66.7.3 Transitive Group Identification

Given a transitive group G whose degree is at most 30, it is possible to obtain the number of the group in the transitive groups database which is isomorphic to G.

`TransitiveGroupIdentification(G)`

`Raw` BoolElt *Default :* `true`

The number (and degree) of the group in the transitive groups database which is isomorphic to the transitive group G.

If the optional parameter `Raw` is set to `false`, a third value is returned. In this case, the third value is a permutation conjugating the given group to the copy in the library.

Example H66E11

We get a transitive permutation group from the small groups database and identify it as a transitive group.

```
> G := SmallGroup(336, IsTransitive: Search:="Insoluble");
> G;
Permutation group G acting on a set of cardinality 16
  (1, 14, 6, 2, 12, 8, 13, 7)(3, 15, 10, 5, 16, 9, 4, 11)
  (2, 5, 6)(3, 10, 9)(4, 15, 16)(7, 11, 13)
> TransitiveGroupIdentification(G : Raw := false);
715 16 (1, 16, 3, 4, 2, 11, 5, 6, 9, 8, 13, 10)(7, 12, 15)
> n, d, p := $1;
> G^p eq TransitiveGroup(d, n);
true
```

We found it to be group 715 of degree 16.

66.8 Database of Primitive Groups

MAGMA has a database containing all primitive permutation groups with degree less than 2500.

The list of primitive groups up to degree 50 was prepared by C. C. Sims (see [Sim70] for the early part of the list). The list up to degree 999 was determined by Roney-Dougal and Unger. See [RDU03] for details of the methods used. The list was extended to degree 2499 by Roney-Dougal, as described in [RD05], and was further extended to degree 4095 by Coutts, Quick and Roney-Dougal [CQRD11].

Within the database the groups are stored by degree. Within each degree they are stored by O'Nan-Scott class in the order soluble affine, insoluble affine, diagonal action, product action, almost simple. Within each class groups are ordered by increasing size. (It follows that the alternating and symmetric groups come last at each degree.)

The basic access function takes two parameters, degree and number, and returns the corresponding primitive group. Functions with name prefixed by `NumberOfPrimitive` tell how many groups of each class there are stored. We recommend the use of the `PrimitiveGroupProcess` or `PrimitiveGroups` functions, with appropriate `Filter` value, to access all primitive groups in a specific class.

66.8.1 Accessing the Databases

`PrimitiveGroupDatabaseLimit()`

The limiting degree of the database of primitive groups.

`NumberOfPrimitiveGroups(d)`

`NumberOfPrimitiveSolubleGroups(d)`

`NumberOfPrimitiveAffineGroups(d)`

`NumberOfPrimitiveDiagonalGroups(d)`

`NumberOfPrimitiveProductGroups(d)`

`NumberOfPrimitiveAlmostSimpleGroups(d)`

Given a degree d in the required range, `NumberOfPrimitiveGroups` returns the number of primitive groups of degree d. The other functions return the number of groups of each class at that degree.

`PrimitiveGroup(d, n)`

Given a degree d in the required range and a positive integer n, return the n-th primitive group of degree d. Also returns a string (possibly empty) giving a description of the group and a string giving the group's O'Nan-Scott type.

`PrimitiveGroupDescription(d, n)`

A string giving a description of the n-th primitive group of degree d.

`PrimitiveGroup(d)`

Given a degree d in the required range, return the first primitive group of degree d. Also returns a string giving a description of the group and a string giving the group's O'Nan-Scott type.

`PrimitiveGroup(d, f)`

Given a degree d in the required range and a predicate f (as a function or intrinsic), return the first transitive (primitive) group of degree d which satisfies f.

`PrimitiveGroup(S, f)`

Given a sequence S of degrees and a predicate f (as a function or intrinsic), return the first transitive (primitive) group with degree in S which satisfies f.

`PrimitiveGroups(d:` *parameters*`)`

`Filter` MonStgElt *Default :* "*All*"

Return a sequence of all primitive groups of degree d, modified by the value assigned to `Filter`. The possible values for the parameter are the strings `All`, `Soluble`, `Affine`, `Diagonal`, `Product`, `AlmostSimple`, `Simple` and `SimpleNA`. Generally these values restrict the list to groups in the appropriate O'Nan-Scott type, with the exceptions being `All` giving no restriction, `Simple` restricting to a lsit of all simple groups in the database, and `SimpleNA` being as for `Simple` but omitting all alternating groups in their natural representations.

`PrimitiveGroups(S:` *parameters*`)`

`PrimitiveGroups( :` *parameters*`)`

`Filter` MonStgElt *Default :* "*All*"

Given a sequence S of degrees, return a sequence of all primitive groups with degree in S. The result is modified by `Filter` with values as above. Omitting the sequence of degrees gives the same result as specifying all legal degrees.

`PrimitiveGroups(d, f:` *parameters*`)`

`PrimitiveGroups(S, f)`

`PrimitiveGroups(f)`

`Filter` MonStgElt *Default :* "*All*"

Given an integer d and a predicate (function or intrinsic) f, return a sequence containing all primitive groups G of degree d passing the filter satisfying `f(G) eq true`. Note that the filter will be generally much quicker in rejecting candidates than the predicate will be, and only groups passing the filter have `f(G)` evaluated.

Instead of giving a single degree, a sequence of degrees may be given. Omitting the degree is the same as specifying the sequence of all legal degrees.

Example H66E12

We apply some of these functions to the degree 625 case.

```
> NumberOfPrimitiveGroups(625);
698
> NumberOfPrimitiveAffineGroups(625);
647
> NumberOfPrimitiveSolubleGroups(625);
509
> NumberOfPrimitiveDiagonalGroups(625);
0
> NumberOfPrimitiveProductGroups(625);
49
> NumberOfPrimitiveAlmostSimpleGroups(625);
2
> PrimitiveGroup(625, 511);
Permutation group acting on a set of cardinality 625
Order = 150000 = 2^4 * 3 * 5^5
5^4:SL(2, 5).2 Affine
> PrimitiveGroup(625,690);
Permutation group acting on a set of cardinality 625
Order = 2^14 * 3^5 * 5^4
Alt(5)^4:Q_8:Sym(4) ProductAction
> Q := PrimitiveGroups(625, func<G|#G eq 3*10^4>
>    : Filter := "Affine");
> #Q;
26
```

66.8.2 Processes

A primitive group process enables iteration over all primitive groups of specified degrees satisfying a given predicate, without having to create and store a list of all such groups.

The intrinsic function `PrimitiveGroupProcess` may be used to create a primitive group process. The standard process functions `IsEmpty`, `Current`, `CurrentLabel` and `Advance` can then be applied to the process.

`PrimitiveGroupProcess(d:` *parameters*`)`

`PrimitiveGroupProcess(S:` *parameters*`)`

`PrimitiveGroupProcess(:` *parameters*`)`

`Filter` MonStgElt *Default :* "*All*"

Return a group process which will iterate though all primitive groups of degree d that pass the filter as described above. A sequence of degrees may be given instead of a single degree. In this case the process will iterate though the groups of all the degrees in S. Omitting any degree information is the same as specifying the sequence of all legal degrees.

`PrimitiveGroupProcess(d, f: parameters)`

`PrimitiveGroupProcess(S, f: parameters)`

`PrimitiveGroupProcess(f: parameters)`

`Filter` MonStgElt *Default : "All"*

Return a process which will iterate though all primitive groups with degree d which pass the filter and satisfy the predicate f. A sequence of degrees may be given instead of a single degree. In this case the process will iterate though the groups of all the degrees in S. Omitting any degree information is the same as specifying the sequence of all legal degrees.

`IsEmpty(p)`

Returns `true` if the process p has passed its last group.

`Current(p)`

Return the current group of the process p, as well as a description of the group.

`CurrentLabel(p)`

Return the label of the current group of the process p. That is, return d and n such that the current group is `TransitiveGroup(d, n)` (or `PrimitiveGroup(d, n)`).

`Advance(~p)`

Move the process p to its next group.

Example H66E13

The use of processes is illustrated by the following code, in which the orders of all primitive groups with degree 60 of diagonal type are listed. We also compute the orbit structures of their Sylow 2-subgroups, which demonstrates that they are non-conjugate.

```
> p := PrimitiveGroupProcess(60:Filter:="Diagonal");
> while not IsEmpty(p) do
>     G := Current(p);
>     CurrentLabel(p), #G,
>     [t[1]:t in OrbitRepresentatives(Sylow(G,2))];
>     Advance(~p);
> end while;
60 1 3600 [ 4, 4, 4, 16, 16, 16 ]
60 2 7200 [ 4, 4, 4, 16, 32 ]
60 3 7200 [ 4, 8, 16, 32 ]
60 4 7200 [ 4, 8, 16, 16, 16 ]
60 5 14400 [ 4, 8, 16, 32 ]
```

66.8.3 Primitive Group Identification

Given a primitive group G whose degree is at most 2499, it is possible to obtain the number of the group in the primitive groups database which is permutation isomorphic to G.

`PrimitiveGroupIdentification(G)`

The number (and degree) of the group in the primitive groups database which is permutation isomorphic to the primitive group G.

Example H66E14

We construct a permutation group of affine type and identify it as a primitive group.

```
> M := WreathProduct(SL(2,5), Sym(2));
> Q := Getvecs(M);
> G := Semidir(M, Q);
> G;
Permutation group G acting on a set of cardinality 625
> PrimitiveGroupIdentification(G);
595 625
```

We found it to be group 595 of degree 625.

66.9 Database of Rational Maximal Finite Matrix Groups

MAGMA includes a database of rational maximal finite matrix groups and their invariant forms, for small dimensions (up to 31 at V2.8 and above). This section defines the interface to that database. See the articles of Nebe & Plesken [NP95] and Nebe [Neb96].

A particular entry of the database can be specified in one of two ways. Firstly, a number in the range 1 to the size of the database can be given. Alternatively, the desired dimension can be provided, together with a number in the range 1 to the number of entries of that dimension.

Each entry can be accessed either as a matrix group or as a lattice. If accessed as a matrix group, the order and base are set on return. If as a lattice, the automorphism group is set.

`RationalMatrixGroupDatabase()`

This function returns a database object which contains information about the database.

`LargestDimension(D)`

Returns the largest dimension of any entry stored in the database. It is an error to refer to larger dimensions in the database.

`#D`

`NumberOfGroups(D)`

`NumberOfLattices(D)`

Returns the number of entries stored in the database.

`NumberOfGroups(D, d)`

`NumberOfLattices(D, d)`

Returns the number of entries stored in the database of dimension d.

`Group(D, i)`

Returns the i-th entry from the database D as a matrix group.

`Lattice(D, i)`

Returns the i-th entry from the database D as a lattice.

`Group(D, d, i)`

Returns the i-th entry of dimension d from the database D as a matrix group.

`Lattice(D, d, i)`

Returns the i-th entry of dimension d from the database D as a lattice.

Example H66E15

```
> D := RationalMatrixGroupDatabase();
> #D;
354
> maxdim := LargestDimension(D);
> maxdim;
31
> &+[ NumberOfGroups(D, d) : d in [ 1 .. maxdim ] ];
354
```

These numbers agree (which is nice). The dimension in that range with the most curves is 24.

```
> S := [ NumberOfGroups(D, d) : d in [ 1 .. maxdim ] ];
> Max(S);
65 24
```

The groups have known order, so it is easy to find the group with smallest order and dimension 24.

```
> time orders := [#Group(D, 24, i): i in [1 .. NumberOfGroups(D, 24)]];
Time: 0.480
> Min(orders);
1872 53
```

66.10 Database of Integral Maximal Finite Matrix Groups

MAGMA includes a database of representatives of the $\mathrm{GL}(n, \mathbf{Z})$-conjugacy classes of irreducible maximal finite subgroups of $\mathrm{GL}(n, \mathbf{Z})$ for $n <= 11$ and $n \in \{13, 17, 19, 23\}$. This section defines the interface to that database.

For $n < 10$ the groups have been described in [PP77, PP80]. The groups of dimension 10 can be found in [Sou94]. In the cases $n > 10$ prime, the representatives have been constructed using the descriptions given in [Ple85].

A particular entry of the database can be specified in one of two ways. Firstly, a number in the range 1 to the size of the database can be given. Alternatively, the desired dimension can be provided, together with a number in the range 1 to the number of entries of that dimension.

Each entry can be accessed either as a matrix group or as a lattice. If accessed as a matrix group, the order and base are set on return. If as a lattice, the automorphism group is set.

`IntegralMatrixGroupDatabase()`

This function returns a database object which contains information about the database.

`LargestDimension(D)`

Returns the largest dimension of any entry stored in the database. It is an error to refer to larger dimensions in the database.

`#D`
`NumberOfGroups(D)`
`NumberOfLattices(D)`

Returns the number of entries stored in the database.

`NumberOfGroups(D, d)`
`NumberOfLattices(D, d)`

Returns the number of entries stored in the database of dimension d.

`Group(D, i)`

Returns the i-th entry from the database D as a matrix group.

`Lattice(D, i)`

Returns a lattice L and sequence of additional forms F fixed by the i-th group in the database D.

`Construction(D, i)`

Returns a string S which describes the construction of the i-th group G in the database D.

If the G-invariant lattice is well known, S equals the name of this lattice. If the Degree d of G is a prime, G usually can be chosen to fix the form $a_0 I_d + a_1(z + z^{-1}) + ... + a_k(z^k + z^{-1})$ with $k = (d-1)/2$ and some $a_i \in \mathbf{Z}$ where z denotes the permutation matrix of some d-cycle in $\mathbf{Z}^{d\times d}$ (see [Ple85]). In this case, S equals $[a_0, a_1, a_2, ...]$. In all other cases, S describes the isomorphism type of G.

The second return value gives the numbers of all groups of degree d in the `Rational Matrix Group Database` which contain a $\mathrm{GL}(d, \mathbf{Q})$-conjugate copy of G.

`Group(D, d, i)`

Returns the i-th entry of dimension d in the database D as a matrix group.

`Lattice(D, d, i)`

Returns a lattice L and sequence of additional forms F fixed by the i-th group of dimension d in the database D.

`Construction(D, d, i)`

Returns a string and integer which describe the construction of the i-th entry of dimension d in the database D.

Example H66E16

```
> D:= IntegralMatrixGroupDatabase();
> #D;
222
> G:= Group(D, 8, 7); Construction(D, 8, 7);
A8* [ 3 ]
```

So G is the automorphism group of the dual of the root lattice A_8 and it is conjugate to a subgroup of the third entry of dimension 8 in the `RationalMatrixgroupDatabase`. We find an explicit embedding T of G into that group.

```
> DQ:= RationalMatrixGroupDatabase();
> H:= Group(DQ, 8, 3); L:= Lattice(DQ, 8, 3);
> F:= PositiveDefiniteForm(G);
> for s in Sublattices(G) do
>   B:= BasisMatrix(s);
>   FF:= B * F * Transpose(B);
>   ok, T:= IsIsometric(LatticeWithGram(FF div GCD(Eltseq(FF))), L);
>   if ok then break; end if;
> end for;
> assert ok;
> T:= Matrix(Rationals(), T*B);
> [Matrix(Integers(), T*Matrix(G.i)*T^-1) in H : i in [1..Ngens(G)]];
[ true, true ]
```

66.11 Database of Finite Quaternionic Matrix Groups

MAGMA includes a database of the finite absolutely irreducible subgroups of $\mathrm{GL}_n(\mathcal{D})$ where $\mathcal{D}$ is a definite quaternion algebra whose centre has degree d over $\mathbf{Q}$ and $nd \leq 10$. This collection is due to Gabriele Nebe [Neb98]. This section defines the interface to that database.

A particular entry of the database can be specified in one of two ways. Firstly, a number in the range 1 to the size of the database can be given. Alternatively, the desired dimension can be provided, together with a number in the range 1 to the number of entries of that dimension.

Each entry can be accessed either as a matrix group or as a lattice. If accessed as a matrix group, the order and base are set on return.

`QuaternionicMatrixGroupDatabase()`

This function returns a database object which contains information about the database.

`LargestDimension(D)`

Returns the largest dimension of any entry stored in the database. It is an error to refer to larger dimensions in the database.

`#D`
`NumberOfGroups(D)`
`NumberOfLattices(D)`

Returns the number of entries stored in the database.

`NumberOfGroups(D, d)`
`NumberOfLattices(D, d)`

Returns the number of entries stored in the database of dimension d.

`Group(D, i)`

Returns the i-th entry from the database D as a matrix group.

`Lattice(D, i)`

Returns a lattice L and sequence of forms F corresponding to the i-th entry of the database D.

`Construction(D, i)`

Returns a string and integer which describe the construction of the i-th entry of the database D.

`Group(D, d, i)`

Returns the i-th entry of dimension d in the database D as a matrix group.

`Lattice(D, d, i)`

Returns a lattice L and sequence of forms F corresponding to the i-th entry of dimension d in the database D.

`Construction(D, d, i)`

Returns a string and integer which describe the construction of the i-th entry of dimension d in the database D.

Example H66E17

We illustrate accessing the quaternionic matrix groups database with a group and lattice of dimension 36.

```
> DB := QuaternionicMatrixGroupDatabase();
> LargestDimension(DB);
40
> NumberOfGroups(DB, 36);
10
> G := Group(DB, 36, 8);
> G : Minimal;
MatrixGroup(36, Integer Ring) of order 43545600 = 2^10 * 3^5
* 5^2 * 7
> #pCore(G, 2);
2
> L, forms := Lattice(DB, 36, 8);
> Determinant(L);
3874204890000
> IsSquare($1);
true 1968300
```

66.12 Database of Finite Symplectic Matrix Groups

MAGMA includes a database of the maximal finite irreducible subgroups of $\mathrm{Sp}_{2n}(\mathbf{Q})$ for $1 \leq i \leq 11$ up to conjugacy in $\mathrm{GL}_{2n}(\mathbf{Q})$. This collection is due to Markus Kirschmer [Kir09]. This section defines the interface to that database.

To avoid non-integral entries, the stored matrix groups do not fix the standard skewsymmetric form but some other nondegenerate skewsymmetric form. The example below illustrates how to construct a conjugate matrix group which fixes the standard skewsymmetric form.

A particular entry of the database can be specified in one of two ways. Firstly, a number in the range 1 to the size of the database can be given. Alternatively, the desired dimension can be provided, together with a number in the range 1 to the number of entries of that dimension.

Each entry can be accessed either as a matrix group or as a lattice with a pair of forms. If accessed as a matrix group, the order and base are set on return.

`SymplecticMatrixGroupDatabase()`

This function returns a database object which contains information about the database.

`LargestDimension(D)`

Returns the largest dimension of any entry stored in the database. It is an error to refer to larger dimensions in the database.

`#D`

`NumberOfGroups(D)`

`NumberOfLattices(D)`

Returns the number of entries stored in the database.

`NumberOfGroups(D, d)`

`NumberOfLattices(D, d)`

Returns the number of entries stored in the database of dimension d.

`Group(D, i)`

Returns the i-th entry from the database D as a matrix group.

`Lattice(D, i)`

Returns a lattice L and a sequence S of two integral forms such that the automorphism group of L with respect to S equals `Group(DB, i)`. The first form in S is the gram matrix of L and the second form is skewsymmetric. The sequence S is normalized as described in the appendix of [Kir09] to simplify the recognition of the matrix group.

`Construction(D, i)`

Returns a string which describes the construction of the i-th entry of the database D.

`Group(D, d, i)`

Returns the i-th entry of dimension d in the database D as a matrix group.

`Lattice(D, d, i)`

Returns a lattice L and a sequence S of forms corresponding to the i-th entry of dimension d in the database D.

`Construction(D, d, i)`

Returns a string which describes the construction of the i-th entry of dimension d in the database D.

Example H66E18

We illustrate accessing the symplectic matrix group database with a group of dimension 16.

```
> DB := SymplecticMatrixGroupDatabase();
> NumberOfGroups(DB, 16);
91
> G := Group(DB, 16, 1);
> G : Minimal;
MatrixGroup(16, Integer Ring) of order 2^21 * 3^4 * 5^2
```

The group G does not fix the standard skewsymmetic form. But it can be conjugated to do so.

```
> _, S := Lattice(DB, 16, 1);
> T := TransformForm(Matrix(Rationals(), S[2]), "symplectic");
> H := ChangeRing(G, Rationals())^(GL(16,Rationals()) ! T);
> J := SymplecticForm(16, Rationals());
> forall{h: h in Generators(H) | h * J * Transpose(h) eq J};
true
```

66.13 Database of Irreducible Matrix Groups

MAGMA has a database containing all irreducible subgroups of $\mathrm{GL}_k(p)$, for p prime, $k \geq 1$ and $p^k < 2500$. One representative of each conjugacy class of subgroups is stored.

The data used is the same as that used to store the affine primitive permutation groups. See the Primitive Groups Database section for the provenance of the data.

Within the database the groups are stored according to p^k. First are the soluble groups, followed by the insoluble. Within each subdivision, the groups are stored by increasing order. (It follows that $\mathrm{GL}_k(p)$ is the last in each list.)

The basic access function takes three parameters, k, p and number, and returns the corresponding group. Functions with name prefixed by `NumberOf` tell how many groups of each class there are stored.

66.13.1 Accessing the Database

`NumberOfIrreducibleMatrixGroups(k, p)`

`NumberOfSolubleIrreducibleMatrixGroups(k, p)`

Given k and p, p prime, $k \geq 1$ and $p^k < 2500$, `NumberOfIrreducibleMatrixGroups` returns the number of subgroups of $\mathrm{GL}_k(p)$ stored. The other function returns the number of soluble subgroups stored.

`IrreducibleMatrixGroup(k, p, n)`

Given k and p p prime, $k \geq 1$ and $p^k < 2500$, and a positive integer n, return the n-th subgroup of $\mathrm{GL}_k(p)$ stored.

Example H66E19

We apply some of these functions to the $\mathrm{GL}_4(5)$ case.

```
> NumberOfIrreducibleMatrixGroups(4, 5);
647
> NumberOfSolubleIrreducibleMatrixGroups(4, 5);
509
> G := IrreducibleMatrixGroup(4, 5, 511);
> ChiefFactors(G);
    G
    |  Cyclic(2)
    *
    |  Alternating(5)
    *
    |  Cyclic(2)
    1
> IsIrreducible(G);
true
> IsAbsolutelyIrreducible(G);
false
```

66.14 Database of Quasisimple Matrix Groups

MAGMA has a database containing characteristic 0 representations of some finite quasisimple groups.

`QuasisimpleMatrixGroup(N, d, p : parameters)`

`OverZ`	BOOLELT	*Default :* `true` $\Leftrightarrow p = 0$
`Automorphisms`	BOOLELT	*Default :* `false`
`RepNo`	RNGINTELT	*Default :* 1

Return an absolutely irreducible matrix group in characteristic p, which may be a prime number or 0, derived from the reduction modulo p of of an absolutely irreducible representation in charateristic 0 and dimension d of the quasisimple group G with name N. The generators of G used are its standard generators. For those quasisimple groups in the ATLAS-database (Section 66.16), the same names are used as there. Other quasisimple groups are named according to the same conventions.

If there is more than one representation of G in dimension d in the database, then the first such is used by default, and the others can be accessed by using the `RepNo` option.

If the reduction modulo p of the representation is not irreducible, then a random non-trivial irreducible constituent is used. (This behaviour may change in the future.)

For those representations that are not realisable over $\mathbf{Z}$ in dimension d, a representation in dimension d over a minimal extension of the rationals and also an irreducible representation in a higher dimension over $\mathbf{Z}$ are both stored in the database. The representation used is the one over $\mathbf{Z}$ if the parameter `OverZ` is `true`, and the one over the number field otherwise. Reduction modulo p is generally faster using the integral representation, so that is the default when $p > 0$.

If the parameter `Automorphisms` is set, then extra generators inducing those outer automorphisms of G that stabilise the representation are included in the group returned. This may result in extra scalars being present in the group returned, and when $p = 0$ this scalar subgroup can sometimes be infinite.

`QuasisimpleMatrixGroups()`

Returns a list of tuples specifying the names of the groups in the quasisimple matrix group database, together with the dimension and the number of stored representations of the group in that dimension.

66.15 Database of Soluble Irreducible Groups

This database contains one representative of each conjugacy class of irreducible soluble subgroups of $\mathrm{GL}(n, p)$, p prime, They may be accessed through specifying a group by its label in the database, as described in the section on basic functions, or through searching using predicates, or through a process. The database was constructed by Mark Short [Sho92].

66.15.1 Basic Functions

The basic access functions for the database are described in this section. The label of a group in the database is three integers, d, p, i. The first, $d \geq 2$, is the degree of the matrix group. The second, a prime p, specifies the base field of the group. The third is the number of the group in this degree/field set.

`IsolGroupDatabase()`

Open the database and return a reference to it. This reference may be passed to other functions so that they do fewer file operations.

`IsolGroup(n, p, i)`

`Group(D, n, p, i)`

Given a positive integer $o \leq 1000$ (with $o \neq 512$ or 768) and a positive integer n, return the n-th group of order o.

`IsolNumberOfDegreeField(n, p)`

The number of groups in the database of degree n over $\mathbf{F}_p$.

`IsolInfo(n, p, i)`

This function returns a string which gives some information about a group in the database given its label. In particular, it contains the order and primitivity information about the group.

`IsolOrder(n, p, i)`

This function returns the order of a group given its label.

`IsolMinBlockSize(n, p, i)`

This function returns the minimal block size of a group given its label. If it is primitive, it returns 0.

`IsolIsPrimitive(n, p, i)`

This function returns whether a group is primitive given its label.

`IsolGuardian(n, p, i)`

This function returns the "guardian" of a group given its label, i.e., the maximal subgroup of $\mathrm{GL}(n, p)$ of which the group is a subgroup.

Example H66E20

We find a group of degree 3 and its guardian.

```
> IsolNumberOfDegreeField(3, 5);
22
> G := IsolGroup(3, 5, 10);
> #G;
62
> GG := IsolGuardian(3, 5, 10);
> #GG;
372
> G;
MatrixGroup(3, GF(5)) of order 62 = 2 * 31
Generators:
  [0 0 1]
  [3 0 4]
  [2 3 1]
> GG;
MatrixGroup(3, GF(5)) of order 372 = 2^2 * 3 * 31
Generators:
  [1 0 0]
  [3 2 2]
  [1 4 2]

  [0 1 0]
  [0 0 1]
  [3 0 4]
```

66.15.2 Searching with Predicates

We may search the database for a group satisfying some predicate. A predicate for a group in this database is one of the following:

- A function f (which may either be an intrinsic function or a user defined function) which takes a matrix group and returns a boolean value.
- A tuple of one function $\langle g \rangle$, where g takes a label and returns a boolean value. Again g is either intrinsic or user defined.
- A tuple of two functions $\langle g, f \rangle$ where g, f are as above. In this case, the tested predicate will be g first, then f. This form is introduced to avoid expanding the group from its label until absolutely necessary.

`IsolGroupSatisfying(f)`

Given a predicate f, return a group satisfying it. This function runs through all the stored groups and applies the predicate until it finds a suitable one. If no group is found, an error message is printed.

`IsolGroupOfDegreeSatisfying(d, f)`

As `IsolGroupSatisfying(f)`, except it only runs through the groups of degree d.

`IsolGroupOfDegreeFieldSatisfying(d, p, f)`

As `IsolGroupSatisfying(f)`, except it only runs through the groups of degree d and defined over $\mathbf{F}_p$.

`IsolGroupsSatisfying(f)`

As `IsolGroupSatisfying(f)`, except a sequence of all such groups is returned.

`IsolGroupsOfDegreeSatisfying(d, f)`

As `IsolGroupOfDegreeSatisfying(d, f)`, except a sequence of all such groups is returned.

`IsolGroupsOfDegreeFieldSatisfying(d, p, f)`

As `IsolGroupOfDegreeFieldSatisfying(d, p, f)`, except a sequence of all such groups is returned.

66.15.3 Associated Functions

Associated with this database are two functions useful for constructing semidirect product of a finite vector space and an irreducible matrix group. Thus for constructing soluble affine permutation groups.

`Getvecs(G)`

This function takes a matrix group G over a finite prime field and returns a sequence, Q say, containing all the vectors of the natural module for G. The ordering of Q does *not* depend on G, but only on its natural module.

`Semidir(G, Q)`

Given an irreducible matrix group G of degree n and over a finite prime field of size p and the sequence Q obtained from `Getvecs`, this function returns the permutation group H of degree p^n that is the semidirect product of G with its natural module. H acts on the set $\{1 \dots p^n\}$ and G is isomorphic to each of the point stabilizers. It is well known that H is primitive, and that every primitive permutation group with soluble socle arises in this way. Note that if `Semidir` is to be called more than once for subgroups of the same general linear group, then `Getvecs` need only be called on the first occasion, since the ordering of Q depends only on n and p. This is why the call to `Getvecs` is not made by `Semidir` itself.

66.15.4 Processes

A small group process enables iteration over all groups with specified degrees and fields, without having to create and store all such groups together.

A process is created via the function `IsolProcess` and its variants. The standard process functions `IsEmpty`, `Current`, `CurrentLabel` and `Advance` can then be applied to the process.

A specifier for degree or field is one of a valid degree (field size), or a tuple $\langle l, h \rangle$, of valid degrees (field sizes) which is interpreted to mean all degrees (prime field sizes) in $[l, h]$.

`IsolProcess()`

Return a process which will iterate though all groups in the database.

`IsolProcessOfDegree(d)`

Return a process which will iterate though all groups in the database of degree d.

`IsolProcessOfField(p)`

Return a process which will iterate though all groups in the database over the specified field.

`IsolProcessOfDegreeField(d, p)`

Return a process for iterating over all the stored groups with degree specifier d and field specifier p. Initially it points to the first such group (the principal key is the degree).

`IsEmpty(p)`

Returns `true` if the process p has passed its last group.

`Current(p)`

Return the current group of the process p.

`CurrentLabel(p)`

Return the label of the current group of the process p. That is, return d, n and i such that the current group is `IsolGroup(d, n, i)`.

`Advance(~p)`

Move the process p to its next group.

Example H66E21

We use a small group process to look at all the groups of degree 3.

```
> P := IsolProcessOfDegree(3);
> ords := {* *};
> repeat
>   Include(~ords, #Current(P));
>   Advance(~P);
> until IsEmpty(P);
> ords;
{* 31, 62, 93, 7, 124, 96^^4, 39, 12^^2, 186, 13, 192^^2, 48^^4,
21, 24^^6, 26 *}
```

66.16 Database of ATLAS Groups

MAGMA includes representations of nearly simple groups from the ATLAS of Finite Group Representations http://web.mat.bham.ac.uk/atlas/v2.0. The data was supplied by Robert Wilson.

Groups in the database are accessed by name. The intrinsic ATLASGroupNames gives a list of the names that may currently be used to access the database. The names are based on ATLAS names for simple groups, with some exceptions (usually caused by an aversion to subscripting automorphisms). Classical group names take precedence over their Lie-type names. Within a name, the letter "T" denotes a twisted group of Lie type. (The two sorts of twisting of D_4 are distinguished by one being "O8m" and the other "TD4".) An initial number on the name denotes a central element, a "d" is used to separate the simple group name from an automorphism (when there is no other letter there), and an "i" denotes an isoclinic variant.

Example H66E22

The list of names in V2.11 is printed as follows.

```
> ATLASGroupNames();
{@ A5, 2A5, 2S5, 2S5i, S5, A6, 2A6, 2S6, 3A6, 3S6, 6A6,

3McLd2, McLd2, S7 @}
```

The basic access function takes a name and returns a special type of group, an ATLAS group, with MAGMA type `GrpAtlas`. Access to the information stored about the named group are then done through this ATLAS group.

66.16.1 Accessing the Database

`ATLASGroupNames()`

The names of the groups that have representations stored in the database.

`ATLASGroup(N)`

The ATLAS group stored in the database that has name N.

66.16.2 Accessing the ATLAS Groups

Once an ATLAS group has been extracted from the database, the following intrinsics give access to the information stored with it.

`Order(A)`
`#G`

The order of A.

`Multiplier(A)`

The order of the multiplier of A, when A is simple.

`MatRepKeys(A)`

The sequence of keys to the matrix representations of A stored in the database. This will be the empty sequence if no matrix representations are stored.

`MatRepDegrees(A)`

The set of degrees of the matrix representations stored for A.

`MatRepFieldSizes(A)`

The set of sizes of the fields for which a matrix representation of A is available.

`MatRepCharacteristics(A)`

The set of characteristics of the fields for which a matrix representation of A is available.

`PermRepKeys(A)`

The sequence of keys to the permutation representations of A stored in the database. This will be the empty sequence if no permutation representations are stored.

`PermRepDegrees(A)`

The set of degrees of the permutation representations stored for A.

66.16.3 Representations of the ATLAS Groups

The intrinsics described below construct concrete representations of the ATLAS groups from the data in the database. Each representation is accessed by its key, sequences of which are produced by the intrinsics `MatRepKeys` and `PermRepKeys` described above. The intrinsics described in this section take a key and produce a concrete representation.

`MatrixGroup(K)`

Given a key to a matrix representation of an ATLAS group, construct and return the corresponding matrix group.

`MatRep(K)`

The generators of the matrix group designated by database key K.

`PermutationGroup(K)`

Given a key to a permutation representation of an ATLAS group, construct and return the corresponding permutation group.

`PermRep(K)`

The generators of the permutation group designated by database key K.

Example H66E23

We get a representation of $2.J_2.2$ from the database.

```
> A := ATLASGroup("2J2d2");
> PermRepKeys(A);
[]
> mrk := MatRepKeys(A);
> mrk;
[
  Matrix rep of degree 12 over GF(3),
  Matrix rep of degree 6 over GF(25) named a,
  Matrix rep of degree 12 over GF(7)
]
```

The database has no permutation representations and three matrix representations. We construct the first of the matrix groups. It is small enough to check its composition factors.

```
> K := mrk[1];
> M := MatrixGroup(K);
```

```
> M`Order := #A;
> RandomSchreier(M);
> CompositionFactors(M);
    G
    |  Cyclic(2)
    *
    |  J2
    *
    |  Cyclic(2)
    1
```

For efficiency, we asserted the order of the matrix group to be the order of the ATLAS group and constructed a BSGS by the random schreier.

66.17 Fundamental Groups of 3-Manifolds

The database consists of the fundamental groups of the 10,986 small-volume closed hyperbolic manifolds in the Hodgson-Weeks census. The presentations included were generated by Jeffrey Weeks' program *SnapPea* `http://www.geometrygames.org/SnapPea/`. Information about finite-index subgroups with homology was generated by Dunfield and Thurston in [DT03].

66.17.1 Basic Functions

The basic access functions for the database are described in this section.

The result returned by the `Manifold` function is a record with a number of fields containing information about the manifold and its fundamental group. The fields of the records are as follows:

Field `Name`: A string giving a name to the manifold M.

Field `Volume`: The volume of M as a floating point number.

Field `Homology`: A sequence of integers describing the first homology group of M.

Field `Group`; The fundamental group of M as a finitely presented group.

Field `GoodCoverImage`: A possibly empty sequence of permutations or integers 1 representing the identity permutation. These permutations define a homomorphism from the fundamental group to S_n, such that the kernel of the homomorphism has infinite abelianization.

Field `GoodCover`: A list describing the construction of the good cover.

Field `Degree`: A positive integer, the degree of the `GoodCoverImage` permutation representation.

Field `KnownPosBettiCover`: A boolean value, always true in the current database.

Field `KnownWeakPosBettiCover`: A boolean value, always true in the current database.

Field `Reason`: A string, one of `"AbelianInvariants"`, `"RationalReconstruction"` or `"MAGMA"`.

Field `Rank`: A positive integer.

Field `GoodCoverImageU`: A possibly empty sequence of permutations or integers 1 representing the identity permutation.

`ManifoldDatabase()`

Open the database and return a reference to it.

`Manifold(D, i)`

Extract the ith record from the database of fundamental groups of 3-dimensional manifolds. The current limits on i are $1 \leq i \leq 11126$.

66.17.2 Accessing the Data

The intrinsic `Manifold` is one way to access the data in the database. It may be more convenient to iterate over the database object returned by `ManifoldDatabase`. The following examples show how this may be done.

Example H66E24

We extract a record from the database.

```
> D := ManifoldDatabase();
> r := Manifold(D, 100);
> r`Name;
m019(1,4)
> r`Homology;
[ 2, 31 ]
> r`Group;
Finitely presented group on 2 generators
Relations
  $.1 * $.2^3 * $.1 * $.2 * $.1^4 * $.2 * $.1 * $.2 * $.1^4
    * $.2 = Id($)
  $.1 * $.2 * $.1 * $.2^2 * $.1^-3 * $.2^2 = Id($)
> r`GoodCoverImage;
[
  (1, 2, 4, 6, 5, 8, 7, 9, 3),
  (1, 3, 5, 4, 7, 6, 9, 8, 2)
]
```

In [DT03], Dunfield and Thurston note that they found 132 manifolds with positive Betti number. We find them in the database as those records where the `Degree` is 1. We then search the database for one of these, but by name. Both searches use the facility to iterate over the database that was mentioned above.

```
> D := ManifoldDatabase();
> pos_betti := {r`Name:r in D|r`Degree eq 1};
```

```
> #pos_betti;
132
> Random(pos_betti);
s527(-5,1)
> exists(r){r:r in D|r`Name eq "s527(-5,1)"};
true
> F := r`Group; F;
Finitely presented group F on 2 generators
Relations
  F.1^2 * F.2^2 * F.1^2 * F.2^-1 * F.1^2 * F.2^2 * F.1^2 *
  F.2^2 * F.1^-1 * F.2^2 = Id(F)
  F.1^2 * F.2^2 * F.1^2 * F.2 * F.1^2 * F.2^2 * F.1^2 * F.2
  * F.1^2 * F.2^2 * F.1^2 * F.2 * F.1^2 * F.2^2 * F.1^2 *
  F.2 * F.1^2 * F.2^2 * F.1^2 * F.2 * F.1^2 * F.2^2 * F.1^2
  * F.2^2 * F.1^-3 * F.2^2 = Id(F)
> AbelianQuotientInvariants(F);
[ 7, 0 ]
> r`Homology;
[ 0, 7 ]
```

As expected, we see that the fundamental group has infinite abelianization.

67 AUTOMORPHISM GROUPS

Chapter 67
AUTOMORPHISM GROUPS

67.1 Introduction

MAGMA provides facilities for constructing and working with automorphism groups of various objects. In this chapter we describe the machinery provided in MAGMA for groups of automorphisms in the case of groups.

An *automorphism* of a group G is a bijective homomorphism from G to itself. The set of all automorphisms of G forms a group U known as the *automorphism group* of G. A subgroup A of U will be referred to as a *group of automorphisms* of G. The group G is called the *base group* of a group of automorphisms A and we say that A acts on G. Each MAGMA automorphism group A stores, as part of its data structure, a generating set for its base group, and each automorphism of A is described by its action on these generators.

The full group of automorphisms may be found using an algorithm that proceeds as follows: A series of characteristic subgroups

$$1 = N_r < N_{r-1} < \ldots < N_1 = L < G$$

is constructed for the given group G, such that each N_i/N_{i+1} is elementary abelian and such that G/L has no non-trivial soluble normal subgroup. The automorphism group is found for each of the associated factor groups of G, starting with the top factor G/L and lifting through each layer N_i/N_{i+1} in turn, until we finally have the automorphism group for G itself. The general algorithm for a non-soluble group is described in Cannon and Holt [CH03]. More specialised versions are described by Eick, Leedham-Green and O'Brien [ELGO02] (p-groups) and Smith [Smi94] (soluble groups). This general class of algorithms will be referred to collectively as *lifting algorithms*.

When G is a non-soluble permutation or matrix group, the algorithm relies on a database of automorphism groups for the non-cyclic simple factors of G, hence the non-abelian composition factors of G must belong to a restricted list. In V2.11 this list includes all simple groups of order at most 1.6×10^7, the alternating groups of degree at most 1000, all groups from several generic families, including $PSL(2, q)$, $PSL(3, q)$, $PSL(4, p)$, $PSL(5, p)$, $PSU(3, p)$ and $PSp(4, p)$ and the sporadic groups M_{11}, M_{12}, M_{22}, M_{23}, M_{24}, J_1, J_2, J_3, HS, McL, $Co3$, He and others. The list is being extended regularly.

An automorphism group A of G is represented as a set of homomorphisms of G into itself. We shall refer to this as the mappings representation of A. The full automorphism group is also returned as a finitely presented group and, in addition, it is also possible to construct a permutation representation of the automorphism.

The family of all groups of automorphisms forms a category. The objects are the automorphism groups and the morphisms are group homomorphisms. The MAGMA designation for this category of automorphism groups is `GrpAuto`.

67.2 Creation of Automorphism Groups

An automorphism group of the finite group G may be created in one of two ways. Firstly, the full automorphism group of G may be constructed by invoking an appropriate lifting algorithm. Secondly, an arbitrary group of automorphisms A of G may be created by giving a set of generators for A defined in terms of their action on a set of generators for G.

`AutomorphismGroup(G)`

Given a finite group G, construct the full automorphism group F of G. The group G may be a permutation group, a (finite) matrix group or a finite soluble group given by a pc-presentation. The function returns the full automorphism group of G as a group of mappings (i.e., as a group of type `GrpAuto`). If G is a permutation or matrix group, then the automorphism group F is also computed as a finitely presented group and can be accessed via the function `FPGroup(F)`. A function `PermutationRepresentation` is provided that when applied to F attempts to construct a faithful permutation representation of reasonable degree (see below).

`SmallOuterAutGroup` RngIntElt *Default :* 20000

`SmallOuterAutGroup := t`: Specify the strategy for the backtrack search when testing an automorphism for lifting to the next layer. If the outer automorphism group O at the previous level has order at most t, then the regular representation of O is used, otherwise the program tries to find a smaller degree permutation representation of O.

`Print` RngIntElt *Default :* 0

The level of verbose printing. The possible values are 0, 1, 2 or 3.

`PrintSearchCount` RngIntElt *Default :* 1000

`PrintSearchCount := s`: If `Print := 3`, then a message is printed at each s-th iteration during the backtrack search for lifting automorphisms.

In the case of a non-soluble group, the algorithm described in Cannon and Holt [CH03] is used. If G is a p-group of type `GrpPC` the algorithm described in Eick, Leedham-Green and O'Brien [ELGO02] is used. For more details see Section 63.12.2. If G is of type `GrpPC` but is not a p-group, the algorithm of Smith [Smi94], as extended by Smith and Slattery, is used. For more details see Section 63.12.

When G is a non-soluble permutation or matrix group, the algorithm relies on a database of automorphism groups for the non-cyclic simple factors of G, hence the non-abelian composition factors of G must belong to a restricted list. In V2.11 this list includes all simple groups of order at most 1.6×10^7, the alternating groups of degree at most 1000, all groups from several generic families, including $PSL(2,q)$, $PSL(3,q)$, $PSL(4,p)$, $PSL(5,p)$, $PSU(3,p)$ and $PSp(4,p)$ and the sporadic groups M_{11}, M_{12}, M_{22}, M_{23}, M_{24}, J_1, J_2, J_3, HS, McL, $Co3$, He and others. The list is being extended regularly.

Example H67E1

We create a non-soluble group G of 4×4 matrices defined over the field of 8-th roots of unity and construct its automorphism group.

```
> L<zeta_8> := CyclotomicField(8);
> i := -zeta_8^2;
> t := zeta_8^3;
> G := MatrixGroup< 4, L |
>             [ 1/2, 1/2, 1/2, 1/2,
>               1/2,-1/2, 1/2,-1/2,
>               1/2, 1/2,-1/2,-1/2,
>               1/2,-1/2,-1/2, 1/2 ],
>             DiagonalMatrix( [1,1,1,-1] ),
>             DiagonalMatrix( [1,i,1,i] ),
>             DiagonalMatrix( [t,t,t,t] ) >;
> Order(G);
92160
> CompositionFactors(G);
    G
    |  Cyclic(2)
    *
    |  Alternating(6)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    1
> A := AutomorphismGroup(G);
> Order(A);
92160
```

`AutomorphismGroup(G, Q, I)`

Let G be a finite group and let Q be a sequence of elements which generate G. Let $\phi_1, \ldots, \phi_r$ be a sequence of automorphisms of G that generate the group of automorphisms A. The group A is specified by a sequence I of length r where the i-th term of I defines ϕ_i in terms of a sequence containing the images of the elements of Q under the action of ϕ_i. The function returns the group of automorphisms A of G.

67.3 Access Functions

The functions described here provide access to basic information stored for an automorphism group A.

`Group(A)`

Given a group of automorphisms A of the group G, return the base group G on which A acts.

`NumberOfGenerators(A)`

`Ngens(A)`

Given a group of automorphisms A of the group G, return the number of defining generators for A.

`NumberOfPCGenerators(A)`

`NPCGenerators(A)`

`NPCgens(A)`

Given a group of automorphisms A of the group G, where a pc-representation has been created for A (and attribute `PCGenerators` is set on A), return the number of pc-generators for A.

`Generators(A)`

Given a group of automorphisms A of the group G, return a set containing the defining generators of A.

`PCGenerators(A)`

Given a group of automorphisms A of the group G, where a pc-representation has been created for A (and attribute `PCGenerators` is set on A), return an indexed set containing the pc-generators of A.

`InnerGenerators(A)`

Given the full group of automorphisms A of the group G, return a sequence of generators for the inner automorphism group of the base group of A (attribute `InnerGenerators`), if this attribute has been set.

`CharacteristicSeries(A)`

Given a group of automorphisms A of the group G, return the value of the characteristic series of G used to compute A, if this attribute has been set.

`IsSoluble(A)`
`IsSolvable(A)`

Given a group of automorphisms A of the group G, return the value of A's attribute `Soluble`, if this attribute has been set.

`IsSolubleAutomorphismGroupPGroup(A)`
`IsSolvableAutomorphismGroupPGroup(A)`

Given a group of automorphisms A of a p-group G constructed using the intrinsic `AutomorphismGroup(G)` or any equivalent alias, determine if A is soluble and return the result. This function also sets the `Soluble` attribute on A.

67.4 Order Functions

Unless the order is already known, each of the functions in this family will create a faithful permutation representation of the group of automorphisms in order to compute the order.

`Order(A)`
`#A`

The order of the group of automorphisms A, returned as an integer. If not already known, this function will create a permutation representation for A.

`FactoredOrder(A)`

The factored order of the group of automorphisms A. If not already known, this function will create a permutation representation for A.

`OuterOrder(A)`

The order of the outer automorphism group associated with the group of automorphisms A.

Example H67E2

We create the non-soluble group $G = PGL(2, 9)$ and examine the properties of its automorphism group.

```
> G := PGL(2, 9);
> A := AutomorphismGroup(G);
> A;
A group of automorphisms of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5
Generators:
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (1, 7, 3, 5, 4, 2, 10, 9)
```

```
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 6, 8)(2, 7, 10)(3, 9, 5)
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (1, 4, 6, 10, 7, 8, 5, 9)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 9, 10)(2, 6, 3)(4, 8, 7)
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (3, 5, 9, 6, 7, 4, 8, 10)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 10, 2)(3, 4, 7)(5, 8, 9)
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (1, 10, 3, 5, 2, 4, 7, 6)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 6, 2)(3, 7, 5)(4, 9, 8)
> #A;
1440
> FactoredOrder(A);
[ <2, 5>, <3, 2>, <5, 1> ]
> OuterOrder(A);
2
> InnerGenerators(A);
[
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (1, 7, 3, 5, 4, 2, 10, 9)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 6, 8)(2, 7, 10)(3, 9, 5),
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (1, 4, 6, 10, 7, 8, 5, 9)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 9, 10)(2, 6, 3)(4, 8, 7),
    Automorphism of GrpPerm: G, Degree 10, Order 2^4 * 3^2 * 5 which maps:
        (3, 5, 9, 6, 7, 4, 8, 10) |--> (3, 5, 9, 6, 7, 4, 8, 10)
        (1, 8, 2)(3, 4, 5)(6, 10, 7) |--> (1, 10, 2)(3, 4, 7)(5, 8, 9)
]
> CharacteristicSeries(A);
[
    Permutation group G acting on a set of cardinality 10
    Order = 720 = 2^4 * 3^2 * 5
        (3, 5, 9, 6, 7, 4, 8, 10)
        (1, 8, 2)(3, 4, 5)(6, 10, 7),
    Permutation group acting on a set of cardinality 10
    Order = 1
]
```

67.5 Representations of an Automorphism Group

To compute with automorphism groups, MAGMA uses various concrete representations of the group. These are summarised in this section.

`PermutationRepresentation(A)`

Construct a permutation representation of the group of automorphisms A. The function finds a union of conjugacy classes of the base group G which is closed under the action of A and with G-normal closure equal to G. The permutation action of A on such a set is faithful. The results returned are the representation of A as a homomorphism $A \to P$, the image of this homomorphism as a permutation group with standard support, and the set of elements of G used.

`PermutationGroup(A)`

Given a group of automorphisms A of a group G, this function returns a permutation group isomorphic to A as defined in the description of the function `PermutationRepresentation`.

`PermutationSupport(A)`

Given a group of automorphisms A of a group G, this function returns the set of elements of G (i.e., a union of conjugacy classes) used as the support of the permutation group constructed by the `PermutationRepresentation` function.

`PCGroupAutomorphismGroupPGroup(A)`

Attempt to directly construct a pc-representation for the group of automorphisms A of a conditioned p-group G. A must have been constructing using the `AutomorphismGroup` intrinsic, or any equivalent alias. The results returned are a boolean value indicating the solubility of A, and if soluble, a representation of A as a homomorphism $A \to P$ and the image of this homomorphism as a pc-group.

`FPGroup(A)`

A presentation for the group of automorphisms A on the generators of A. The isomorphism from the finitely presented group to the group of automorphisms A is also returned.

`OuterFPGroup(A)`

Suppose that A is the full group of automorphisms of a group G. This function returns a finitely presented group O isomorphic to the outer automorphism group of the base group G. The natural homomorphism from `FPGroup(A)` onto O is also returned.

Example H67E3

We calculate a permutation representation and presentation for the group of automorphisms of $PSL(2, 9)$.

```
> G := PGL(2, 9);
> A := AutomorphismGroup(G);
> PermutationGroup(A);
Permutation group acting on a set of cardinality 36
Order = 1440 = 2^5 * 3^2 * 5
    (1, 30)(3, 27)(5, 17)(6, 24)(8, 9)(10, 14)(11, 13)(12, 32) (15, 34)(16, 21)
       (18, 25)(19, 28)(22, 29)(23, 31)(26, 33)(35, 36)
    (1, 32, 19, 22)(2, 34)(3, 18, 7, 17)(4, 25, 30, 31) (5, 23, 33, 24)
       (6, 15, 26, 21)(8, 16, 29, 20)(9, 35, 14, 27) (10, 13, 11, 12)(28, 36)
    (1, 2, 3, 5, 8, 13, 22, 31)(4, 7, 9, 15, 24, 26, 34, 29)
       (6, 10, 17, 23, 32, 33, 28, 35)(11, 19, 27, 16, 25, 21, 30, 36)
       (12, 20, 14, 18)
    (1, 32, 33, 12, 21, 6)(2, 34, 26, 35, 17, 16)(3, 28, 22, 7, 18, 13)
       (4, 31, 20, 29, 24, 11)(5, 19, 25, 10, 15, 8)(9, 30, 36, 14, 23, 27)
> F<x, y, z, t> := FPGroup(A);
> F;
Finitely presented group F on 4 generators
Relations
    x^2 = Id(F)
    y^4 = Id(F)
    (x * y^-1)^5 = Id(F)
    y^-2 * x * y^-2 * x * y^-2 * x * y^2 * x * y^2 * x = Id(F)
    z^-1 * x * z * y^-1 * x^-1 * y^-2 * x^-1 * y * x^-1 *
       y^-2 * x^-1 * y * x^-1 * y^-1 * x^-1 = Id(F)
    z^-1 * y * z * y * x^-1 * y * x^-1 * y^-1 * x^-1 = Id(F)
    z^2 * y^-1 * x^-1 * y * x^-1 * y^-1 * x^-1 = Id(F)
    x^t = y * x * y^-1
    y^t = y^-1 * x * y * x * y
    z^t = z * x * y^-1 * x
    t^2 = x * y^2 * x * y^-1 * x * y
```

Example H67E4

We illustrate the process of finding a low degree permutation representation of an automorphism group using the above functions. We start with the Higman-Sims sporadic simple group, construct its automorphism group, and then use the function `PermutationGroup` to obtain a permutation representation.

```
> load hs100;
Loading "/home/magma/libs/pergps/hs100"
The simple group of Higman-Sims represented as a
permutation group of degree 100.
Order: 44 352 000 = 2^9 * 3^2 * 5^3 * 7 * 11.
Base: 1, 2, 3, 4, 5, 6.
```

```
Group: G
> aut := AutomorphismGroup(G);
> P := PermutationGroup(aut);
> P;
Permutation group P acting on a set of cardinality 5775
Order = 88704000 = 2^10 * 3^2 * 5^3 * 7 * 11
```

We've got a permutation representation on 5775 letters. Now we want to get it on 100 letters, so we need to find the subgroup of index 100.

```
> lix := LowIndexSubgroups(P, 100);
> [ Index(P, H) : H in lix];
[ 1, 2, 100 ]
```

There it is, so we can compute the corresponding permutation representation.

```
> H := CosetImage(P, lix[3]);
> H;
Permutation group H acting on a set of cardinality 100
> CompositionFactors(H);
    G
    |  Cyclic(2)
    *
    |  HS
    1
```

67.6 Automorphisms

The elements of a group of automorphisms are automorphisms of the base group, so MAGMA treats them as both homomorphisms and group elements. Thus they may be applied to elements and subgroups of the base group as a homomorphism, or they may be multiplied and have inverses taken as group elements. Of course, these last two operations are also homomorphism operations, being composition and the usual inverse of a bijection. Elements of a group of automorphisms are of type `GrpAutoElt`.

`A . i`

Let A be a group of automorphisms of a group G and let i be an integer such that $-n \leq i \leq n$, where n is the number of generators of A. This operator returns the i-th generator for A. A negative subscript indicates that the inverse of the generator is to be created. Finally, $A.0$ denotes the identity of A.

`Identity(A)`

`Id(A)`

`A ! 1`

The identity element of the group of automorphisms A.

`A ! f`

Let A be a group of automorphisms of a group G. Given an automorphism f of G, represented as a MAGMA map, this function returns the element of A corresponding to f. An error will result if f is not in the group generated by the generators of A. This uses the permutation representation of A to test for membership.

`Order(f)`

The order of the group automorphism f.

`f * g`

The product of the group automorphisms f and g. If f and g are regarded as maps, this function returns their composite: first apply f, then apply g.

`f ^ n`

The nth power of the group automorphism f. The integer n may be positive or negative.

`(g1, ..., gr)`

The left-normed commutator of the group automorphisms $g_1, \ldots, g_r$. Each of $g_1, \ldots, g_r$ must belong to a common automorphism group.

`g eq h`

Given group automorphisms g and h belonging to the same automorphism group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given group automorphisms g and h belonging to the same automorphism group, return `false` if g and h are the same element, `true` otherwise.

`IsInner(f)`

Returns `true` if the group automorphism f is an inner automorphism of the base group, `false` otherwise. If f is inner, then an element of the base group with conjugation action equal to the action of f is also returned.

Example H67E5

We illustrate some arithmetic operations with elements of the full group of automorphisms of a group of order 81.

```
> G := SmallGroup(81, 10);
> G;
GrpPC : G of order 81 = 3^4
PC-Relations:
  G.1^3 = G.4,
  G.2^3 = G.4^2,
  G.2^G.1 = G.2 * G.3,
  G.3^G.1 = G.3 * G.4
> A := AutomorphismGroup(G);
> #A;
486
> Ngens(A);
5
> IsInner(A.3);
false
> Order(A.3);
3
> A.3;
Automorphism of GrpPC : G of order 3 which maps:
  G.1 |--> G.1
  G.2 |--> G.2 * G.4^2
  G.3 |--> G.3
  G.4 |--> G.4
> A.3*A.4;
Automorphism of GrpPC : G which maps:
  G.1 |--> G.1
  G.2 |--> G.2 * G.3 * G.4^2
  G.3 |--> G.3 * G.4
  G.4 |--> G.4
> (A.3*A.4)^3;
Automorphism of GrpPC : G which maps:
  G.1 |--> G.1
  G.2 |--> G.2
  G.3 |--> G.3
  G.4 |--> G.4
> $1 eq Id(A);
true
```

Example H67E6

We can use the automorphism group machinery to determine the characteristic subgroups of a group.

```
> CharacteristicSubgroups := function(G)
```

```
>    local A, outers, NS, CS;
>    A := AutomorphismGroup(G);
>    outers := [ a : a in Generators(A) | not IsInner(a) ];
>    NS := NormalSubgroups(G);
>    CS := [n : n in NS | forall{a: a in outers| a(n`subgroup) eq n`subgroup }];
>    return CS;
> end function;
>
> CS := CharacteristicSubgroups(DirectProduct(Alt(4),Alt(4)));
> [c`order: c in CS];
[ 1, 16, 144 ]
> G := SmallGroup(512,298);
> #NormalSubgroups(G);
42
> #CharacteristicSubgroups(G);
28
```

67.7 Stored Attributes of an Automorphism Group

Groups of automorphisms have several attributes that may be stored as part of their data structure. The function `HasAttribute` is used to test if an attribute is stored and to retrieve its value, while the function `AssertAttribute` is used to set attribute values. The user is warned that when using `AssertAttribute` the data given is *not* checked for validity, apart from some simple type checks. *Setting attributes incorrectly will result in errors.*

`HasAttribute(A, s)`

`AssertAttribute(A, s, v)`

The `HasAttribute` function returns whether the group of automorphisms A has the attribute named by the string s defined and, if so, also returns the value of the attribute.

The `AssertAttribute` procedure sets the attribute of the group of automorphisms group named by string s to have value v. The possible names are:
`Group`: The base group of the automorphism group. This is always set.
`Order`: The order of the automorphism group. It is an integer and may be set by giving either an integer or a factored integer.
`OuterOrder`: The order of the outer automorphism group associated with A. It is an integer and may be set by giving either an integer or a factored integer.
`Soluble`: (also `Solvable`) A boolean value telling whether or not the automorphism group is soluble.
`InnerGenerators`: A sequence of generators of A known to be inner automorphisms.
`InnerMap`: A homomorphism from the base group to the automorphism group taking each base group element to its corresponding inner automorphism.
`ClassAction`: Stores the result of the `PermutationRepresentation` function call.

`ClassImage`: Stores the result of the `PermutationGroup` function call.
`ClassUnion`: Stores the result of the `ClassUnion` function call.
`FpGroup`: Stores the result of the `FPGroup` function call. The attribute is a pair $\langle F, m\rangle$ where F is an fp-group and m is an isomorphism $m : F \to A$. F and m are the two return values of `FPGroup(A)`.
`OuterFpGroup`: Stores the result of the `OuterFPGroup` function call. The attribute is a pair $\langle O, f\rangle$ where O is an fp-group and f is an epimorphism $f : F \to O$, where F is the first component of the `FpGroup` attribute. The kernel of f is the inner automorphism group. O and f are the two return values of `OuterFPGroup(A)`.
`GenWeights`: `WeightSubgroupOrders`: See the section on automorphism groups in the chapter on soluble groups for details.

Example H67E7

We select a group of order 904 from the small groups database and compute its group of automorphisms.

```
> G := SmallGroup(904, 4);
> FactoredOrder(G);
[ <2, 3>, <113, 1> ]
> FactoredOrder(Centre(G));
[ <2, 1> ]
> A := AutomorphismGroup(G);
> FactoredOrder(A);
[ <2, 7>, <7, 1>, <113, 1> ]
> HasAttribute(A, "FpGroup");
false
> HasAttribute(A, "OuterFpGroup");
false
> F,m := FPGroup(A);
> AssertAttribute(A, "FpGroup", <F,m>);
```

Note that values for some attributes, such as `FpGroup`, have not been calculated by the original `AutomorphismGroup` call, but they may be calculated and set later if desired. The outer automorphism group has order $2^5 \times 7$. We find the characteristic subgroups of `G`.

```
> n := NormalSubgroups(G);
> [x`order : x in n];
[ 1, 2, 113, 4, 226, 452, 452, 452, 904 ]
> characteristics := [s : x in n |
>   forall{f: f in Generators(A) | s@f eq s}
>   where s is x`subgroup];
> [#s : s in characteristics];
[ 1, 2, 113, 4, 226, 452, 904 ]
```

Note that two of the normal subgroups of order 452 are not characteristic.

Example H67E8

```
> G := AlternatingGroup(6);
> A := AutomorphismGroup(G);
> HasAttribute(A, "OuterFpGroup");
true
> F, f := FPGroup(A);
> O, g := OuterFPGroup(A);
> O;
Finitely presented group O on 2 generators
Relations
  O.1^2 = Id(O)
  O.2^2 = Id(O)
  (O.1 * O.2)^2 = Id(O)
> A`OuterOrder;
4
```

We find the outer automorphism group is elementary abelian of order 4. The direct product of `G` with itself has maximal subgroups isomorphic to `G`, in the form of diagonal subgroups. We can construct four non-conjugate examples using the outer automorphism group. The first example can be constructed without using an outer automorphism.

```
> GG, ins := DirectProduct(G, G);
> M := sub<GG|[(x@ins[1])*(x@ins[2]):x in Generators(G)]>;
> IsMaximal(GG, M);
true
```

The subgroup `M` is the first, the obvious diagonal, constructed using just the embeddings returned by the direct product function. We get others by twisting the second factor using an outer automorphism. First we get (representatives of) the outer automorphisms explicitly.

```
> outers := {x @@ g @ f : x in [O.1, O.2, O.1*O.2]};
> Representative(outers);
Automorphism of GrpPerm: G, Degree 6, Order 2^3 * 3^2 * 5 which maps:
  (1, 2)(3, 4, 5, 6) |--> (1, 3, 6, 2)(4, 5)
  (1, 2, 3) |--> (1, 4, 2)(3, 5, 6)
```

The set `outers` now contains three distinct outer automorphisms of `G`. We use them to get three more diagonal subgroups.

```
> diags := [M] cat
> [sub<GG|[(x @ ins[1])*(x @ f @ ins[2]):x in Generators(G)]>:
>   f in outers];
> [IsMaximal(GG, m) : m in diags];
[ true, true, true, true ]
> IsConjugate(GG, diags[2], diags[4]);
false
```

The other five tests for conjugacy will give similarly negative results.

67.8 Holomorphs

Given a group G and the full group of automorphisms A of G then the holomorph of G is the semidirect product $G \times_\theta A$, where $\theta : A \to Aut(G)$ is the identity map.

`Holomorph(G)`

`Holomorph(GrpFP, G)`

Given a finite permutation, matrix or pc-group G with full group of automorphisms A, this function returns the semidirect product E of G by A. The group E is returned as a permutation group (or a finitely presented group if `GrpFP` is specified) of degree $|G|$ in which G is a regular normal subgroup, and A is the stabilizer of the point 1. The embedding map $G \to E$, and the natural epimorphism $E \to A$ are also returned. In the returned group E, the generators of G appear first, followed by those of A.

`Holomorph(G, A)`

`Holomorph(GrpFP, G, A)`

Given a finite permutation, matrix or pc-group G and a group of automorphisms A, this function returns the semidirect product E of G by A. The group E is returned as a permutation group (or a finitely presented group if `GrpFP` is specified) of degree $|G|$ in which G is a regular normal subgroup, and A is the stabilizer of the point 1. The embedding map $G \to E$, and the natural epimorphism $E \to A$ are also returned. In the returned group E, the generators of G appear first, followed by those of A.

Example H67E9

We construct the holomorph of the group $G = PGL(2, 9)$.

```
> G := PGL(2, 9);
> E := Holomorph(G); E;
Permutation group E acting on a set of cardinality 720
> #E;
1036800
> CompositionFactors(E);
    G
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Alternating(6)
    *
    |  Alternating(6)
    1
```

68 COHOMOLOGY AND EXTENSIONS

Chapter 68
COHOMOLOGY AND EXTENSIONS

68.1 Introduction

The following collection of cohomology functions is designed to provide a flexible set of tools for computing with first and second cohomology groups of any type of finite group acting on any reasonable module, including a module defined by an action on an arbitrary finitely generated abelian group. First (but not second) cohomology groups can also be calculated for infinite groups defined by a finite presentation.

Zero-cocycles, one-cocycles and two-cocycles may be computed and identified. Extensions of modules by groups can be constructed as finitely presented groups, or as PC-groups when the acting group is a PC-group. It is also possible to compute a representative set of extensions of the module by the group each of which is distinct up to a group isomorphism fixing the module. These functions complement, but do not completely supplant, an older collection of functions pertaining to cohomology groups, Schur multiplicators and covering groups which apply to permutation groups (see Chapter 58 on Permutation Groups).

The first cohomology group $H^1(G, M)$ is calculated as the nullspace of a certain matrix. The details can be found in Section 5 of [CCH01]. This immediately allows manipulation and identification of one-cocycles. The second cohomology group $H^2(G, M)$ is more difficult to compute. While it can also be found as the nullspace of a suitable matrix, this matrix can be uncomfortably large in big examples. For soluble groups defined by a PC-presentation, the matrix corresponds to solving the consistency equations for a PC-presentation of a general extension of the module by the group, which depends on the number of group generators rather than its order, and is manageable for quite large groups. For permutation and matrix groups G, the size of the matrix for which the nullspace is required is much larger, but can often be reduced to a reasonable size by using a base and strong generating set for G. In the case where only the dimension of $H^2(G, M)$ is required, and M is a module over a finite field of prime order p, then the calculation of this dimension can be reduced to the determination of $H^2(Q, M)$ for a suitable collection of p-subgroups Q of G. The latter calculation can be carried out efficiently using the PC-presentation approach (see [Hol85b] for details).

To use the new functions, the user must initially invoke the function `CohomologyModule`, which creates a special object for the group action corresponding to the module, and all subsequent (new) cohomology functions take this object as their first argument.

In the case of a finite permutation or matrix group G acting on a module M over a prime field, the dimension of $H^2(G, M)$ may be found much more quickly by executing `CohomologicalDimension(CM, 2)`, where CM is the cohomology module for the action of G on M, rather than by invoking `Dimension(CohomologyGroup(CM, 2))`. However, the

former call does not allow the possibility of subsequent calculations with two-cocycles or extensions.

The equivalent older function, `CohomologicalDimension(G, M, 2);` (for a permutation group G) is often faster still for small examples, but the new function will succeed on much larger examples than the old. For the convenience of the reader, some of these older functions are described in this section of the Handbook. For complete details about the older functions, see the section on cohomology in the chapter on Permutation Groups.

68.2 Creation of a Cohomology Module

In order to compute the cohomology of a group with respect to a G-module M, it is first necessary to construct a data structure known as a *cohomology module*.

`CohomologyModule(G, M)`

Given a group G and a G-module M with acting group G this function returns a cohomology module for the action of G. The group G may be a finite permutation group, a finite matrix group, a PC-group, or any finitely presented group. For the PC-group case, however, the PC-presentation of G must be conditioned. This can be achieved by first executing the statement `G := ConditionedGroup(G);`

`CohomologyModule(G, Q, T)`

Let G be a group which acts on a finitely-generated abelian group with invariants given by the sequence Q, and action described by T. The action T is given in the form of a sequence of $d \times d$ matrices over the integers, where d is the length of T, and `T[i]` defines the action of the i-th generator of G on the abelian group. The function returns a cohomology module for the action of G. The group G may be a finite permutation group, a finite matrix group, a PC-group or any finitely presented group. For the PC-group case, however, the PC-presentation of G must be conditioned. This can be achieved by first executing the statement `G := ConditionedGroup(G);`

Example H68E1

We construct the cohomology module for $PSL(3,2)$ acting on a module of dimension 3 over $GF(2)$. We first need to find a module of dimension 3.

```
> G := PSL(3, 2);
> Irrs := AbsolutelyIrreducibleModules(G, GF(2));
> Irrs;
[
    GModule of dimension 1 over GF(2),
    GModule of dimension 3 over GF(2),
    GModule of dimension 3 over GF(2),
    GModule of dimension 8 over GF(2)
]
> M := Irrs[2];
> CM := CohomologyModule(G, M);
```

```
> CM;
Cohomology Module
```

`CohomologyModule(G, A, M)`

For a permutation group G acting on some abelian group A through M, compute the cohomology module. M has to be either a map from G into the endomorphisms of A, or a sequence of endomorphisms of A, one for each of the generators of G.

68.3 Accessing Properties of the Cohomology Module

The functions described in this section merely return data used to define the cohomology module. In each case, the argument CM must be a cohomology module returned by a call to `CohomologyModule`.

`Module(CM)`

The $K[G]$-module used to define the cohomology module CM. An error occurs if CM was defined by an action on a finitely generated abelian group.

`Invariants(CM)`

Given a cohomology module CM that was defined by an action on a finitely generated abelian group A, return the invariants of A. If CM was not defined by an action on an abelian group, an error results.

`Dimension(CM)`

Let CM be a cohomology module. If CM was defined by the action of a group on an R-module M, return the dimension of M. In the case in which CM was defined by the action of a group on a finitely generated abelian group A, the rank of A is returned.

`Ring(CM)`

The ring over which the module used to define the cohomology module CM is defined. If CM is defined in terms of an action on a finitely generated abelian group A, then the ring will be the integers if A is infinite, and the integers modulo the exponent of A if A is finite.

`Group(CM)`

The group used to define action on the cohomology module CM.

`FPGroup(CM)`

Given a cohomology module CM with associated group G, return a finitely presented group F isomorphic to G and the isomorphism from F to G. This presentation is on a strong generating set if G is a permutation or matrix group. It is used in the construction of presentations of extensions returned by the function `Extension`.

`MatrixOfElement(CM, g)`

The matrix representing the action of the element g in the group of CM on the module of CM.

68.4 Calculating Cohomology

`CohomologyGroup(CM, n)`

Given a cohomology module CM for the group G acting on the module M and a non-negative integer n taking one of the values 0, 1 or 2, this function returns the cohomology group $H^n(G, M)$. For modules defined over the ring of integers only, n may also be equal to 3. (In this case, $H^3(G, M)$ is computed as the second cohomology group of M regarded as a module over Q/Z.) If the group used to define CM was a finitely presented group, then n may only be equal to 0 or 1. Note that CM must be a module returned by invoking `CohomologyModule`.

`CohomologicalDimension(CM, n)`

Given a cohomology module CM for the group G acting on the module M defined over a finite field K and a non-negative integer n taking one of the values 0, 1 or 2, this function returns the dimension of $H^n(G, M)$ over K. Note that this function may only be applied to the module returned by a call to `CohomologyModule(G, M)`, where M is a module over a finite field K. When $n = 2$, this function is faster and may be applied to much larger examples than `CohomologyGroup(CM, n)` but, unlike that function, it does not enable the user to compute with explicit extensions and two-cocycles.

Note that there are some alternative functions for performing these calculations described in other manual chapters.

`CohomologicalDimension(M, n)`

For $K[G]$-module M (with K a finite field and G a finite group), compute and return the K-dimension of the cohomology group $H^n(G, M)$ for $n \geq 0$. For $n = 0$ and 1, this is carried out by using the function `CohomologicalDimension(CM,n)` just described. For $n \geq 2$, it is done recursively using projective covers and dimension shifting to reduce to the case $n = 1$.

`CohomologicalDimensions(M, n)`

For $K[G]$-module M (with K a finite field and G a finite group), compute and return the sequence of K-dimensions of the cohomology groups $H^k(G, M)$ for $1 \leq k \leq n$. On account of the recursive method used, this is quicker than computing them all individually.

`CohomologicalDimension(G, M, n)`

Given the permutation group G, the $K[G]$-module M and an integer n (equal to 1 or 2), return the dimension of the n-th cohomology group of G acting on M. *Note that K must be a finite field of prime order.* This function invokes Derek Holt's original C cohomology code (see [Hol85b]). In some cases it will be faster than the function that uses the cohomology module data structure.

Example H68E2

We examine the first and second cohomology groups of the group A_8.

```
> G := Alt(8);
> M := PermutationModule(G, GF(3));
```

We first calculate the dimensions of $H^1(G, M)$ and $H^2(G, M)$ using the old functions.

```
> time CohomologicalDimension(G, M, 1);
0
Time: 0.020
> time CohomologicalDimension(G, M, 2);
1
Time: 0.020
```

We now recalculate the dimensions of $H^1(G, M)$ and $H^2(G, M)$ using the new functions.

```
> X := CohomologyModule(G, M);
> time CohomologicalDimension(X, 1);
0
Time: 0.020
> time CohomologicalDimension(X, 2);
1
Time: 0.920
> X := CohomologyModule(G, M);
> time C:=CohomologyGroup(X, 2);
Time: 4.070
> C;
Full Vector space of degree 1 over GF(3)
```

Example H68E3

In the case of $\Omega^-(8, 3)$ acting on its natural module, the new function succeeds, but the old function does not.

```
> G := OmegaMinus(8, 3);
> M := GModule(G);
> X := CohomologyModule(G, M);
> time CohomologicalDimension(X, 2);
2
Time: 290.280
> phi, P := PermutationRepresentation(G);
```

```
> MM := GModule(P, [ActionGenerator(M, i): i in [1..Ngens(G)]] );
>  time CohomologicalDimension(P, MM, 2);
Out of space.
>> time CohomologicalDimension(P, MM, 2);
                                ^
Runtime error in 'CohomologicalDimension': Cohomology failed
```

68.5 Cocycles

Before invoking the functions in this section, it is necessary to first invoke the function `CohomologyGroup(CM, n)` for the appropriate n.

For $n = 0, 1$ or 2, an *n-cocycle* is a function from G^n to the module M, where elements of G^n are represented as an n-tuple $\langle g_1, \ldots, g_n \rangle$ of group elements, for which a certain relation is satisfied. These relations are consistent with the MAGMA convention of the use of right actions, and so they are slightly different from those encountered in many textbooks, where left actions are more common.

0-, 1- and 2-cocycles z, o and t, respectively, satisfy the following relations for all $g, h, \in G$.

$$z(\langle\rangle)^g = z(\langle\rangle);$$

$$o(\langle gh \rangle) = o(\langle g \rangle)^h + o(\langle h \rangle);$$

$$t(\langle gh, k \rangle) + t(\langle g, h \rangle)^k = t(\langle g, hk \rangle) + t(\langle h, k \rangle).$$

`ZeroCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and an element s of the cohomology group $H^0(G, M)$ associated with CM, this function returns the corresponding zero-cocycle. The zero-cocycle is returned as a function of the 0-tuple $\langle\rangle$, of which the image is an element of the fixed point submodule of M. The argument s may either be given as an element of $H^0(G, M)$ or as a sequence of integers defining such an element.

`IdentifyZeroCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and a zero-cocycle given as a function of the 0-tuple $\langle\rangle$, of which the image is an element of the fixed point submodule of M, this function returns the corresponding element of $H^0(G, M)$. Hence this function is the inverse function to `ZeroCocycle`.

`OneCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and an element s of the cohomology group $H^1(G, M)$ associated with CM, the function returns a corresponding one-cocycle. The one-cocycle is returned as a function from G to the module M, where elements g of G are represented as 1-tuples $\langle g \rangle$. The argument s may either be given as an element of $H^1(G, M)$ or as a sequence of integers defining such an element.

`IdentifyOneCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and a one-cycle s for CM, specified as a function from G to the module M (where elements g of G are represented as 1-tuples $\langle g \rangle$), this function returns the corresponding element of $H^1(G, M)$. Thus, the function is the inverse to `OneCocycle`.

`IsOneCoboundary(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and a one-cycle s for CM, specified as a function from G to the module M (where elements g of G are represented as 1-tuples $\langle g \rangle$), this function determines whether the cocyle is a 1-coboundary; that is, whether it corresponds to the zero element of $H^1(G, M)$. If so, then it also returns a corresponding 0-cochain $t(\langle\rangle)$ that satisfies $s(\langle g \rangle) = t(\langle\rangle) - t(\langle\rangle)^g$ for all $g \in G$.

`TwoCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and an element s of the cohomology group $H^2(G, M)$ associated with CM, the function returns a corresponding two-cocycle. The two-cocycle is returned as a function from $G \times G$ to the module M, where elements of $G \times G$ are represented as 2-tuples $\langle g_1, g_2 \rangle$. The argument s may either be given as an element of $H^2(G, M)$ or as a sequence of integers defining such an element.

`IdentifyTwoCocycle(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and a two-cycle s for CM, specified as a function from $G \times G$ to the module M (where elements of $G \times G$ are represented as 2-tuples $\langle g_1, g_2 \rangle$), this function returns the corresponding element of $H^2(G, M)$. Thus, the function is the inverse to `TwoCocycle`.

`IsTwoCoboundary(CM, s)`

Given a cohomology module CM constructed from the $K[G]$-module M and a two-cycle s for CM, specified as a function from G to the module M (where elements of $G \times G$ are represented as 2-tuples $\langle g_1, g_2 \rangle$), this function determines whether the cocyle is a 2-coboundary; that is, whether it corresponds to the zero element of $H^2(G, M)$. If so, then it also returns a corresponding 1-cochain $t(\langle g \rangle)$ that satisfies $s(\langle g, h \rangle) = t(\langle g \rangle)^h + t(\langle h \rangle) - t(\langle gh \rangle)$ for all $g, h \in G$.

Example H68E4

An easy example where the module is an abelian group defined by its invariant factors.

```
> G := PermutationGroup< 4 | (1,2,3,4) >;
> invar:=[2,4,4];
> mats := [ Matrix(Integers(),3,3,[1,2,0,0,0,1,0,1,2]) ];
> X := CohomologyModule(G,invar,mats);
> C := CohomologyGroup(X,0);
> C;
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 4 ]
> ZeroCocycle(X,[3]);
function(tp) ... end function
> IdentifyZeroCocycle(X,func<x|-$1(<>)>);
(1)
> C := CohomologyGroup(X,1);
> C;
Full Quotient RSpace of degree 2 over Integer Ring
Column moduli:
[ 2, 2 ]
> z1 := OneCocycle(X,[1,0]);
> z2 := OneCocycle(X,[0,1]);
> z1(<G.1>);
(1 0 0)
> z := func< x | z1(x)+z2(x) >;
> IdentifyOneCocycle(X,z);
(1 1)
> C := CohomologyGroup(X,2);
> C;
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 4 ]
> z1 := TwoCocycle(X,[1]);
> z1(<G.1,G.1^2>);
(1 1 3)
> z := func< xy | z1(xy)+z1(xy) >;
> IdentifyTwoCocycle(X,z);
(2)
```

68.6 The Restriction to a Subgroup

`Restriction(CM, H)`

Given a cohomology module for a group G and a subgroup H of G, form the restriction of the input cohomology module to H.

Note that, denoting this restriction by CMH, we can define the restriction maps on the first and second cohomology groups of CM by

```
>  res1 := hom<CohomologyGroup(CM, 1) -> CohomologyGroup(CMH, 1) |
>                          x:->IdentifyOneCocycle(CMH,OneCocycle(CM,x)) >;
>  res2 := hom<CohomologyGroup(CM, 2) -> CohomologyGroup(CMH, 2) |
>                          x:->IdentifyTwoCocycle(CMH,TwoCocycle(CM,x)) >;
```

Example H68E5

In this example we define G to be the group $GL(3,2)$ and H to be the Sylow 2-subgroup of G. We illustrate how to calculate the restriction mappings of $H^n(G,M)$ to $H^n(G,MH)$, where MH is the restriction of M to H.

```
> G := GL(3, 2);
> M := GModule(G);
> H := Sylow(G, 2);
> CG := CohomologyModule(G, M);
> CH := Restriction(CG, H);
```

We first consider $H^1(G,M)$.

```
> H1G := CohomologyGroup(CG, 1); H1G;
Full Vector space of degree 1 over GF(2)
> H1H := CohomologyGroup(CH, 1); H1H;
Full Vector space of degree 2 over GF(2)
> res1 := hom<H1G -> H1H | x:->IdentifyOneCocycle(CH,OneCocycle(CG,x)) >;
> res1(H1G.1);
(1 1)
```

We now consider $H^2(G,M)$.

```
> H2G := CohomologyGroup(CG, 2); H2G;
Full Vector space of degree 1 over GF(2)
> H2H := CohomologyGroup(CH, 2); H2H;
Full Vector space of degree 3 over GF(2)
> res2 := hom<H2G -> H2H | x:-> IdentifyTwoCocycle(CH,TwoCocycle(CG,x)) >;
> res2(H2G.1);
(0 0 1)
```

In the case of a zero restriction, we can find a corresponding coboundary.

```
> H:=sub< G | G.2, G.2^(G.1*G.2*G.1) >;
> #H;
21
```

```
> CH := Restriction(CG, H);
> CohomologyGroup(CH, 1); CohomologyGroup(CH, 2);
Full Vector space of degree 0 over GF(2)
Full Vector space of degree 0 over GF(2)
> t:=TwoCocycle(CG,[1]);
> isc, o := IsTwoCoboundary(CH, t);
> isc;
true
> forall{ <h,k> : h in H, k in H | t(<h,k>) eq
>            o(<h>)*MatrixOfElement(CH,k) + o(<k>) - o(<h*k>) };
true
```

68.7 Other Operations on Cohomology Modules

`CorestrictionMapImage(G, C, c, i)`

`CorestrictCocycle(G, C, c, i)`

Given an i-cochain c for the cohomology module C which has to be defined wrt. to some subgroup U of G, return the corestriction of c to $H^i(G, \ldots)$.

`InflationMapImage(M, c)`

`LiftCocycle(M, c)`

`NewCodomain`	ANY	*Default :* `false`
`Level`	RNGINTELT	*Default :* `false`

Given a cochain $c : G^i \to X$ and a (transversal) map $H \to G$, return the inflation (lift) of c to H, ie. a cochain $d : H^i \to X$ defined by $d(h) := c(M(h))$. If `Level` is given c is assumed to be in the cohomology group of that level, ie. i :=`Level`. If `Level` is not specified, MAGMA tries its best to guess the correct level.

If `NewCodomain` is given, the values of d are coerced into this structure.

`CoboundaryMapImage(M, i, c)`

For a cohomology module M, a level i and a i-cochain c (as a user program), return a $i+1$-coboundary as obtained from the cohomological coboundary operator.

68.8 Constructing Extensions

`Extension(CM, s)`

Given the cohomology module CM for the group G acting on the module M and an element s of $H^2(G, M)$, this function returns the corresponding extension E of the module M by G as a finitely presented group. The generators of E are chosen so that the generators of the acting group G (or rather strong generators for G when G is a permutation or matrix group) come first, and the generators of M come last. The argument s should be either an element of $H^2(G, M)$ or a sequence of integers defining such an element.

The projection from E to G and the injection from an abelian group isomorphic to M to E are also returned.

This function may only be applied when the module M used to define CM is defined over a finite field of prime order, the integers, or as an abelian group in a call of `CohomologyModule(G, Q, T)`.

`SplitExtension(CM)`

Given the cohomology module CM for the group G acting on the module M, this function returns the split extension E of the module M by G as a finitely presented group. The generators of E are chosen so that the generators of the acting group G (or strong generators for G when G is a permutation or matrix group) come first, and the generators of M come last. The extension returned is the same as for `Extension(CM, s)` with s taken as the zero element of $H^2(G, M)$, but `SplitExtension` is much faster, and does not require $H^2(G, M)$ to be calculated first. This function will also work when the group used to define CM was a finitely presented group.

The projection from E to G and the injection from an abelian group isomorphic to M to E are also returned.

This function may only be applied when the module M used to define CM is defined over a finite field of prime order, the integers, or as an abelian group in a call of `CohomologyModule(G, Q, T)`.

`pMultiplicator(G, p)`

Given the permutation group G and a prime p dividing the order of G, return the invariant factors of the p-part of the Schur multiplicator of G. This function calls Derek Holt's original cohomology code (see [Hol84]).

`pCover(G, F, p)`

Given the permutation group G and the finitely presented group F such that G is an epimorphic image of F in the sense described below, and a prime p, return a presentation for the p-cover of G, constructed as an extension of the p-multiplier by F. Note that the epimorphism of F onto G must satisfy the conditions that, firstly, the generators of F are in one-to-one correspondence with those of G and, secondly, the relations of F are satisfied by the generators of G. In other words, the mapping

taking the i-th generator of F to the i-th generator of G must be an epimorphism. Usually this mapping will be an isomorphism, although this is not mandatory. This function calls Derek Holt's original cohomology code (see [Hol85a]).

Example H68E6

We apply the machinery to construct a non-split extension of the elementary abelian group of order 3^8 by A_8.

```
> G := Alt(8);
> M := PermutationModule(G,GF(3));
> X := CohomologyModule(G,M);
> C := CohomologyGroup(X,2);
> C;
Full Vector space of degree 1 over GF(3)
```

The function `Extension` is used to construct a non-split extension E of the module M by the group G.

```
> E := Extension(X,[1]);
```

The object E is a finitely presented group, in which the 8 module generators come last. We now construct a (rather large-degree) faithful permutation representation of E.

```
> n := Ngens(E);
> D := sub< E | [E.i : i in [n-7..n-1]] >;
> ct := CosetTable(E,D:CosetLimit:=10^6,Hard:=true);
> P := CosetTableToPermutationGroup(E,ct);
> Degree(P);
60480
> #P eq 3^8 * #G;
true
```

We extract the normal subgroup of order 3^8 of the extension E, and verify that the extension is non-split.

```
> Q := sub<P | [P.i : i in [n-7..n]] >;
> #Q eq 3^8;
true
> IsNormal(P,Q);
true
> Complements(P,Q);
[]
```

Example H68E7

We investigate the cohomology of the permutation module for A_5 taken over the integers.

```
> G := Alt(5);
> M := PermutationModule(G,Integers());
> X := CohomologyModule(G,M);
```

```
> CohomologyGroup(X,0);
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 0 ]
> CohomologyGroup(X,1);
Full Quotient RSpace of degree 0 over Integer Ring
Column moduli:
[ ]
> CohomologyGroup(X,2);
Full Quotient RSpace of degree 1 over Integer Ring
Column moduli:
[ 3 ]
```

While we can form extensions of M in this case, we are unable to determine the distinct extensions.

```
> E := Extension(X,[1]);
> E;
Finitely presented group E on 8 generators
Relations
    (E.4, E.5) = Id(E)
    (E.4, E.6) = Id(E)
    (E.4, E.7) = Id(E)
    (E.4, E.8) = Id(E)
    (E.5, E.6) = Id(E)
    (E.5, E.7) = Id(E)
    (E.5, E.8) = Id(E)
    (E.6, E.7) = Id(E)
    (E.6, E.8) = Id(E)
    (E.7, E.8) = Id(E)
    (E.1, E.4^-1) = Id(E)
    (E.1, E.5^-1) = Id(E)
    E.1^-1 * E.6 * E.1 * E.7^-1 = Id(E)
    E.1^-1 * E.7 * E.1 * E.8^-1 = Id(E)
    E.1^-1 * E.8 * E.1 * E.6^-1 = Id(E)
    E.2^-1 * E.4 * E.2 * E.5^-1 = Id(E)
    E.2^-1 * E.5 * E.2 * E.6^-1 = Id(E)
    E.2^-1 * E.6 * E.2 * E.4^-1 = Id(E)
    (E.2, E.7^-1) = Id(E)
    (E.2, E.8^-1) = Id(E)
    (E.3, E.4^-1) = Id(E)
    E.3^-1 * E.5 * E.3 * E.6^-1 = Id(E)
    E.3^-1 * E.6 * E.3 * E.7^-1 = Id(E)
    E.3^-1 * E.7 * E.3 * E.5^-1 = Id(E)
    (E.3, E.8^-1) = Id(E)
    E.1^-3 * E.4^-1 * E.5^-2 = Id(E)
    (E.1^-1 * E.3^-1)^2 = Id(E)
    E.3^-3 * E.4 * E.8^2 = Id(E)
    E.2^-1 * E.1 * E.3^-1 * E.2 * E.1^-1 * E.4^-1 * E.8^2 = Id(E)
    E.2 * E.3 * E.2 * E.3 * E.8^-4 = Id(E)
```

```
    E.2^-1 * E.3^-1 * E.2^2 * E.3^-1 * E.4 * E.5 * E.6^-2 * E.7 = Id(E)
> DE := DistinctExtensions(X);
Sorry, can only compute distinct extensions over prime field or finite abelian
group
```

68.9 Constructing Distinct Extensions

The functions below compute the distinct extensions of one group by another.

`DistinctExtensions(CM)`

Given the cohomology module CM for the group G acting on the module M, this function returns a sequence containing all of the distinct extensions of the module M by G, each in the form returned by `Extension(CM, s)`. Two such extensions E_1, E_2 are regarded as being distinct if there is no group isomorphism from one to the other that maps the subgroup of E_1 corresponding to M to the subgroup of E_2 corresponding to M.

This function may only be applied when the module M used to define CM is defined over a finite field of prime order, the integers, or as an abelian group in a call of `CohomologyModule(G, Q, T)`.

Example H68E8

We consider the extensions of the trivial module over $GF(2)$ by the group $Z_2 \times Z_2$.

```
> G := DirectProduct(CyclicGroup(2),CyclicGroup(2));
> M := TrivialModule(G,GF(2));
> C := CohomologyModule(G,M);
> CohomologicalDimension(C,2);
3
> D := DistinctExtensions(C);
> #D;
4
```

So there are $2^3 = 8$ equivalence classes of extensions. But only four are distinct up to an isomorphism fixing the module. To examine them, we form permutation representations:

```
> DP := [ CosetImage(g,sub<g|>) : g in D ];
> [IsAbelian(d): d in DP];
[ true, true, false, false ]
// the first two are abelian
> [IsIsomorphic(d,DihedralGroup(4)) : d in DP];
[ false, false, true, false ]
// The third one is dihedral
> #[g : g in DP[4] | Order(g) eq 4];
6
```

So the fourth group must be the quaternion group.

`ExtensionsOfElementaryAbelianGroup(p, d, G)`

Given a prime p, a positive integer d, and a permutation group G, this function returns a list of finitely presented groups which are isomorphic to the distinct extensions of an elementary abelian group N of order p^d by G. Two such extensions E_1 and E_2 with normal subgroups N_1 and N_2 isomorphic to N are considered to be distinct if there is no group isomorphism $G_1 \to G_2$ that maps N_1 to N_2. Each extension E is defined on $d+r$ generators, where r is the number of generators of G. The last d of these generators generate the normal subgroup N, and the quotient of E by N is a presentation of G on its own generators.

Example H68E9

We form the distinct extensions of the elementary abelian group $Z_2 \times Z_2$ by the alternating group A_4.

```
> E := ExtensionsOfElementaryAbelianGroup(2,2,Alt(4));
> #E;
4
```

So there are four distinct extensions of an elementary group of order 4 by A_4

```
> EP := [ CosetImage(g,sub<g|>) : g in E ];
> [#Centre(e): e in EP];
[ 1, 1, 4, 4 ]
```

The first two have nontrivial action on the module. The module generators in the extensions come last, so these will be $e.3$ and $e.4$. We can use this to test which of the extensions are non-split.

```
> [ Complements(e,sub<e|e.3,e.4>) eq [] : e in EP];
[ false, true, false, true ]
> AbelianInvariants(Sylow(EP[2],2));
[ 4, 4 ]
```

So the first and fourth extensions split and the second and third do not. $EP[2]$ has a normal abelian subgroup of type $[4, 4]$.

`ExtensionsOfSolubleGroup(H, G)`

Given permutation groups G and H, where H is soluble, this function returns a sequence of finitely presented groups, the terms of which are isomorphic to the distinct extensions of H by G. Two such extensions E_1 and E_2 with normal subgroups H_1 and H_2 isomorphic to H are considered to be distinct if there is no group isomorphism $G_1 \to G_2$ that maps H_1 to H_2. Each extension E is defined on $d + r$ generators, where the last d generators generate the normal subgroup H, and the quotient of E by H is a presentation for G on its own generators. (The last d generators of E do not correspond to the original generators of H, but to a PC-generating sequence for H.)

Example H68E10

How many extensions are there of a dihedral group of order 8 by itself? This calculation is currently rather slow.

```
> D4 := DihedralGroup(4);
> time S := ExtensionsOfSolubleGroup(D4, D4);
Time: 120.210
> #S;
20
> ES := [CosetImage(g,sub<g|>) : g in S ];
> [#Centre(g): g in ES];
[ 4, 2, 4, 2, 4, 2, 2, 4, 2, 4, 4, 2, 4, 2, 4, 2, 4, 2, 4, 2 ]
> [NilpotencyClass(g) : g in ES ];
[ 2, 3, 2, 3, 2, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3, 3 ]
> [Exponent(g): g in ES];
[ 4, 8, 4, 8, 4, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8, 8 ]
```

Example H68E11

We determine the distinct extensions of the abelian group with invariants $[2, 4, 4]$ by the cyclic group of order 4.

```
> Z := Integers();
> G := PermutationGroup<4 | (1,2,4,3)>;
> Q := [2, 4, 4];
> T := [ Matrix(Z,3,3,[1,2,0,0,0,1,0,1,2]) ];
> CM := CohomologyModule(G, Q, T);
> extns := DistinctExtensions(CM);
> extns;
[
    Finitely presented group on 4 generators

        $.1^-1 * $.4 * $.1 * $.4^-2 * $.3^-1 = Id($)
        $.1^4 * $.3^-2 * $.4^-2 = Id($)
]
```

Since the extensions are soluble groups, we construct pc-presentations of each and verify that no two of the groups are isomorphic.

```
> E1 := SolubleQuotient(extns[1]);
> E2 := SolubleQuotient(extns[2]);
> E3 := SolubleQuotient(extns[3]);
> IsIsomorphic(E1, E2);
false
> IsIsomorphic(E1, E3);
false
> IsIsomorphic(E2, E3);
false
```

`IsExtensionOf(G)`

`Degree`	RngInt	*Default :* 0
`MaxId`	RngInt	*Default :* 15
`DegreeBound`	RngInt	*Default :* ∞

For a given permutation group G, find normal abelian subgroup $A < G$ such that G can be obtained by extending G/A by A. The function returns a sequence of tuples T containing

- the cohomology module of G/A acting on A
- the 2-cocyle as an element in $H^2(G/A, A)$ corresponding to G
- the actual 2-cocyle as a user defined function

- a pair $\langle a, b\rangle$ giving the degree a of the transitive group G/A and the number b identifying the group in the data base. If b is larger than 20 (or `MaxId`) the hash value of the group is returned instead.
- the abelian invariants of A
- a set containing all pairs $\langle a, b\rangle$ such that ${}_aT_b$ can be obtained through this extension process.

If `DegreeBound` is given, only subgroups A are considered such that G/A has less than `DegreeBound` many elements. The list considered contains only sugroups that are maximal under the restrictions. If `Degree` is given, G/A must have exactly `Degree` many elements.

`IsExtensionOf(L)`

`Degree`	RngInt	*Default :* 0
`MaxId`	RngInt	*Default :* 15
`DegreeBound`	RngInt	*Default :* ∞

For all groups G in L, `IsExtensionOf` is called. The first sequence returned contains tuples as in `IsExtensionOf` above. The sequence is minimal such that all groups in L can be generated using the cohomology modules in the sequence. The second return value contains a set of pairs $\langle a, b\rangle$ describing all transitive groups that can be obtained through the processes.

68.10 Finite Group Cohomology

This section describes Magma functions for computing the first cohomology group of a finite group with coefficient in a finite (not necessarily abelian) group. These functions are based on [Hal05].

Let Γ be a group. A group A on which Γ acts by group automorphisms from the right, is called a Γ-*group*. Given a Γ-group A, define

$$H^0(\Gamma, A) := \{a \in A \mid a^\sigma = a \text{for all } \sigma \in \Gamma\}.$$

A 1-*cocycle of* Γ *on* A is a map

$$\alpha : \Gamma \to A, \quad \sigma \mapsto \alpha_\sigma,$$

such that

$$\alpha_{\sigma\tau} = (\alpha_\sigma)^\tau \alpha_\tau \quad \text{for all } \sigma, \tau \in \Gamma.$$

Two cocycles α, β on A are called *cohomologous* (with respect to a) if there exists $a \in A$, such that $\beta_\sigma = a^{-\sigma} \cdot \alpha_\sigma \cdot a$ for all $\sigma \in \Gamma$. Note that being cohomologous is an equivalence relation.

We denote by $Z^1(\Gamma, A)$ the set of all 1-cocycles of Γ on A. We denote by $[\alpha]$ the equivalence class of α and by $H^1(\Gamma, A)$ the set of equivalence classes of 1-cocycles.

$Z^1(\Gamma, A)$ and $H^1(\Gamma, A)$ are *pointed sets*.

The constant map $t : \sigma \mapsto 1$ is the distinguished element of $Z^1(\Gamma, A)$, called the *trivial* 1-*cocycle*. Its cohomology class is the distinguished element of $H^1(\Gamma, A)$.

A twisted form A_β of A by the cocycle $\beta \in Z^1(\Gamma, A)$ is the same group A but with a different action of Γ on it, given by

$$a * \sigma := a^{\sigma\alpha_\sigma} \quad \text{for } \sigma \in \Gamma \text{ and } a \in A.$$

68.10.1 Creation of Gamma-groups

This section describes intrinsics dealing with cocycles and the first cohomology.

`GammaGroup(Gamma, A, action)`

Given a group A and a group Γ acting on it by the map *action*, return the object of type `GGrp`, which is the Group A together with this particular action of Γ. The map *action* must be a homomorphism from Γ to the automorphism group of A.

If B is a normal subgroup of A and normalised by the action of Γ on A (thus a Γ-group itself), then the action of Γ on A induces in the natural way to A/B. It is possible to create such a group:

`InducedGammaGroup(A, B)`

Given a Γ-group A and a normal subgroup B normalised by the action of Γ, return the induced Γ-group A/B.

Example H68E12

Let Γ act on A by conjugation:

```
> A := SymmetricGroup(4);
> Gamma := sub<A|(1,2,3), (1,2)>;
> action := hom< Gamma -> Aut(A) |
>             g :-> iso< A -> A | a :-> a^g, a :-> a^(g^-1) > >;
> A := GammaGroup( Gamma, A, action );
> A;
Gamma-group:  Symmetric group acting on a set of cardinality 4
Order = 24 = 2^3 * 3
(1, 2, 3, 4)
(1, 2)
Gamma-action: Mapping from: GrpPerm: $, Degree 4 to
Set of all automorphisms of GrpPerm: $, Degree 4, Order 2^3 * 3
given by a rule [no inverse]
Gamma:        Permutation group acting on a set of cardinality 4
(1, 2, 3)
(1, 2)
>
```

and B be a normal subgroup of A:

```
> B := AlternatingGroup(4);
```

```
> AmodB := InducedGammaGroup( A, B );
> AmodB;
Gamma-group:  Symmetric group acting on a set of cardinality 2
Order = 2
(1, 2)
(1, 2)
Gamma-action: Mapping from: GrpPerm: $, Degree 4, Order 2 * 3 to
Set of all automorphisms of GrpPerm: $, Degree 2, Order 2
given by a rule [no inverse]
Gamma:        Permutation group acting on a set of cardinality 4
Order = 6 = 2 * 3
(1, 2, 3)
(1, 2)
Induced from another Gamma-group
```

`IsNormalised(B, action)`

Returns `true` if the group B is normalised by the action *action*, where *action* is as above.

`IsInduced(AmodB)`

Returns `true` iff the Γ-group *AmodB* was created as an induced Γ-group. If it is, then the Γ-groups A, B, the projection and representative maps are returned as well.

68.10.2 Accessing Information

`Group(A)`

Returns the group A as a `Grp` object to be used in MAGMA.

`GammaAction(A)`

Returns the action of Γ on A as a map.

`ActingGroup(A)`

Returns the group Γ acting on A.

68.10.3 One Cocycles

`OneCocycle(A, imgs)`

`OneCocycle(A, alpha)`

`Check` BoolElt *Default :* `true`

If the map $\alpha : \Gamma \to A$ or the sequence *imgs* of images of the generators $\Gamma.1, ..., \Gamma.n$ defines a 1-cocycle, return the 1-cocycle. By default, the map is checked to define a 1-cocycle. If it doesn't, `OneCocycle` will abort with an error. This check can be disabled by setting the optional argument `Check` to `false`.

`TrivialOneCocycle(A)`

Return the trivial 1-cocycle.

`IsOneCocycle(A, imgs)`

`IsOneCocycle(A, alpha)`

Return true if the map $\alpha : \Gamma \to A$ or the sequence *imgs* of images of the generators $\Gamma.1, ..., \Gamma.n$ defines a 1-cocycle and `false` otherwise. If `true`, return the cocycle as the second argument.

Note that `IsOneCocycle` does not abort with an error in contrast to `OneCocycle` if the map does not define a cocycle.

`AreCohomologous(alpha, beta)`

Return `true` if and only if the 1-cocycles α and β are cohomologous. If they are, return the intertwining element as the second return value.

`CohomologyClass(alpha)`

Return the cohomology class of the 1-cocycle α.

`InducedOneCocycle(AmodB, alpha)`

`InducedOneCocycle(A, B, alpha)`

Given a 1-cocycle on A, return the induced 1-cocycle on $AmodB$. The second version will generate the induced Γ-group A/B first.

`ExtendedOneCocycle(alpha)`

`OnlyOne` BoolElt *Default :* `false`

Given a 1-cocycle on an induced Γ-group A/B, return the set of all non-cohomologous 1-cocycles on A, which induce to α. If the optional argument `OnlyOne` is `true`, the set will contain at most one 1-cocycle. If α is not extendible, the returned set is empty.

`ExtendedCohomologyClass(alpha)`

Given a 1-cocycle on an induced Γ-group A/B, return the the set of all non-cohomologous 1-cocycles on A, which induce to a cocycle in the cohomology class of α. If no such cocycles on A exist, the returned set is empty.

`GammaGroup(alpha)`

Return the Γ-group on which α is defined.

`CocycleMap(alpha)`

Return the `Map` object corresponding to α.

68.10.4 Group Cohomology

`Cohomology(A, n)`

Given a finite group A and an integer n (currently restricted to being 1) return the n-th cohomology group $H^n(\Gamma, A)$. Since the group A is not assumed to be abelian, only $n = 0, 1$ can be used. Currently, only $n = 1$ implemented. (The zero cohomology of A is the subgroup of A centralised by Γ and can be constructed using group theoretical methods available in Magma.)

`OneCohomology(A)`

Return the first cohomology $H^1(\Gamma, A)$. as a set of representatives of all cohomology classes. If the group A is abelian, existing code by Derek Holt is used (see Chapter 68). Otherwise use [Hal05].

`TwistedGroup(A, alpha)`

Given the Γ-group A and a 1-cocycle α on it, return the twisted group A_α.

Example H68E13

First, we create the group $A = D_8$. The returned group is the usual permutation group on the octagon. Γ is the Normaliser of A in S_8 and is acting by conjugation.

```
> A := DihedralGroup(8);
> Gamma := sub< Sym(8) | (1, 2, 3, 4, 5, 6, 7, 8),
>    (1, 8)(2, 7)(3, 6)(4, 5), (2, 4)(3, 7)(6, 8) >;
> A^Gamma eq A;
true
> Gamma;
Permutation group Gamma acting on a set of cardinality 8
Order = 32 = 2^5
    (1, 2, 3, 4, 5, 6, 7, 8)
    (1, 8)(2, 7)(3, 6)(4, 5)
    (2, 4)(3, 7)(6, 8)
> action := hom< Gamma -> Aut(A) |
>             g :-> iso< A -> A | a :-> a^g, a :-> a^(g^-1) > >;
```

```
> A := GammaGroup( Gamma, A, action );
```

Now let B be the center of A and create the induced Γ-group A/B:

```
> B := Center(Group(A));
> AmodB := InducedGammaGroup(A, B);
```

Create the trivial 1-cocycle on A/B and compute its cohomology class:

```
> triv := TrivialOneCocycle(AmodB);
> CohomologyClass( triv );
{@
    One-Cocycle
    defined by [
    Id($),
    Id($),
    Id($)
    ],
    One-Cocycle
    defined by [
    Id($),
    (1, 4)(2, 7)(3, 8)(5, 6),
    (1, 4)(2, 7)(3, 8)(5, 6)
    ],
    One-Cocycle
    defined by [
    (1, 4)(2, 7)(3, 8)(5, 6),
    Id($),
    (1, 4)(2, 7)(3, 8)(5, 6)
    ],
    One-Cocycle
    defined by [
    (1, 4)(2, 7)(3, 8)(5, 6),
    (1, 4)(2, 7)(3, 8)(5, 6),
    Id($)
    ]
@}
```

Pick one of the cocycles in this class and compute the intertwining element:

```
> alpha := Random($1);alpha;
One-Cocycle
defined by [
(1, 4)(2, 7)(3, 8)(5, 6),
(1, 4)(2, 7)(3, 8)(5, 6),
Id($)
]
> bo, a := AreCohomologous(alpha,triv);
> bo; a;
true
```

```
(1, 5)(2, 8)(3, 7)(4, 6)
```

Now create another cocycle on A/B and extend it to A:

```
> alpha := OneCocycle( AmodB,
>                [Group(AmodB)| (1, 7, 4, 2)(3, 5, 8, 6),
>                               (1, 2, 4, 7)(3, 6, 8, 5),
>                               1 ] );
> ExtendedOneCocycle(alpha);
{
    One-Cocycle
    defined by [
    (1, 4, 7, 2, 5, 8, 3, 6),
    (1, 2, 3, 4, 5, 6, 7, 8),
    Id($)
    ],
    One-Cocycle
    defined by [
    (1, 8, 7, 6, 5, 4, 3, 2),
    (1, 6, 3, 8, 5, 2, 7, 4),
    Id($)
    ]
}
```

Pick a cocycle β in this set and check if it really induces to α:

```
> beta := Rep($1);
> InducedOneCocycle(AmodB, beta) eq alpha;
true
```

Finally, create the twisted group A_β:

```
> A_beta := TwistedGroup(A, beta);
> A_beta;
Gamma-group:  Permutation group acting on a set of cardinality 8
Order = 16 = 2^4
(1, 2, 3, 4, 5, 6, 7, 8)
(1, 8)(2, 7)(3, 6)(4, 5)
Gamma-action: Mapping from: GrpPerm: $, Degree 8, Order 2^5 to
Set of all automorphisms of GrpPerm: $, Degree 8, Order 2^4
given by a rule [no inverse]
Gamma:        Permutation group acting on a set of cardinality 8
Order = 32 = 2^5
(1, 2, 3, 4, 5, 6, 7, 8)
(1, 8)(2, 7)(3, 6)(4, 5)
(2, 4)(3, 7)(6, 8)
>
```

PART X
FINITELY-PRESENTED GROUPS

69 ABELIAN GROUPS

Chapter 69
ABELIAN GROUPS

69.1 Introduction

This Chapter contains a description of the MAGMA machinery provided for computing with abstract abelian groups. Such a group may be described either in terms of defining relations (category `GrpAb`) or by defining the group operations on some finite set (category `GrpAbGen`). In the case of finitely presented groups, the abelian groups may be finite and infinite, the only restriction being that the group be finitely generated.

69.2 Construction of a Finitely Presented Abelian Group and its Elements

69.2.1 The Free Abelian Group

`FreeAbelianGroup(n)`

Construct the free abelian group F on n generators, where n is a positive integer. The i-th generator may be referenced by the expression `F.i`, $i = 1, \ldots, n$. Note that a special form of the assignment statement is provided which enables the user to assign names to the generators of F. In this form of assignment, the list of generator names is enclosed within angle brackets and appended to the variable name on the *left hand side* of the assignment statement.

Example H69E1

The statement

```
> F := FreeAbelianGroup(2);
```

creates the free abelian group on two generators. Here the generators may be referenced using the standard names, $F.1$ and $F.2$.
The statement

```
> F<x, y> := FreeAbelianGroup(2);
```

defines F to be the free abelian group on two generators and assigns the names x and y to the generators.

69.2.2 Relations

`w1 = w2`

Given words w_1 and w_2 over the generators of an abelian group A, create the relation $w_1 = w_2$. Note that this relation is not automatically added to the existing set of defining relations R for S. It may be added to R, for example, through use of the `quo`-constructor (see below).

`r[1]`
`LHS(r)`

Given a relation r over the generators of A, return the left hand side of the relation r. The object returned is a word over the generators of A.

`r[2]`
`RHS(r)`

Given a relation r over the generators of A, return the right hand side of the relation r. The object returned is a word over the generators of A.

`Parent(r)`

Group over which the relation r is taken.

Example H69E2

We may define a group and a set of relations as follows:

```
> F<x, y> := FreeAbelianGroup(2);
> rels := { 2*x = 3*y, 4*x + 4*y = Id(F)} ;
```

To replace one side of a relation, the easiest way is to reassign the relation. So for example, to replace the relation $2x = 3y$ by $2x = 4y$:

```
> r := 2*x = 3*y;
> r := LHS(r) = 4*y;
```

69.2.3 Specification of a Presentation

An abelian group with non-trivial relations is constructed as a quotient of an existing abelian group, possibly a free abelian group.

```
AbelianGroup<  X | R  >
```

Given a list X of variables $x_1, \ldots, x_r$, and a list of relations R over these generators, let F be the free abelian group on the generators $x_1, \ldots, x_r$. Then construct (a) an abelian group A isomorphic to the quotient of F by the subgroup of F defined by R, and (b) the natural homomorphism $\phi : F \to A$.

Each term of the list R is either a *word*, a *relation*, a *relation list* or a *subgroup* of F.

- A *relation* consists of a pair of words, separated by '='.
- A *word* w is interpreted as a *relator*, that is, it is equivalent to the relation $w = 0$. (See above).
- A *relation list* consists of a list of words, where each pair of adjacent words is separated by '=': $w_1 = w_2 = \cdots = w_r$. This is interpreted as the set of relations $w_1 = w_r, \ldots, w_{r-1} = w_r$. Note that the relation list construct is only meaningful in the context of the `quo`-constructor.

A *subgroup* H appearing in the list R contributes its generators to the relation set for A, i.e., each generator of H is interpreted as a relator for A.

The group F may be referred to by the special symbol `$` in any word appearing to the right of the '`|`' symbol in the `quo`-constructor. Also, in the context of the `quo`-constructor, the identity element (empty word) may be represented by the digit 0. The function returns:

(a) The quotient group A;

(b) The natural homomorphism $\phi : F \to A$.

Example H69E3

We create the abelian group defined by the presentation $< a, b, c \mid 7a + 4b + c, 8a + 5b + 2c, 9a + 6b + 3c >$.

```
> F<a, b, c> := FreeAbelianGroup(3);
> A := quo< F | 7*a + 4*b + c, 8*a + 5*b + 2*c, 9*a + 6*b + 3*c >;
> A;
AbelianGroup isomorphic to Z_3 + Z
Defined on 2 generators
Relations:
    3*A.1 = 0
```

A simple way of specifying an abelian group is as a product of cyclic groups.

`AbelianGroup([n1,...,nr])`

Construct the abelian group defined by the sequence $[n_1, \ldots, n_r]$ of non-negative integers as an abelian group. The function returns the direct product of cyclic groups $C_{n_1} \times C_{n_2} \times \cdots \times C_{n_r}$, where C_0 is interpreted as an infinite cyclic group.

Example H69E4

We create the abelian group $Z_2 \times Z_3 \times Z_4 \times Z_5 \times Z_6 \times Z \times Z$.

```
> G<[x]> := AbelianGroup([2,3,4,5,6,0,0]);
> G;
Abelian Group isomorphic to Z/2 + Z/6 + Z/60 + Z + Z
Defined on 7 generators
Relations:
    2*G.1 = 0
    3*G.2 = 0
    4*G.3 = 0
    5*G.4 = 0
    6*G.5 = 0
```

69.2.4 Accessing the Defining Generators and Relations

The functions described here provide access to basic information stored for an abelian group A.

`A . i`

The i-th defining generator for A.

`Generators(A)`

A set containing the generators for A.

`NumberOfGenerators(A)`

`Ngens(A)`

The number of generators for A.

`Parent(u)`

The parent group A of the word u.

`Relations(A)`

A sequence containing the defining relations for A.

`RelationMatrix(A)`

A matrix where each row corresponds to one of the defining relations of A.

69.3 Construction of a Generic Abelian Group

The term generic abelian group refers to the situation in which a group A is described by giving a set X together with functions acting on X that perform the fundamental group operations for A. Specifically, the user must provide functions which compute the product, the inverse and the identity. For efficiency, the user may also optionally specify the order and a generating set for the group. This is made explicit below.

Going from such a definition of an abelian group A to a presentation for A will often be extremely expensive and so a small number of operations are implemented so as to not require this information. The two key operations are computing the order of an element and computing the discrete logarithm of an element to a given base. For many abelian group operations, knowledge of a presentation is required and if such an operation is invoked, the structure of A (and hence a presentation) will be automatically constructed.

There are two possible ways of computing the structure of the group. If the order of the group is known (or can be computed) then it is relatively easy to construct each of the p-Sylow subgroups. If the order is not available, the structure is computed from a set of generators supplied by the user.

69.3.1 Specification of a Generic Abelian Group

`GenericAbelianGroup(U: parameters)`

`IdIntrinsic`	MonStg	*Default :*
`AddIntrinsic`	MonStg	*Default :*
`InverseIntrinsic`	MonStg	*Default :*
`UseRepresentation`	Bool	*Default :* `false`
`Order`	RngIntElt	*Default :*
`UserGenerators`	SetEnum	*Default :*
`ProperSubset`	Bool	*Default :* `false`
`RandomIntrinsic`	MonStg	*Default :*
`ComputeStructure`	Bool	*Default :* `false`

Construct the generic abelian group A over the domain U. The domain U can be an aggregate (set, indexed set or sequence) of elements or it can be any structure, for example, an elliptic curve, a jacobian, a magma of quadratic forms.

If the parameters `IdIntrinsic`, `AddIntrinsic` and `InverseIntrinsic` are not set, then the identity, the composition and the inverse function of A are taken to be the identity, the composition and the inverse function of U or of `Universe(`U`)` if U is an aggregate. If the parameters `IdIntrinsic`, `AddIntrinsic` and `InverseIntrinsic` are set, they define the identity, the composition and the inverse function of A.

The parameter `IdIntrinsic` must be a function name whose sole argument is U or `Universe(`U`)` if U is an aggregate. `AddIntrinsic` must be a function name whose only two arguments are elements of U or of `Universe(`U`)` if U is

an aggregate. `InverseIntrinsic` must be a function name whose only two arguments are elements of U or of `Universe(`U`)` if U is an aggregate. That is, it is required that `InverseIntrinsic` be a binary operation (see the example below where `InverseIntrinsic := "/"` is indeed binary). Defining any of the three above parameters implies that the other two must be defined as well.

Setting the parameter `UseRepresentation` to true implies that all elements of A will be internally represented as linear combinations of the generators of A obtained while computing the structure of A. This can be a costly procedure, since such a representation is akin to solving the discrete logarithm problem. The advantage of such a representation is that arithmetic for elements of A as well as computing the order of elements of A are then essentially trivial operations.

The parameter `Order` can be set to the order of the group, if known. Knowledge of the order may save a considerable amount of time for operations such as computing a Sylow subgroup, determining the group structure or solve a discrete logarithm problem. More importantly, if A is a proper subset of U, or of `Universe(`U`)` if U is an aggregate, then one of `Order` or `UserGenerators` must be set.

One can set `UserGenerators` to some set of elements of U, or of `Universe(`U`)` if U is an aggregate, which generate the group A. This can be useful when A is a subset of U (`Universe(`U`)`), or more generally when the computation of the group structure of A is made from a set of generators. Finally, setting `UserGenerators` may be an alternative to setting `RandomIntrinsic`.

The parameter `ProperSubset` must be set when A is a proper subset of U (`Universe(`U`)`).

The parameter `RandomIntrinsic` indicates the random function to use. If it is not set, the random function (if it is required) is taken to be the random function applying to U (`Universe(`U`)`).

The parameter `RandomIntrinsic` must be the name of a function taking as its sole argument U (`Universe(`U`)`) and returning an element of U (`Universe(`U`)`) which is also an element of the group A, which is important when A is a proper subset of U (`Universe(`U`)`. Therefore, if A is a proper subset of U (`Universe(`U`)`), then `RandomIntrinsic` must be set, unless the parameter `UserGenerators` is set.

The parameter `Structure` indicates that the group structure should be determined at the time of creation. If this parameter is set then the user may also want to set the following parameters:

`UseUserGenerators`	BOOL	*Default :* `false`
`PollardRhoRParam`	RNGINT	*Default :* 20
`PollardRhoTParam`	RNGINT	*Default :* 8
`PollardRhoVParam`	RNGINT	*Default :* 3

Their meaning is detailed in Section 69.3.3.

Example H69E5

In our first example we create the subset U of $\mathbf{Z}/34384\mathbf{Z}$ corresponding to its unit group as a

generic abelian group G. Note that U is an indexed set.

```
> m :=  34384;
> Zm := Integers(m);
> U := {@ x : x in Zm | GCD(x, m) eq 1 @};
> G := GenericAbelianGroup(U :
>        IdIntrinsic := "Id",
>        AddIntrinsic := "*",
>        InverseIntrinsic := "/");
> G;
Generic Abelian Group over
Residue class ring of integers modulo 34384
```

In our next example we construct unique representatives for the classes of binary quadratic forms corresponding to elements of a subgroup of the class group of the imaginary quadratic field of discriminant -4000004.

```
> n := 6;
> Dk := -4*(10^n + 1);
> Q := QuadraticForms(Dk);
>
> p := 2;
> S := { };
> while #S lt 10 do
>    if KroneckerSymbol(Dk,p) eq 1 then
>       I := Reduction(PrimeForm(Q,p));
>       Include(~S, I);
>    end if;
>    p := NextPrime(p);
> end while;
>
> QF := GenericAbelianGroup(Q : UserGenerators := S,
>                               ComputeStructure := true,
>                               UseUserGenerators := true);
> QF;
Generic Abelian Group over
Binary quadratic forms of discriminant -4000004
Abelian Group isomorphic to Z/2 + Z/516
Defined on 2 generators
Relations:
  2*$.1 = 0
  516*$.2 = 0
```

So the structure of the subgroup is $Z_2 \times Z_{516}$

69.3.2 Accessing Generators

These functions give access to generating sets for a generic group A. If a generating set is requested and none has been supplied by the user then this will require the determination of the group structure which could be very expensive. Note the distinction between `Generators` and `UserGenerators`. From now on, unless otherwise specified, whenever mention is made of the generators of A, we refer to the generators as given by the `Generators` function.

`Universe(A)`

The universe over which the generic abelian group A is defined.

`A . i`

The i-th generator for the generic abelian group A.

`Generators(A)`

A sequence containing a generating set for the generic abelian group A as elements of A. The set of generators returned for A is a reduced set of generators as constructed during the structure computation. Therefore, if the group structure of A has been computed from a user-supplied set of generators, it is unlikely that `Generators(`A`)` and `UserGenerators(`A`)` will be the same.

`UserGenerators(A)`

A sequence containing the user-supplied generators for the generic abelian group A as elements of A.

`NumberOfGenerators(A)`

`Ngens(A)`

The number of generators for the generic abelian group A.

69.3.3 Computing Abelian Group Structure

If the order of a generic abelian group A can be obtained then the structure of A is found by constructing each p-Sylow subgroup of A. The p-Sylow subgroups are built from random elements of the underlying set X of A. Recall that U (`Universe(`U`)`) is the domain of A. Random elements are obtained using either a random function attached to X or using a user-supplied function (the `RandomIntrinsic` parameter), or using ser-supplied generators (the `UserGenerators` parameter). It is therefore vital that user-supplied generators truly generate the group one wishes to construct. A drawback of this method of obtaining the structure of A is the memory needed to store all the elements of a specific p-Sylow subgroup while under construction. This algorithm is mostly based on work by Michael Stoll.

The second approach computes the group structure from a set of generators as supplied by the user, removing the need to compute the order of A. This can be particularly useful when computing this order is expensive. Note that computing the structure of a group from a set of generators is akin to solving a number of the discrete logarithm problems.

This second algorithm uses a variant of the Pollard–Rho algorithm and is due to Edlyn Teske [Tes98a].

If A is a subgroup of a generic abelian group, G say, then the structure of G is computed first. The rationale is that once the structure of G is known, computing the structure of A is almost always cheap.

`AbelianGroup(A: parameters)`

`UseUserGenerators`	BOOL	*Default :* `false`
`PollardRhoRParam`	RNGINT	*Default :* 20
`PollardRhoTParam`	RNGINT	*Default :* 8
`PollardRhoVParam`	RNGINT	*Default :* 3

Compute the group structure of the generic abelian group A, which may be a subgroup as created by the subgroup constructor or the Sylow function. The two values returned are the abstract abelian group and the invertible map from the latter into A.

If `UseUserGenerators` is false, then the group structure computation is made via the construction of each p-Sylow subgroup, using the factorization of the order of A.

If `UseUserGenerators` is set to `true`, the group structure computation uses the user-supplied set of generators for A. In this case, the additional parameters `PollardRhoRParam`, `PollardRhoTParam`, and `PollardRhoVParam` can be supplied. Their values will be passed to the Pollard–Rho algorithm used in the group structure computation: `PollardRhoRParam` sets the size of the r-adding walks, `PollardRhoTParam` sets the size of the internal storage of elements, and `PollardRhoVParam` is used for an efficient finding of the periodic segment. It is conjectured that the default values as given above are 'best' (see [Tes98b]), therefore there should be no need to set these parameters in general.

Example H69E6

The following statement computes the structure of the unit group of $\mathbf{Z}_{34384}$.

```
> G := AbelianGroup(G); G;
Generic Abelian Group over
Residue class ring of integers modulo 34384
Abelian Group isomorphic to Z/2 + Z/2 + Z/6 + Z/612
Defined on 4 generators
Relations:
  2*G.1 = 0
  2*G.2 = 0
  6*G.3 = 0
  612*G.4 = 0
```

69.4 Elements

69.4.1 Construction of Elements

Unless otherwise stated, the operations in this section apply to fp-abelian groups and generic abelian groups.

`A ! [a`$_1$`, ... ,a`$_n$`]`

Given an abelian group A with generators $e_1, \ldots, e_r$ and a sequence $Q = [a_1, \cdots, a_r]$ of integers, construct the element $a_1e_1 + \cdots + a_re_r$ of A.

`A ! e`

Given a generic abelian group A and an element e of the domain over which it is defined, return e as an element of A. If A is a proper subset of its underlying domain, then e must be a linear combination of the generators (which may be user-supplied) of A.

`A ! g`

Given a generic abelian group A and an element g of the underlying set X of A, return g as an element of A.

`A ! n`

Given an abelian group A with exactly one generator x, construct the element nx.

`Random(A)`

Given either a finite fp-abelian group or a generic abelian group A, return a random element of A.

`Identity(A)`

`Id(A)`

`A ! 0`

Construct the identity element (empty word) for the abelian group A.

Let A be a generic abelian group defined in the universe U of A. If g is an element of A, then $U!g$ is an element of U.

69.4.2 Representation of an Element

An element g of an abelian group A can be represented as a linear combination with respect to a given generating sequence. The coefficients appearing in this linear combination provide an alternative representation for g. If A is a fp-group, the generating set will be the one on which the group was defined. In the case of a generic group, the generating set can either be that obtained when constructing a presentation for A or a user-supplied generating set.

`Representation(g)`

`ElementToSequence(g)`

`Eltseq(g)`

Let A be an abelian group with generating set $e_1, \ldots, e_n$ and suppose g is an element of A, where $g = a_1e_1 + \ldots + a_ne_n$. These functions return the sequence Q of n integers defined by $Q[i] = a_i$, for $i = 1, \ldots, n$. Moreover, each a_i, $i = 1, \ldots, n$, is the integer residue modulus the order of the ith generator.

`UserRepresentation(g)`

Let A be a generic abelian group with a user-supplied set of generators $u_1, \ldots, u_n$ and suppose g is an element of A, where $g = a_1u_1 + \ldots + a_nu_n$. This function returns the sequence Q of n integers defined by $Q[i] = a_i$, for $i = 1, \ldots, n$. Moreover, each a_i, $i = 1, \ldots, n$, is the integer residue modulus the order of the ith generator.

`Representation(S, g)`

Let A be a generic abelian group and let $S = [s_1, \ldots, s_m]$ be any sequence of elements of A. Assume g is an element of A such that $bg = a_1s_1 + \ldots + a_ms_m$. This function returns as its first value the sequence Q of m integers defined by $Q[i] = a_i$, for $i = 1, \ldots, m$. The second value returned is the coefficient b of g. Note that b might not be 1.

Example H69E7

We use the quadratic forms example considered above to illustrate these functions.

```
> Generators(QF);
[ <2,2,500001>, <206,-102,4867> ]
> g := QF ! [5, 6];
> g;
<837,-766,1370>
> Representation(g);
[ 1, 6 ]
>
> g := Random(QF);
> Representation(g);
[ 1, 270 ]
>
```

```
> UserRepresentation(g);
[ 377, 0, 515, 0, 0, 0, 0, 0, 0, 0 ]
>
> S := [];
> for i in [1..3] do
>     d := Random(QF);
>     Include(~S, d);
> end for;
> seq, coeff := Representation(S, g);
> seq; coeff;
[ -170, -3, 0 ]
1
```

69.4.3 Arithmetic with Elements

If the generic abelian group A has been constructed with the flag `UseRepresentation` set true, then arithmetic with elements of A is trivial.

`u + v`

Given elements u and v belonging to the same abelian group A, return the sum of u and v.

`-u`

The inverse of element u.

`u - v`

Given elements u and v belonging to the same abelian group A, return the sum of u and the inverse of v.

`m * u`
`u * m`

Given an integer m, return the element $w+w+\cdots w$ ($|m|$ summands), where $w = u$, if m is positive and $w = -u$ if m is negative.

69.5 Construction of Subgroups and Quotient Groups

The operations in this section apply to both, free abelian groups and arbitrary abelian groups.

69.5.1 Construction of Subgroups

`sub< A | L >`

Construct the subgroup B of the abelian group A generated by the elements specified by the terms of the *generator list* L. A term $L[i]$ of the generator list may consist of any of the following objects:

(a) An element liftable to A;

(b) A sequence of integers representing an element of A;

(c) A subgroup of A;

(d) A set or sequence of type (a), (b), or (c).

The collection of words and groups specified by the list must all belong to the group A and the group B will be constructed as a subgroup of A.

Example H69E8

We create a subgroup of the group $A = Z_2 + Z_3 + Z_4 + Z_5 + Z_6 + Z + Z$.

```
> A<[x]> := AbelianGroup([2,3,4,5,6,0,0]);
> A;
Abelian Group isomorphic to Z/2 + Z/6 + Z/60 + Z + Z
Defined on 7 generators
Relations:
    2*x[1] = 0
    3*x[2] = 0
    4*x[3] = 0
    5*x[4] = 0
    6*x[5] = 0
> B<[y]> := sub< A | x[1], x[3], x[5], x[7] >;
> B;
Abelian Group isomorphic to Z/2 + Z/2 + Z/12 + Z
Defined on 4 generators in supergroup A:
    y[1] = 2*x[3] + 3*x[5]
    y[2] = x[1]
    y[3] = 3*x[3] + x[5]
    y[4] = x[7]
Relations:
    2*y[1] = 0
    2*y[2] = 0
    12*y[3] = 0
```

In the case of subgroups of generic groups, a number of parameters are provided.

`sub< A | L: parameters >`

Construct the subgroup of the generic abelian group A generated by the elements specified by the terms of the *generator list* L. A term $L[i]$ of the generator list may consist of any of the following objects:

(a) An element liftable into A;

(b) A sequence of integers representing an element of A;

(c) A set or sequence whose elements may be of either of the above types.

An element liftable into A may be an element of A itself, or it may be an element of U (`Universe(U)`), U being as usual the domain over which A is defined. For consistency with the construction, the values of the following parameters may also be passed to the subgroup constructor:

`Order`	RngInt	*Default :*
`RandomIntrinsic`	MonStg	*Default :*
`ComputeStructure`	Bool	*Default :* `false`
`UseUserGenerators`	Bool	*Default :* `false`
`PollardRhoRParam`	RngInt	*Default :* 20
`PollardRhoTParam`	RngInt	*Default :* 8
`PollardRhoVParam`	RngInt	*Default :* 3

In particular, it is possible to construct a subgroup by giving its order and a random function generating elements of the *subgroup*. In this case, the list L would be empty since calculation of the subgroup structure would result in the construction of the p-Sylow subgroups from random elements of the subgroup. Further, when the structure of A is already known and if the subgroup is defined in terms of a set of generators in L then the subgroup structure is computed at the time of creation.

Example H69E9

We create a subgroup of the quadratic forms group considered above.

```
> S := [];
> for j in [1..2] do
>     P := Random(QF);
>     Include(~S, P);
> end for;
> S;
[ <45,26,22226>, <937,-930,1298> ]
> QF1 := sub< QF | S>;
> QF1;
Generic Abelian Group over
Binary quadratic forms of discriminant -4000004
Abelian Group isomorphic to Z/2 + Z/258
Defined on 2 generators in supergroup A:
```

```
  QF1.1 = QF.1
  QF1.2 = 2*QF.2
Relations:
  2*QF1.1 = 0
  258*QF1.2 = 0
>
```

69.5.2 Construction of Quotient Groups

`quo< F | R >`

Given an abelian group F, and a set of relations R in the generators of F, construct (a) an abelian group A isomorphic to the quotient of F by the subgroup of F defined by R, and (b) the natural homomorphism $\phi : F \to A$.

The expression defining F may be either simply the name of a previously constructed group, or an expression defining an abelian group. The possibilities for the relation list R are the same as for the `AbelianGroup` construction.
The function returns:

(a) The quotient group A;

(b) The natural homomorphism $\phi : F \to A$.

`A / B`

Given a subgroup B of the abelian group A, construct the quotient of A by B.

69.6 Standard Constructions and Conversions

`AbelianGroup(GrpAb, Q)`

`AbelianGroup(Q)`

Let $Q = [a_1, \ldots, a_r]$ be a sequence of non-negative integers. This function creates the abelian group $\mathbf{Z}_1 + \cdots + \mathbf{Z}_r$, where Z_i is the cyclic group of order $|a_i|$ if $a_i \neq 0$ or the infinite cyclic group $\mathbf{Z}$ otherwise, $i = 1, \ldots, r$.

`AbelianGroup(G)`

Given an abelian permutation, matrix or polycyclic group G, represent it as an abelian group A. The function also returns the isomorphism $\phi : G \to A$ as its second value.

`AbelianQuotient(G)`

Given a finitely presented, permutation, matrix or polycyclic group G, return the maximal abelian quotient A of G. The function returns the natural homomorphism $\phi : G \to A$ as its second value.

`DirectSum(A, B)`

The direct sum of abelian groups A and B.

`PCGroup(A)`

A pc-group representation G of A. The isomorphism $\phi : A \to G$ is also returned.

`PermutationGroup(A)`

A permutation group representation of A. The particular group G is generated by disjoint cycles whose lengths are the abelian invariants of A. The isomorphism $\phi : G \to A$ is also returned.

`FPGroup(A)`

A fp-group group representation of A. The particular group G is generated by commuting generators whose orders are the abelian invariants of A. The isomorphism $\phi : G \to A$ is also returned.

`CommutatorSubgroup(G)`
`DerivedSubgroup(G)`

The derived subgroup of G, that is the trivial group, since G is abelian.

`CommutatorSubgroup(H, K)`
`CommutatorSubgroup(G, H, K)`

The commutator subgroup of groups H and K in their common overgroup G.

`Centralizer(G, a)`
`Centraliser(G, a)`

The centraliser of a in G.

`Core(G, H)`

The maximal normal subgroup of G that is contained in the subgroup H of G. Since G is abelian, this is H itself.

`Centre(G)`
`Center(G)`

The center of G, ie. G itself.

69.7 Operations on Elements

69.7.1 Order of an Element

`Order(x)`

Order of the element x belonging to an fp-abelian group. If the element has infinite order, the value zero is returned.

Example H69E10

We compute the orders of some elements in the group $Z_2 \times Z_3 \times Z_4 \times Z_5 \times Z$.

```
> G<[x]> := AbelianGroup([2,3,4,5,0]);
> Order( x[1] + 2*x[2] + 3*x[4]);
30
> Order( x[1] + x[5] );
0
```

It is possible to determine the order of an element of a generic group with first calculating the structure of the group. The order function involves the use of one of several algorithms:

– an improved baby-step giant-step algorithm, due to J. Buchmann, M.J. Jacobson, E. Teske [BJT97],

– the Pollard–Rho method based algorithm, described above [Tes98a].

When computing the order of an element whose lower and upper bounds are known, or where lower and upper bounds for the group order are known, the following two algorithms have been shown to be significantly faster than the two algorithms mentioned above.

– the standard baby-step giant-step Shanks algorithm,

– another variant of the Pollard–Rho method which is due to P. Gaudry and R. Harley [GH00].

To avoid confusion we will distinguish the algorithms due to Teske *et al* and name them the `T` baby-step giant-step algorithm and the `T` Pollard–Rho algorithm respectively. The Pollard–Rho algorithm has smaller space requirements than the baby-step giant-step algorithm, so it is recommended for use in very large groups.

In all cases, if the group order is known beforehand, the element order is computed using this knowledge. This is a trivial operation.

`Order(g: parameters)`

`ComputeGroupOrder`	Bool	*Default :* `true`
`BSGSLowerBound`	RngIntElt	*Default :* 0
`BSGSStepWidth`	RngIntElt	*Default :* 0

Assume that g is an element of the generic abelian group A. This functions returns the order of the element g. Note that if `UseRepresentation` is set to true for A, then this is a trivial operation.

If the parameter `ComputeGroupOrder` is true, the order of A is computed first (unless it is already known). The order of g is then computed using this knowledge; this last computation is trivial.

If `ComputeGroupOrder` is false, the order of g is computed using the `T` baby-step giant-step algorithm.

`BSGSLowerBound` and `BSGSStepWidth` are parameters which can be passed to the baby-step giant-step algorithm.

`BSGSLowerBound` sets a lowerbound on the order of the element g, and `BSGSStepWidth` sets the step-width in the algorithm.

`Order(g, l, u:` *parameters*`)`

`Alg`	MonStg	*Default :* "*Shanks*"
`UseInversion`	BoolElt	*Default :* `false`

Assume that g is an element of the generic abelian group A such that the order of g or the order of A is bounded by u and l. This function returns the order of the element g.

If the parameter `Alg` is set to `"Shanks"` then the generic Shanks algorithm is used, and when `Alg` is set to `"PollardRho"`, the Gaudry–Harley Pollard–Rho variant is used. Setting `UseInversion` halves the search space. To be effective element inversion must be fast.

`Order(g, l, u, n, m:` *parameters*`)`

`Alg`	MonStg	*Default :* "*Shanks*"
`UseInversion`	BoolElt	*Default :* `false`

Assume that g is an element of the generic abelian group A such that the order of g or the order of A is bounded by u and l. Assume also that `Order(`g`)` $\equiv n$ `(mod` m`)` or that $\#A \equiv$ `(mod` m`)` This function returns the order of the element g. The two parameters `Alg` and `UseInversion` have the same meaning as for the previous `Order` function.

69.7.2 Discrete Logarithm

`Log(g, d:` *parameters*`)`

`ComputeGroupOrder`	Bool	*Default :* `true`
`AlInPohligHellmanLoop`	MonStg	*Default :* "*BSGS*"
`BSGSStepWidth`	RngIntElt	*Default :* 0
`PollardRhoRParam`	RngInt	*Default :* 20
`PollardRhoTParam`	RngInt	*Default :* 8
`PollardRhoVParam`	RngInt	*Default :* 3

Assume that g and d are elements of the generic abelian group A. This function returns the discrete logarithm of d to the base g. If `ComputeGroupOrder` is true, then the group order is computed first (if not already known) and from this the order of the base g is computed. The discrete logarithm problem is then solved using a Pohlig–Hellman loop calling either the `T` baby-step giant-step algorithm (`AlInPohligHellmanLoop := "BSGS"`) or the `T` Pollard–Rho algorithm (`AlInPohligHellmanLoop := "PollardRho"`).

The parameter `BSGSStepWidth` has the same meaning as for the Order function. Parameters `PollardRhoRParam`, `PollardRhoTParam`, and `PollardRhoVParam` have the same meaning as they do for the determination of structure (function AbelianGroup). If `ComputeGroupOrder` is false then the discrete logarithm problem is solved using the `T` baby-step giant-step algorithm. Here again the parameter `BSGSStepWidth` applies.

Example H69E11

It is assumed that the structure of the groups QF has already been computed. We illustrate the computation of the discrete logarithm relative to a given base.

```
> n := 38716;
> Ip := Reduction(PrimeForm(Q,11));
> g := GA_qf!Ip;
> d := n * g;
>
> l1 := Log(g, d : BSGSStepWidth := Floor((-Dk)^(1/4)/2));
> l2 := Log(g, d : AlInPohligHellmanLoop := "PollardRho");
> l3 := Log(g, d : ComputeGroupOrder := false);
> l4 := Log(g, d: ComputeGroupOrder := false,
>                 BSGSStepWidth := Floor((-Dk)^(1/4)/2));
> assert l1 eq l2 and l2 eq l3 and l3 eq l4;
> assert IsDivisibleBy(n - l1, Order(g));
```

69.7.3 Equality and Comparison

`u eq v`

Returns `true` if the elements u and v are identical (as elements of the appropriate free abelian group), `false` otherwise.

`u ne v`

Returns `true` if the elements u and v are not identical (as elements of the appropriate free abelian group), `false` otherwise.

`IsIdentity(u)`

`IsId(u)`

Returns `true` if the element u, belonging to the abelian group A, is the identity element (zero), `false` otherwise.

69.8 Invariants of an Abelian Group

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient of the group G as `GrpAb`. The natural epimorphism is returned as second value.

`FreeAbelianQuotient(G)`

The maximal free abelian quotient of the group G as `GrpAb`. The natural epimorphism is returned as second value.

`Invariants(A)`

The invariants of the abelian group G. Each infinite cyclic factor is represented by zero.

`TorsionFreeRank(A)`

The torsion-free rank of the abelian group G.

`TorsionInvariants(A)`

The torsion invariants of the abelian group G.

`PrimaryInvariants(A)`

The primary invariants of the abelian group G.

`pPrimaryInvariants(A, p)`

The p-primary invariants of the abelian group G.

69.9 Canonical Decomposition

`TorsionFreeSubgroup(A)`

The torsion-free subgroup of the abelian group G.

`TorsionSubgroup(A)`

The torsion subgroup of the abelian group G.

`pPrimaryComponent(A, p)`

The p-primary component of the abelian group G.

69.10 Set-Theoretic Operations

69.10.1 Functions Relating to Group Order

`Order(G)`
`#G`

The order of the group G, returned as an ordinary integer. If G is an infinite group, the value zero is returned. Note that if G is a generic group then determining the order will require the structure of G to be determined.

`FactoredOrder(G)`

The factored order of the group G, returned as a sequence of prime-exponent pairs. If G is an infinite group, the empty sequence is returned. Note that if G is a generic group then determining the order will require the structure of G to be determined.

`Exponent(G)`

The exponent of the group G. If the group is infinite, the value zero is returned. Note that if G is a generic group then determining the exponent will require the structure of G to be determined.

`IsFinite(G)`

Return `true` if the group G is finite.

`IsInfinite(G)`

Return `true` if G , `false` otherwise.

69.10.2 Membership and Equality

`g in G`

Given an element g and a group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given an element g and a group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given an group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is not a subset of G, `false` otherwise.

`H subset G`

Given groups G and H, subgroups of some common overgroup, return `true` if H is a subgroup of G, and `false` otherwise.

`H notsubset G`

Given groups G and H, subgroups of some common overgroup, return `true` if H is not a subgroup of G, and `false` otherwise.

`G eq H`

Given groups G and H, subgroups of some common overgroup, return `true` if G and H are identical, and `false` otherwise.

`G ne H`

Given groups G and H, subgroups of some common overgroup, return `true` if G and H are distinct groups, and `false` otherwise.

69.10.3 Set Operations

`NumberingMap(G)`

A bijective mapping from the finite group G onto the set of integers $\{1 \dots |G|\}$. The actual mapping depends upon choice of standard generators for G.

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 100

Create a process to generate randomly chosen elements from the finite group G. The process is based on the product-replacement algorithm of [CLGM$^+$95], modified by the use of an accumulator. At all times, N elements are stored where N is the maximum of the specified value for `Slots` and `Ngens`$(G)+1$. Initially, these are just the generators of G. As well, one extra group element is stored, the accumulator. Initially, this is the identity. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses one of the elements in the slots and adds it into the accumulator. The element in that slot is replaced by the sum of it and another randomly chosen slot. The random value returned is the new accumulator value. Setting `Scramble := m` causes m such sum-replacement operations to be performed before the process is returned. Note that this algorithm cannot produce well-distributed random elements of an infinite group.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the finite abelian group G, return the next random element of G defined by the process.

`Random(G)`

An element chosen at random from the finite group G.

`Rep(G)`

A representative element of G.

69.11 Coset Spaces

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a group G and a subgroup H of G, this function returns:

(a) An indexed set of elements T of G forming a right transversal for G over H; and,

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = \{t_1, \ldots, t_r\}$ and g in G, ϕ is defined by $\phi(g) = t_i$, where $g \in Ht_i$.

69.11.1 Coercions Between Groups and Subgroups

`G ! g`

Given an element g belonging to the subgroup H of the group G, rewrite g as an element of G.

`H ! g`

Given an element g belonging to the group G, and given a subgroup H of G containing g, rewrite g as an element of H.

`K ! g`

Given an element g belonging to the group H, and a group K, such that H and K are subgroups of G, and both H and K contain g, rewrite g as an element of K.

`Morphism(H, G)`

The integer matrix defining the inclusion monomorphism from the subgroup H of G into G.

69.12 Subgroup Constructions

Although, in the case of an abelian group, many of the standard subgroup constructors are trivial, they are all implemented for the sake of uniformity. Here we document only those which are meaningful in the conrext of abelian groups.

`H meet K`

Given subgroups H and K of some group G, construct their intersection.

`H meet:= K`

Replace H with the intersection of groups H and K.

`H + K`

Given subgroups H and K of some group G, construct the smallest subgroup containing both.

`n * G`

For an integer n and some abelian group G, construct the subgroup nG. The second return value is the map $G \to G$ sending $g \to ng$.

`FrattiniSubgroup(G)`

The Frattini subgroup of the finite abelian group G.

`SylowSubgroup(G, p : parameters)`

`Sylow(G, p : parameters)`

`Structure` BOOL *Default :* `false`

The Sylow p-subgroup for the group G. If G is a generic group and the parameter `Structure` is true, or if the group structure of A is known, then the group structure of the Sylow subgroup is computed.

Example H69E12

In the following example, we construct the Sylow 2-subgroup of $G = Z_{34384}$.

```
> m := 34384;
> Zm := Integers(m);
> U := {@ x : x in Zm | GCD(x, m) eq 1 @};
> G := GenericAbelianGroup(U : IdIntrinsic := "Id",
>    AddIntrinsic := "*", InverseIntrinsic := "/");
> _ := AbelianGroup(G);
> Factorization(#G);
> Sylow(G, 2);
2-Sylow subgroup: Generic Abelian Group over
Residue class ring of integers modulo 34384
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/4
Defined on 4 generators in supergroup G:
  GAp.1 = G.1
  GAp.2 = G.2
```

```
  GAp.3 = 3*G.3
  GAp.4 = 153*G.4
Relations:
  2*GAp.1 = 0
  2*GAp.2 = 0
  2*GAp.3 = 0
  4*GAp.4 = 0
```

69.13 Subgroup Chains

`CompositionSeries(G)`

A composition series for the finite abelian group G returned as a sequence of subgroups.

`Agemo(G, i)`

Given a finite p-group G, return the characteristic subgroup of G generated by the elements x^{p^i}, $x \in G$, where i is a positive integer.

`Omega(G, i)`

Given a finite p-group G, return the characteristic subgroup of G generated by the elements of order dividing p^i, where i is a positive integer.

69.14 General Group Properties

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise.

`IsFree(G)`

Returns `true` if G is free, `false` otherwise.

`IsMixed(G)`

Returns `true` if G is a mixed group, `false` otherwise. An abelian group is mixed if it is neither a torsion group nor free.

`IspGroup(G)`

Returns `true` if the finite group G is a p-group, ie. if all elements have order a power of p.

69.14.1 Properties of Subgroups

`IsMaximal(G, H)`

Returns `true` if the subgroup H of the finite group G is a maximal subgroup of G, `false` otherwise.

`Index(G, H)`

The index of the subgroup H in the group G, returned as an ordinary integer. If H has infinite index in G, the value zero is returned.

`FactoredIndex(G, H)`

The factored index of the subgroup H in the group G, returned as a sequence of prime-exponent pairs. If H has infinite index in G, the empty sequence is returned.

`IsPure(G, H)`

Returns `true` if the subgroup H of the finite group G is pure, ie. if for all n we have $nG \cap H = nH$.

`IsNeat(G, H)`

Returns `true` if the subgroup H of the finite group G is neat, i.e., if for all primes p we have $pG \cap H = pH$.

69.14.2 Enumeration of Subgroups

`MaximalSubgroups(G)`

The maximal subgroups of the finite group G returned as a sequence of subgroups.

`Subgroups(G:`*parameters*`)`

The subgroups of the finite group G are returned as a sequence of records. The record fields are `subgroup`, storing the actual group; `order`, storing the group order; and `length`, storing the length of the conjugacy class, which is always 1 for abelian groups.

`Sub` [RngIntElt] *Default :* []

If parameter `Sub` is set, only subgroups with invariants equal to the given sequence are found. The given sequence should contain positive integers, such that each divides the following.

`Quot` [RngIntElt] *Default :* []

If parameter `Quot` is set, only subgroups such that the quotient group has invariants equal to the given sequence are found. The given sequence should contain positive integers, such that each divides the following.

`NumberOfSubgroupsAbelianPGroup (A)`

Return the number of subgroups of each non-trivial order in the abelian p-group G where $A = [a_1, a_2, \ldots]$ and $G = C_{a_1} \times C_{a_2} \times \ldots$. The m-th entry in the sequence returned is the number of subgroups of order p^m.

`HasComplement(G, U)`

For a finite abelian group G and a subgroup U decide if there exist some other subgroup V such that $G = U + V$ and $U \cap V = \{0\}$. In case such a V exists, it is returned as the second value.

Example H69E13

We look at subgroups of an abelian group of order 12.

```
> G := AbelianGroup([2,6]);
> s := Subgroups(G); #s;
10
> s[7];
rec<recformat<order, length, subgroup, presentation> |
   order := 3, length := 1,
   subgroup := Abelian Group isomorphic to Z/3
Defined on 1 generator in supergroup G:
  $.1 = 2*G.2
Relations:
  3*$.1 = 0>
> [x`order:x in s];
[ 12, 6, 4, 2, 6, 6, 3, 2, 2, 1 ]
```

Now we find the elementary abelian subgroup of order 4.

```
> s22 := Subgroups(G:Sub := [2,2]); #s22;
1
> s22;
Conjugacy classes of subgroups
------------------------------
 [1]     Order 4            Length 1
        Abelian Group isomorphic to Z/2 + Z/2
        Defined on 2 generators in supergroup G:
          $.1 = G.1
          $.2 = 3*G.2
        Relations:
          2*$.1 = 0
          2*$.2 = 0
```

There is more than one subgroup of index 2 in G.

```
> q2 := Subgroups(G:Quot := [2]); #q2;
3
> q2[3]`subgroup;
```

```
Abelian Group isomorphic to Z/6
Defined on 1 generator in supergroup G:
  $.1 = G.1 + G.2
Relations:
  6*$.1 = 0
```

69.15 Representation Theory

`CharacterTable(G)`

The table of irreducible characters for the group G.

69.16 The Hom Functor

`Hom(G, H)`

Given finite abelian groups G and H, return an abelian group A isomorphic to $\mathrm{Hom}(G, H)$, and a transfer map t such that, given an element a of A, $t(a)$ yields the corresponding (MAGMA `Map` type) homomorphism from G to H. The structure of $\mathrm{Hom}(G, H)$ may thus be analyzed by examining A.

`HomGenerators(G, H)`

Given finite abelian groups G and H, return a sequence of (Z-module) generators of $\mathrm{Hom}(G, H)$. The generators are returned as actual (MAGMA `Map` type) homomorphisms. Note that $\mathrm{Hom}(G, H)$ is usually not free, so it is difficult to generate all homomorphisms uniquely using the generators alone (use `Hom` or `Homomorphisms` if that is desired).

`Homomorphisms(G, H)`

Given finite abelian groups G and H, return a sequence containing all elements of $\mathrm{Hom}(G, H)$. The elements are returned as actual (MAGMA `Map` type) homomorphisms. Note that this function simply uses `Hom`, transferring each element of the returned group to the actual MAGMA `Map` type homomorphism.

Example H69E14

We examine $A = \mathrm{Hom}(G, H)$, for certain abelian groups G and H.

```
> G := AbelianGroup([2, 3]);
> H := AbelianGroup([4, 6]);
> A, t := Hom(G, H);
> #A;
12
> A;
Abelian Group isomorphic to Z/2 + Z/6
Defined on 2 generators
Relations:
    2*A.1 = 0
    6*A.2 = 0
> h := t(A.1);
> h;
Mapping from: GrpAb: G to GrpAb: H
> h(G.1);
3*H.2
> h(G.2);
0
```

We now enumerate all elements of A and examine the images of each generator of G under each homomorphism. We note that each possible list of images occurs only once.

```
> I := [<h(G.1), h(G.2)> where h is t(x): x in A];
> I;
[
    <0, 0>,
    <3*H.2, 0>,
    <2*H.1, 2*H.2>,
    <2*H.1 + 3*H.2, 2*H.2>,
    <0, 4*H.2>,
    <3*H.2, 4*H.2>,
    <2*H.1, 0>,
    <2*H.1 + 3*H.2, 0>,
    <0, 2*H.2>,
    <3*H.2, 2*H.2>,
    <2*H.1, 4*H.2>,
    <2*H.1 + 3*H.2, 4*H.2>
]
> #I;
12
> #Set(I);
12
```

69.17 Automorphism Groups

The full automorphism group of the abelian group G.

69.18 Cohomology

`Dual(G)`

Computes the dual group G^* of G and a map M from $G \times G^* \to \mathbf{Z}/m\mathbf{Z}$ for m the exponent of G that allows G^* to act on G. G must be finite.

`H2_G_QmodZ(G)`

Computes $H := H^2(G, \mathbf{Q}/\mathbf{Z})$ and a map $f : H \to (G \times G \to \mathbf{Z}/m\mathbf{Z})$ that will give the cocycles as maps from $G \times G \to \mathbf{Z}/m\mathbf{Z}$. $m := \#G$.

`Res_H2_G_QmodZ(U, H2)`

For a subgroup U of G and $H2 = H^2(G, \mathbf{Q}/\mathbf{Z})$ computes $H^2(U, \mathbf{Q}/\mathbf{Z})$ in a compatible way together with the restriction map into $H2$.

$H2$ must be the result of `H2_G_QmodZ` as this function relies on the attributes stored in there.

69.19 Homomorphisms

Two functions are provided to construct homomorphisms or isomorphisms from one group into another, where either of the groups, or both, may be generic abelian groups.

`hom< A -> B | L >`

Given groups A and B, construct a homomorphism from A to B as defined by the extension L. If one or both of A and B are generic abelian groups this works as usual, with one minor difference as explained below. Suppose that the generators of A are $g_1, \ldots, g_n$, and that $\phi(g_i) = h_i$ for each i, where ϕ is the homomorphism one wishes to construct. The list L as required by the constructors must be one of the following:

(a) a list of the n 2-tuples $< g_i, h_i >$ (order not important);

(b) a list of the n arrow-pairs $g_i \to h_i$ (order not important);

(c) $h_1, \ldots, h_n$ (order is important).

If A is a generic abelian group this rule is relaxed somewhat in the following sense: If L is a list of n 2-tuples or of n arrow-pairs, the elements g_i need not be the defining generators of A. The only requirement is that the set $\{g_1, \ldots, g_n\}$ does actually generate the whole of A.

`Homomorphism(A, B, X, Y)`

Creates a homomorphism from A into B as given by the mapping of X into Y. The arguments A and B may be any type of group, including of course, generic abelian groups.

The function `Homomorphism` does not require the elements of the argument X to be generators of A as given by `Generators(`A`)`, so it allows more freedom when creating a homomorphism. If, however, these elements fail to generate the whole of A then the subsequent map application will fail.

`iso< A -> B | L >`

Given groups A and B, construct an isomorphism from A to B as defined by the extension L. If one or both of A and B are generic abelian groups this works as usual, with one minor difference as explained below. Suppose that the generators of A are $g_1, \ldots, g_n$, and that $\phi(g_i) = h_i$ for each i, where ϕ is the isomorphism one wishes to construct. The list L as required by the constructors must be one of the following:

(a) a list of the n 2-tuples $< g_i, h_i >$ (order not important);

(b) a list of the n arrow-pairs $g_i \to h_i$ (order not important);

(c) $h_1, \ldots, h_n$ (order is important).

If A is a generic abelian group this rule is relaxed somewhat in the following sense: If L is a list of n 2-tuples or of n arrow-pairs, the elements g_i may not necessarily be generators of A as given by the function `Generators(`A`)`. The only requirement is that the set $\{h_1, \ldots, h_n\}$ does actually generate the whole of B.

`Isomorphism(A, B, X, Y)`

Creates a isomorphism from A into B as given by the mapping of X into Y. The arguments A and B can be any type of group, including of course, generic abelian groups.

The function `Isomorphism` does not require the elements of the argument X to be generators of A as given by `Generators(`A`)`, so it allows more freedom when creating an isomorphism. If, however, these elements fail to generate the whole of A then the subsequent map application will fail.

Example H69E15

Recall that we defined the subgroups $GH1_{Zm}$ and $GH2_{Zm}$ of G as:

```
> GH1_Zm;
Generic Abelian Group over
Residue class ring of integers modulo 34384
Abelian Group isomorphic to Z/6 + Z/612
Defined on 2 generators in supergroup G:
  GH1_Zm.1 = G.2 + G.3
  GH1_Zm.2 = G.4
```

```
Relations:
  6*GH1_Zm.1 = 0
  612*GH1_Zm.2 = 0
> GH2_Zm;
Generic Abelian Group over
Residue class ring of integers modulo 34384
Abelian Group isomorphic to Z/2 + Z/2 + Z/6 + Z/612
Defined on 4 generators in supergroup G:
  GH2_Zm.1 = G.1
  GH2_Zm.2 = G.2
  GH2_Zm.3 = G.3
  GH2_Zm.4 = G
Relations:
  2*GH2_Zm.1 = 0
  2*GH2_Zm.2 = 0
  6*GH2_Zm.3 = 0
  612*GH2_Zm.4 = 0
```

We construct the homomorphism

```
> h := hom<GH1_Zm -> GH2_Zm | GH2_Zm.1, GH2_Zm.2 >;
> h(GH1_Zm);
Generic Abelian Group over
Residue class ring of integers modulo 34384
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators in supergroup GH2_Zm:
  $.1 = GH2_Zm.2
  $.2 = GH2_Zm.1
Relations:
  2*$.1 = 0
  2*$.2 = 0
```

but we cannot construct the isomorphism

```
>  i := iso<GH1_Zm -> GH2_Zm | GH2_Zm.1, GH2_Zm.2 >;
>> i := iso<GH1_Zm -> GH2_Zm | GH2_Zm.1, GH2_Zm.2 >;
           ^
Runtime error in map< ... >: Images do not generate the (whole) codomain
```

An alternative way of creating the homomorphism h would be

```
> h := Homomorphism(GH1_Zm, GH2_Zm, Generators(GH1_Zm), [GH2_Zm.1, GH2_Zm.2]);
```

70 FINITELY PRESENTED GROUPS

Chapter 70
FINITELY PRESENTED GROUPS

70.1 Introduction

This Chapter presents the functions designed for computing with finitely-presented groups (fp-groups for short). The name of the corresponding MAGMA category is `GrpFP`. The functions considered here are designed for doing what is sometimes referred to as *combinatorial group theory*.

70.1.1 Overview of Facilities

The facilities provided for fp-groups fall into a number of natural groupings:

- The construction of fp-groups in terms of generators and relations;
- The construction of particular types of quotient groups: abelian quotient, p-quotient, nilpotent quotient and soluble quotient;
- Index determination and subgroup building based on the Todd-Coxeter procedure;
- Calculations with subgroups having finite index in a group, where the subgroups are represented by coset tables;
- The construction of all subgroups having index less than some (small) specified bound;
- The construction of representations of an fp-group corresponding to actions on coset spaces and elementary abelian sections;
- The use of a rewriting process for constructing presentations of subgroups;
- The simplification of words with respect to a given set of relations.

For a description of fundamental algorithms for finitely presented groups, we refer the reader to [Sim94].

70.1.2 The Construction of Finitely Presented Groups

The construction of fp-groups utilises the fact that every group is a quotient of some free group. Thus, two general fp-group constructors are provided: `FreeGroup(n)` which constructs a free group of rank n, and `quo< F | R >` which constructs the quotient of group F by the normal subgroup defined by the relations R.

The naming of generators presents special difficulties since they are not always used in a consistent manner in the mathematical literature. A generator name is used in two distinct ways. Firstly, it plays the role of a *variable* having as its value a designated generator of G. Secondly, it appears as the *symbol* designating the specified generator whenever elements of the group are output. These two uses are separated in the MAGMA semantics.

In MAGMA, a standard indexing notation is provided for referencing the generators of any fp-group G. Thus, `G.i` denotes the i-th generator of G. However, users may give

individual names to the generators by means of the *generator*-assignment. Suppose that the group G is defined on r generators. Then if the right hand side of the following statement creates a group, the special assignment

```
> G< v_1, ..., v_r> := construction;
```

is equivalent to the statements

```
> G := construction;
>    v_1 := G.1;
>    ...
>    v_r := G.r;
```

It should be noted that when the fp-group G is created as the quotient of the group F, any names that the user may have associated with the generators of F will not be associated with the corresponding generators of G. If this were allowed, then it would violate the fundamental principle that every object is viewed as belonging to a *unique* structure.

70.2 Free Groups and Words

70.2.1 Construction of a Free Group

`FreeGroup(n)`

Construct the free group F of rank n, where n is a positive integer.

The i-th generator of F may be referenced by the expression `F.i`, $i = 1, \ldots, n$. Note that a special form of the assignment statement is provided which enables the user to assign names to the generators of F. In this form of assignment, the list of generator names is enclosed within angle brackets and appended to the variable name on the *left hand side* of the assignment statement: `F< v`$_1$`, ..., v`$_n$` > := FreeGroup(n);`

Example H70E1

The statement

```
> F := FreeGroup(2);
```

creates the free group of rank 2. Here the generators may be referenced using the standard names, `F.1` and `F.2`.
The statement

```
> F<x, y> := FreeGroup(2);
```

defines F to be the free group of rank 2 and assigns the names x and y to the two generators.

70.2.2 Construction of Words

The operations in this section apply to both, free groups and arbitrary fp-groups.

`G ! [ i1, ..., is ]`

Given a group G defined on r generators and a sequence $[i_1, \cdots, i_s]$ of integers lying in the range $[-r, r]$, excluding 0, construct the word

$$G.|i_1|^{\epsilon_1} * G.|i_2|^{\epsilon_2} * \cdots * G.|i_s|^{\epsilon_s}$$

where ϵ_j is $+1$ if i_j is positive, and -1 if i_j is negative.

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity element, represented as the empty word, for the fp-group G. For a sample application of this function, see Example H70E3.

`Random(G, m, n)`

A random word of length l in the generators of the group G, where $m \leq l \leq n$. For a sample application of this function, see Example H70E3.

70.2.3 Access Functions for Words

This section describes some basic access functions for words. These operations apply to both, free groups and arbitrary fp-groups.

`#w`

The length of the word w.

`ElementToSequence(w)`

`Eltseq(w)`

The sequence Q obtained by decomposing the word w into its constituent generators and generator inverses. Suppose w is a word in the group G. Then, if $w = G.i_1^{e_1} \cdots G.i_m^{e_m}$, with each $e_i = \pm 1$, then $Q[j] = i_j$ if $e_j = +1$ and $Q[j] = -i_j$ if $e_j = -1$, for $j = 1, \ldots, m$.

`ExponentSum(w, x)`

`Weight(w, x)`

Given a word w, and the name of a generator x of a group G, compute the sum of the exponents of the generator x in the word w. For a sample application of this function, see Example H70E3.

`GeneratorNumber(w)`

Suppose w is a word belonging to a group G. Assume x is the name of the i-th generator of G. Then

(i) if $w =$ `Identity(G)`, `GeneratorNumber(w)` is 0;

(ii) if $w = x * w'$, w' a word in G, `GeneratorNumber(w)` is i;

(iii) if $w = x^{-1} * w'$, w' a word in G, `GeneratorNumber(w)` is $-i$.

`LeadingGenerator(w)`

Suppose w is a word belonging to a group G. If $w = x^{\epsilon} * w'$, w' a word in G, x a generator of G and $\epsilon \in \{-1, +1\}$, the functions returns x^{ϵ}. If $w =$ `Identity(G)`, it returns `Identity(G)`. For a sample application of this function, see Example H70E3.

`Parent(w)`

The parent group G of the word w.

Example H70E2

Consider the free group F on 6 generators

```
> F<u,v,w,x,y,z> := FreeGroup(6);
```

and the sequence of words

```
> rels := [ (u*v)^42, (v,x), (x*z^2)^4,
>           v^2*y^3, (v*z)^3, y^4, (x*z)^3 ];
```

The abelianised relation matrix of the quotient

$$\langle u, v, w, x, y, z \mid (uv)^{42}, (v, x), (xz^2)^4, v^2y^3, (vz)^3, y^4, (xz)^3 \rangle$$

can be obtained using the following construction

```
> R := Matrix(Integers(),
>        [ [ Weight(r, F.j) : j in [1..6] ] : r in rels ]);
> R;
[42 42  0  0  0  0]
[ 0  0  0  0  0  0]
[ 0  0  0  4  0  8]
[ 0  2  0  0  3  0]
[ 0  3  0  0  0  3]
[ 0  0  0  0  4  0]
[ 0  0  0  3  0  3]
```

(The function `Matrix` constructs a matrix from a sequence of row vectors.)

70.2.4 Arithmetic Operators for Words

Suppose G is an fp-group for which generators have already been defined. This subsection defines the elementary arithmetic operations on words that are derived from the multiplication and inversion operators. The availability of the operators defined here enables the user to construct an element (*word*) of G in terms of the generators as follows:

(i) A generator is a word;

(ii) The expression (u) is a word, where u is a word;

(iii) The product $u * v$ of the words u and v is a word;

(iv) The conjugate u^v of the word u by the word v, is a word (u^v expands into the word $v^{-1} * u * v$);

(v) The power of a word, u^n, where u is a word and n is an integer, is a word;

(vi) The commutator (u, v) of the words u and v is a word ((u, v) expands into the word $u^{-1} * v^{-1} * u * v$). Note that (u, v, w) is equivalent to $((u, v), w)$, i.e. commutators are *left-normed*.

The word operations defined here may be applied either to the words of a free group or the words of a group with non-trivial relations. If such an operator is applied to a group possessing non-trivial relations, only free reduction will be applied to the resulting words.

`u * v`

Given words u and v belonging to the same fp-group G, return the product of u and v.

`u ^ n`

The n-th power of the word u, where n is an integer. When invoked with $n = -1$, the function computes the inverse of u. When invoked with $n = 0$, the function returns the identity element.

`u ^ v`

Given words u and v belonging to the same fp-group G, return the conjugate $v^{-1} * u * v$ of the word u by the word v.

`(u, v)`

Given words u and v belonging to the same fp-group G, return the commutator $u^{-1}v^{-1}uv$ of the words u and v.

`(u1, ..., un)`

Given the n words $u_1, \ldots, u_n$ belonging to the same fp-group G, return their commutator. Commutators are *left-normed*, so that they are evaluated from left to right.

70.2.5 Comparison of Words

Words in an fp-group may be compared both for equality and for their relationship with respect to a natural lexicographic ordering. It should be noted that even when a pair of words belong to a group defined by non-trivial relations, only the free reductions of the words are compared. Thus, a pair of words belonging to a group G may be declared to be distinct even though they may represent the same element of G.

The words of an fp-group G are ordered first by length and then lexicographically. The lexicographic ordering is determined by the following ordering on the generators and their inverses:

$$G.1 < G.1^{-1} < G.2 < G.2^{-1} < \cdots$$

Here, u and v are words belonging to some common fp-group.

`u eq v`

Return `true` if the free reductions of the words u and v are identical.

`u ne v`

Return `true` if the free reductions of the words u and v are not identical.

`u lt v`

Return `true` if the word u precedes the word v, with respect to the ordering defined above for elements of an fp-group. The words u and v are freely reduced before the comparison is made.

`u le v`

Return `true` if the word u either precedes, or is equal to, the word v, with respect to the ordering defined above for elements of an fp-group. The words u and v are freely reduced before the comparison is made.

`u ge v`

Return `true` if the word u either follows, or is equal to, the word v, with respect to the ordering defined above for elements of an fp-group. The words u and v are freely reduced before the comparison is made.

`u gt v`

Return `true` if the word u follows the word v, with respect to the ordering defined above for elements of an fp-group. The words u and v are freely reduced before the comparison is made.

Example H70E3

We construct the free group on three generators and generate a random word w of length between 4 and 6.

```
> F<a,b,c> := FreeGroup(3);
>
> w := Random(F, 4, 6);
> w;
b^-1 * a^-1 * b^2 * a^-1
```

We print the length of w and the weight (the exponent sum) of generator a in w.

```
> #w;
5
>
> Weight(w, a);
-2
```

We now strip the generators from w one by one, using arithmetic and comparison operators for words and the access function `LeadingGenerator`.

```
> while w ne Identity(F) do
>     g := LeadingGenerator(w);
>     print g;
>     w := g^-1 * w;
> end while;
b^-1
a^-1
b
b
a^-1
```

70.2.6 Relations

A *relation* is an equality between two words in a fp-group. To facilitate working with relations, a *relation type* is provided.

`w1 = w2`

Given words w_1 and w_2 over the generators of an fp-group G, create the relation $w_1 = w_2$. Note that this relation is not automatically added to the existing set of defining relations R for G. It may be added to R, for example, through use of the `quo`-constructor (see below).

`r[1]`

`LHS(r)`

Given a relation r over the generators of G, return the left hand side of the relation r. The object returned is a word over the generators of G.

`r[2]`

`RHS(r)`

Given a relation r over the generators of G, return the right hand side of the relation r. The object returned is a word over the generators of G.

`r[1] := w`

Redefine the left hand side of the relation r to be the word w.

`r[2] := w`

Redefine the right hand side of the relation r to be the word w.

`f(r)`

Given a homomorphism of the group G for which r is a relation, return the image of r under f.

`Parent(r)`

Group over which the relation r is taken.

Example H70E4

We may define a group and a set of relations as follows:

```
> F<x, y> := FreeGroup(2);
> rels := { x^2 = y^3, (x*y)^4 = Id(F)} ;
```

To replace one side of a relation, the easiest way is to reassign the relation. So for example, to replace the relation $x^2 = y^3$ by $x^2 = y^4$, we go:

```
> r := x^2 = y^3;
> r := LHS(r) = y^4;
```

70.3 Construction of an FP-Group

An fp-group is normally constructed either by giving a presentation in terms of generators and relations or it is defined to be a subgroup or quotient group of an existing fp-group. However, fp-groups may be also created from finite permutation and matrix groups. Finally, Magma has separate types for a number of families of fp-groups that satisfy a condition such as being polycyclic. Again functions are provided to convert a member of one of these families into a general fp-group.

70.3.1 The Quotient Group Constructor

A group with non-trivial relations is constructed as a quotient of an existing group, usually a free group. For convenience, the necessary free group may be constructed in-line.

`quo< F | R >`

Given an fp-group F, and a set of relations R in the generators of F, construct the quotient G of F by the normal subgroup of F defined by R. The group G is defined by means of a presentation which consists of the relations for F (if any), together with the additional relations defined by the list R.

The expression defining F may be either simply the name of a previously constructed group, or an expression defining an fp-group.

If R is a list then each term of the list is either a *word*, a *relation*, a *relation list* or a *subgroup* of F.

A *word* is interpreted as a relator.

A *relation* consists of a pair of words, separated by '='. (See above.)

A *relation list* consists of a list of words, where each pair of adjacent words is separated by '=': $w_1 = w_2 = \cdots = w_r$. This is interpreted as the set of relations $w_1 = w_r, \ldots, w_{r-1} = w_r$. Note that the relation list construct is only meaningful in the context of the `quo`-constructor.

A *subgroup* H appearing in the list R contributes its generators to the relation set for G, i.e. each generator of H is interpreted as a relator for G.

The group F may be referred to by the special symbol $ in any word appearing to the right of the '`|`' symbol in the `quo`-constructor. Also, in the context of the `quo`-constructor, the identity element (empty word) may be represented by the digit `1`.

The function returns:

(a) The quotient group G;

(b) The natural homomorphism $\phi : F \to G$.

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function `SetGlobalTCParameters`. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`G / H`

Given a subgroup H of the group G, construct the quotient of G by the normal closure N of H. The quotient is formed by taking the presentation for G and including the generating words of H as additional relators.

Example H70E5

The symmetric group of degree 4 may be represented as a two generator group with presentation $< a, b \mid a^2, b^3, (ab)^4 >$. Giving the relations as a list of relators, the presentation would be specified as:

```
> F<a, b> := FreeGroup(2);
> G<x, y>, phi := quo< F | a^2, b^3, (a*b)^4 >;
```

Alternatively, giving the relations as a relations list, the presentation would be specified as:

```
> F<a, b> := FreeGroup(2);
> G<x, y>, phi :=  quo< F | a^2 = b^3 = (a*b)^4 = 1>;
```

Finally, giving the relations in the form of a set of relations, this presentation would be specified as:

```
> F<a, b> := FreeGroup(2);
> rels := { a^2, b^3, (a*b)^4 };
> G<x, y>, phi :=  quo< F | rels >;
```

Example H70E6

A group may be defined using the quo-constructor without first assigning a free group. The $ symbol is used to reference the group whose quotient is being formed.

```
> S4<x, y> := quo< FreeGroup(2) | $.1^2, $.2^3, ($.1*$.2)^4 >;
> S4;
Finitely presented group S4 on 2 generators
Relations
      x^2 = Id(S4)
      y^3 = Id(S4)
      (x * y)^4 = Id(S4)
```

Example H70E7

We illustrate the use of the quo-constructor in defining the quotient of a group other than a free group.

```
> F<x, y> := Group< x, y | x^2 = y^3 = (x*y)^7 = 1 >;
> F;
Finitely presented group F on 2 generators
Relations
      x^2 = Id(F)
      y^3 = Id(F)
```

```
      (x * y)^7 = Id(F)
> G<a, b> := quo< F | (x, y)^8 >;
> G;
Finitely presented group G on 2 generators
Relations
      a^2 = Id(G)
      b^3 = Id(G)
      (a * b)^7 = Id(G)
      (a, b)^8 = Id(G)
> Order(G);
10752
```

70.3.2 The FP-Group Constructor

For convenience, a constructor is provided which allows the user to define an fp-group in a single step.

```
Group<  X | R  >
```

Given a list X of variables $x_1, \ldots, x_r$, and a list of relations R over these generators, first construct the free group F on the generators $x_1, \cdots, x_r$ and then construct the quotient of F corresponding to the normal subgroup of F defined by the relations R.

The syntax for the relations R is the same as for the quo-constructor. The function returns:

(a) The quotient group G;

(b) The natural homomorphism $\phi : F \to G$.

Example H70E8

We illustrate the Group-constructor by defining the binary tetrahedral group in terms of the presentation $< r, s \mid r^3 = s^3 = (rs)^2 >$:

```
> G<r, s> := Group< r, s | r^3 = s^3 = (r*s)^2 >;
```

Example H70E9

Again, using the Group-constructor, the group $< r, s, t \mid r^2, s^2, t^2, rst = str = trs >$ would be specified as:

```
> G<r, s, t> := Group<r, s, t | r^2, s^2, t^2, r*s*t = s*t*r = t*r*s>;
```

Example H70E10

In our final example we illustrate the use of functions to represent parametrised families of groups. In the notation of Coxeter, the symbol $(l, m|n, k)$ denotes the family of groups having presentation

$$< a, b \mid a^l, b^m, (a * b)^n, (a * b^{-1})^k > .$$

```
> Glmnk := func< l, m, n, k | Group< a, b | a^l, b^m, (a*b)^n, (a*b^-1)^k > >;
> G<a, b> := Glmnk(3, 3, 4, 4);
> G;
Finitely presented group G on 2 generators
Relations
      a^3 = Id(G)
      b^3 = Id(G)
      (a * b)^4 = Id(G)
      (a * b^-1)^4 = Id(G)
> Order(G);
168
> G<a, b> := Glmnk(2, 3, 4, 5);
> G;
Finitely presented group G on 2 generators
Relations
    a^2 = Id(G)
    b^3 = Id(G)
    (a * b)^4 = Id(G)
    (a * b^-1)^5 = Id(G)
> Order(G);
1
```

Thus $(2, 3 \mid 4, 5)$ is the trivial group.

70.3.3 Construction from a Finite Permutation or Matrix Group

`FPGroup(G)`

Given a finite group G in category GrpPerm or GrpMat, this function returns a finitely presented group F, isomorphic to G, together with the isomorphism $\phi : F \to G$. The generators of F correspond to the generators of G, so this function can be used to obtain a set of defining relations for the given generating set of G.

It should be noted that this function is only practical for groups of order at most a few million. In the case of much larger permutation groups, an isomorphic fp-group can be constructed using the function FPGroupStrong.

FPGroupStrong(G)

Given a finite group G in category GrpPerm or GrpMat, this function returns a finitely presented group F, isomorphic to G, together with the isomorphism $\phi : F \to G$. The generators of F correspond to a set of strong generators of G. If no strong generating set is known for G, one will be constructed.

For a detailed description of this function, in particular for a list of available parameters, we refer to Chapter 58 and Chapter 59, respectively.

FPGroupStrong(G, N)

Given a permutation group G and a normal subgroup N of G, this function returns a finitely presented group F, isomorphic to G/N, together with a homomorphism $\phi : G \to F$.

For a detailed description of this function, we refer to Chapter 58.

Example H70E11

We start with defining the alternating group $G \simeq A_5$ as a permutation group.

```
> G := AlternatingGroup(5);
> G;
Permutation group G acting on a set of cardinality 5
Order = 60 = 2^2 * 3 * 5
    (3, 4, 5)
    (1, 2, 3)
```

Now we create an fp-group F isomorphic to G, using the function FPGroup. The presentation is constructed by computing a set of defining relations for the generators of G, i.e. the generators of the returned fp-group correspond to the generators of G. This defines a homomorphism from F to G, which the function FPGroup returns as second return value.

```
> F<x,y>, f := FPGroup(G);
> F;
Finitely presented group F on 2 generators
Relations
    x^3 = Id(F)
    y^3 = Id(F)
    (x^-1 * y * x * y)^2 = Id(F)
    (x * y^-1 * x * y)^2 = Id(F)
> f;
Mapping from: GrpFP: F to GrpPerm: G
> f(x);
(3, 4, 5)
> f(y);
(1, 2, 3)
```

Using the function FPGroupStrong, we now create another fp-group Fs, isomorphic to G, whose generators correspond to a set of strong generators of G.

```
> Fs<[z]>, fs := FPGroupStrong(G);
```

```
> Fs;
Finitely presented group Fs on 3 generators
Relations
    z[1]^-3 = Id(Fs)
    (z[1]^-1 * z[3]^-1)^2 = Id(Fs)
    z[3]^-3 = Id(Fs)
    z[1]^-1 * z[2]^-1 * z[1] * z[3]^-1 * z[2] = Id(Fs)
    z[2]^-3 = Id(Fs)
    (z[3]^-1 * z[2]^-1)^2 = Id(Fs)
> fs;
Mapping from: GrpFP: Fs to GrpPerm: G
```

Applying the isomorphism fs, we have a look at the strong generating set constructed for G.

```
> [ fs(z[i]) : i in [1..#z] ];
[
    (3, 4, 5),
    (1, 2, 3),
    (2, 3, 4)
]
```

70.3.4 Construction of the Standard Presentation for a Coxeter Group

There is a special MAGMA category GrpPermCox, a subcategory of GrpPerm, for finite Coxeter groups. Here, we describe a function to create from a Coxeter group W a finitely presented group F, isomorphic to W, which is given by the standard Coxeter group presentation. We refer to Chapter 98.

`CoxeterGroup(GrpFP, W)`

Given a finite Coxeter group W in the category GrpFPCox or GrpPermCox, construct a finitely presented group F isomorphic to W, given by a standard Coxeter presentation. The isomorphism from W to F is returned as second return value. The first argument to this function must be the category GrpFP.

`Local` BOOLELT *Default :* `false`

If the parameter `Local` is set to `true`, F is the appropriate subgroup of the FP version of the overgroup of W.

Example H70E12

We construct a Coxeter group W of Cartan type $C5$ and create an isomorphic fp-group F. We can use the isomorphism from W to F to map words in the generators of F to permutation group elements and vice versa.

```
> W := CoxeterGroup("C5");
> F<[s]>, h := CoxeterGroup(GrpFP, W);
> F;
```

```
Finitely presented group F on 5 generators
Relations
    s[3]^2 = Id(F)
    s[2] * s[4] = s[4] * s[2]
    s[1]^2 = Id(F)
    s[1] * s[2] * s[1] = s[2] * s[1] * s[2]
    s[2] * s[5] = s[5] * s[2]
    s[4]^2 = Id(F)
    s[1] * s[3] = s[3] * s[1]
    s[3] * s[4] * s[3] = s[4] * s[3] * s[4]
    s[2]^2 = Id(F)
    s[1] * s[4] = s[4] * s[1]
    s[5]^2 = Id(F)
    (s[4] * s[5])^2 = (s[5] * s[4])^2
    s[3] * s[5] = s[5] * s[3]
    s[1] * s[5] = s[5] * s[1]
    s[2] * s[3] * s[2] = s[3] * s[2] * s[3]
> h;
Mapping from: GrpCox: W to GrpFP: F given by a rule
> h(W.1*W.2);
s[1] * s[2]
> (s[1]*s[2]*s[3]*s[4]) @@ h;
(1, 39, 4, 3, 2)(5, 13, 19, 23, 25)(6, 36, 35, 8, 7)(9, 16, 21,
    24, 17)(10, 33, 32, 31, 11)(12, 18, 22, 15, 20)(14, 29, 28,
    27, 26)(30, 38, 44, 48, 50)(34, 41, 46, 49, 42)(37, 43, 47,
    40, 45)
```

70.3.5 Conversion from a Special Form of FP-Group

Groups that satisfy certain properties, such as being abelian or polycyclic, are known to possess presentations with respect to which the word problem is soluble. Specialised categories have been constructed in Magma for several of these, e.g. the categories GrpGPC, GrpPC and GrpAb. The functions described in this section allow a group created in one of the special presentation categories to be recast as an fp-group.

`FPGroup(G)`

Given a group G, defined either by a polycyclic group presentation (types GrpPC and GrpGPC) or an abelian group presentation (type GrpAb), return a group H isomorphic to G, together with the isomorphism $\phi : G \to H$. The generators for H will correspond to the generators of G. The effect of this function is to convert a presentation in a special form into a general fp-group presentation.

Example H70E13

We illustrate the cast from special forms of fp-groups to the category `GrpFP` by converting a polycyclic group.

```
> G := DihedralGroup(GrpGPC, 0);
> G;
GrpGPC : G of infinite order on 2 PC-generators
PC-Relations:
    G.1^2 = Id(G),
    G.2^G.1 = G.-2
> F := FPGroup(G);
> F;
Finitely presented group F on 2 generators
Relations
    F.1^2 = Id(F)
    F.2^F.1 = F.2^-1
    F.1^-1 * F.2^-1 * F.1 = F.2
```

70.3.6 Construction of a Standard Group

A number of functions are provided which construct presentations for various standard groups.

`AbelianGroup(GrpFP, [n1,...,nr])`

Construct the abelian group defined by the sequence $[n_1, \ldots, n_r]$ of non-negative integers as an fp-group. The function returns the direct product of cyclic groups $C_{n_1} \times C_{n_2} \times \cdots \times C_{n_r}$, where C_0 is interpreted as an infinite cyclic group.

`AlternatingGroup(GrpFP, n)`

`Alt(GrpFP, n)`

Construct the alternating group of degree n as an fp-group, where the generators correspond to the permutations $(3, 4, \ldots, n)$ and $(1, 2, 3)$, for n odd, or $(1, 2)(3, 4, \ldots, n)$ and $(1, 2, 3)$, for n even.

`BraidGroup(GrpFP, n)`

Construct the braid group on n strings ($n - 1$ Artin generators) as an fp-group.

`CoxeterGroup(GrpFP, t)`

Construct the Coxeter group of Cartan type t as a finitely presented group, given by the standard Coxeter presentation. The Cartan type t is passed to this function as a string; we refer to Chapter 97 for details.

`CyclicGroup(GrpFP, n)`

Construct the cyclic group of order n as an fp-group.

`DihedralGroup(GrpFP, n)`

For $n > 2$, return the dihedral group of order $2n$ as an fp-group. For $n = 0$, return the infinite dihedral group as an fp-group.

`ExtraSpecialGroup(GrpFP, p, n : parameters)`

Given a small prime p and a small positive integer n, construct an extra-special group G of order p^{2n+1} in the category `GrpFP`. The isomorphism type of G can be selected using the parameter `Type`.

`Type` MonStgElt *Default :* "+"

Possible values for this parameter are "+" (default) and "−".

If `Type` is set to "+", the function returns for $p = 2$ the central product of n copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p.

If `Type` is set to "−", the function returns for $p = 2$ the central product of a quaternion group of order 8 and $n - 1$ copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p^2.

`SymmetricGroup(GrpFP, n)`

`Sym(GrpFP, n)`

Construct the symmetric group of degree n as an fp-group, where the generators correspond to the permutations $(1, 2, \ldots, n)$ and $(1, 2)$.

Example H70E14

We create the symmetric group Sym(8) as an fp-group:

```
> S8 := SymmetricGroup(GrpFP, 8);
> S8;
Finitely presented group S8 on 2 generators
Relations
      S8.1^8 = Id(S8)
      S8.2^2 = Id(S8)
      (S8.1 * S8.2)^7 = Id(S8)
      (S8.1^-1 * S8.2 * S8.1 * S8.2)^3 = Id(S8)
      (S8.2 * S8.1^-2 * S8.2 * S8.1^2)^2 = Id(S8)
      (S8.2 * S8.1^-3 * S8.2 * S8.1^3)^2 = Id(S8)
      (S8.2 * S8.1^-4 * S8.2 * S8.1^4)^2 = Id(S8)
```

We create the Coxeter group of Cartan type $F4$ as an fp-group:

```
> F := CoxeterGroup(GrpFP, "F4");
> F;
```

```
Finitely presented group F on 4 generators
Relations
    (F.2 * F.3)^2 = (F.3 * F.2)^2
    F.1^2 = Id(F)
    F.1 * F.3 = F.3 * F.1
    F.2 * F.4 = F.4 * F.2
    F.1 * F.2 * F.1 = F.2 * F.1 * F.2
    F.2^2 = Id(F)
    F.3^2 = Id(F)
    F.3 * F.4 * F.3 = F.4 * F.3 * F.4
    F.4^2 = Id(F)
    F.1 * F.4 = F.4 * F.1
```

70.3.7 Construction of Extensions

`Darstellungsgruppe(G)`

Given an fp-group G, construct a maximal central extension $\tilde{G}$ of G. The group $\tilde{G}$ is created as an fp-group.

`DirectProduct(G, H)`

Given two fp-groups G and H, construct the direct product of G and H.

`DirectProduct(Q)`

Given a sequence Q of r fp-groups, construct the direct product $Q[1] \times \ldots \times Q[r]$.

`FreeProduct(G, H)`

Given two fp-groups G and H, construct the free product of G and H.

`FreeProduct(Q)`

Given a sequence Q of r fp-groups, construct the free product of the groups $Q[1], \ldots, Q[r]$.

Example H70E15

We construct a maximal central extension of the following group of order 36.

```
> G<x1, x2> := Group<x1, x2 | x1^4,(x1*x2^-1)^2,x2^4,(x1*x2)^3>;
> G;
Finitely presented group G on 2 generators
Relations
       x1^4 = Id(G)
       (x1 * x2^-1)^2 = Id(G)
       x2^4 = Id(G)
       (x1 * x2)^3 = Id(G)
> D := Darstellungsgruppe(G);
> D;
Finitely presented group D on 4 generators
Relations
       D.1^4 * D.3^-1 * D.4^2 = Id(D)
       D.1 * D.2^-1 * D.1 * D.2^-1 * D.4 = Id(D)
       D.2^4 = Id(D)
       D.1 * D.2 * D.1 * D.2 * D.1 * D.2 * D.4 = Id(D)
       (D.1, D.3) = Id(D)
       (D.2, D.3) = Id(D)
       (D.1, D.4) = Id(D)
       (D.2, D.4) = Id(D)
       (D.3, D.4) = Id(D)
> Index(D, sub< D | >);
108
```

Thus, a maximal central extension of G has order 108

Example H70E16

We create the direct product of the alternating group of degree 5 and the cyclic group of order 2.

```
> A5 := Group<a, b | a^2, b^3, (a*b)^5 >;
> Z2 := quo< FreeGroup(1) | $.1^2 >;
> G := DirectProduct(A5, Z2);
> G;
Finitely presented group G on 3 generators
Relations
      G.1^2 = Id(G)
      G.2^3 = Id(G)
      (G.1 * G.2)^5 = Id(G)
      G.3^2 = Id(G)
      G.1 * G.3 = G.3 * G.1
      G.2 * G.3 = G.3 * G.2
```

70.3.8 Accessing the Defining Generators and Relations

The functions in this group provide access to basic information stored for a finitely-presented group G.

`G . i`

The i-th defining generator for G. A negative subscript indicates that the inverse of the generator is to be created. $G.0$ is `Identity(G)`, the empty word in G.

`Generators(G)`

A set containing the generators for the group G.

`NumberOfGenerators(G)`
`Ngens(G)`

The number of generators for the group G.

`PresentationLength(G)`

The total length of the relators for G.

`Relations(G)`

A sequence containing the defining relations for G.

70.4 Homomorphisms

For a general description of homomorphisms, we refer to Chapter 16. This section describes some special aspects of homomorphisms the domain of which is a finitely presented group.

70.4.1 General Remarks

The kernel of a homomorphism with a domain of type `GrpFP` can be computed using the function `Kernel`, if the codomain is of one of the types `GrpGPC`, `GrpPC` (cf. Chapter 63), `GrpAb` (cf. Chapter 69), `GrpPerm` (cf. Chapter 58), `GrpMat` (cf. Chapter 59), `ModAlg` or `ModGrp` (cf. Chapter 89), if the image is finite and its order sufficiently small. In this case, a regular permutation representation of the image is constructed and the kernel is created as a subgroup of the domain, defined by a coset table.

The kernel may also be computable, if the codomain is of the type `GrpFP`, the image is sufficiently small and a presentation for the image is known.

If the kernel of a map can be computed successfully, forming preimages of substructures is possible. An attempt to compute the kernel of a map will be made automatically, if the preimage of a substructure of the codomain is to be computed.

Note, that trying to compute the kernel may be very time and memory consuming; use this feature with care.

70.4.2 Construction of Homomorphisms

```
hom< P -> G | S >
```

Returns the homomorphism from the fp-group P to the group G defined by the assignment S. S can be the one of the following:

(i) A list, sequence or indexed set containing the images of the n generators $P.1, \ldots, P.n$ of P. Here, the i-th element of S is interpreted as the image of $P.i$, i.e. the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing n tuples $< x_i, y_i >$ or arrow pairs $x_i -> y_i$, where x_i is a generator of P and $y_i \in G$ $(i = 1, \ldots, n)$ and the set $\{x_1, \ldots, x_n\}$ is the full set of generators of P. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important.

Note, that it is currently not possible to define a homomorphism by assigning images to the elements of an arbitrary generating set of P. It is the user's responsibility to ensure that the arguments passed to the `hom`-constructor actually yield a well-defined homomorphism. For certain codomain categories, this may be checked using the function `IsSatisfied` described below.

```
IsSatisfied(U, E)
```

U is a set or sequence of either words belonging to an n-generator fp-group H or relations over H. E is a sequence of n elements $[e_1, \ldots, e_n]$ belonging to a group G for which both, multiplication and comparison of elements are possible. Using the mapping $H.i \to e_i$ $(i = 1, \ldots, n)$, we evaluate the relations given by U. If U is a set or sequence of relations, the left and right hand sides of each relation are evaluated and compared for equality. Otherwise, each word in U is evaluated and compared to the identity. If all relations are satisfied, `IsSatisfied` returns the Boolean value `true`. On the other hand, if any relation is not satisfied, `IsSatisfied` returns the value `false`.

This function may be used to verify the correctness of the definition of a homomorphism from an fp-group to a group in a category for which both, multiplication and comparison of elements are possible.

70.4.3 Accessing Homomorphisms

```
w @ f
```

```
f(w)
```

Given a homomorphism whose domain is an fp-group G and an element w of G, return the image of w under f as an element of the codomain of f.

```
H @ f
```

```
f(H)
```

Given a homomorphism whose domain is an fp-group G and a subgroup H of G, return the image of H under f as a subgroup of the codomain of f.

Some maps do not support images of subgroups.

`g @@ f`

Given a homomorphism whose domain is an fp-group G and an element g of the image of f, return the preimage of g under f as an element of G.

Some maps do not support inverse images.

`H @@ f`

Given a homomorphism whose domain is an fp-group G and a subgroup H of the image of f, return the preimage of H under f as a subgroup of G.

Some maps do not support inverse images. The inverse image of a subgroup of the codomain can only be computed if the kernel of the homomorphism can be computed, i.e. if the kernel has moderate index in the domain.

`Domain(f)`

The domain of the homomorphism f.

`Codomain(f)`

The codomain of the homomorphism f.

`Image(f)`

The image or range of the homomorphism f as a subgroup of the codomain of f.

Some maps do not support this function.

`Kernel(f)`

The kernel of the homomorphism f as a (normal) subgroup of the domain of f, represented by a coset table.

Some maps do not support this function. The kernel of a homomorphism can only be computed, if it has moderate index in the domain.

Example H70E17

For arbitrary $n > 0$, the symmetric group of degree $n + 1$ is an epimorphic image of the braid group on n generators. In this example, we exhibit this relationship for $n = 4$.
We start with creating the braid group B on 5 strings, i.e. 4 Artin generators.

```
> B := BraidGroup(GrpFP, 5);
> B;
Finitely presented group B on 4 generators
Relations
    B.1 * B.2 * B.1 = B.2 * B.1 * B.2
    B.1 * B.3 = B.3 * B.1
    B.1 * B.4 = B.4 * B.1
    B.2 * B.3 * B.2 = B.3 * B.2 * B.3
    B.2 * B.4 = B.4 * B.2
```

```
    B.3 * B.4 * B.3 = B.4 * B.3 * B.4
```

In the symmetric group of degree 5, we define 4 transpositions which will be the images of the generators of B.

```
> S := SymmetricGroup(5);
> imgs := [ S!(1,2), S!(2,3), S!(3,4), S!(4,5) ];
```

In order to verify that this assignment actually gives rise to a well defined homomorphism, we check whether the potential images satisfy the defining relations of B.

```
> rels := Relations(B);
> rels;
[ B.1 * B.2 * B.1 = B.2 * B.1 * B.2, B.1 * B.3 = B.3 * B.1,
  B.1 * B.4 = B.4 * B.1, B.2 * B.3 * B.2 = B.3 * B.2 * B.3,
  B.2 * B.4 = B.4 * B.2, B.3 * B.4 * B.3 = B.4 * B.3 * B.4 ]
> IsSatisfied(rels, imgs);
true
```

They do. So we can define the homomorphism from B to S.

```
> f := hom< B->S | imgs >;
```

We see that f is surjective, i.e. S is an epimorphic image of B as claimed above.

```
> f(B) eq S;
true
```

We now check the kernel of f.

```
> Kernel(f);
Finitely presented group
Index in group B is 120 = 2^3 * 3 * 5
Subgroup of group B defined by coset table
```

Using the function GeneratingWords described later, we can obtain a set of generators of $\ker(f)$ as a subgroup of B.

```
> GeneratingWords(B, Kernel(f));
{ B.2^-2, (B.1 * B.2 * B.3^-1 * B.2^-1 * B.1^-1)^2, B.1^-2,
  (B.3 * B.4^-1 * B.3^-1)^2, (B.2 * B.3^-1 * B.2^-1)^2,
  (B.2 * B.3 * B.4^-1 * B.3^-1 * B.2^-1)^2, B.4^-2,
  (B.1 * B.2^-1 * B.1^-1)^2, B.3^-2,
  (B.1 * B.2 * B.3 * B.4^-1 * B.3^-1 * B.2^-1 * B.1^-1)^2 }
```

It is easy to see that all generators of $\ker(f)$ are conjugates of words of the form $g^{\pm 2}$, where g is a generator of B. We check this, using the normal closure constructor ncl described later.

```
> Kernel(f) eq ncl< B | B.1^2, B.2^2, B.3^2, B.4^2 >;
true
```

Thus, the braid relations together with the relations $B.1^2, B.2^2, B.3^2, B.4^2$ are a set of defining relations for S.

70.4.4 Computing Homomorphisms to Finite Groups

This section describes functions for computing representatives of the classes of homomorphisms from a finitely presented group F to a finite group G modulo a group A of automorphisms of G.

`Homomorphisms(F, G, A` : *parameters*`)`

`Homomorphisms(F, G` : *parameters*`)`

Given a finitely presented group F and two permutation groups G and A with $G \triangleleft A$, return a sequence containing representatives of the classes of homomorphisms from F to G modulo automorphisms of G induced by elements of A. (That is, two homomorphisms f_1, $f_2 : F \to G$ are considered equivalent if there exists an element $a \in A$ such that $f_1(x) = f_2(x)^a$ for all $x \in F$.) The call `Homomorphisms(F, G)` is equivalent to `Homomorphisms(F, G, G)`.

The function uses a backtrack algorithm testing certain conjugates of representatives of the A-classes in G as possible images of the generators of F.

The following parameters are available for this function.

`Surjective` BoolElt *Default :* `true`

If this parameter is set to `true` (default), only epimorphisms are considered.

`Limit` RngIntElt *Default :* 0 (no limit)

If this parameter is set to n, the function terminates after n classes of homomorphisms satisfying the specified conditions have been found. A value of 0 (default) means no limit.

`TimeLimit` RngIntElt *Default :* 0 (no limit)

A limit in seconds for the amount of time spent in the backtrack search for homomorphisms. The time spent in initial coset enumerations is *not* counted towards this limit. A value of 0 (default) means no limit.

`CosetEnumeration` BoolElt *Default :* `true`

If this parameter is set to `true` (default), a number of short coset enumerations are performed for each generator of F in order to check whether some A-classes in G can be ruled out as possible images for this generator. If a class can be ruled out, the complexity of the backtrack search may be reduced significantly.

In situations where it seems unlikely that classes can be ruled out as possible generator images, experienced users may wish to turn this feature off in order to save the time spent on the coset enumerations.

`CacheCosetAction` BoolElt *Default :* `true`

The value of this parameter indicates whether the actions of A on the cosets of the centralisers of representatives of the A-classes in G are cached during the backtrack search.

Setting this parameter to `true` (default) results in faster computations and is recommended for normal applications. When computing homomorphisms to large

groups with many conjugate classes, this parameter can be set to `false` in order to reduce memory requirements at the expense of increased computing time.

Example H70E18

Consider the finitely presented group

$$F := < a, b, c \mid ac^{-1}bc^{-1}aba^{-1}b, abab^{-1}c^2b^{-1}, a^2b^{-1}(ca)^4cb^{-1} > .$$

```
> F := Group< a,b,c | a*c^-1*b*c^-1*a*b*a^-1*b,
>                     a*b*a*b^-1*c^2*b^-1,
>                     a^2*b^-1*c*a*c*a*c*a*c*a*c*b^-1 >;
```

We use the function Homomorphisms to prove that F maps onto A_5.

```
> G := Alt(5);
> homs := Homomorphisms(F, G : Limit := 1);
> #homs gt 0;
true
```

`Homomorphisms(F, G, A : parameters)`

`Homomorphisms(F, G : parameters)`

Given a finitely presented group F and two finite polycyclic groups G and A with $G \triangleleft A$, return a sequence containing representatives of the classes of homomorphisms from F to G modulo automorphisms of G induced by elements of A. (That is, two homomorphisms f_1, $f_2 : F \to G$ are considered equivalent if there exists an element $a \in A$ such that $f_1(x) = f_2(x)^a$ for all $x \in F$.) The call `Homomorphisms(F, G)` is equivalent to `Homomorphisms(F, G, G)`.

The following parameters are available for this function.

`Surjective` BoolElt *Default :* `true`

If this parameter is set to `true` (default), only epimorphisms are considered.

`Limit` RngIntElt *Default :* 0 (no limit)

If this parameter is set to n, the function terminates after n classes of homomorphisms satisfying the specified conditions have been found. A value of 0 (default) means no limit.

70.4.4.1 Computing Homomorphisms to Permutation Groups Interactively

A process version of the algorithm used by Homomorphisms is available for computing homomorphisms one at a time. The functions relevant for this interactive version are described in this section.

`HomomorphismsProcess(F, G, A : parameters)`

`HomomorphismsProcess(F, G : parameters)`

Given a finitely presented group F and two permutation groups G and A with $G \triangleleft A$, return a process P for computing representatives of the classes of homomorphisms from F to G modulo automorphisms of G induced by elements of A. (That is, two homomorphisms $f_1, f_2 : F \to G$ are considered equivalent if there exists an element $a \in A$ such that $f_1(x) = f_2(x)^a$ for all $x \in F$.) `HomomorphismsProcess(F, G)` is equivalent to `HomomorphismsProcess(F, G, G)`.

After constructing the process, the search for homomorphisms is started and runs until the first homomorphism is found, the time limit is reached (in which case P is marked as *invalid*) or the search is completed without finding a homomorphism (in which case P is marked as *empty*).

The parameters have the same meaning as for the function Homomorphisms.

`Surjective`	BoolElt	*Default :* `true`
`Limit`	RngIntElt	*Default :* 0 (no limit)
`TimeLimit`	RngIntElt	*Default :* 0 (no limit)
`CosetEnumeration`	BoolElt	*Default :* `true`
`CacheCosetAction`	BoolElt	*Default :* `true`

Setting a time limit for a process P limits the total amount of time spent in the backtrack search for homomorphisms during the construction of P and in subsequent calls to NextElement and Complete. The time spent in initial coset enumerations is *not* counted towards this limit.

If the time limit or the limit on the number of homomorphisms set for a process P is reached, P becomes *invalid*. Calling NextElement or Complete for an invalid process or for a process which is *empty*, that is, which has found all possible classes of homomorphisms, will cause a runtime error. The functions IsValid and IsEmpty can be used to check whether a process is valid or empty, respectively. The use of these functions is recommended to avoid runtime errors in loops or user written functions.

`NextElement(~P)`

Given a valid and non-empty process P, continue the backtrack search until a new class of homomorphisms is found. If the search completes without a new representative being found, P is marked as empty. If a limit set for P is reached, P is marked as invalid.

`Complete(~P)`

Given a valid and non-empty process P, continue the search for homomorphisms until all classes of homomorphisms have been found or a limit set for P is reached. If the search for homomorphisms completes, P is marked as empty. If a limit set for P is reached, P is marked as invalid.

`IsEmpty(P)`

Returns whether P is empty, that is, whether all possible classes of homomorphisms have been found.

`IsValid(P)`

Returns `false` if a limit set for P has been reached and `true` otherwise. Note that the return value of `IsValid` is not related to whether or not P currently defines a homomorphism.

`DefinesHomomorphism(P)`

Returns whether P currently defines a homomorphism which can be extracted using the function `Homomorphism`.

`Homomorphism(P)`

Given a process P which defines a homomorphism, return this homomorphism, that is, the homomorphism most recently found by P. If P does not define a homomorphism, a runtime error will result. The function `DefinesHomomorphism` can be used to test whether a call to `Homomorphism` is legal for a process.

`#P`

Return the number of homomorphisms that have been found by the process P.

`Homomorphisms(P)`

Return a sequence containing all homomorphisms that have been found by the process P. Note that the sequence will only contain a complete set of representatives of the classes of homomorphisms if P is empty, that is, if the backtrack search for P has been completed.

Example H70E19

Consider the braid group B on 4 strings. We show how the interactive computation of homomorphisms can be used to determine a homomorphism $f : B \to \mathrm{PSL}(2, 16)$ whose image is a maximal subgroup of $\mathrm{PSL}(2, 16)$.

Note how the functions `IsValid`, `IsEmpty` and `DefinesHomomorphism` are used to avoid runtime errors in the `while` loop.

```
> B := BraidGroup(GrpFP, 4);
> G := PSL(2,16);
> P := HomomorphismsProcess(B, G : Surjective := false,
```

```
>                                  TimeLimit := 10);
> while not IsEmpty(P) do
>    if DefinesHomomorphism(P) then
>       f := Homomorphism(P);
>       img := Image(f);
>       if IsMaximal(G,img) then
>          print "found image which is maximal subgroup";
>          break;
>       end if;
>    end if;
>    if IsValid(P) then
>       NextElement(~P);
>     else
>       print "Limit has been reached";
>       break;
>    end if;
> end while;
found image which is maximal subgroup
>
> f;
Homomorphism of GrpFP: B into GrpPerm: G, induced by
  B.1 |--> (1, 4, 3, 6, 12)(2, 11, 9, 16, 7)(5, 17, 8, 15, 13)
  B.2 |--> (1, 4, 2, 10, 16)(3, 11, 9, 12, 14)(5, 15, 8, 13, 17)
  B.3 |--> (1, 4, 3, 6, 12)(2, 11, 9, 16, 7)(5, 17, 8, 15, 13)
```

Example H70E20

This example sketches how the interactive version of the homomorphism algorithm could be used as part of a function trying to prove that a group is infinite.

Note again how the functions IsValid, IsEmpty and DefinesHomomorphism are used to avoid runtime errors.

```
> function MyIsInfinite(F)
>
>  // ...
>
>  // quotient approach: check whether an obviously infinite
>  //    normal subgroup can be found in reasonable time.
>  S := [ Alt(5), PSL(2,7), PSL(2,9), PSL(2,11) ];
>  for G in S do
>     P := HomomorphismsProcess(F, G : Surjective := false,
>                                      TimeLimit := 5);
>     while IsValid(P) and not IsEmpty(P) do
>       if DefinesHomomorphism(P) then
>          f := Homomorphism(P);
>          if 0 in AQInvariants(Kernel(f)) then
>             print "found infinite normal subgroup";
```

```
>             print "Hence group is infinite";
>             return true;
>          end if;
>       end if;
>       if IsValid(P) then
>          NextElement(~P);
>       end if;
>    end while;
>  end for;
>  print "quotient approach failed; trying other strategies";
>
>  // ...
>
> end function;
```

We try the code fragment on the group

$$< a, b \mid ab^{-1}a^{-1}ba^{-1}b^{-1}abb, ab^{-1}a^{-1}baaba^{-1}b^{-1}ab^{-1}a^{-1}baba^{-1}b^{-1} > .$$

```
> F := Group< a,b |
>    a*b^-1*a^-1*b*a^-1*b^-1*a*b*b,
>    a*b^-1*a^-1*b*a*a*b*a^-1*b^-1*a*b^-1*a^-1*b*a*b*a^-1*b^-1 >;
> MyIsInfinite(F);
found infinite normal subgroup
Hence group is infinite
true
```

70.4.4.2 Finding Homomorphisms onto Simple Groups

We describe utilities for finding homomorphisms onto simple groups. As in the previous example, this may be useful when the presentation defines a perfect group. The methods used are similar to the example, with a list of simple groups to try, and using the function Homomorphisms.

The list of simple groups supplied in V2.10 contains all non-abelian simple groups with order $\leq 10^9$. Such a list is dominated by $PSL(2, q)$'s with q odd. In this implementation these $PSL(2, q)$'s are treated as an infinite family rather than stored individually, and so continue beyond the above limit.

`SimpleQuotients(F, deg1, deg2, ord1, ord2:` *parameters*`)`

`SimpleQuotients(F, ord1, ord2:` *parameters*`)`

`SimpleQuotients(F, ord2:` *parameters*`)`

`Family`	ANY	*Default :* "*All*"
`Limit`	RNGINTELT	*Default :* 1
`HomLimit`	RNGINTELT	*Default :* 0

Uses Homomorphisms to find epimorphisms from F onto simple groups in a fixed list. The arguments $deg1$ and $deg2$ are respectively lower and upper bounds for the degree of the image group. If the degree arguments are not present then bounds of 5 and 10^7 are used. The arguments $ord1$ and $ord2$ are respectively lower and upper bounds for the orders of the image group. (Setting $ord2$ low enough is particularly important if a quick search is wanted.) If $ord1$ is not given then it defaults to 1.

The return value is a list of sequences of epimorphisms found. Each sequence contains epimorphisms onto one simple group. The parameter `Limit` limits the number of successful searches to be carried out by Homomorphisms. The default value is 1, so by default the search terminates with the first simple group found to be a homomorphic image of F.

The parameter `HomLimit` limits the number of homomorphisms that will be searched for by any particular call to Homomorphisms. It defaults to zero, so that all homomorphisms for any group found will be returned.

The parameter `Family` selects sublists of the main list to search. Possible values of this parameter are `"All"`, `"PSL"`, `"PSL2"`, `"Mathieu"`, `"Alt"`, `"PSp"`, `"PSU"`, `"Other"`, and `"notPSL2"`; sets of these strings are also allowed, which searches on the union of the appropriate sublists.

`SimpleQuotientProcess(F, deg1, deg2, ord1, ord2: parameters)`

`Family` ANY *Default : "All"*

Produce a record that defines a process for searching for simple quotients of F as SimpleQuotients does. Calling this function sets up the record and conducts the initial search until a quotient is found. Continuing the search for another quotient is done by calling NextSimpleQuotient. Extracting the epimorphisms found is achieved using SimpleEpimorphisms, and testing if the process has expired is the task of IsEmptySimpleQuotientProcess.

`NextSimpleQuotient(~P)`

When P is a record returned by SimpleQuotientProcess, advance the search to the next simple group which is a homomorphic image of the finitely presented group. Does nothing if the process has expired.

`IsEmptySimpleQuotientProcess(P)`

When P is a record returned by SimpleQuotientProcess, test whether or not P has expired.

`SimpleEpimorphisms(P)`

When P is a record returned by SimpleQuotientProcess, extract the most recently found epimorphisms onto a simple group, plus a tuple describing the image group. This is a valid operation when IsEmptySimpleQuotientProcess returns `false`.

Example H70E21

We take a perfect finitely presented group and search for simple quotients.

```
> F := Group<a,b,c|a^13,b^3,c^2,a = b*c>;
> IsPerfect(F);
true
> L := SimpleQuotients(F,1, 100, 2, 10^5:Limit := 2);
> #L;
2
> for x in L do CompositionFactors(Image(x[1])); end for;
    G
    |  A(1, 13)               = L(2, 13)
    1
    G
    |  A(2, 3)                = L(3, 3)
    1
> L[2,1];
Homomorphism of GrpFP: F into GrpPerm: $, Degree 13, Order
2^4 * 3^3 * 13 induced by
F.1 |--> (1, 10, 4, 5, 11, 8, 3, 6, 7, 12, 9, 13, 2)
F.2 |--> (2, 10, 4)(3, 6, 7)(5, 11, 13)(8, 12, 9)
F.3 |--> (1, 10)(2, 5)(3, 12)(8, 13)
> #L[2];
2
```

We've found L(2,13) and L(3,3) as images, with 2 inequivalent homomorphisms onto the second. We'll try a process looking through a smaller family.

```
> P := SimpleQuotientProcess(F,1, 100, 2, 10^6:Family:="PSU");
> IsEmptySimpleQuotientProcess(P);
false
> eps, info := SimpleEpimorphisms(P);
> info;
<65, 62400, PSU(3, 4)>
```

We've found PSU(3,4) of order 62400 and degree 65 as an image. We continue with this process.

```
> NextSimpleQuotient(~P);
> IsEmptySimpleQuotientProcess(P);
true
```

No, there are no more within the limits given.

70.4.5 The L_2-Quotient Algorithm

Given a finitely presented group G on two generators, the L_2-quotient algorithm of Plesken and Fabianska [PF09] computes all quotients of G which are isomorphic to some $\mathrm{PSL}(2,q) = L_2(q)$, simultaneously for any prime power q. It can handle the case of infinitely many quotients, and also works for very large prime powers.

Note that, at the moment, the algorithm does not return images onto the groups $\mathrm{PSL}(2,2)$, $\mathrm{PSL}(2,3)$, and $\mathrm{PSL}(2,4) = \mathrm{PSL}(2,5)$.

`L2Quotients(G)`

This is the main method. It takes as parameter a finitely presented group on two generators, and returns a list of prime ideals of $Z[x_1, x_2, x_{12}]$. These prime ideals contain all information about the L_2-quotients.

`L2Type(P)`

For a prime ideal P in $Z[x_1, x_2, x_{12}]$, this method returns a string describing the L_2-type which the ideal encodes. The possible types are "`reducible`", "`dihedral`", "`Alt(4)`", "`Sym(4)`", "`Alt(5)`", "`infinite (characteristic zero)`", "`infinite (characteristic p)`", "`PGL(2, q)`", and "`PSL(2, q)`". Note that for prime ideals which are returned by `L2Quotients` or `L2Ideals`, only the last four types can occur; the other types are eliminated in these methods.

`L2Generators(P)`

Given a maximal ideal M in $Z[x_1, x_2, x_{12}]$, compute two matrices with entries in $Z[x_1, x_2, x_{12}]/M$ corresponding to M.

`L2Ideals(I)`

Given an ideal I in $Z[x_1, x_2, x_{12}]$, compute the minimal associated primes of I which give rise to L_2-quotients. This is mainly used for ideals returned by `L2Quotients` which encode infinitely many L_2 images.

Example H70E22

The first few examples are taken from Conder, Havas and Newman [CHN11].

```
> Gamma< x, y > := Group< x, y | x^2, y^3 >;
> u := x*y; v := x*y^-1;
> G := quo< Gamma | u^10*v^2*u*v*u*v^2 >;
> quot := L2Quotients(G); quot;
[
Ideal of Polynomial ring of rank 3 over Integer Ring
Order: Lexicographical
Variables: x1, x2, x12
Inhomogeneous, Dimension 0
Groebner basis:
[
    x1,
```

```
    x2 + 1,
    x12^2 + 4*x12 + 2,
    5
]
]
```

`L2Quotients` returns only one ideal, so there is only one L_2 quotient. We can use `L2Type` to check what group this is.

```
> L2Type(quot[1]);
PSL( 2, 5^2 )
```

Finally, `L2Generators` returns matrices in $\mathrm{SL}(2, 25)$ which map onto generators in $\mathrm{PSL}(2, 25)$.

```
> L2Generators(quot[1]);
MatrixGroup(2, GF(5^2))
Generators:
    [     3 $.1^21]
    [     0      2]
    [     0      4]
    [     1      4]
Mapping from: MatrixGroup(2, GF(5^2)) to GL(2, ext<GF(5) | Polynomial(GF(5),
\[3, 3, 1])>)
```

There are other quotients of the modular group with only finitely many L_2 quotients:

```
> G := quo< Gamma | u^3*v*u^3*v*u^3*v^2*u*v^2 >;
> quot := L2Quotients(G);
> [L2Type(P) : P in quot];
[ PGL( 2, 13 ) ]
>
> G := quo< Gamma | u^3*v*u^3*v^2*u*v^3*u*v^2 >;
> quot := L2Quotients(G);
> [L2Type(P) : P in quot];
[]
```

This tells us that the first group has only one L_2 quotient, isomorphic to $\mathrm{PGL}(2, 13)$, and the second group has no L_2 quotients at all.

Example H70E23

Next, we look at Coxeter presentations of the form

$$(l, m|n, k) = \langle x, y | x^l, y^m, (xy)^n, (x^(- 1)y)^k \rangle$$

and

$$(l, m, n; q) = \langle x, y | x^l, y^m, (xy)^n, [x, y]^k \rangle$$

for various values of l, m, n, k, q.

```
> G := Group< x,y | x^8, y^9, (x*y)^5, (x^-1*y)^7 >;
> [L2Type(P) : P in L2Quotients(G)];
[ PSL( 2, 71 ), PSL( 2, 71 ), PSL( 2, 71 ), PSL( 2, 2521 ), PSL( 2, 239 ),
```

```
PSL( 2, 449 ), PSL( 2, 3876207679 ), PSL( 2, 1009 ), PSL( 2, 29113631 ),
PSL( 2, 41 ), PSL( 2, 3056201 ) ]
```

The group $\mathrm{PSL}(2,71)$ occurs three times. This means that there are three essentially different epimorphisms of G onto $\mathrm{PSL}(2,71)$, i.e., there is no automorphism of $\mathrm{PSL}(2,71)$ which transforms one epimorphism into another.
Here is another example, this time for the other family.

```
> G := Group< x, y | x^4, y^3, (x*y)^5, (x,y)^6 >;
> [L2Type(P) : P in L2Quotients(G)];
[ PSL( 2, 79 ), PSL( 2, 3^2 ), PSL( 2, 5^2 ) ]
```

There are three groups in the second family for which it is not known whether they are finite or infinite (Havas & Holt (2010) [HH10]). They are $(3,4,9;2)$, $(3,4,11;2)$, and $(3,5,6;2)$. Each of them has only one L_2 image.

```
> G := Group< x, y | x^3, y^4, (x*y)^9, (x,y)^2 >;
> [L2Type(P) : P in L2Quotients(G)];
[ PSL( 2, 89 ) ]
> G := Group< x, y | x^3, y^4, (x*y)^11, (x,y)^2 >;
> [L2Type(P) : P in L2Quotients(G)];
[ PSL( 2, 769 ) ]
> G := Group< x, y | x^3, y^5, (x*y)^6, (x,y)^2 >;
> [L2Type(P) : P in L2Quotients(G)];
[ PSL( 2, 61 ) ]
```

The algorithm currently only works for finitely presented groups on two generators. However, it is sometimes possible to reduce the number of generators for finitely presented groups on more than two generators.
The following examples are taken from Cavicchioli, O'Brien and Spaggiari [COS08], with code supplied by Eamonn O'Brien.

```
> CHR := function (X)
>    n := X[1]; m := X[2]; k := X[3];
>    F := FreeGroup (n);
>    R := [];
>    for i in [1..n] do
>       a := i + m;
>       if a gt n then repeat a := a - n; until a le n; end if;
>       b := i + k;
>       if b gt n then repeat b := b - n; until b le n; end if;
>       Append (~R, F.i * F.a = F.b);
>    end for;
>    Q := quo < F | R >;
>    return Q;
> end function;
> G := CHR([9, 1, 3]); G;
Finitely presented group G on 9 generators
Relations
    G.1 * G.2 = G.4
    G.2 * G.3 = G.5
```

```
    G.3 * G.4 = G.6
    G.4 * G.5 = G.7
    G.5 * G.6 = G.8
    G.6 * G.7 = G.9
    G.7 * G.8 = G.1
    G.8 * G.9 = G.2
    G.9 * G.1 = G.3
> H := ReduceGenerators(G); H;

    H.1^-1 * H.2 * H.1^-1 * H.2^2 * H.1^-1 * H.2^3 * H.1^-1 * H.2 * H.1^-1 * H.2^2
    * H.1^-1 * H.2 * H.1^-1 = Id(H)
> [L2Type(Q) : Q in L2Quotients(H)];
[]
```

Example H70E24

The algorithm also handles the case in which there are infinitely many L2 quotients. This is the case if one of the prime ideals returned by `L2Quotients` is not maximal. They can be handled theoretically to get a precise list of all images. The functions in Magma can be used to get information for a specified ideal containing the prime ideal.
We start again with a quotient of the modular group.

```
> Gamma< x, y > := Group< x, y | x^2, y^3 >;
> u := x*y; v := x*y^-1;
> G := quo< Gamma | u^5*v*u*v*u*v^5*u*v*u*v >;
> quot := L2Quotients(G);
> [L2Type(P) : P in quot];
[ infinite (characteristic zero) ]
```

This means that there are infinitely many L_2 quotients of G (which already proves that G is infinite). Let's look at the prime ideal.

```
> P := quot[1]; P;
Ideal of Polynomial ring of rank 3 over Integer Ring
Order: Lexicographical
Variables: x1, x2, x12
Inhomogeneous, Dimension 0
Groebner basis:
[
    x1,
    x2 + 1,
    x12^8 - 5*x12^6 + 6*x12^4 - 1
]
```

The residue class ring of P is a finite algebraic extension S of Z, and the algorithm found a homomorphism of G into $\mathrm{PSL}(2, S)$. Since S has epimorphisms onto finite fields in every characteristic, this gives homomorphisms of G into $\mathrm{PSL}(2, p^k)$ for every prime p and suitable k. To check what images there are in characteristic p, we construct the ideal $I = \langle p \rangle + P$. This is no longer prime in general. We can use `L2Ideals` to compute the associated primes of I; this method also removes all ideals which don't give rise to epimorphisms.

```
> R := Generic(P);
> I := ideal< R | 2 > + P;
> quot := L2Ideals(I);
> [L2Type(Q) : Q in quot];
[ PSL( 2, 2^4 ) ]
```

So G has one quotient isomorphic to $\mathrm{PSL}(2, 16)$, and we can construct images of the generators of G.

```
> L2Generators(quot[1]);
MatrixGroup(2, GF(2^4))
Generators:
    [     1  $.1^6]
    [     0      1]
```

```
    [     0      1]
    [     1      1]
Mapping from: MatrixGroup(2, GF(2^4)) to GL(2, ext<GF(2) | Polynomial(GF(2),
\[1, 0, 0, 1, 1])>)
```

We can check the images in various other characteristics:

```
> for p in PrimesInInterval(3, 19) do
>     [L2Type(Q) : Q in L2Ideals(ideal< R | p > + P)];
> end for;
[ PGL( 2, 3^4 ) ]
[ PGL( 2, 5^2 ) ]
[ PSL( 2, 7^2 ), PSL( 2, 7^2 ), PGL( 2, 7^2 ) ]
[ PGL( 2, 11 ), PGL( 2, 11 ), PGL( 2, 11^2 ) ]
[ PSL( 2, 13^2 ), PSL( 2, 13^2 ), PSL( 2, 13^2 ), PSL( 2, 13^2 ) ]
[ PSL( 2, 17^4 ), PSL( 2, 17^4 ) ]
[ PSL( 2, 19 ), PSL( 2, 19 ), PSL( 2, 19^2 ), PSL( 2, 19^2 ), PGL( 2, 19 ) ]
```

There is virtually no limit on the size of the prime:

```
> p := RandomPrime(200);
> p;
307941320171307176726971038693755343299358400663182805777637
> I := ideal< R | p > + P;
> [L2Type(Q) : Q in L2Ideals(I)];
[ PGL( 2, 307941320171307176726971038693755343299358400663182805777637^2 ),

```

Example H70E25

In the previous example, the group had infinitely many L_2 quotients, finitely many in every characteristic. The next example presents a group which has infinitely many L_2r quotients, but only in a single characteristic.

```
> G := Group< x, y | x*y*x^-1*y*x*y^4*x^-1*y^-4 >;
> quot := L2Quotients(G);
> [L2Type(Q) : Q in quot];
[ infinite (characteristic 41) ]
> P := quot[1]; P;
Ideal of Polynomial ring of rank 3 over Integer Ring
Order: Lexicographical
Variables: x1, x2, x12
Inhomogeneous, Dimension >0
Groebner basis:
[
    x1 + 30*x2*x12,
    x2^2 + 22,
    41
]
```

The residue class ring of P is $S = F_{41^2}[x_{12}]$, and the algorithm found a homomorphism into $\mathrm{PSL}(2, S)$. Since S has epimorphisms onto every finite extension of F_{41^2}, this gives homomorphisms of G into $\mathrm{PSL}(2, 41^{(}2 * k))$ for every k.
We specialize x_{12} to different elements of extensions of F_{41^2}. For example, for different specializations in F_{41^2} we get an image onto $\mathrm{PGL}(2, 41)$ or $\mathrm{PSL}(2, 41^2)$:

```
> R< x1, x2, x12 > := Generic(P);
>
> I := ideal< R | x12 - 1 > + P;
> [L2Type(Q) : Q in L2Ideals(I)];
[ PGL( 2, 41 ) ]
>
> I := ideal< R | x12 - (x2 + 1) > + P;
> [L2Type(Q) : Q in L2Ideals(I)];
[ PSL( 2, 41^2 ) ]
```

We can check the images for a random specialization:

```
> pol := &+[Random([0..40])*x12^i : i in [0..30]]; pol;
19*x12^30 + x12^29 + 16*x12^28 + 14*x12^27 + 38*x12^26 + 27*x12^25 + 20*x12^24 +
    31*x12^23 + 15*x12^22 + 22*x12^21 + 32*x12^20 + 26*x12^19 + 26*x12^18 +
    18*x12^17 + 16*x12^16 + 29*x12^15 + 18*x12^14 + 11*x12^13 + 3*x12^12 +
    11*x12^11 + 36*x12^10 + 13*x12^9 + 15*x12^8 + 33*x12^7 + 30*x12^6 + 8*x12^5 +
    12*x12^4 + 40*x12^3 + 12*x12^2 + 25*x12 + 8;
> I := ideal< R | pol > + P;
> [L2Type(Q) : Q in L2Ideals(I)];
[ PGL( 2, 41 ), PGL( 2, 41 ), PGL( 2, 41 ), PSL( 2, 41^2 ), PSL( 2, 41^2 ),
PSL( 2, 41^2 ), PSL( 2, 41^2 ), PSL( 2, 41^14 ), PSL( 2, 41^14 ),
```

```
PGL( 2, 41^9 ) ]
```

And again, this works for very large fields:

```
> pol := IrreduciblePolynomial(GF(41), 301);
> pol;
$.1^301 + $.1^2 + 6*$.1 + 30
> I := ideal< R | x12^301 + x12^2 + 6*x12 + 30 > + P;
> [L2Type(Q) : Q in L2Ideals(I)];
[ PGL( 2, 41^301 ) ]
```

70.4.6 Infinite L2 quotients

This section contains functions that use the L2-quotient algorithm of Plesken and Fabianska ([PF09]) to establish the existence or not of an infinite quotient of a finitely-presented group in $PSL_2(K)$ for K a field of characteristic zero. The algorithm is often used to find surjective quotients over finite fields but as a test for non-finiteness it is easier to work directly in characteristic zero. We make some comments on the relation to finite fields below.

The algorithm first constructs an affine scheme X over $\mathbf{Q}$ from the "trace ideal" of the group G, for which the algebraic points over a field K are in 1-1 correspondence with equivalence classes of representations of G into $SL_2(K)$. If $g_1, \ldots, g_n$ are the generators of G, then the affine coordinates of X correspond to the trace under the representation of various products of the G_i. For example, when $n = 2$, X lies in 3-dimensional affine space and the coordinates correspond to the traces of g_1, g_2 and g_1g_2. The ideal is actually generated by polynomials with coefficients in $\mathbf{Z}$ so X is naturally defined as a scheme over $Spec(\mathbf{Z})$, whose reduction mod p just gives the scheme corresponding to characteristic p representations of G for $p > 2$.

Homomorphisms into PSL_2 rather than SL_2 are dealt with by considering a number of X schemes for a particular G. Each one represents the homomorphisms from the free cover of G to SL_2 that takes each word in the set of relations defining G to either I or $-I$. Each of the 2^r choices of sign for the r defining relations gives an X (by the same procedure) and the totality cover all possibilities for maps to PSL_2.

The set of points of X corresponding to geometrically reducible, dihedral A_4, S_4 or A_5 images in PSL_2 is a closed subscheme Y. In fact the first two possibilities give closed subschemes with equations defined over $\mathbf{Z}$ and the last three give a dimension zero scheme over $\mathbf{Q}$. The overall equations defining Y reduce mod p to those defining the corresponding subscheme in characteristic p for almost all primes p. The explicit equations defing Y are determined by the algorithm as explained for $n = 2$ or 3 in the above reference or in more detail in Fabianska's MSc thesis ([Fab09]). Let U be the open complement of Y in X.

There are two possibilities.

1 A U is non-empty, so an algebraic point gives $\phi : G \to PSL_2(K)$, K a number field, with infinite image, so G is infinite. Further, for all but finitely many primes p, ϕ can be reduced mod v for any place v of characteristic p AND the reduction ϕ_v corresponds to

a point in the analogue of U over the finite field. Thus the reductions give surjections of G onto a $PSL_2(k)$ [or maybe a $PGL_2(k)$] for finite fields of any characteristic outside of a finite set.

2 All Us are empty. Here, all the homomorphisms of G into $PSL_2(K)$ in characteristic zero have geometrically reducible, dihedral, A_4, S_4 or A_5 images and the same holds for K a field of characteristic p for all p outside of a finite set of primes. G may or may not be infinite.

NB: In case 2), there may still be images of G which ARE infinite, but lie in a Cartan or Borel subgroup, so are geometrically reducible, or lie in the normaliser of a Cartan and have an infinite dihedral image. These infinite reducible/dihedral possibilities are not currently checked for.

`HasInfinitePSL2Quotient(G)`

`signs`	SeqEnum	*Default :* 0
`full`	BoolElt	*Default :* `false`
Verbose	`IsInfGrp`	*Maximum :* 1

Function to return whether the two-generator finitely-presented group G has an infinite quotient lying in a $PSL_2(K)$ with K a field of characteristic 0 as described above.

For the convenience of the user, we have provided some parameters to output more detailed information coming from the analysis of the X representation schemes as well as to control which sign variations are considered.

Let ws be the sequence of words giving the defining relations of G (if a defining relation is of the form $w = v$ where v is not the identity word, then the corresponding word is $w * v^{-1}$). Let $ws = [w_1, .., w_r]$.

As described in the introduction, for each of the 2^r combinations of signs attached to the w_i - let s be one - the program will consider the scheme X of homomorphisms of G into PSL_2 such that, when lifted to a homomorphism of the two-generator free cover F of G into SL_2, w_i maps to $s_i * I$.

In some cases, the user may realise that there is no point in considering certain choices of signs. For example, if g_1^2 is a relation in ws, $g_1^2 \mapsto I$ in $SL_2(K)$ means that $g_1 \mapsto 1$ in $PSL_2(K)$, so the $PSL_2(K)$ image would be (maybe infinitely) cyclic, and it is a waste of time to consider this possibility. Similarly, if g_1^r, r odd, is a relation then ,without loss of generality, in a PSL_2 to SL_2 lift, $g_1^r \mapsto I$, which could be specified.

The parameter `signs` allows the user to specify a restricted set of sign options to analyse. `signs` should be an $0, 1, -1$ or a sequence of length $\#ws$ of such integers. A single value is converted into the sequence containing that value $\#ws$ times. An entry e of 1 or -1 in position i means that the function will only consider sign sequences s with $s[i] = e$, ie homomorphisms where w_i map to eI in the lift to SL_2. If $e = 0$, then there is no condition at place i of the sign sequences considered. The default value for `signs` is the single value 0.

For each representation space X (corresponding to an allowable choice of signs s), after removing positive dimensional components of Y corresponding to geometrically reducible or dihedral type representations, there is often a zero-dimensional subscheme left. The existence of an infinite (non-cyclic or dihedral) image homomorphism to PSL_2 then comes down to examining the finite set of closed points remaining and finding one that is not geometrically reducible, dihedral, A_4, S_4 or A_5 type. Clearly, once one such is found the procedure can stop. However, it might be of interest for the user to see the types of ALL of the representations corresponding to closed points if the zero-dimensional analysis stage is performed.

If parameter `full` is set to `true` (the default is `false`), the program will continue analysing all of the representations in the 0-dimensional locus, even after one corresponding to an infinite image is found. Furthermore a sequence of (signs,types) pairs is also returned which gives, for each sign combination s of maps considered, the sequence of types corresponding to the 0-dimensional locus (or empty if we don't reduce to dimension 0). These types are given as strings: "infinite", "reducible", "dihedral", "A4", "S4", and "A5".

Setting the verbose flag `IsInfGrp` to `true` or 1 gives output of information on the various stages as the function progresses, including the analysis of dimension zero loci.

Example H70E26

We look at two examples of quotients of the two-generator free group with relations g_1^2, g_2^3 and one further word. The first is infinite, the second is not. As noted above, we may as well specify that g_1^2 maps to $-I$ and g_2^3 to I in SL_2 and this can be done with the `signs` parameter.

```
> F := FreeGroup(2);
> rel := (F.1 * F.2 * F.1 * F.2 * F.1 * F.2 * F.1 * F.2 * F.1 * F.2 *
>   F.1 * F.2 * F.1 * F.2 * F.1 * F.2^-1 * F.1 * F.2 * F.1 * F.2^-1)^2;
> G := quo<F | [F.1^2 ,F.2^3, rel]>;
> HasInfinitePSL2Quotient(G : full := true);
true
[ [*
    [ 1, 1, 1 ],
    []
*], [*
    [ 1, 1, -1 ],
    []
*], [*
    [ 1, -1, 1 ],
    []
*], [*
    [ 1, -1, -1 ],
    []
*], [*
    [ -1, 1, 1 ],
```

```
    [ A4, A4 ]
*], [*
    [ -1, 1, -1 ],
    [ A5, A5, infinite ]
*], [*
    [ -1, -1, 1 ],
    [ A4, A4 ]
*], [*
    [ -1, -1, -1 ],
    [ A5, A5, infinite ]
*] ]
```

Now try it with the sign restriction.

```
> HasInfinitePSL2Quotient(G : full := true, signs := [-1,1,0]);
true
[ [*
    [ -1, 1, 1 ],
    [ A4, A4 ]
*], [*
    [ -1, 1, -1 ],
    [ A5, A5, infinite ]
*] ]
```

The second example is just A_5.

```
> G := quo<F | [F.1^2 ,F.2^3, (F.1*F.2)^5]>;
> HasInfinitePSL2Quotient(G);
false
> HasInfinitePSL2Quotient(G : full := true, signs := [-1,1,0]);
false
[ [*
    [ -1, 1, 1 ],
    [ A5 ]
*], [*
    [ -1, 1, -1 ],
    [ A5 ]
*] ]
```

70.4.7 Searching for Isomorphisms

This section describes a function for searching for isomorphisms between two finitely presented groups.

`SearchForIsomorphism(F, G, m : parameters)`

Attempt to find an isomorphism from the finitely presented group F to the finitely presented group G. The search will be restricted to those homomorphisms for which the sum of the word-lengths of the images of the generators of F in G is at most m.

If an isomorphism ϕ is found, then the values `true`, ϕ, ϕ^-1 are returned. Otherwise, the values `false`, _, _ are returned; of course, that does not necessarily mean that the groups are not isomorphic.

An error will result if any of the generators of F turn out to be trivial.

By setting the verbose flag `"IsoSearch"` to 1, information about the progress of the search will be printed.

The parameters available for the function SearchForIsomorphism are:

`All` BoolElt *Default :* `false`

If `All` is `false` (default), then the function halts and returns as soon as a single isomorphism is found. If `All` is `true`, then the search continues through all possible images that satisfy the image length condition, and a list of pairs $\langle \phi, \phi^-1 \rangle$ for all isomorphisms $\phi : F \to G$ found is returned as the second return value.

`IsomsOnly` BoolElt *Default :* `true`

If `IsomsOnly` is set to `false`, then all homomorphisms $F \to G$ will be returned if `All` is `true`, and the first nontrivial homomorphism found will be returned if `All` is `false`.

`MaxRels` RngIntElt *Default :* $250 * m$

The value of the `MaxRelations` parameter used in runs of RWSGroup. It is hard to find a sensible default, because if the value is unnecessarily large then time can be wasted unnecessarily. This may need to be increased if the function is used with finite groups, for example (although it is usually much more efficient to use permutation or matrix representations when testing isomorphism of finite groups).

`CycConjTest` BoolElt *Default :* `true`

When `CycConjTest` is `true` and `All` is `false`, then images of the first generator which have a cyclic conjugate that comes earlier in the lexicographical order are rejected, because there would be a conjugate isomorphism in which the image was the cyclic conjugate. This nearly always results in faster run-times, but occasionally it can happen that the conjugate isomorphism has a larger sum of lengths of generator images, which is clearly bad. So the user has the option of not rejecting such images.

Example H70E27

John Hillman asked whether the following two groups are isomorphic.

```
> G1<s,t,u> := Group <s,t,u | s*u*s^-1=u^-1, t^2=u^2, t*s^2*t^-1=s^-2,
```

```
>                              u*(s*t)^2=(s*t)^2*u >;
> G2<x,y,z> := Group<x,y,z | x*y^2*x^-1=y^-2, y*x^2*y^-1=x^-2, x^2=z^2*(x*y)^2,
>                            y^2=(z^-1*x)^2, z*(x*y)^2=(x*y)^2*z >;
> isiso, f1, f2 := SearchForIsomorphism(G1,G2,7);
> isiso;
true
> f1;
Homomorphism of GrpFP: G1 into GrpFP: G2 induced by
    s |--> x * z^-1
    t |--> y * z
    u |--> x * y^-1 * z
> f2;
Homomorphism of GrpFP: G2 into GrpFP: G1 induced by
    x |--> s^2 * u * t^-1
    y |--> s^-1 * u^-1
    z |--> s * u * t^-1
```

The search for an isomorphism succeeeded and returns the isomorphisms explicitly.

Example H70E28

Walter Neumann asked whether the next two groups are isomorphic.

```
> G1<x,y,z> := Group< x,y,z | x^2*y^5, x^14*z^23, (x^2,y), (x^2,z), x*y*z>;
> G2<a,b> := Group<a,b | a*b^16*a*b^-7, a^4*b^7*a^-1*b^7>;
```

It is a good idea to minimize the number of generators of `G1` - since there is clearly a redundant generator here.

```
> G1s := Simplify(G1);
> Ngens(G1s);
2
> G1!G1s.1, G1!G1s.2;
x z
```

Now a direct call `SearchForIsomorphism(G1, G2, 15)` will succeed, but will take many hours, and also use a lot of memory.
In contrast to `G1`, it can sometimes help to introduce a new generator in `G2` if there are common substrings in relators.

```
> G2b<a,b,c> := Group< a,b,c | a*b^16*a*b^-7, a^4*b^7*a^-1*b^7, c=b^7>;
> isiso, f1, f2 := SearchForIsomorphism(G1s,G2b,4);
> isiso;
true
> f1;
Homomorphism of GrpFP: G1s into GrpFP: G2b induced by
    G1s.1 |--> a * c^-1
    G1s.2 |--> c
> f2;
Homomorphism of GrpFP: G2b into GrpFP: G1s induced by
```

```
a |--> G1s.1 * G1s.2
b |--> G1s.1^6 * G1s.2^10
c |--> G1s.2
```

70.5 Abelian, Nilpotent and Soluble Quotient

70.5.1 Abelian Quotient

The functions in this section compute information about the abelian quotient of an fp-group G. Some functions may require the computation of a coset table. Experienced users can control the behaviour of an implicit coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

The functions returning the abelian quotient or the abelian quotient invariants report an error if the abelian quotient cannot be computed, for example, because the relation matrix is too large. To avoid problems in user written programs or loops, the functions HasComputableAbelianQuotient and HasInfiniteComputableAbelianQuotient can be used.

`AbelianQuotient(G)`

The maximal abelian quotient G/G' of the group G as GrpAb (cf. Chapter 69). The natural epimorphism $\pi : G \to G/G'$ is returned as second value.

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient Q of the group G as GrpAb (cf. Chapter 69). The natural epimorphism $\pi : G \to Q$ is returned as second value.

`AbelianQuotientInvariants(G)`

`AQInvariants(G)`

Given a finitely presented group G, this function computes the elementary divisors of the derived quotient group G/G', by constructing the relation matrix for G and transforming it into Smith normal form. The algorithm used is an algorithm of Havas which does the reduction entirely over the ring of integers $\mathbf{Z}$ using clever heuristics to minimize the growth of coefficients.

The divisors are returned as a sequence of integers.

`AbelianQuotientInvariants(H)`

`AQInvariants(H)`

`AbelianQuotientInvariants(G, T)`

`AQInvariants(G, T)`

Given a subgroup H of the finitely presented group G, this function computes the elementary divisors of the derived quotient group of H. (The coset table T may be used to define H.) This is done by abelianising the Reidemeister-Schreier presentation for H and then proceeding as above. The divisors are returned as a sequence of integers.

`AbelianQuotientInvariants(G, n)`

`AQInvariants(G, n)`

Given a finitely presented group G, this function computes the elementary divisors of the quotient group G/N, where N is the normal subgroup of G generated by the derived group G' together with all n-th powers of elements of G. The algorithm constructs the relation matrix corresponding to the presentation of G and computes its Smith normal form over the ring Z/nZ. The calculation is particularly efficient when n is a small prime. The divisors are returned as a sequence of integers.

`AbelianQuotientInvariants(H, n)`

`AQInvariants(H, n)`

`AbelianQuotientInvariants(G, T, n)`

`AQInvariants(G, T, n)`

Given a subgroup H of the finitely presented group G, this function computes the elementary divisors of the quotient group H/N, where N is the normal subgroup of H generated by H' together with all n-th powers of elements of H. (The coset table T may be used to define H.) This is done by abelianising the Reidemeister-Schreier presentation for H and then proceeding as above. The divisors are returned as a sequence of integers.

`HasComputableAbelianQuotient(G)`

Given an fp-group G, this function tests whether the abelian quotient of G can be computed. If so, it returns the value `true`, the abelian quotient A of G and the natural epimorphism $\pi : G \to A$. If the abelian quotient of G cannot be computed, the value `false` is returned.

This function is especially useful to avoid runtime errors in user written loops or functions.

`HasInfiniteComputableAbelianQuotient(G)`

Given an fp-group G, this function tests whether the abelian quotient of G can be computed and is infinite. If so, it returns the value `true`, the abelian quotient A of G and the natural epimorphism $\pi : G \to A$. If the abelian quotient of G cannot be computed or if it is finite, the value `false` is returned.

The function first checks the modular abelian invariants for a set of small primes. If for one of these primes, the modular abelian quotient is trivial, A must be finite and the function returns without actually computing the abelian quotient. If one is interested only in infinite quotients, this heuristics may save time.

`IsPerfect(G)`

Given an fp-group G, this function tries to decide whether G is perfect by checking whether the abelian quotient of G is trivial.

`TorsionFreeRank(G)`

Given the finitely presented group G, return the torsion-free rank of the derived quotient group of G.

Example H70E29

The Fibonacci group $F(7)$ has the following 2-generator presentation:

$$< a, b \mid a^2b^{-2}a^{-1}b^{-2}(a^{-1}b^{-1})^2, abab^2abab^{-1}(ab^2)^2 > .$$

We proceed to investigate the structure of this group.

```
> F<a, b> := FreeGroup(2);
> F7<a, b> := quo< F |  a^2*b^-2*a^-1*b^-2*(a^-1*b^-1)^2,
>        a*b*a*b^2*a*b*a*b^-1*(a*b^2)^2 >;
> F7;
Finitely presented group F7 on 2 generators
Relations
       a^2 * b^-2 * a^-1 * b^-2 * a^-1 * b^-1 * a^-1 * b^-1 =Id(F7)
       a * b * a * b^2 * a * b * a * b^-1 * a * b^2 * a * b^2 = Id()7
```

We begin by determining the structure of the maximal abelian quotient of $F(7)$.

```
> AbelianQuotientInvariants(F7);
[ 29 ]
```

The maximal abelian quotient of $F(7)$ is cyclic of order 29. At this point there is no obvious way to proceed, so we attempt to determine the index of some subgroups.

```
> Index( F7, sub< F7 | a > );
1
```

We are in luck: $F(7)$ is generated by a and so must be cyclic. This fact coupled with the knowledge that its abelian quotient has order 29 tells us that the group is cyclic of order 29.

Example H70E30

The group $G = (8, 7 \mid 2, 3)$ is defined by the presentation

$$< a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3 > .$$

We consider the subgroup H of G, generated by the words a^2 and $a^{-1}b$:

```
> G<a, b> := Group<a, b| a^8, b^7, (a * b)^2, (a^-1 * b)^3>;
> H<x, y> := sub< G | a^2, a^-1 * b >;
```

The fastest way to determine the order of the maximal 2-elementary abelian quotient of H is to use the function `AbelianQuotientInvariants`:

```
> #AbelianQuotientInvariants(H,2);
1
```

We see that the maximal 2-elementary abelian quotient of H has order 2^1.

70.5.2 p-Quotient

Let F be a finitely presented group, p a prime and c a positive integer. A p-quotient algorithm constructs a consistent power-conjugate presentation for the largest p-quotient of F having lower exponent-p class at most c. The p-quotient algorithm used by MAGMA is part of the ANU p-Quotient program. For details of the algorithm, see [NO96]. In MAGMA the result is returned as a group of type `GrpPC` (cf. Chapter 63).

Assume that the p-quotient has order p^n, Frattini rank d, and that its generators are $a_1, \ldots, a_n$. Then the power-conjugate presentation constructed has the following additional structure. The set $\{a_1, \ldots, a_d\}$ is a generating set for G. For each a_k in $\{a_{d+1}, \ldots, a_n\}$, there is at least one relation whose right hand side is a_k. One of these relations is taken as the *definition* of a_k. (The list of definitions is also returned by `pQuotient`.) The power-conjugate generators also have a *weight* associated with them: a generator is assigned a weight corresponding to the stage at which it is added and this weight is extended to all normal words in a natural way.

The p-quotient function and its associated commands allows the user to construct a power-conjugate presentation (pcp) for a p-group. Note that there is also a process version of the p-quotient algorithm, which gives the user complete control over its execution. For a description, we refer to Chapter 71.

70.5.3 The Construction of a p-Quotient

`pQuotient(F, p, c: parameters)`

Given an fp-group F, a prime p and a positive integer c, construct a pcp for the largest p-quotient G of F having lower exponent-p class at most c. If c is given as 0, then the limit 127 is placed on the class. The function also returns the natural homomorphism π from F to G, a sequence S describing the definitions of the pc-generators of G and a flag indicating whether G is the maximal p-quotient of F.

The k-th element of S is a sequence of two integers, describing the definition of the k-th pc-generator $G.k$ of G as follows.

- If $S[k] = [0, r]$, then $G.k$ is defined via the image of $F.r$ under π.
- If $S[k] = [r, 0]$, then $G.k$ is defined via the power relation for $G.r$.
- If $S[k] = [r, s]$, then $G.k$ is defined via the conjugate relation involving $G.r^{G.s}$.

There exist a number of parameters for controlling the behaviour of this function, which are described below.

Example H70E31

We construct the largest 2-quotient of class 6 for a two-generator, two-relator group.

```
> F<a,b> := FreeGroup(2);
> G := quo< F | (b, a, a) = 1, (a * b * a)^4 = 1 >;
> Q, fQ := pQuotient(G, 2, 6);
> Order(Q);
524288
> fQ;
Mapping from: GrpFP: G to GrpPC: Q
```

The parameters available for the function `pQuotient` are:

`Exponent` RngIntElt *Default :* 0

If `Exponent := m`, enforce the exponent law, $x^m = 1$, on the group.

`Metabelian` BoolElt *Default :* `false`

If `Metabelian := true`, then a consistent pcp is constructed for the largest metabelian p-quotient of F having lower exponent-p class at most c.

`Print` RngIntElt *Default :* 0

This parameter controls the volume of printing. By default its value is that returned by `GetVerbose("pQuotient")`, which is 0 unless it has been changed through use of `SetVerbose`. The effect is the following:

`Print := 0`: No output.

`Print := 1`: Report order of p-quotient at each class.

`Print := 2`: Report statistics and redundancy information about tails, consistency, collection of relations and exponent enforcement components of calculation.

`Print := 3`: Report in detail on the construction of each class.

Note that the presentation displayed is a *power-commutator* presentation (since this is the version stored by the p-quotient).

`Workspace` RngIntElt *Default :* 5000000

The amount of space requested for the p-quotient computation.

Example H70E32

We construct the largest 3-quotient of class 6 for a two-generator group of exponent 9.

```
> F<a,b> := FreeGroup(2);
> G := quo< F | a^3 = b^3 = 1 >;
> q := pQuotient(G, 3, 6: Print := 1, Exponent := 9);
Lower exponent-3 central series for G
Group: G to lower exponent-3 central class 1 has order 3^2
Group: G to lower exponent-3 central class 2 has order 3^3
Group: G to lower exponent-3 central class 3 has order 3^5
Group: G to lower exponent-3 central class 4 has order 3^7
Group: G to lower exponent-3 central class 5 has order 3^9
Group: G to lower exponent-3 central class 6 has order 3^11
```

Example H70E33

We use the metabelian parameter to construct a metabelian 5-quotient of the group

$$< a, b \mid a^{625} = b^{625} = 1, (b, a, b) = 1, (b, a, a, a, a) = (b, a)^5 > .$$

```
> F<a, b> := FreeGroup(2);
> G := quo< F | a^625 = b^625 = 1, (b, a, b) = 1,
>           (b, a, a, a, a) = (b, a)^5 >;
> q := pQuotient(G, 5, 20: Print := 1, Metabelian := true);
Lower exponent-5 central series for G
Group: G to lower exponent-5 central class 1 has order 5^2
Group: G to lower exponent-5 central class 2 has order 5^5
Group: G to lower exponent-5 central class 3 has order 5^8
Group: G to lower exponent-5 central class 4 has order 5^11
Group: G to lower exponent-5 central class 5 has order 5^12
Group: G to lower exponent-5 central class 6 has order 5^13
Group: G to lower exponent-5 central class 7 has order 5^14
Group: G to lower exponent-5 central class 8 has order 5^15
Group: G to lower exponent-5 central class 9 has order 5^16
Group: G to lower exponent-5 central class 10 has order 5^17
Group: G to lower exponent-5 central class 11 has order 5^18
Group: G to lower exponent-5 central class 12 has order 5^19
Group: G to lower exponent-5 central class 13 has order 5^20
Group completed. Lower exponent-5 central class = 13, order = 5^20
```

Example H70E34

In the final example, we construct the largest finite 2-generator group having exponent 5.

```
> F := FreeGroup(2);
> q := pQuotient (F, 5, 14: Print := 1, Exponent := 5);
Lower exponent-5 central series for F
Group: F to lower exponent-5 central class 1 has order 5^2
Group: F to lower exponent-5 central class 2 has order 5^3
Group: F to lower exponent-5 central class 3 has order 5^5
Group: F to lower exponent-5 central class 4 has order 5^8
Group: F to lower exponent-5 central class 5 has order 5^10
Group: F to lower exponent-5 central class 6 has order 5^14
Group: F to lower exponent-5 central class 7 has order 5^18
Group: F to lower exponent-5 central class 8 has order 5^22
Group: F to lower exponent-5 central class 9 has order 5^28
Group: F to lower exponent-5 central class 10 has order 5^31
Group: F to lower exponent-5 central class 11 has order 5^33
Group: F to lower exponent-5 central class 12 has order 5^34
Group completed. Lower exponent-5 central class = 12, order = 5^34
```

70.5.4 Nilpotent Quotient

A nilpotent quotient algorithm constructs, from a finite presentation of a group, a polycyclic presentation of a nilpotent quotient of the finitely presented group. The nilpotent quotient algorithm used by MAGMA is the Australian National University Nilpotent Quotient program, as described in [Nic96]. The version included in MAGMA is Version 2.2 of January 2007.

The lower central series $G_0, G_1, \ldots$ of a group G can be defined inductively as $G_0 = G$, $G_i = [G_(i-1), G]$. G is said to have nilpotency class c if c is the smallest non-zero integer such that $G_c = 1$. If N is a normal subgroup of G and G/N is nilpotent, then N contains G_i for some non-negative integer i. G has infinite nilpotent quotients if and only if G/G_1 (the maximal abelian quotient of G) is infinite and a prime p divides a finite factor of a nilpotent quotient if and only if p divides a cyclic factor of G/G_1. The i-th ($i > 1$) factor G_{i-1}/G_i of the lower central series is generated by the elements $[g, h]G_i$, where g runs through a set of representatives of G/G_1 and h runs through a set of representatives of G_{i-2}/G_{i-1}.

Any finitely generated nilpotent group is polycyclic and, therefore, has a subnormal series with cyclic factors. Such a subnormal series can be used to represent the group in terms of a polycyclic presentation. The ANU NQ computes successively the factor groups modulo the terms of the lower central series. Each factor group is represented by a special form of polycyclic presentation, a nilpotent presentation, that makes use of the nilpotent structure of the factor group.

The algorithm has highly efficient code for enforcing the n-Engel identity in nilpotent groups. When appropriate parameters are set, the algorithm computes the largest n-Engel quotient of G/G_c.

More generally, the algorithm has code for enforcing arbitrary identical relations. You can even enforce relations which combine generators of G with "free variables". (Werner Nickel calls these "identical generators".) For instance, the relation `(a,x) = 1`, where a is a group generator and x is a free variable, will force the construction of quotients where the image of a is central.

Mike Vaughan-Lee offers advice on when to use the nilpotent quotient algorithm. If you know nothing about the finitely presented group, it is probably a good idea to look at the abelian quotient first. If the abelian quotient is trivial then all nilpotent quotients will be trivial. Similarly, if the abelian quotient is cyclic, then all nilpotent quotients will be cyclic. Less trivially, if the abelian quotient is finite then all nilpotent quotients will be finite and so will be the direct product of finite p-groups. Moreover, the relevant primes p will all occur in the abelian quotient. Usually it will be more effective to use the p-quotient algorithm to study the direct factors. However, if you want to study 3-Engel quotients (say), then you are better using the nilpotent quotient even when the abelian quotient is finite.

`NilpotentQuotient(G, c: parameters)`

This function returns the class c nilpotent quotient of G as a group in category GrpGPC, together with the epimorphism π from G onto this quotient. When c is set to zero, the function attempts to compute the maximal nilpotent quotient of G. Using the parameters described below, the user can enforce certain conditions on the quotient found.

Example H70E35

Here is a finitely presented group. The abelian quotient is infinite, so we look at the class 2 nilpotent quotient.

```
> G := Group<x,y,z|(x*y*z^-1)^2, (x^-1*y^2*z)^2, (x*y^-2*x^-1)^2 >;
> AbelianQuotient(G);
Abelian Group isomorphic to Z/2 + Z/2 + Z
Defined on 3 generators
Relations:
  2*$.1 = 0
  2*$.2 = 0
> N := NilpotentQuotient(G,2); N;
GrpGPC : N of infinite order on 6 PC-generators
PC-Relations:
  N.1^2 = N.3^2 * N.5,
  N.2^2 = N.4 * N.6,
  N.4^2 = Id(N),
  N.5^2 = Id(N),
  N.6^2 = Id(N),
  N.2^N.1 = N.2 * N.4,
  N.3^N.1 = N.3 * N.5,
  N.3^N.2 = N.3 * N.6
```

Example H70E36

The free nilpotent group of rank r and class e is defined as $F/\gamma_{e+1}(F)$, where F is a free group of rank r and $\gamma_{e+1}(F)$ denotes the $(e+1)$ st term of the lower central series of F.
We construct the free nilpotent group N of rank 2 and class 3 as quotient of the free group F of rank 2 and the natural epimorphism from F onto N.

```
> F<a,b> := FreeGroup(2);
> N<[x]>, pi := NilpotentQuotient(F, 3);
> N;
GrpGPC : N of infinite order on 5 PC-generators
PC-Relations:
    x[2]^x[1] = x[2] * x[3],
    x[2]^(x[1]^-1) = x[2] * x[3]^-1 * x[4],
    x[3]^x[1] = x[3] * x[4],
    x[3]^(x[1]^-1) = x[3] * x[4]^-1,
    x[3]^x[2] = x[3] * x[5],
    x[3]^(x[2]^-1) = x[3] * x[5]^-1
```

Using the function NilpotencyClass described in Chapter 72, we check the nilpotency class of the quotient.

```
> NilpotencyClass(N);
3
```

Example H70E37

The Baumslag-Solitar groups

$$BS(p,q) = \langle < a, b | ab^p a^{-1} = b^q \rangle$$

form a fascinating class of 1-relator groups. We compute the nilpotent of class 4 quotient of two of them, and print out the resulting presentations, and the structure of the generators.

```
> G<a,b> := Group<a,b|a*b*a^-1=b^4>;
> N,f := NilpotentQuotient(G,4);
> N;
GrpGPC : N of infinite order on 5 PC-generators
PC-Relations:
  N.2^3 = N.3^2 * N.4^2 * N.5,
  N.3^3 = N.4^2 * N.5^2,
  N.4^3 = N.5^2,
  N.5^3 = Id(N),
  N.2^N.1 = N.2 * N.3,
  N.2^(N.1^-1) = N.2 * N.3^2 * N.4^2 * N.5,
  N.3^N.1 = N.3 * N.4,
  N.3^(N.1^-1) = N.3 * N.4^2 * N.5^2,
  N.4^N.1 = N.4 * N.5,
  N.4^(N.1^-1) = N.4 * N.5^2
> for i := 1 to Ngens(N) do
```

```
> N.i @@ f;
> end for;
a
b
(b, a)
(b, a, a)
(b, a, a, a)
> G<a,b> := Group<a,b|a*b^2*a^-1=b^4>;
> N,f := NilpotentQuotient(G,4);
> N;
GrpGPC : N of infinite order on 8 PC-generators
PC-Relations:
  N.2^2 = Id(N),
  N.3^2 = N.5 * N.8,
  N.4^2 = N.7,
  N.5^2 = N.8,
  N.6^2 = Id(N),
  N.7^2 = Id(N),
  N.8^2 = Id(N),
  N.2^N.1 = N.2 * N.3,
  N.2^(N.1^-1) = N.2 * N.3 * N.4 * N.5 * N.6,
  N.3^N.1 = N.3 * N.4,
  N.3^(N.1^-1) = N.3 * N.4 * N.6 * N.7,
  N.3^N.2 = N.3 * N.5,
  N.4^N.1 = N.4 * N.6,
  N.4^(N.1^-1) = N.4 * N.6,
  N.4^N.2 = N.4 * N.7,
  N.5^N.1 = N.5 * N.7,
  N.5^(N.1^-1) = N.5 * N.7,
  N.5^N.2 = N.5 * N.8
> for i := 1 to Ngens(N) do
> N.i @@ f;
> end for;
a
b
(b, a)
(b, a, a)
(b, a, b)
(b, a, a, a)
(b, a, b, a)
(b, a, b, b)
```

The parameters available for the function `NilpotentQuotient` are:

`NumberOfEngelGenerators`

RngIntElt *Default :* 1

Setting this parameter to k forces the first k generators to be left or right Engel elements, provided one (or both) of the parameters `LeftEngel` or `RightEngel` is positive. Otherwise it is ignored.

`LeftEngel` RngIntElt *Default :* 0

Setting this parameter to n forces the first k generators $g_1, \ldots, g_k$ of the quotient Q to be left n-Engel elements. That is, they satisfy $[x, \ldots, x, g_i] = 1$ (x appearing n times) for all x in Q. The value of k is determined by the parameter `NumberOfEngelGenerators`.

`RightEngel` RngIntElt *Default :* 0

This is the same as for `LeftEngel`, but here the generators are right n-Engel elements, so $[g_i, x, \ldots, x] = 1$.

`Engel` RngIntElt *Default :* 0

Setting this parameter to n enforces the nth Engel law on the quotient Q. That is, $[x, y, \ldots, y] = 1$ (y appearing n times) for all x, y in Q.

`SemigroupOnly` BoolElt *Default :* `true`

This option causes the program to check only semigroup words in the generating set of the nilpotent quotient when an Engel condition is enforced. If none of the Engel parameters are set, then it is ignored.

`SemigroupFirst` BoolElt *Default :* `false`

This option causes the program to check semigroup words in the generating set of the quotient first and then all other words, when an Engel condition is enforced. If `SemigroupOnly` is set, or no Engel condition is enforced, then it is ignored.

`ReverseOrder` BoolElt *Default :* `false`

In checking Engel identities, instances are processed in order of increasing weight. This flag reverses the order.

`ReverseEngel` BoolElt *Default :* `false`

This flag changes the Engel conditions from the first k generators, to the *last* k generators.

`CheckFewInstances` BoolElt *Default :* `false`

This option stops checking the Engel law at each class if all the checks of a certain weight did not yield any non-trivial instances of the law.

`Nickel` BoolElt *Default :* `false`

Enforce the identities x^8 and $[[x_1, x_2, x_3], [x_4, x_5, x_6]]$ on the nilpotent quotient.

`NumberOfFreeVariables` RngIntElt *Default :* 0

If this parameter is set to $n > 0$ then the last n variables of the group are treated as variables rather than generators of the group. In any relation they are treated as standing for all group elements, enabling the user to enforce identical relations on the quotient being computed. The value of n must be less than the number of generators

of the input group. When this facility is used, the domain of the epimorphism returned is the subgroup of G generated by the (first) non-free generators.

`PrintResult` BoolElt *Default :* `false`

If set to true, this parameter switches on the printing of results given by the stand alone version of NQ.

`SetVerbose("NilpotentQuotient", n)`

Turn on and off the printing of information as the nilpotent quotient algorithm proceeds. n may be set to any of 0, 1, 2 or 3. Setting n to be 0 turns printing off, while successively higher values for n print more and more information as the algorithm progresses. The default value of n is 0.

Example H70E38

We compute the maximal nilpotent quotient $N1$ of the group G given by the following presentation

$$\langle a, b, c, d, e \mid (b, a),\ (c, a),\ (d, a) = (c, b),\ (e, a) = (d, b),\ (e, b) = (d, c),\ (e, c),\ (e, d)\rangle.$$

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> :=
>          quo<F | (b,a), (c,a),
>          (d,a)=(c,b), (e,a)=(d,b), (e,b)=(d,c),
>          (e,c), (e,d)>;
> N1<[x]>, pi1 := NilpotentQuotient(G, 0);
```

Using the function `NilpotencyClass` described in Chapter 72, we check the nilpotency class of the quotient. It turns out to have nilpotency class 6.

```
> NilpotencyClass(N1);
6
```

Next we compute a metabelian quotient $N2$ of G, construct the natural epimorphism from $N1$ onto $N2$ and check its kernel. (The functions applied to the nilpotent quotients are described in Chapter 72.) To get a metabelian quotient we adjoin 4 variables and a relation to the presentation of G and use the "free variables" facility.

```
> M := Group<w,x,y,z|((w,x),(y,z))>; // metabelian identity
> D := FreeProduct(G,M); // adjoin to G
> N2, pi2 := NilpotentQuotient(D, 0: NumberOfFreeVariables := 4);
> NilpotencyClass(N2);
4
> DerivedLength(N2);
2
> f := hom< N1->N2 | [ pi1(G.i)->pi2(D.i) : i in [1..Ngens(G)] ] >;
> PCGenerators(Kernel(f), N1);
{@ x[14], x[15] * x[17], x[16], x[17]^2, x[18], x[19], x[20],
x[21], x[22], x[23], x[24], x[25], x[26], x[27], x[28], x[29],
```

```
x[30], x[31] @}
```

We compute a quotient $N3$ of G satisfying the 4 th Engel law, construct the natural epimorphism from $N1$ onto $N3$ and again check the kernel. (The functions applied to the nilpotent quotients are described in Chapter 72.)

```
> N3, pi3 := NilpotentQuotient(G, 0 : Engel := 4);
> NilpotencyClass(N3);
4
> DerivedLength(N3);
3
> h := hom< N1->N3 | [ pi1(g)->pi3(g) : g in Generators(G) ] >;
> PCGenerators(Kernel(h), N1);
{@ x[19], x[20], x[21], x[22], x[23], x[24], x[25], x[26], x[27],
x[28], x[29], x[30], x[31] @}
```

70.5.5 Soluble Quotient

A soluble quotient algorithm computes a consistent power-conjugate presentation of the largest finite soluble quotient of a finitely presented group, subject to certain algorithmic and user supplied restrictions. In this section we describe only the simplest use of such an algorithm within MAGMA. For more information the user is referred to Chapter 71.

`SolvableQuotient(G : parameters)`

`SolubleQuotient(G : parameters)`

Let G be a finitely presented group. The function constructs the largest finite soluble quotient of G.

Example H70E39

We compute the soluble quotient of the group

$$\langle a, b \mid a^2, b^4, ab^{-1}ab(abab^{-1})^5ab^2ab^{-2}\rangle.$$

```
> G<a,b> := Group< a, b | a^2, b^4,
>                     a*b^-1*a*b*(a*b*a*b^-1)^5*a*b^2*a*b^-2 >;
> Q := SolubleQuotient(G);
> Q;
GrpPC : Q of order 1920 = 2^7 * 3 * 5
PC-Relations:
    Q.1^2 = Q.4,
    Q.2^2 = Id(Q),
    Q.3^2 = Q.6,
    Q.4^2 = Id(Q),
    Q.5^2 = Q.7,
    Q.6^2 = Id(Q),
```

```
Q.7^2 = Id(Q),
Q.8^3 = Id(Q),
Q.9^5 = Id(Q),
Q.2^Q.1 = Q.2 * Q.3,
Q.3^Q.1 = Q.3 * Q.5,
Q.3^Q.2 = Q.3 * Q.6,
Q.4^Q.2 = Q.4 * Q.5 * Q.6 * Q.7,
Q.4^Q.3 = Q.4 * Q.6 * Q.7,
Q.5^Q.1 = Q.5 * Q.6,
Q.5^Q.2 = Q.5 * Q.7,
Q.5^Q.4 = Q.5 * Q.7,
Q.6^Q.1 = Q.6 * Q.7,
Q.8^Q.1 = Q.8^2,
Q.8^Q.2 = Q.8^2,
Q.9^Q.1 = Q.9^3,
Q.9^Q.2 = Q.9^4,
Q.9^Q.4 = Q.9^4
```

`SolvableQuotient(F, n : parameters)`

`SolubleQuotient(F, n : parameters)`

`SolvableQuotient(F, P : parameters)`

`SolubleQuotient(F, P : parameters)`

Find a soluble quotient G and the epimorphism $\pi : F \twoheadrightarrow G$ with a specified order. n must be a nonnegative integer. P must be a set of primes.

The three forms reflect possible information about the order of an expected soluble quotient. In the first form the order of G is given by n, if n is greater than zero. If n equals zero, nothing about the order is known and the relevant primes will be calculated completely.

The second form, with no n argument, is equivalent to the first with $n = 0$. This is a standard argument, and usually it is the most efficient way to calculate soluble quotients.

Note that, if $n > 0$ is not the order of the maximal finite soluble quotient, it may happen that no group of order n can be found, since an epimorphic image of size n may not be exhibited by the chosen series.

In the third form a set P of relevant primes is given. The algorithm calculates the biggest quotient such that the order has prime divisors only in P. P may have a zero as element, this is just for consistency reasons. It is equivalent to the first form with n equal zero.

For a description of the algorithm used and of the set of parameters available for this function, see Chapter 71. Other more specialised functions for computing soluble quotients and some examples can be found there as well.

Example H70E40

Consider the group G defined by the presentation

$$\langle x, y \mid x^3, y^8, [x, y^4], x^{-1}yx^{-1}y^{-1}xyxy^{-1}, (xy^{-2})^2(x^{-1}y^{-2})^2(xy^2)^2(x^{-1}y^2)^2, (x^{-1}y^{-2})^6(x^{-1}y^2)^6\rangle.$$

```
> G<x, y> := Group< x, y |
>     x^3, y^8, (x,y^4), x^-1*y*x^-1*y^-1*x*y*x*y^-1,
>     (x*y^-2)^2*(x^-1*y^-2)^2*(x*y^2)^2*(x^-1*y^2)^2,
>     (x^-1*y^-2)^6*(x^-1*y^2)^6 >;
```

We apply the soluble quotient algorithm to G and compute the order of the soluble quotient Q.

```
> time Q := SolubleQuotient(G);
Time: 116.920
> Order(Q);
165888
```

Note that $165888 = 2^{11} \cdot 3^4$. If we knew the possible primes in advance the soluble quotient can be computed much more quickly by using this knowledge.

```
> time Q := SolubleQuotient(G, {2, 3});
Time: 39.400
```

Note that this reduces the execution time by a factor of almost three.

We now assume that G is finite and try to compute its order by means of the Todd-Coxeter algorithm.

```
> Order(G);
165888
```

Hence the group is finite and soluble and G is isomorphic to Q. We may use the tools for finite soluble groups to investigate the structure of G. For example we can easily find the number of involutions in G.

```
> cls := ConjugacyClasses(Q);
> &+ [ cl[2] : cl in cls | cl[1] eq 2 ];
511
```

70.6 Subgroups

70.6.1 Specification of a Subgroup

`sub< G | L >`

Construct the subgroup H of the fp-group G generated by the words specified by the terms of the *generator list* $L = L_1, \ldots, L_r$.

A term L_i of the generator list may consist of any of the following objects:

(a) A word;

(b) A set or sequence of words;

(c) A sequence of integers representing a word;

(d) A set or sequence of sequences of integers representing words;

(e) A subgroup of an fp-group;

(f) A set or sequence of subgroups.

The collection of words and groups specified by the list must all belong to the group G and H will be constructed as a subgroup of G.

The generators of H consist of the words specified directly by terms L_i together with the stored generating words for any groups specified by terms of L_i. Repetitions of an element and occurrences of the identity element are removed (unless H is trivial).

If the `sub`-constructor is invoked with an empty list L, the trivial subgroup will be constructed.

`sub< G | f >`

Given a homomorphism f from G onto a transitive subgroup of $\mathrm{Sym}(n)$, construct the subgroup of G which affords this permutation representation.

`ncl< G | L >`

Construct the subgroup N of the fp-group G as the normal closure of the subgroup H generated by the words specified by the terms of the *generator list* L.

The possible forms of a term of the generator list are the same as for the `sub`-constructor.

This constructor may be applied even when H has infinite index in G, provided that its normal closure N has finite index. The subgroup N is obtained by computing the coset table of the trivial subgroup in the group defined by the relations of G together with relators corresponding to the words generating H. For a sample application of this function, see Example H70E17.

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function `SetGlobalTCParameters`. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`ncl< G | f >`

Given a homomorphism f from G onto a transitive subgroup of $\mathrm{Sym}(n)$, construct the subgroup of G that is the normal closure of the subgroup K of G which affords this permutation representation.

`CommutatorSubgroup(G)`

`DerivedSubgroup(G)`

`DerivedGroup(G)`

Given an fp-group G, try to construct the derived subgroup G' of G as finite index subgroup of G. The construction fails if no presentation for G is known or can be constructed, or if the index of G' in G is too large or infinite.

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

Example H70E41

The group $(8, 7 \mid 2, 3)$ is defined by the presentation

$$< a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3 >,$$

and has a subgroup of index 448 generated by the words a^2 and $a^{-1}b$:

```
> G<a, b> := Group<a, b| a^8, b^7, (a * b)^2, (a^-1 * b)^3>;
> G;
Finitely presented group G on 2 generators
Relations
     a^8 = Id(G)
       b^7 = Id(G)
       (a * b)^2 = Id(G)
> H<x, y> := sub< G | a^2, a^-1 * b >;
> H;
Finitely presented group H on 2 generators
Generators as words in group G
      x = a^2
      y = a^-1 * b
```

Example H70E42

Given the group G defined by the presentation

$$< a, b \mid a^8, b^7, (ab)^2, (a, b)^9 >,$$

there is a homomorphism into Sym(9) defined by

$$a \to (2,4)(3,5)(6,7)(8,9)$$
$$b \to (1,2,3)(4,6,7)(5,8,9)$$

We construct the subgroup H of G that is the preimage of the stabiliser of the point 1 in G.

```
> G<a, b> := Group< a, b | a^2, b^3, (a*b)^7, (a, b)^9>;
> T := PermutationGroup< 9 | (2, 4)(3, 5)(6, 7)(8, 9),
>    (1, 2, 3)(4, 6, 7)(5, 8, 9) >;
> f := hom< G -> T | a -> T.1, b ->T.2 >;
> H := sub< G | f >;
> H;
Finitely presented group H
Subgroup of group G defined by coset table
> Index(G, H);
9
```

Using the function GeneratingWords, we obtain a set of generators for H.

```
> print GeneratingWords(G, H);
      { a, b^-1 * a * b^3 * a * b, b * a * b * a * b * a * b^-1,
        b^3, b^-1 * a * b * a * b * a * b, b * a * b^3 * a * b^-1 }
```

70.6.2 Index of a Subgroup: The Todd-Coxeter Algorithm

This section describes the simplest use of coset enumeration techniques in MAGMA. MAGMA also provides interactive facilities for coset enumeration. For information on these more advanced uses, the user is referred to Chapter 71.

The Todd-Coxeter implementation installed in MAGMA is based on the stand alone coset enumeration programme ACE3 developed by George Havas and Colin Ramsay at the University of Queensland. The reader should consult [CDHW73] and [Hav91] for an explanation of the terminology and a general description of the algorithm. A manual for ACE3 as well as the sources of ACE3 can be found online [Ram].

Experienced users can control the Todd-Coxeter procedures invoked by the functions described in this section with a wide range of parameters. For a complete description of these parameters and their meanings we refer to the manual entry for the function CosetEnumerationProcess in Chapter 71. We just mention briefly the most important ones:

CosetLimit RNGINTELT *Default :* 0

If CosetLimit is set to n, where n is a positive integer, then the coset table may have at most n rows. In other words, a maximum of n cosets can be defined at any instant during the enumeration. It is ensured in this case, that enough memory is allocated to store the requested number of cosets, regardless of the value of the parameter Workspace.

If `CosetLimit` is set to 0 (default), the maximal number of active cosets is determined by the size of the coset table (cf. parameter `Workspace`) and the number of columns of the coset table (i.e. the number of group generators).

`Workspace` RngIntElt *Default :* 4000000

The number of words allocated for the coset table. Note that if `CosetLimit` is set, at least as much memory is allocated as is necessary to store the requested number of cosets.

`Strategy` MonStgElt *Default :*

Using this parameter one of several predefined strategies can be selected. (See the manual entry for the function `CosetEnumerationProcess` in Chapter 71 for a complete list.) The most important values of this parameter are:

- "Easy": This selects a combination of parameters, which in situations where an overflow is not expected is likely to produce a result more quickly and using less memory than the default strategy. This strategy will fail for more complicated enumerations.
- "Hard": This selects a combination of parameters, which is more likely to produce a finite result for difficult coset enumerations than the default strategy. This strategy will use more memory and enumerations usually will take longer.

`ToddCoxeter(G, H: parameters)`

Given a subgroup H of the fp-group G, this function attempts to build up a coset table of H in G using the Todd-Coxeter procedure.

The first return value is the index of H in G (or 0, if the enumeration fails to complete). The other values returned are the coset table map, the maximum number of simultaneously active cosets, and the total number of cosets defined during the enumeration.

Experienced users can control the Todd-Coxeter procedure invoked by this function with a wide range of parameters. This function accepts the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

`Index(G, H: parameters)`

`FactoredIndex(G, H: parameters)`

Given a subgroup H of the fp-group G, these functions attempt to determine the index of H in G by enumerating the cosets of H using the Todd-Coxeter procedure. The index is returned as a positive integer (`Index`) or as a sequence of factors (`FactoredIndex`), respectively. If the coset enumeration fails to complete with a closed coset table, `Index` returns a value of 0, whereas `FactoredIndex` reports an error. No conclusion can be drawn in this case.

Experienced users can control the Todd-Coxeter procedure invoked by these functions with a wide range of parameters. Both functions accept the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

Example H70E43

The classical test example for Todd-Coxeter programmes is the enumeration of the 448 cosets of the subgroup $H = < a^2, a^{-1}b >$ in the group $G = < a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3 >$.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | x^8, y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | a^2,a^-1*b>;
> Index(G, H);
448
```

`Order(G: parameters)`

`FactoredOrder(G: parameters)`

Given an fp-group G, this function attempts to determine the order of G or to prove that G is infinite. If a finite order can be computed, the function `Order` returns the order as a positive integer, whereas the function `FactoredOrder` returns a sequence of prime power factors. The function `FactoredOrder` reports an error in all other cases, whereas the function `Order` returns the object `Infinity`, if G can be shown to be infinite and returns a value of 0 if neither a finite value for the group order nor a proof for the infinity of G can be obtained. No conclusions can be drawn from a return value 0 of `Order`.

In addition to the parameters controlling possibly invoked coset enumerations, there exist some other parameters controlling the strategy used by the functions `Order` and `FactoredOrder`. These parameters are described below.

Example H70E44

We use the function `Order` without any parameters to compute the order of the group

$$G = < a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3 > .$$

```
> G<x, y> := Group<x,y | x^8, y^7, (x*y)^2, (x^-1*y)^3>;
> G;
Finitely presented group G on 2 generators
Relations
    x^8 = Id(G)
    y^7 = Id(G)
    (x * y)^2 = Id(G)
    (x^-1 * y)^3 = Id(G)
> Order(G);
10752
```

The strategy employed by the functions `Order` and `FactoredOrder` may involve trying to obtain information on certain subgroups of G. Whether or not an attempt is made to construct a presentation for a subgroup arising in the course of the computation by means of Reidemeister-Schreier rewriting, is controlled by three parameters:

`UseRewrite`	BoolElt	*Default :* `true`
`MinIndex`	RngIntElt	*Default :* 10
`MaxIndex`	RngIntElt	*Default :* 1000

If `UseRewrite` is set to `false`, attempts to construct presentations for subgroups are not made. Otherwise, `MinIndex` and `MaxIndex` specify for subgroups of which index range Reidemeister-Schreier rewriting is done.

The following strategy is used for trying to determine the order of G.

(1) Check whether G is free. If so, G is either trivial or infinite.

(2) Check whether the presentation for G is deficient (i.e. whether the number of relations is smaller than the number of generators). If it is, G is infinite.

(3) Check the subgroups of G with known order. If such a subgroup is known to be infinite or if we can compute its index in G, we're done.

(4) Try to compute the index of G in a supergroup of known order. (An infinite supergroup in which G has finite index proves G to be infinite.)

(5) Try to enumerate the cosets of the trivial subgroup in G.

(6) Check the subgroups of known or easily computable index in G. If we can compute the order of such a subgroup or prove that it is infinite, we're done.

(7) Try to enumerate the cosets of some subgroups occurring "naturally" in the presentation of G.

(8) Check the supergroups in which G has known or easily computable index. If we can compute the order of a supergroup or prove that it is infinite, we're done.

(9) Try to rewrite G w.r.t. some supergroup and to enumerate the cosets of the trivial subgroup using the resulting presentation.

Steps requiring coset enumeration in G or a supergroup of G are skipped, if no relations are known for this group. Steps involving Reidemeister-Schreier rewriting may be skipped according to the values of the parameters mentioned above.

Experienced users can control the behaviour of coset enumerations which may be invoked by the functions `Order` and `FactoredOrder` with a wide range of parameters. Both functions – in addition to the parameters mentioned above – accept the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

Example H70E45

The Harada-Norton simple group has the presentation

$$\begin{aligned} < x, a, b, c, d, e, f, g \mid & x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2, (x,a), (x,g), \\ & (bc)^3, (bd)^2, (be)^2, (bf)^2, (bg)^2, (cd)^3, (ce)^2, (cf)^2, (cg)^2, \\ & (de)^3, (df)^2, (dg)^2, (ef)^3, (eg)^2, (fg)^3, (b, xbx), (a, edcb), \\ & (a,f)dcbdcd, (ag)^5, (cdef, xbx), (b, xcdefx), (cdef, xcdefx) > \end{aligned}$$

The subgroup generated by x, b, c, d, e, f, g has index 1,140,000. We use the parameter `CosetLimit` to request a sufficiently large coset table. For the enumeration we choose the predefined strategy `Hard` with the modification of a complete C-style lookahead (`Lookahead := 2`).

```
> HN<x, a, b, c, d, e, f, g> :=
>     Group< x, a, b, c, d, e, f, g |
>               x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2,
>               (x, a), (x, g),
>               (b*c)^3, (b*d)^2, (b*e)^2, (b*f)^2, (b*g)^2,
>               (c*d)^3, (c*e)^2, (c*f)^2, (c*g)^2,
>               (d*e)^3, (d*f)^2, (d*g)^2,
>               (e*f)^3, (e*g)^2,
>               (f*g)^3,
>               (b, x*b*x),
>               (a, e*d*c*b), (a, f)*d*c*b*d*c*d, (a*g)^5,
>               (c*d*e*f, x*b*x), (b, x*c*d*e*f*x),
>               (c*d*e*f, x*c*d*e*f*x)
>           >;
> H := sub<HN | x,b,c,d,e,f,g >;
> idx := Index(HN, H: Print := true, CosetLimit := 1200000,
>                     Strategy := "Hard", Lookahead := 2);
INDEX = 1140000
 (a=1140000 r=1471 h=1168483 n=1168483;
  l=2945 c=201.17;
  m=1142416 t=1470356)
> idx;
1140000
```

Example H70E46

We use a function representing a parametrised presentation to determine the order of a collection of groups obtained by systematically varying one relation. We select the predefined coset enumeration strategy `Easy` for the order computations.

```
> Grp := func< p, q, r, s |
>
>   Group<
>     x, y, z, h, k, a |
```

```
>     x^2, y^2, z^2, (x,y), (y,z), (x,z), h^3, k^3, (h,k),
>     (x,k), (y,k), (z,k), x^h*y, y^h*z, z^h*x, a^2, a*x*a*y,
>     a*y*a*x, (a,z), (a,k), x^p*y^q*z^r*k^s*(a*h)^2 >
>        >;
> [ < <i,j,k,l>, Order(Grp(i,j,k,l) : Strategy := "Easy") >
>   : i, j, k in [0..1], l in [0..2] ];
[ <<0, 0, 0, 0>, 144>, <<0, 0, 1, 0>, 18>, <<0, 1, 0, 0>, 72>,
  <<0, 1, 1, 0>, 36>, <<1, 0, 0, 0>, 18>, <<1, 0, 1, 0>, 144>,
  <<1, 1, 0, 0>, 36>, <<1, 1, 1, 0>, 72>, <<0, 0, 0, 1>, 144>,
  <<0, 0, 1, 1>, 18>, <<0, 1, 0, 1>, 72>, <<0, 1, 1, 1>, 36>,
  <<1, 0, 0, 1>, 18>, <<1, 0, 1, 1>, 144>, <<1, 1, 0, 1>, 36>,
  <<1, 1, 1, 1>, 72>, <<0, 0, 0, 2>, 144>, <<0, 0, 1, 2>, 18>,
  <<0, 1, 0, 2>, 72>, <<0, 1, 1, 2>, 36>, <<1, 0, 0, 2>, 18>,
  <<1, 0, 1, 2>, 144>, <<1,1, 0, 2>, 36>, <<1, 1, 1, 2>, 72> ]
```

70.6.3 Implicit Invocation of the Todd-Coxeter Algorithm

Several functions working with finitely presented groups at some point require a coset table of a subgroup and may invoke a coset enumeration indirectly, e.g. the function `meet` or the function `Normaliser`. The default behaviour for such implicitly called coset enumerations is the same as the one for coset enumerations invoked explicitly, e.g. using the function `ToddCoxeter`.

If such an implicitly called coset enumeration fails to produce a closed coset table, the calling function may terminate with a runtime error.

Experienced users can control the behaviour of indirectly invoked coset enumerations with a set of global parameters. These global parameters are valid for all implicitly called coset enumerations. For a detailed description of the available parameters and their meanings, we refer to Chapter 71. Note that coset enumerations which are *explicitly* invoked, e.g. by a call to the function `Index`, are not affected by this global set of parameters. Parameters for these functions have to be specified in the function call.

`SetGlobalTCParameters(: parameters)`

This function sets the parameter values used for indirect invocations of the Todd-Coxeter coset enumeration procedure. The parameters accepted and their default values are the same as for the function `CosetEnumerationProcess` described in Chapter 71.

`UnsetGlobalTCParameters()`

This function restores the default values for the parameters used for indirect invocations of the Todd-Coxeter coset enumeration procedure. For a description of the meanings of the parameters and their default values, see `CosetEnumerationProcess` in Chapter 71.

Example H70E47

We consider again the Harada-Norton simple group with the presentation

$$< x, a, b, c, d, e, f, g \mid x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2, (x,a), (x,g),$$
$$(bc)^3, (bd)^2, (be)^2, (bf)^2, (bg)^2, (cd)^3, (ce)^2, (cf)^2, (cg)^2,$$
$$(de)^3, (df)^2, (dg)^2, (ef)^3, (eg)^2, (fg)^3, (b, xbx), (a, edcb),$$
$$(a,f)dcbdcd, (ag)^5, (cdef, xbx), (b, xcdefx), (cdef, xcdefx) >$$

and the subgroup H generated by x, b, c, d, e, f, g.

```
> HN<x, a, b, c, d, e, f, g> :=
>     Group< x, a, b, c, d, e, f, g |
>              x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2,
>              (x, a), (x, g),
>              (b*c)^3, (b*d)^2, (b*e)^2, (b*f)^2, (b*g)^2,
>              (c*d)^3, (c*e)^2, (c*f)^2, (c*g)^2,
>              (d*e)^3, (d*f)^2, (d*g)^2,
>              (e*f)^3, (e*g)^2,
>              (f*g)^3,
>              (b, x*b*x),
>              (a, e*d*c*b), (a, f)*d*c*b*d*c*d, (a*g)^5,
>              (c*d*e*f, x*b*x), (b, x*c*d*e*f*x),
>              (c*d*e*f, x*c*d*e*f*x) >;
> H := sub<HN | x,b,c,d,e,f,g >;
```

H has index 1,140,000 in HN. Using the default settings, the normaliser of H in HN cannot be computed.

```
>  N := Normaliser(HN, H);

>> N := Normaliser(HN, H);
                  ^
Runtime error in 'Normaliser': Coset table is not closed
```

We change the global parameters for implicitly called coset enumerations and try again.

```
> SetGlobalTCParameters( : Strategy := "Hard");
> N := Normaliser(HN, H);
```

With these parameters, the computation works. We see that H is self-normalising in HN.

```
> Index(HN, N);
1140000
> IsSelfNormalising(HN, H);
true
```

70.6.4 Constructing a Presentation for a Subgroup

70.6.4.1 Introduction

Let H be a subgroup of finite index in the finitely presented group G. It frequently happens that it is desirable to construct a set of defining relations for H from those of G. Such a presentation can be obtained either on a set of Schreier generators for H or on the given generators of H using the Reidemeister-Schreier rewriting technique [MKS76], if necessary together with extended coset enumeration [AR84, HKRR84].

We emphasise that if the user wishes only to determine the structure of the maximal abelian quotient of H, then the function `AbelianQuotientInvariants` should be used. In this case there is no need to first construct a presentation for H using the `Rewrite` function described below, since `AbelianQuotientInvariants` employs a special form of the Reidemeister-Schreier rewriting process which abelianises each relator as soon as it is constructed. Thus, compared to the function `Rewrite`, the function `AbelianQuotientInvariants` can be applied to subgroups of much larger index.

70.6.4.2 Rewriting

`Rewrite(G, H : parameters)`

Given a finitely presented group G and a subgroup H having finite index in G, return a group R isomorphic to H with a presentation on (some of) the Schreier generators of H in G. The group R will be created as a subgroup of G and defining relations of R on its generators will be available. Note that the generators of R will, in general, not correspond to the generators of H. The isomorphism from H onto R is returned as second return value.

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function `SetGlobalTCParameters`. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`Simplify`	BoolElt	*Default :* `true`

If this Boolean-valued parameter is given the value `true`, then the resulting presentation for H will be simplified (default). The function `Rewrite` returns a finitely presented group that is isomorphic to H. If simplification is requested (by setting `Simplify := true`) then the simplification procedures are invoked (see next section). These procedures perform a sequence of Tietze transformations which typically result in a considerable simplification of the presentation produced by the rewriting process. Alternatively, the user can set `Simplify := false` and then perform the simplification directly if desired. (See next section). If simplification is not requested as part of `Rewrite`, a small amount of simplification is performed on the presentation before it is returned.

`EliminationLimit`	RngIntElt	*Default :* 100
`ExpandLimit`	RngIntElt	*Default :* 150
`GeneratorsLimit`	RngIntElt	*Default :* 0

`LengthLimit`	RngIntElt	*Default :* ∞
`SaveLimit`	RngIntElt	*Default :* 10
`SearchSimultaneous`	RngIntElt	*Default :* 20
`Iterations`	RngIntElt	*Default :* 10000
`Print`	RngIntElt	*Default :* 0

These parameters control the simplification. See the description of `Simplify` for an explanation of these parameters.

`Rewrite(G, ~H : parameters)`

Given a finitely presented group G and a subgroup H having finite index in G, compute a defining set of relations for H on the existing generators, using extended coset enumeration and Reidemeister-Schreier rewriting, and change the presentation of H accordingly.

If the computation is successful, defining relations for H on its generators will be available at the end; any previously computed relations of H will be discarded. If the computation is unsuccessful, H is not changed. In any case, both the isomorphism type of H and its embedding into G as a subgroup is preserved by this function.

`Simplify`	BoolElt	*Default :* `true`

If this parameter is given the value `true` (default), then an attempt will be made to simplify the constructed set of relations by substring searches, that is, Tietze transformations not changing any generators. The generating set of H is not modified by this process.

Moreover, the extended coset enumeration can be controlled by a wide range of parameters. The function `Rewrite` – in addition to the parameter `Simplify` – accepts the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

Example H70E48

Starting with the group G defined by

$$< x, y \mid x^2, y^3, (xy)^{12}, (xy)^6(xy^{-1})^6 >,$$

we construct a subgroup K of index 3 generated by the words x, yxy^{-1} and $yxy^{-1}xy^{-1}xy$. We present the subgroup K, compute its abelian quotient structure and then show that the class 30 2-quotient of K has order 2^{62}.

```
> G<x, y> := Group< x, y | x^2, y^3, (x*y)^12, (x*y)^6*(x*y^-1)^6 >;
> G;
Finitely presented group G on 2 generators
Relations
       x^2 = Id(G)
       y^3 = Id(G)
       (x * y)^12 = Id(G)
       x * y * x * y * x * y * x * y * x * y * x * y * x * y * x * y^-1 * x *
```

```
          y^-1 * x * y^-1 * x * y^-1 * x * y^-1 * x * y^-1 = Id(G)
> K := sub< G | x, y*x*y^-1, y*x*y^-1*x*y^-1*x*y >;
> K;
Finitely presented group K on 3 generators
Generators as words in group G
       K.1 = x
       K.2 = y * x * y^-1
       K.3 = y * x * y^-1 * x * y^-1 * x * y
> Index(G, K);
3
> T := Rewrite(G, K);
> T;
Finitely presented group T on 3 generators
Generators as words in group G
    T.1 = x
    T.2 = y * x * y^-1
    T.3 = x^y
Relations
    T.1^2 = Id(T)
    T.2^2 = Id(T)
    T.3^2 = Id(T)
    (T.3 * T.2 * T.1 * T.3 * T.2)^2 = Id(T)
    (T.1 * T.3 * T.2 * T.1 * T.3)^2 = Id(T)
    (T.1 * T.2 * T.1 * T.3 * T.2)^2 = Id(T)
> AbelianQuotientInvariants(T);
[ 2, 2, 2 ]
> Q2 := pQuotient(T, 2, 30);
> FactoredOrder(Q2);
[ <2, 62> ]
```

Example H70E49

In this example we illustrate how the function `Rewrite` can be used to obtain a presentation of a finitely presented group on a different set of generators.

We start with a presentation of $L_2(7)$ on two generators x and y.

```
> F<x,y> := Group< x, y | x^3 = 1, y^3 = 1, (x*y)^4 = 1,
>                         (y*y^x)^2 = y^x*y >;
```

The group is also generated by the elements $a = (xy)^2$ and $b = y$.

```
> H<a,b> := sub<F | (x*y)^2, y >;
> Index(F,H);
1
```

At the moment, no defining relations of $H \cong F$ on the generators a and b are known.

```
> H;
Finitely presented group H on 2 generators
```

```
Index in group F is 1
Generators as words in group F
    a = (x * y)^2
    b = y
```

We apply the function Rewrite to H as a subgroup of F in order to compute defining relations on the generators a and b.

```
> Rewrite(F, ~H);
> H;
Finitely presented group H on 2 generators
Index in group F is 1
Generators as words in group F
    a = (x * y)^2
    b = y
Relations
    a^2 = Id(H)
    b^3 = Id(H)
    (a * b)^7 = Id(H)
    (a * b^-1 * a * b)^4 = Id(H)
    (b * a * b^-1 * a * b * a)^4 = Id(H)
```

The last relation turns out to be redundant; a and b are standard generators for $L_2(7)$.

```
> Order(DeleteRelation(H,5)) eq Order(H);
true
```

70.7 Subgroups of Finite Index

The functions in this section are concerned with the construction of subgroups of finite index. We first describe a method for computing all subgroups whose index does not exceed some (modest) integer bound. The next family of functions are concerned with constructing new subgroups of finite index from one or more known ones.

70.7.1 Low Index Subgroups

`LowIndexSubgroups(G, R : parameters)`

Given a finitely presented group G (possibly the free group), and an expression R defining a positive integer range (see below), determine the conjugacy classes of subgroups of G whose indices lie in the range specified by R. The subgroups are generated by systematically building all coset tables consistent with the defining relations for G and which satisfy the range condition R. The argument R is one of the following:

(a) An integer n representing the range $[1, n]$;

(b) A tuple $< a, b >$ representing the range $[a, b]$;

The generation of subgroups can be controlled by a set of parameters described below. The returned sequence contains the subgroups found and is sorted in order of increasing index in G.

Example H70E50

(Peter Lorimer) The two graphs known as Tutte's 8-cage and the Conder graph may be constructed as the Cayley graphs of two conjugacy classes of subgroups having index 10 in the finitely presented group

$$< q, r, s, h, a \mid h^3 = a^2 = p^2 = 1, p^h = p, p^a = q, q^h = r, r^a = s,$$
$$h^s = h^{-1}, r^h = pqr, sr = pqrs, pq = qp, pr = rp, ps = sp, qr = rq, qs = sq > .$$

We use the low index function to construct these subgroups.

```
> G<p, q, r, s, h, a> := Group<p, q, r, s, h, a |
>                         h^3 = a^2 = p^2 = 1, p^h = p, p^a = q,
>                         q^h = r, r^a = s, h^s = h^-1, r^h = p * q * r,
>                         s * r = p * q * r * s, p * q = q * p,
>                         p * r = r * p, p * s = s * p, q * r = r * q,
>                         q * s = s * q>;
> LowIndexSubgroups(G, <10, 10>);
[
       Finitely presented group on 6 generators
       Index in group G is 10 = 2 * 5
       Generators as words in group G
              $.1 = p
              $.2 = s
              $.3 = h
              $.4 = q^-2
              $.5 = a * h^-1 * a * r^-1
              $.6 = a * h * a * h^-1 * a * q^-1,

       Finitely presented group on 6 generators
       Index in group G is 10 = 2 * 5
       Generators as words in group G
              $.1 = p
              $.2 = s
              $.3 = h
              $.4 = q^-2
              $.5 = a * h^-1 * a * r^-1
              $.6 = a * h * a * h^-1 * a
]
```

Example H70E51

A fairly surprising application for the low index subgroup algorithm is the enumeration of the conjugacy classes of a finite fp-group. In this example, we consider the group

$$G \simeq \mathrm{PGL}_2(9) = \langle a, b | a^2, b^3, (ab)^8, [a,b]^5, [a,(ba)^3b^{-1}]^2 \rangle.$$

```
> G<a,b> := Group< a,b | a^2, b^3, (a*b)^8, (a,b)^5,
>                       (a,(b*a)^3*b^-1)^2  >;
> Order(G);
720
```

In an infinite fp-group, finding all classes of subgroups up to an index of 720 by applying the low index subgroup algorithm, would be extremely hard. In the case of the finite group G, however, we succeed.

```
> time sgG := LowIndexSubgroups(G, Order(G));
Time: 31.859
> #sgG;
26
```

We get a list of 26 representatives of the conjugacy classes of subgroups. For every representative, its index in G and a set of generating words are known. We just have a look at two of them.

```
> sgG[10];
Finitely presented group on 2 generators
Index in group G is 60 = 2^2 * 3 * 5
Generators as words in group G
    $.1 = b
    $.2 = a * b * a * b * a * b^-1 * a * b * a * b * a * b^-1 * a
       * b^-1 * a
> sgG[21];
Finitely presented group on 1 generator
Index in group G is 180 = 2^2 * 3^2 * 5
Generators as words in group G
    $.1 = (b * a)^2
```

The function LowIndexSubgroups constructs all conjugacy classes of subgroups of G satisfying the following two conditions:

(i) The index of each subgroup is in the range defined by R;

(ii) If the parameter Subgroup defines a subgroup H, then at least one subgroup in each conjugacy class contains the subgroup H.

The subgroups are returned as a sequence of subgroups G, unless otherwise specified by the parameter GeneratingSets (see below). The sequence is sorted by increasing index of the subgroups in G.

The subgroups are constructed using an algorithm due to Sims [Sim94, sect. 5.6]. This algorithm constructs the coset tables by using a backtrack algorithm. At a given position in the coset table, coset definitions are made systematically. Once a new definition has been made, the group relations are traced in an attempt to deduce further entries or to infer that this partial table will not extend to a table corresponding to a new class of subgroups. When either it cannot define a new entry, or when a complete table has been constructed, the algorithm backtracks to try the next possibility (this may introduce a new row, increasing the index). This algorithm may also be run as a process in such a way that the subgroups are returned one at a time, thereby allowing the user to analyze each subgroup as soon as it is found.

`ColumnMajor` BoolElt *Default :* `false`

If `ColumnMajor` is set `false` (*default*), then the location for a new definition in the coset table is determined by searching the table in row major order for undefined entries. If `ColumnMajor` is set `true`, then the position for a new definition is determined by searching the table in column major order. If the presentation for G contains explicit relators expressing the fact that certain of the generators have large order, then the presentation should be organized so that these generators appear first and the column major order should be selected for new coset definition. This strategy often leads to greatly improved performance.

`GeneratingSets` BoolElt *Default :* `false`

The conjugacy classes of subgroups are returned in the form of a sequence of sets of words, where the i-th set is a generating set for a representative subgroup from the i-th conjugacy class of subgroups satisfying the given conditions. This is a much more compact representation than returning the subgroups as a sequence of actual *subgroups* of G and should be used when a very large number of subgroups is expected, as there may be insufficient space to store each of them as a subgroup.

`Limit` RngIntElt *Default :* ∞

Terminate after finding n conjugacy classes of subgroups satisfying the designated conditions.

`Long` [RngIntElt] *Default :* []

This option enables the user to designate certain of the defining relators for G as *long relators*. The relators of G are numbered from 1 to r, in the order they appear in the `quo`- or `Group`-constructors. The value L of `Long` is a subset of the integer set $\{1, \ldots, r\}$. Magma interprets the relators whose numbers appear in L as long relators. A relator designated as long is not used during the construction of a coset table. Rather, it is applied once a complete table has been found. There is some evidence to suggest that better performance is achieved in those groups having one or more very long relators by deferring application of these relators until such time as a complete coset table has been obtained.

`Print` RngIntElt *Default :* 0

A description of each class of subgroups may be printed immediately after it is constructed. The value n assigned to the `Print` parameter specifies just what information is to be printed, according to the following rules:

$n = 0$: No printing (*default*).

$n = 1$: For each class, print a heading and a set of generators for the class representative.

$n = 2$: The information printed for $n = 1$, together with the permutation representation of G on the right cosets of the class representative.

$n = 3$: The information printed for $n = 2$, together with generators for the normalizer N of the class representative, and a system of right coset representatives for N in G.

`Subgroup` GrpFP *Default :* `sub< G | >`

By specifying a value H for `Subgroup`, only subgroups containing H will be constructed.

`TimeLimit` RngIntElt *Default :* 0 (no limit)

A time limit in seconds. A value of 0 (default) means no limit.

`LowIndexProcess(G, R : parameters)`

`ColumnMajor`	BoolElt	*Default :* `false`
`GeneratingSets`	BoolElt	*Default :* `false`
`Long`	[RngIntElt]	*Default :* []
`Print`	RngIntElt	*Default :* 0
`Subgroup`	GrpFP	*Default :* `sub< G | >`
`TimeLimit`	RngIntElt	*Default :* 0 (no limit)

Create a low index subgroups *process*. This process may be used to create the conjugacy classes of proper subgroups one at time, with control being handed back to the Magma language processor each time a new class of subgroups is found. This function returns a process which is used by the function `NextSubgroup` to actually produce the subgroups.

The arguments and parameters have the same interpretation as for the function `LowIndexSubgroups`, except that `Limit` is not available (since the same effect can be achieved by limiting the number of calls to `NextSubgroup`).

Setting a time limit for a process P limits the total amount of time spent in calls to `NextSubgroup`. If the time limit is exceeded in a call to `NextSubgroup`, this call is aborted and P becomes invalid. Further attempts to access P will cause a runtime error. The function `IsValid` can be used to check whether a process is valid in order to avoid runtime errors in loops or user written functions.

`NextSubgroup(~P)`

`NextSubgroup(~P, ~G)`

Given a low index subgroups process P, construct the next conjugacy class of proper subgroups. The process P must have been previously created using the function `LowIndexProcess` and must be valid. Calling `NextSubgroup` for an empty process has no effect.

`ExtractGroup(P)`

Extract a representative subgroup for the conjugacy class currently defined by the low index process P. The subgroup extracted will be the one found by the previous invocation of `NextSubgroup`, or the first subgroup if `NextSubgroup` has never been invoked on this process. Note that `ExtractGroup` will not search for a new subgroup. If P is empty or invalid, a runtime error will result.

`ExtractGenerators(P)`

Extract a generating set for the representative subgroup of the conjugacy class currently defined by the low index process P. The subgroup extracted will be the one found by the previous invocation of `NextSubgroup`, or the first subgroup if `NextSubgroup` has never been invoked on this process. Note that `ExtractGenerators` will not search for a new subgroup. If P is empty or invalid, a runtime error will result.

`IsEmpty(P)`

Return `true` if the low index process P has already found all conjugacy classes of subgroups. If `IsEmpty` is called immediately following the creation of the low index process, then it will return the value `false` if there are no subgroups satisfying the specified conditions or advance P to the first such subgroup otherwise.

`IsValid(P)`

Return `true` if the low index process P is valid, that is, no limit has been exceeded. If `IsValid` is called immediately following the creation of the low index process, then it will return the value `false` if no subgroups satisfying the specified conditions can be found within the specified time or advance P to the first such subgroup otherwise.

Example H70E52

We determine all conjugacy classes of subgroups having index at most 15 in the triangle group

$$< a, b \,|\, a^2, b^3, (ab)^7 > .$$

```
> G<a, b> := Group< a, b | a^2, b^3, (a*b)^7 >;
> L := LowIndexSubgroups(G, 15: Print := 1);
Subgroup class 1        Index 7 Length 7        Subgroup generators :-
{ a, b * a * b^-1, b^-1 * a * b * a * b^-1 * a * b }
```

```
Subgroup class 2        Index 7 Length 7        Subgroup generators :-
{ a, b^-1 * a * b^-1 * a * b * a * b, b * a * b^-1 }
Subgroup class 3        Index 15        Length 15       Subgroup generators :-
{ a, b^-1 * a * b * a * b^-1 * a * b * a * b^-1 * a * b, b * a * b^-1 }

Subgroup class 4        Index 15        Length 15       Subgroup generators :-
{ a, b * a * b^-1, b^-1 * a * b^-1 * a * b * a * b^-1 * a * b * a * b }

Subgroup class 5        Index 14        Length 14       Subgroup generators :-
{ a, b^-1 * a * b * a * b^-1 * a * b * a * b * a * b^-1 * a * b, b * a * b^-1 }

Subgroup class 6        Index 14        Length 7        Subgroup generators :-
{ a, b^-1 * a * b * a * b^-1 * a * b * a * b^-1 * a * b * a * b^-1 * a * b, b *
a * b * a * b^-1 }

Subgroup class 7        Index 14        Length 14       Subgroup generators :-
{ a, b^-1 * a * b * a * b^-1 * a * b^-1 * a * b * a * b * a * b^-1 * a * b, b *
a * b * a * b^-1 }

Subgroup class 8        Index 14        Length 7        Subgroup generators :-
{ a, b * a * b * a * b^-1 * a * b^-1 * a * b * a * b * a * b^-1 * a * b^-1, b^-1
 * a * b * a * b }

Subgroup class 9        Index 15        Length 15       Subgroup generators :-
{ a, b * a * b * a * b^-1 * a * b^-1, b^-1 * a * b^-1 * a * b * a * b }

Subgroup class 10       Index 9 Length 9        Subgroup generators :-
{ a, b * a * b * a * b * a * b^-1 }
Subgroup class 11       Index 14        Length 7        Subgroup generators :-
{ a, b * a * b * a * b * a * b^-1 * a * b, b * a * b^-1 * a * b * a * b^-1 }
Subgroup class 12       Index 14        Length 7        Subgroup generators :-
{ a, b * a * b * a * b^-1 * a * b * a * b, b * a * b^-1 * a * b * a * b^-1 }
Subgroup class 13       Index 14        Length 7        Subgroup generators :-
{ a, b^-1 * a * b * a * b^-1 * a * b, b * a * b * a * b * a * b^-1 * a * b^-1 }

Subgroup class 14       Index 14        Length 7        Subgroup generators :-
{ a, b * a * b * a * b^-1 * a * b * a * b, b^-1 * a * b * a * b^-1 * a * b }

Subgroup class 15       Index 14        Length 14       Subgroup generators :-
{ a, b^-1 * a * b * a * b * a * b^-1 * a * b, b * a * b * a * b * a * b^-1 * a *
 b^-1 }
Subgroup class 16       Index 8 Length 8        Subgroup generators :-
{ b, a * b * a * b * a * b^-1 * a }
```

Example H70E53

In this example we illustrate the use of the low index subgroup process by using it to determine whether the simple group PSL$(2, 8)$ is a homomorphic image of the triangle group

$$< x, y \mid x^2, y^3, (xy)^7 > .$$

```
> F<x, y> := FreeGroup(2);
> G<x, y> := quo< F | x^2, y^3, (x*y)^7 >;
> LP := LowIndexProcess(G, 30);
> i := 0;
> while i le 100 and not IsEmpty(LP) do
>    H := ExtractGroup(LP);
>    NextSubgroup(~LP);
>    P := CosetImage(G, H);
>    if Order(P) eq 504 and IsSimple(P) then
>       Ψprint "The group G has L(2, 8) as a homomorphic image.";
>        print "It is afforded by the subgroup:-", H;
>       Ψbreak;
>    end if;
>    i +:= 1;
> end while;
The group G has L(2, 8) as a homomorphic image.
It is afforded by the subgroup:-
Finitely presented group H on 4 generators
Index in group G is 28 = 2^2 * 7
Generators as words in group G
       H.1 = x
       H.2 = y * x * y^-1
       H.3 = y^-1 * x * y * x * y^-1 * x * y * x * y^-1 * x * y * x * y^-1 *
       x * y * x * y
       H.4 = y^-1 * x * y * x * y^-1 * x * y^-1 * x * y * x * y^-1 * x * y *
       x * y * x * y^-1 * x * y
```

Example H70E54

This example shows how the low index subgroup machinery may be used as part of a function trying to prove that a group is infinite:

```
> function MyIsInfinite(G)
>
>  // ...
>
>  // Low index subgroup approach: check whether an obviously
>  //    infinite subgroup can be found in reasonable time.
>  P := LowIndexProcess(G, 30 : TimeLimit := 5);
>  while IsValid(P) and not IsEmpty(P) do
>     H := ExtractGroup(P);
```

```
>     NextSubgroup(~P);
>     if 0 in AbelianQuotientInvariants(H) then
>        print "The group G has subgroup:-", H;
>        print "whose abelian quotient is infinite";
>        print "Hence G is infinite.";
>        return true;
>     end if;
>  end while;
>  print "Low index approach fails; trying other methods...";
>
>  // ...
>
> end function;
```

We try the code fragment on the group

$$< x, z \mid z^3xz^3x^{-1}, z^5x^2z^2x^2 > .$$

```
> G<x, z> := Group<x,z | z^3*x*z^3*x^-1, z^5*x^2*z^2*x^2 >;
> MyIsInfinite(G);
The group G has subgroup:-
Finitely presented group H on 4 generators
Index in group G is 4 = 2^2
Generators as words in group G
    H.1 = x
    H.2 = z * x * z
    H.3 = z^3
    H.4 = z * x^-1 * z * x * z^-1
whose abelian quotient has structure [ 2, 6, 0 ]
Hence G is infinite.
true
```

`LowIndexNormalSubgroups(G, n: parameters)`

The normal subgroups of finitely presented group G up to index n, $n \leq 100\,000$. The subgroups are returned as a sequence of records (ordered by subgroup index) where the ith record contains fields

`Group`: A presentation of the ith normal subgroup.

`Index`: The index of the ith normal subgroup in G.

`Supegroups`: The set of positions in the sequence of the groups which are supergroups of the ith group.

`PrintLevel` RingIntElt *Default :* 0

This parameter may be set to 0, 1 or 2. At 0, the function prints no diagnostic output. At level 1, it outputs details of each normal subgroup being tested for further normal subgroups. Level 2 gives details of each test being performed on each normal subgroup.

`Simplify` MonStgElt *Default : "No"*

The possible values are `"No"`, `"Yes"` and `"LengthLimit"`. This determines the parameter values passed to the `Rewrite(G,H)` function, when this function is used. The value `"No"` sets parameter `Simplify:=false`. The value `"Yes"` sets parameter `Simplify:=true`. The value `"LengthLimit"` sets parameter `LengthLimit:=Index(G,H)`.

70.7.2 Subgroup Constructions

Most operations described in this subsection require a closed coset table for at least one subgroup of an fp-group. If a closed coset table is needed and has not been computed, a coset enumeration will be invoked. If the coset enumeration does not produce a closed coset table, a runtime error is reported.

Experienced users can control the behaviour of such indirectly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function `SetGlobalTCParameters`. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`H ^ u`
`Conjugate(H, u)`

Given an fp-group H and a word u in an fp-group K, such that H and K are subgroups of some common fp-group G and words in terms of the generators of G are known for the generators of both H and K, construct the subgroup of G obtained by conjugating H by u.

`H meet K`

Given subgroups H and K, both of finite index in some fp-group G, return the subgroup which is the intersection of H and K.

This function requires closed coset tables for both, H and K in G.

`Core(G, H)`

Given a subgroup H of finite index in the fp-group G, construct the core of H in G.

This function requires a closed coset table for H in G.

`GeneratingWords(G, H)`

Given a subgroup H of the fp-group G, this function returns a set of words in the generators of G, generating H as a subgroup of G (assuming such words are known or can be constructed). Note that the returned generating set does not necessarily correspond to the internal generators of H. In particular, generating words obtained using the function `GeneratingWords` cannot be used to coerce elements from H to G.

`MaximalOvergroup(G, H)`

Given a subgroup H of finite index in the fp-group G, construct a maximal overgroup of H in G. A *maximal overgroup* of H is a maximal subgroup of G that contains H. If H is already maximal, the group G is returned.

This function requires a closed coset table for H in G.

`MinimalOvergroup(G, H)`

Given a subgroup H of finite index in the fp-group G, construct a minimal overgroup of H in G. A *minimal overgroup* of a subgroup H is a subgroup K of G such that K contains H as a maximal subgroup. If H is already maximal in G, the group G is returned.

This function requires a closed coset table for H in G.

`H ^ G`

`NormalClosure(G, H)`

Given a subgroup H of finite index in the fp-group G, construct the normal closure of H in G.

This function requires a closed coset table for H in G.

`Normaliser(G, H)`

`Normalizer(G, H)`

Given a subgroup H of finite index in the fp-group G, construct the normaliser of H in G. For a sample application of this function, see Example H70E47.

This function requires a closed coset table for H in G.

`SchreierGenerators(G, H :` *parameters*`)`

`Simplify` BoolElt *Default :* `true`

Given a subgroup H of finite index in the fp-group G, return the Schreier generators for H as a set of words in G.

If the parameter `Simplify` is set to `true` (default), a heuristic method of eliminating redundant Schreier generators is applied. To switch this feature off, set `Simplify` to `false`.

This function requires a closed coset table for H in G.

`SchreierSystem(G, H)`

`Transversal(G, H)`

Given a subgroup H of finite index in the fp-group G, construct a (right) Schreier system of coset representatives for H in G. The function returns

(a) the Schreier system as a set of words in G;

(b) the corresponding Schreier coset function.

This function requires a closed coset table for H in G.

`Transversal(G, H, K)`

Given subgroups H and K, both of finite index in the fp-group G, return an indexed set of words which comprise a set of representatives for the double cosets HuK of H and K in G, as well as a map from G to the representatives. It should be noted that this function is evaluated by first constructing the right cosets of H in G and then computing the orbits of the cosets under the action of the generators of the subgroup K.

This function requires a closed coset table for H in G.

Example H70E55

We illustrate some of the subgroup constructions by using them to construct subgroups of small index in the two-dimensional space group p4g which has the presentation

$$< r, s \,|\, r^2, s^4, (r,s)^2 > .$$

```
> p4g<r, s> := Group< r, s | r^2 = s^4 = (r*s^-1*r*s)^2 = 1 >;
> p4g;
Finitely presented group p4g on 2 generators
Relations
    r^2 = Id(p4g)
    s^4 = Id(p4g)
    (r * s^-1 * r * s)^2 = Id(p4g)
```

We define two subgroups of $p4g$ and compute their indices in $p4g$.

```
> h := sub< p4g | (s^-1*r)^4, s*r >;
> k := sub< p4g | (s^-1*r)^2, (s*r)^2 >;
> Index(p4g, h);
8
> Index(p4g, k);
8
```

We construct the normal closure of h in $p4g$.

```
> n := NormalClosure(p4g, h);
> n;
Finitely presented group n on 6 generators
Index in group p4g is 2
Generators as words in group p4g
    n.1 = (s^-1 * r)^4
    n.2 = s * r
    n.3 = r * s
    n.4 = r^-1 * s * r^2
    n.5 = s^2 * r * s^-1
    n.6 = r * s
```

Next, we construct a subgroup of $p4g$ containing h as maximal subgroup...

```
> m := MinimalOvergroup(p4g, h);
```

```
> m;
Finitely presented group m on 3 generators
Index in group p4g is 4 = 2^2
Generators as words in group p4g
    m.1 = (s^-1 * r)^4
    m.2 = s * r
    m.3 = (r * s)^2
```

... and a maximal subgroup of $p4g$ containing k.

```
> n := MaximalOvergroup(p4g, k);
> n;
Finitely presented group n on 4 generators
Index in group p4g is 2
Generators as words in group p4g
    n.1 = (s^-1 * r)^2
    n.2 = (s * r)^2
    n.3 = r
    n.4 = s^2
```

Finally, we construct a transversal in $p4g$ for the normaliser of h in $p4g$...

```
> T := Transversal(p4g, Normaliser(p4g, h));
> T;
{@ Id(p4g), r, s^-1, r * s @}
```

... compute the intersection of h and the conjugate of h by r...

```
> l := h meet h^r;
> l;
Finitely presented group l
Index in group p4g is 32 = 2^5
Subgroup of group p4g defined by coset table
```

... and construct the core of h in $p4g$.

```
> c := Core(p4g, h);
> c;
Finitely presented group c
Index in group p4g is 32 = 2^5
Subgroup of group p4g defined by coset table
```

Note, that the two subgroups l and c constructed last are defined as finite index subgroups of $p4g$ by a coset table and that there are no generators known for them. Generators can be obtained e.g. by using the function GeneratingWords. We show this for the subgroup l.

```
> GeneratingWords(p4g, l);
{ (s * r)^4, (s^-1 * r)^4 }
```

Once computed, these generators are memorised. Compare the result of printing l to the output obtained above.

```
> l;
```

```
Finitely presented group l on 2 generators
Index in group p4g is 32 = 2^5
Generators as words in group p4g
    l.1 = (s * r)^4
    l.2 = (s^-1 * r)^4
```

Example H70E56

Consider the group G given by the presentation $\langle x, y \mid x^2, y^3, (xy)^7 \rangle$.

```
> G<x,y> := Group< x,y | x^2, y^3, (x*y)^7 >;
```

We construct the subgroups of index less than or equal to 7 using the low index algorithm.

```
> L := LowIndexSubgroups(G, 7);
> L;
[
    Finitely presented group on 2 generators
    Index in group G is 1
    Generators as words in group G
        $.1 = x
        $.2 = y,
     Finitely presented group on 3 generators
    Index in group G is 7
    Generators as words in group G
        $.1 = x
        $.2 = y * x * y^-1
        $.3 = y^-1 * x * y^-1 * x * y * x * y,
     Finitely presented group on 3 generators
    Index in group G is 7
    Generators as words in group G
        $.1 = x
        $.2 = y * x * y^-1
        $.3 = y^-1 * x * y * x * y^-1 * x * y
]
```

We define a subgroup as the core of one of the subgroups of index 7. The function `Core` returns a subgroup of G defined by a coset table.

```
> H := Core(G, L[2]);
> H;
Finitely presented group H
Index in group G is 168 = 2^3 * 3 * 7
Subgroup of group G defined by coset table
```

A set of generators for H can be obtained e.g. with the function `SchreierGenerators`.

```
> sgH := SchreierGenerators(G, H);
> #sgH;
```

```
6
```

By default, SchreierGenerators returns a reduced generating set. The unreduced set of Schreier generators can be obtained by setting the value of the parameter Simplify to false.

```
> sgHu := SchreierGenerators(G, H : Simplify := false);
> #sgHu;
85
```

70.7.3 Properties of Subgroups

The operations described in this subsection all require a closed coset table for at least one subgroup of an fp-group. If a closed coset table is needed and has not been computed, a coset enumeration will be invoked. If the coset enumeration does not produce a closed coset table, a runtime error is reported.

Experienced users can control the behaviour of such indirectly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`u in H`

Given an fp-group H and a word u in an fp-group K, such that H and K are subgroups of some common fp-group G, H is of finite index in G, and words for the generators of K in terms of the generators of G are known, return `true`if u is an element of H and `false` otherwise.

This function requires a closed coset table for H in G.

`u notin H`

Given an fp-group H and a word u in an fp-group K, such that H and K are subgroups of some common fp-group G, H is of finite index in G, and words for the generators of K in terms of the generators of G are known, return `true`if u is not an element of H and `false` otherwise.

This function requires a closed coset table for H in G.

`H eq K`

Given subgroups H and K, both of finite index in the fp-group G, return `true`if H and K are equal and `false` otherwise.

This function may require closed coset tables for both, H and K in G.

`H ne K`

Given subgroups H and K, both of finite index in the fp-group G, return `true`if H and K are not equal and `false` otherwise.

This function may require closed coset tables for both, H and K in G.

`H subset K`

Given subgroups H and K, both of finite index in the fp-group G, return `true`if H is contained in K and `false` otherwise.

This function requires a closed coset table for K in G.

`H notsubset K`

Given subgroups H and K, both of finite index in the fp-group G, return `true`if H is not contained in K and `false` otherwise.

This function requires a closed coset table for K in G.

`IsConjugate(G, H, K)`

Given subgroups H and K, both of finite index in the fp-group G, return `true`if H and K are conjugate subgroups of G and `false` otherwise. If H and K are conjugate in G, a conjugating element is returned as second return value.

This function requires a closed coset table for both, H and K in G.

`IsNormal(G, H)`

Given a subgroup H of finite index in the fp-group G, return `true`if H is a normal subgroup of G and `false` otherwise.

This function requires a closed coset table for H in G.

`IsMaximal(G, H)`

Given a subgroup H of finite index in the fp-group G, return `true`if H is a maximal subgroup of G and `false` otherwise.

This function requires a closed coset table for H in G.

`IsSelfNormalizing(G, H)`

Given a subgroup H of finite index in the fp-group G, return `true`if H is a self-normalizing subgroup of G and `false` otherwise. For a sample application of this function, see Example H70E47.

This function requires a closed coset table for H in G.

Example H70E57

We illustrate some of the subgroup predicates by applying them to some subgroups of the two-dimensional space group $p4g =< r, s | r^2, s^4, (r,s)^2 >$ from Example H70E55.

```
> p4g<r, s> := Group< r, s | r^2 = s^4 = (r*s^-1*r*s)^2 = 1 >;
> h := sub< p4g | (s^-1*r)^4, s*r >;
> k := sub< p4g | (s^-1*r)^2, (s*r)^2 >;
```

h and k have the same index in $p4g\ldots$

```
> Index(p4g, h);
8
> Index(p4g, k);
```

```
8
```

. . . but they are not equal.

```
> h eq k;
false
```

We check for normality of h and k in $p4g$.

```
> IsNormal(p4g, h);
false
> IsNormal(p4g, k);
true
```

We construct the normal closure of h in $p4g$.

```
> n := NormalClosure(p4g, h);
```

We see that it is maximal. . .

```
> IsMaximal(p4g, n);
true
```

. . . and that it contains k.

```
> k subset n;
true
```

We define another subgroup of $p4g$.

```
> l := sub< p4g | (s*r)^4, s^-1*r >;
```

In fact, it is conjugate to h.

```
> IsConjugate(p4g, h, l);
true r^-1
```

I.e. $l = h^{r^{-1}}$. The intersection of h and $h^{r^{-1}}$ already yields the core of h in $p4g$.

```
> h meet l eq Core(p4g, h);
true
```

Example H70E58

The constructions of the previous section together with the Boolean function `IsMaximal` may be used to locate large maximal subgroups in a finite group. Consider the Hall-Janko group J_2, which may be defined by the presentation

$$\begin{aligned} < a, b, c \mid\ & a^3, b^3, c^3, abab^{-1}a^{-1}b^{-1}, (ca)^5, (cb)^5, \\ & (cb^{-1}cb)^2, a^{-1}baca^{-1}bac^{-1}a^{-1}b^{-1}ac^{-1}, \\ & aba^{-1}caba^{-1}c^{-1}ab^{-1}a^{-1}c^{-1} > . \end{aligned}$$

We examine subgroups generated by pairs of randomly chosen short words. Whenever we obtain a proper subgroup, if it is not already maximal we replace it by a maximal subgroup that contains it.

```
> J2<a, b, c> := Group<a, b, c | a^3, b^3, c^3, a*b*a*b^-1*a^-1*b^-1, (c*a)^5,
>                                  (c*b)^5, (c*b^-1*c*b)^2,
>                                  a^-1*b*a*c*a^-1*b*a*c^-1*a^-1*b^-1*a*c^-1,
>                                  a*b*a^-1*c*a*b*a^-1*c^-1*a*b^-1*a^-1*c^-1>;
>
> Seen := { 0, 1};
> Found := { };
> Sgs := [ ];
> for i := 1 to 30 do
>     u := Random(J2, 1, 1);
>     v := Random(J2, 3, 5);
>     H := sub< J2 | u, v >;
>     Indx := Index(J2, H);
>     if Indx notin Seen then
>        Include(~Seen, Indx);
>          if not IsMaximal(J2, H) then
>            H := MaximalOvergroup(J2, H);
>         end if;
>        if Indx notin Found then
>            Include(~Sgs, H);
>            Include(~Seen, Indx);
>            Include(~Found, Indx);
>        end if;
>    end if;
> end for;
> Sgs;
[
      Finitely presented group on 3 generators
      Index in group J2 is 315 = 3^2 * 5 * 7
      Generators as words in group J2
             $.1 = b^-1
             $.2 = a^-2 * c * a^-1
             $.3 = c,

      Finitely presented group on 3 generators
      Index in group J2 is 1008 = 2^4 * 3^2 * 7
      Generators as words in group J2
             $.1 = b^-1
             $.2 = c^-1 * a^-1 * c^-1 * b
             $.3 = a * c * b * c^-1 * a^-1 * c * b * c^-1,

      Finitely presented group on 3 generators
      Index in group J2 is 100 = 2^2 * 5^2
      Generators as words in group J2
```

```
            $.1 = c
            $.2 = (b * a^-1)^2
            $.3 = a * b^-1
]
```

Thus after taking 30 2-generator random subgroups, we have obtained three maximal subgroups, including the two largest maximal subgroups.

70.8 Coset Spaces and Tables

Let $G =< X|R >$ be a finitely presented group. Suppose that H is a subgroup of G having finite index m. Let $V = \{c_1(= H), c_2, \ldots, c_m\}$ denote the set of distinct right cosets of H in G. This set admits a natural G-action

$$f : V \times G \to V$$

where

$$f :< c_i, x >= c_k \quad \Longleftrightarrow \quad c_i * x = c_k,$$

for $c_i \in V$ and $x \in G$. The set V together with this action is a G-set called a *right coset space* for H in G. The action may also be represented using a coset table T.

If certain of the products $c_i * x$ are unknown, the corresponding images under f are undefined. In this case, T is not closed, and V is called an *incomplete coset space* for H in G.

70.8.1 Coset Tables

A coset table is represented in MAGMA as a mapping. Given a finitely-presented group G and a subgroup H, the corresponding (right) coset table is a mapping $f : \{1, \ldots, r\} \times G \to \{0, \ldots, r\}$, where r is the index of H in G. $f(i, x)$ is the coset to which coset i is mapped under the action of $x \in G$. The value 0 is only included in the codomain if the coset table is not closed, and it denotes that the coset is not known.

`CosetTable(G, H: parameters)`

The (right) coset table for G over subgroup H, constructed by means of the Todd-Coxeter procedure. If the coset table does not close then the codomain will include the value 0.

Experienced users can control the Todd-Coxeter procedure invoked by this function with a wide range of parameters. This function accepts the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

`CosetTableToRepresentation(G, T)`

Given a coset table T for a subgroup H of G, construct the permutation representation of G given by its action on the cosets of H, using the columns of T. The function returns:

(a) The homomorphism $f : G \to P$;

(b) The permutation group image P;

(c) The kernel K of the action (a subgroup of G).

`CosetTableToPermutationGroup(G, T)`

Given a coset table T for a subgroup H of G, construct the permutation group image of G given by its action on the cosets of H, using the columns of T. This is the second return value of `CosetTableToRepresentation(G, T)`.

Example H70E59

Consider the infinite dihedral group.

```
> G<a,b> := DihedralGroup(GrpFP, 0);
> G;
Finitely presented group G on 2 generators
Relations
    b^2 = Id(G)
    (a * b)^2 = Id(G)
```

We define a subgroup S of G and compute the coset table map for S in G.

```
> S := sub<G|a*b, a^10>;
> ct := CosetTable(G, S);
> ct;
Mapping from: Cartesian Product<{ 1 .. 10 }, GrpFP: G>
        to { 1 .. 10 }
     $1  $2 -$1
 1.   2   2   3
 2.   4   1   1
 3.   1   4   5
 4.   6   3   2
 5.   3   6   7
 6.   8   5   4
 7.   5   8   9
 8.  10   7   6
 9.   7  10  10
10.   9   9   8
```

When printing the coset table, the action of the generators and of the non-trivial inverses of generators on the enumerated transversal is shown in table form.

Using the coset table, we now construct the permutation representation of G on the cosets of S in G. We assign the representation (a homomorphism), the image (a permutation group of degree $[G : S] = 10$) and the kernel of the permutation representation (a subgroup of G).

```
> fP, P, K := CosetTableToRepresentation(G, ct);
> fP;
Homomorphism of GrpFP: G into GrpPerm: P, Degree 10,
Order 2^2 * 5 induced by
    a |--> (1, 2, 4, 6, 8, 10, 9, 7, 5, 3)
    b |--> (1, 2)(3, 4)(5, 6)(7, 8)(9, 10)
```

Note that the images of a and b correspond to the first two columns of the printed coset table above.

```
> P;
Permutation group P acting on a set of cardinality 10
Order = 20 = 2^2 * 5
    (1, 2, 4, 6, 8, 10, 9, 7, 5, 3)
    (1, 2)(3, 4)(5, 6)(7, 8)(9, 10)
> K;
Finitely presented group K
Index in group G is 20 = 2^2 * 5
Subgroup of group G defined by coset table
```

Now, we define a subgroup of infinite index in G and compute a coset table for it.

```
> H := sub<G|b>;
> ct := CosetTable(G, H);
```

Of course, the coset table cannot be complete; note that 0 is in its codomain, indicating unknown images of cosets.

```
> ct;
Mapping from: Cartesian Product<{ 1 .. 1333331 }, GrpFP: G>
        to { 0 .. 1333331 }
```

70.8.2 Coset Spaces: Construction

The indexed (right) coset space V of the subgroup H of the group G is a G-set consisting of the set of integers $\{1, ..., m\}$, where i represents the right coset c_i of H in G. The action of G on this G-set is that induced by the natural G-action

$$f : V \times G \to V$$

where

$$f :< c_i, x >= c_k \quad \Longleftrightarrow \quad c_i * x = c_k,$$

for $c_i \in V$ and $x \in G$. If certain of the products $c_i * x$ are unknown, the corresponding images under f are undefined, and V is called an *incomplete coset space* for H in G.

`CosetSpace(G, H: parameters)`

This function attempts to construct a coset space for the subgroup H in the group G by means of the Todd-Coxeter procedure. If the enumeration fails to complete, the function returns an incomplete coset space. The coset space is returned as an indexed right coset space. For a sample application of this function see Example H70E61.

Experienced users can control the Todd-Coxeter procedure invoked by this function with a wide range of parameters. This function accepts the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

`RightCosetSpace(G, H: parameters)`

`LeftCosetSpace(G, H: parameters)`

The explicit right coset space of the subgroup H of the group G is a G-set containing the set of right cosets of H in G. The elements of this G-set are the pairs $< H, x >$, where x runs through a transversal for H in G. Similarly, the explicit left coset space of H is a G-set containing the set of left cosets of H in G, represented as the pairs $< x, H >$. These functions use the Todd-Coxeter procedure to construct the explicit right (left) coset space of the subgroup H of the group G. For a sample application see Example H70E61.

Experienced users can control the Todd-Coxeter procedure invoked by these functions with a wide range of parameters. Both functions accept the same parameters as the function `CosetEnumerationProcess` described in Chapter 71.

70.8.3 Coset Spaces: Elementary Operations

`H * g`

Right coset of the subgroup H of the group G, where g is an element of G (as an element of the right coset of H).

`C * g`

Coset to which the right coset C of the group G is mapped by the (right) action of g, where g is an element of G.

`C * D`

and D.

Given two right cosets of the same normal subgroup H of the group G, return the right coset that is the product of C and D.

`g in C`

Return `true` if element g of group G lies in the coset C.

`g notin C`

Return `true` if element g of group G does not lie in the coset C.

`C1 eq C2`

Returns `true` if the coset $C1$ is equal to the coset $C2$.

`C1 ne C2`

Returns `true` if the coset $C1$ is not equal to the coset $C2$.

70.8.4 Accessing Information

`#V`

The cardinality of the coset space V.

`Action(V)`

The mapping $V \times G \to V$ giving the action of G on the coset space V. This mapping is a coset table.

`<i, w> @ T`
`T(i, w)`

The image of coset i as defined in the coset table T, under the action of word w.

`ExplicitCoset(V, i)`

The element of the explicit coset space that corresponds to indexed coset i.

`IndexedCoset(V, w)`

The element of the indexed coset space V to which the element w of G corresponds.

`IndexedCoset(V, C)`

The element of the indexed coset space V to which the explicit coset C of G corresponds.

`Group(V)`

The group G for which V is a coset space.

`Subgroup(V)`

The subgroup H of G such that V is a coset space for G over H.

`IsComplete(V)`

Returns `true` if the coset space V is complete.

`ExcludedConjugates(V)`

`ExcludedConjugates(T)`

Given a partial or complete coset space V for the group G over the subgroup H, or a coset table T corresponding to this coset space, this function returns the set of words $E = \{g_i^{-1} h_j g_i \mid g_i$ a generator of G, h_j a generator of H, and, modulo V, $g_i^{-1} h_j g_i$ does not lie in $H\}$. If E is empty, then H is a normal subgroup of G, while if E is non-empty, the addition of the elements of E to the generators of H will usually be a larger subgroup of the normal closure of H. This function may be used with incomplete coset spaces for G over H; it may then happen that some of the elements of E actually lie in H but there is insufficient information for this to be detected. This function is normally used in conjunction with the Todd-Coxeter algorithm when seeking some subgroup having index sufficiently small so that the Todd-Coxeter procedure completes. The conjugates are returned as a set of words.

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a finitely presented group G and a subgroup H of G, this function returns

(a) A set of elements T of G forming a right transversal for G over H; and

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and $g \in G$, ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

These functions may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

Example H70E60

Consider the infinite dihedral group.

```
> G<a,b> := DihedralGroup(GrpFP, 0);
```

We define a subgroup H of index 10 in G...

```
> H := sub< G | a*b, a^10 >;
> Index(G, H);
10
```

... and construct a right transversal for H in G and the associate transversal map.

```
> RT, transmap := Transversal(G, H);
> RT;
{@ Id(G), a, a^-1, a^2, a^-2, a^3, a^-3, a^4, a^-4, a^5 @}
> transmap;
Mapping from: GrpFP: G to SetIndx: RT
```

From this a left transversal is easily obtained:

```
> LT := {@ x^-1 : x in RT @};
```

```
> LT;
{@ Id(G), a^-1, a, a^-2, a^2, a^-3, a^3, a^-4, a^4, a^-5 @}
```

We construct the coset table and check whether the enumeration of the cosets is compatible to the enumeration of the right transversal RT.

```
> ct := CosetTable(G, H);
> forall(culprit){ i : i in [1..Index(G, H)]
>                    | ct(1, RT[i]) eq i};
true
```

It is. Thus, we can very easily define a function $RT \times G \to RT$, describing the action of G on the set of right cosets of H in G.

```
> action := func< r, g | RT[ct(Index(RT, r), g)] >;
```

Note that the definition of the function `action` relies on the fact that the computed right transversal and its enumeration match the ones internally used for the coset table ct.

```
> action(Id(G), b);
a
```

I.e. $H * b = H * a$.

```
> action(a^-4, a*b);
a^4
```

I.e. $Ha^{-4} * (ab) = Ha^4$.

Example H70E61

Consider the group $G =< a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3 >$ and the subgroup H of G, generated by a^2 and $a^{-1}b$.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo< F | x^8, y^7, (x*y)^2, (x^-1*y)^3 >;
> H := sub< G | a^2,a^-1*b >;
```

We construct an indexed right coset space V and an explicit right coset space Vr for H in G.

```
> V := CosetSpace(G, H);
> Vr := RightCosetSpace(G, H);
```

The coset H always has index 1.

```
> trivial_coset := ExplicitCoset(Vr, 1);
> trivial_coset;
<GrpFP: H, Id(G)>
> IndexedCoset(V, trivial_coset);
1
```

We now pick a coset...

```
> coset := ExplicitCoset(Vr, 42);
> coset;
```

```
<GrpFP: H, a^-1 * b^-1 * a^3 * b^-1>
```

... multiply from the right with b...

```
> coset * b;
<GrpFP: H, a^-1 * b^-1 * a^3>
```

... and check where this gets us in the indexed coset space V.

```
> IndexedCoset(V, coset * b);
23
```

Example H70E62

We present a function which computes the derived subgroup G' for the finitely presented group G. It assumes that the Todd-Coxeter procedure can enumerate the coset space of G' in G.

```
> function DerSub(G)
>
> /* Initially define S to contain the commutator of each pair of distinct
>  generators of G */
>
>     S := { (x,y) : x, y in Generators(G) | (x,y) ne Id(G) };
>
> /* successively extend S until it is closed under conjugation by the
>   generators of G */
>
>         repeat
>             V := CosetSpace(G, sub<G | S>);
>             E := ExcludedConjugates(V);
>             S := S join E;
>         until # E eq 0;
>     return sub<G | S>;
> end function;
```

Example H70E63

Given a subgroup H of the finitely presented group G, for which the Todd-Coxeter procedure does not complete, add excluded conjugates one at a time to the generators of G until a subgroup K is reached such that either K is normal in G, or K has sufficiently small index for the Todd-Coxeter method to complete. The set *hgens* contains a set of generating words for H.

```
> function NormClosure(G, hgens)
> xgens := hgens;
> kgens := hgens;
> indx := 0;
> while # xgens ne 0 do
>       Include(~kgens, Representative(xgens));
>       V := CosetSpace(G, sub<G | kgens>);
>       if IsComplete(V) then break; end if;
```

```
>       xgens := ExcludedConjugates(V);
> end while;
> if IsComplete(V) then
>           print "The subgroup generated by", kgens, "has index", #V;
>           return kgens;
> else
>           print "The construction was unsuccessful";
>           return {};
> end if;
> end function;
```

70.8.5 Double Coset Spaces: Construction

`DoubleCoset(G, H, g, K )`

The double coset $H * g * K$ of the subgroups H and K of the group G, where g is an element of G.

`DoubleCosets(G, H, K)`

Set of double cosets $H * g * K$ of the group G.

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

Example H70E64

Consider again the infinite dihedral group G...

```
> G<a,b> := DihedralGroup(GrpFP, 0);
```

... and the subgroup H of index 10 in G.

```
> H := sub< G | a*b, a^10 >;
```

The set of H-H double cosets in G can be obtained with the statement

```
> DoubleCosets(G, H, H);
{ <GrpFP: H, Id(G), GrpFP: H>, <GrpFP: H, a^5, GrpFP: H>,
  <GrpFP: H, a^4, GrpFP: H>, <GrpFP: H, a^2, GrpFP: H>,
  <GrpFP: H, a, GrpFP: H>, <GrpFP: H, a^3, GrpFP: H> }
```

70.8.6 Coset Spaces: Selection of Cosets

`CosetsSatisfying(T, S: parameters)`

`CosetSatisfying(T, S: parameters)`

`CosetsSatisfying(V, S: parameters)`

`CosetSatisfying(V, S: parameters)`

Given a fp-group G, and a partial or complete coset space V or coset table T for G over the subgroup H generated by the set of words S, these functions return representatives for the cosets of V which satisfy the conditions defined in the parameters. In the description of the parameters below, the symbol l will denote a Boolean value, while the symbol n will denote a positive integer in the range $[1, \#V]$.

The functions are not identical. `CosetsSatisfying` returns a set of coset representatives for V as defined in the parameters. `CosetSatisfying` is the same as `CosetsSatisfying` with the `Limit` parameter equal to 1; thus it returns a set containing a single coset representative, or an empty set if no cosets satisfy the conditions.

`First` RngIntElt *Default :* 1

Start looking for coset representatives satisfying the designated conditions beginning with coset i of V.

`Last` RngIntElt *Default :* $\#V$

Stop looking for coset representatives after examining coset j of V.

`Limit` RngIntElt *Default :* ∞

Terminate the search for coset representatives as soon as l have been found which satisfy the designated conditions. This parameter is not available for `CosetSatisfying`, since `Limit` is set to 1 for this function.

`Normalizing` BoolElt *Default :* `false`

If `true`, select coset representatives x such that, modulo V, the word $x^{-1}h_1x$, ..., x_1h_sx is contained in H.

`Order` RngIntElt *Default :* 0

Select coset representatives x such that, modulo V, the word x^n is contained in H.

`Print` RngIntElt *Default :* 0

If $t > 0$, print the coset representatives found to satisfy the designated conditions.

Example H70E65

Consider the braid group G on 4 strings with Artin generators a, b and c and the subgroup H of G generated by a and b.

```
> G<a,b,c> := BraidGroup(GrpFP, 4);
```

```
> H := sub< G | a,b >;
```

We construct an – obviously incomplete – explicit right coset space for H in G.

```
> V := RightCosetSpace(G, H);
```

Using the function CosetSatisfying, we compute an element of G, not contained in H, which normalises H.

```
> cs := CosetSatisfying(V, Generators(Subgroup(V))
>                       : Normalizing := true, First := 2);
> cs;
{
    <GrpFP: H, c * b * a^2 * b * c>
}
> rep := c * b * a^2 * b * c;
```

The conjugates of a and b by this element had better be in H...

```
> rep^-1 * a * rep in H;
true
> rep^-1 * b * rep in H;
true
```

... OK.

70.8.7 Coset Spaces: Induced Homomorphism

`CosetAction(G, H)`

Given a subgroup H of the group G, this function constructs the permutation representation ϕ of G given by the action of G on the cosets of H. It returns:

(a) The homomorphism ϕ;

(b) The image group $\phi(G)$.

(c) (if possible) the kernel of ϕ.

The permutation representation is obtained by using the Todd-Coxeter procedure to construct the coset table for H in G. Note that G may be an infinite group: it is only necessary that the index of H in G be finite.

`CosetAction(V)`

Construct the permutation representation L of G given by the action of G on the coset space V. It returns the permutation representation ϕ (as a map) and its image.

`CosetImage(G, H)`

Construct the image of G given by its action on the (right) coset space of H in G.

`CosetImage(V)`

Construct the image of G as defined by its action on the coset space V.

`CosetKernel(G, H)`

The kernel of G in its action on the (right) coset space of H in G. (Only available when the index of H in G is very small).

This function may require the computation of a coset table. Experienced users can control the behaviour of a possibly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

`CosetKernel(V)`

The kernel of G in its action on the (right) coset space V. (Only available when the index of the subgroup H of G defining the coset space is very small).

Example H70E66

The first Conway group has a representation as the image of the group

$$\begin{aligned} G = < a,b,c,d,e,f,g,h \mid\ & a^2, b^2, c^2, d^2, e^2, f^2, g^2, h^2, \\ & (ab)^3, (ac)^2, (ad)^2, (ae)^4, (af)^2, (ag)^2, (ah)^3, \\ & (bc)^5, (bd)^2, (be)^2, (bf)^2, (bg)^4, (bh)^4, \\ & (cd)^3, (ce)^3, (cf)^4, (cg)^2, (ch)^2, \\ & (de)^2, (df)^3, (dg)^2, (dh)^2, \\ & (ef)^6, (eg)^2, (eh)^2, \\ & (fg)^4, (fh)^6, \\ & (gh)^2, \\ & a(cf)^2 = (adfh)^3 = b(ef)^3 = (baefg)^3 = 1, \\ & (cef)^7 = d(bh)^2 = d(aeh)^3 = e(bg)^2 = 1 > \end{aligned}$$

under the homomorphism defined by the action of G on the cosets of the subgroup

$$H = < a,b,c,d,e,f,g,(adefcefgh)^{39} > .$$

The permutation group can be constructed as follows:

```
> F<s, t, u, v, w, x, y, z> := FreeGroup(8);
> G<a, b, c, d, e, f, g, h> := quo<F | s^2, t^2, u^2, v^2, w^2, x^2, y^2, z^2,
> (s*t)^3, (s*u)^2, (s*v)^2, (s*w)^4, (s*x)^2, (s*y)^2, (s*z)^3,
> (t*u)^5, (t*v)^2, (t*w)^2, (t*x)^2, (t*y)^4, (t*z)^4,
> (u*v)^3, (u*w)^3, (u*x)^4, (u*y)^2, (u*z)^2,
> (v*w)^2, (v*x)^3, (v*y)^2, (v*z)^2,
```

```
> (w*x)^6, (w*y)^2, (w*z)^2,
> (x*y)^4, (x*z)^6,
> (y*z)^2,
> s*(u*x)^2 = (s*v*x*z)^3 = t*(w*x)^3 = (t*s*w*x*y)^3 = 1,
> (u*w*x)^7 = v*(t*z)^2 = v*(s*w*z)^3 = w*(t*y)^2 = 1>;
> H := sub< G | a, b, c, d, e, f, g, (a*d*e*f*c*e*f*g*h)^39 >;
> V := CosetSpace(G, H: FillFactor := 100000);
> Co1 := CosetImage(V);
> Degree(Co1);
    98280
```

Example H70E67

The group $G_2(3)$ is a homomorph of the fp-group G defined below. We construct a permutation representation $G1$ for $G_2(3)$ on 351 points, and then compute the subgroup generated by the images of the first four generators of G in $G1$. (The functions applied to permutation groups are described in Chapter 58.)

```
> F<a,b,c,d,y,x,w> := FreeGroup(7);
> z := y*c*a^2*b;
> u := x*d;
> t := w*c*a*d*b^2*c;
> G<a,b,c,d,y,x,w>, g :=
>            quo< F | a^4, b^4, c^2, d^2, (a,b), (a*c)^2, (b*c)^2,
>                       (c*d)^2, d*a*d*b^-1, y^3, (a^-1*b)^y*d*a^-1*b^-1,
>                       (c*d*a^-1*b)^y*b^-1*a*d*c, a*d*y*d*a^-1*y, x^3,
>                       a^x*b^-1, b^x*a*b, c^x*c, (x*d)^2, (u*z)^6, w^3,
>                       (w,y), (a*b)^w*b^-1*a*d*c, (c*d*a^-1*b)^w*d*c*b^2,
>                       (b^2*c*d)^w*a^-1*b^-1, (c*a^2*b*w)^2,
>                      (a^-1*b)^w*d*a^-1*b^-1, (t*u)^3 >;
> z1 := g(z);
> u1 := g(u);
> t1 := g(t);
> H := sub< G | z1*a^2*b^2, u1*c, t1*a^2*b^2 >;
> f, G1, K := CosetAction(G, H);
> Degree(G1);
351
> print Order(G1), FactoredOrder(G1);
4245696 [ <2, 6>, <3, 6>, <7, 1>, <13, 1> ]
> CompositionFactors(G1);
    G
    |  G(2, 3)
    1
> S := sub< G1 | f(a), f(b), f(c), f(d) >;
> BSGS(S);
> S;
Permutation group S of degree 351
```

```
Order = 64 = 2^6
```

Thus the images of a, b, c and d in G1 generate the Sylow 2-subgroup

---

70.9 Simplification

70.9.1 Reducing Generating Sets

Subgroups of finitely presented groups constructed in certain ways may be created with a generating set containing redundant generators. The most important case in which this situation may occur is a subgroup of the domain of a homomorphism f of groups, defined as the preimage under f of some given subgroup of the codomain of f. In this case, the generating set of the preimage will contain generators of the kernel of f and is likely to be not minimal.

Since reducing the generating set may be expensive and is not necessary in all situations, a reduction is not done automatically. Instead, MAGMA provides a function for reducing generating sets of finitely presented groups.

`ReduceGenerators(G)`

Given a finitely presented group G, attempt to construct a presentation H on fewer generators. H is returned as a subgroup of G (which of course is equal to G), so that element coerce is possible. The isomorphism from G to H is returned as second return value.

If a presentation for G is known, this function attempts to simplify this presentation (cf. section 70.9.2). Otherwise, it tries to rewrite G with respect to a suitable supergroup to obtain a presentation on fewer generators.

For a sample application of this function, see Example H70E73.

70.9.2 Tietze Transformations

Given a finitely presented group G, the user can attempt to simplify its presentation using Tietze transformations and substring searching. The choice of simplification strategy can either be left to MAGMA or selected by the user.

`Simplify(G: parameters)`

Given a finitely presented group G, attempt to simplify the presentation of G by repeatedly eliminating generators and subsequently shortening relators by substitution of substrings that correspond to the left or right hand side of a relation. The order in which transformations are applied is determined by a set of heuristics. The transformation process terminates when no more eliminations of generators and no more length reducing substring replacements are possible.

A new group K isomorphic to G is returned which is (hopefully) defined by a simpler presentation than G. K is returned as a subgroup of G. The isomorphism $f : G \to K$ is returned as second return value.

The simplification process can be controlled by a set of parameters described below.

Example H70E68

```
Consider the Fibonacci group $F(8)$.
> F<x1, x2, x3, x4, x5, x6, x7, x8> := FreeGroup(8);
> F8<x1, x2, x3, x4, x5, x6, x7, x8> :=
>     quo< F | x1*x2=x3, x2*x3=x4, x3*x4=x5, x4*x5=x6,
>              x5*x6=x7, x6*x7=x8, x7*x8=x1, x8*x1=x2>;
```

We use the function `Simplify` in order to obtain a presentation of $F(8)$ on two generators.

```
> H<[y]>, f := Simplify(F8);
> H;
Finitely presented group H on 2 generators
Generators as words in group F8
    y[1] = x3
    y[2] = x4
Relations
    y[2] * y[1]^-2 * y[2] * y[1]^-1 * y[2]^2 * y[1] * y[2]^2 *
       y[1]^-1 = Id(H)
    y[1] * y[2] * y[1] * y[2]^2 * y[1] * y[2] * y[1]^2 * y[2]^-1
       * y[1] = Id(H)
```

The isomorphism f can be used to express the old generators in terms of the new ones.

```
> f;
Mapping from: GrpFP: F8 to GrpFP: H
> f(x1);
y[1]^2 * y[2]^-1
```

The strategy employed by the function `Simplify` can be controlled using the following set of parameters.

`Preserve` [RngIntElt] *Default :* []

This parameter can be used to indicate that certain generators of G should not be eliminated (*default*: no restrictions). `Preserve` is assigned a sequence of integers in the range $[1, \ldots, n]$, where n is the number of generators of G, containing the numbers of those generators of G which should be preserved. See Example H70E70 for a sample application.

`Iterations` RngIntElt *Default :* 10000

This parameter sets the maximal number of iterations of the main elimination / simplification cycle which will be performed.

`EliminationLimit` RngIntElt *Default :* 100

This parameter sets the maximal number of generators which may be eliminated in each elimination phase.

`LengthLimit` RngIntElt *Default :* ∞

If `LengthLimit` is set to n, any eliminations which would make the total length of the relators grow beyond n will not be performed (*default*: no limit).

`ExpandLimit` RngIntElt *Default :* 150

If `ExpandLimit` is set to n, the total length of the relators is not permitted to grow by more than a factor of $n\%$ in any elimination phase (*default*: 150%). If this limit is reached, the elimination phase is aborted.

`GeneratorsLimit` RngIntElt *Default :* 0

Any eliminations which would reduce the number of generators below the value of `GeneratorsLimit` will not be performed (*default*: 0).

`SaveLimit` RngIntElt *Default :* 10

If `SaveLimit` is set to n, any simplification phase is repeated, if the reduction in the total length of the relators achieved during this phase exceeds $n\%$ (*default*: 10%).

`SearchSimultaneous` RngIntElt *Default :* 20

This parameter sets the number of relators processed simultaneously in a simplification phase.

`Print` RngIntElt *Default :* 0

This parameter controls the volume of printing. By default its value is that returned by `GetVerbose("Tietze")`, which is 0 unless it has been changed through use of `SetVerbose`.

`SimplifyLength(G: parameters)`

Given a finitely presented group G, attempt to eliminate generators and shorten relators by locating substrings that correspond to the left or right hand side of a relation. The order in which transformations are applied is determined by a set of heuristics. As opposed to the function `Simplify`, this function terminates the transformation process when the total length of the presentation starts to increase with the elimination of further generators.

A new group K isomorphic to G is returned which is (hopefully) defined by a simpler presentation than G. K is returned as a subgroup of G. The isomorphism $f : G \to K$ is returned as second return value. This function accepts the same set of parameters as the function `Simplify`.

`TietzeProcess(G: parameters)`

Create a Tietze process that takes the presentation for the fp-group G as its starting point. This process may now be manipulated by various procedures that will be described below.

`Preserve` [RngIntElt] *Default :* []

`Iterations` RngIntElt *Default :* 10000

`EliminationLimit`	RngIntElt	*Default :* 100
`LengthLimit`	RngIntElt	*Default :* ∞
`ExpandLimit`	RngIntElt	*Default :* 150
`GeneratorsLimit`	RngIntElt	*Default :* 0
`SaveLimit`	RngIntElt	*Default :* 10
`SearchSimultaneous`	RngIntElt	*Default :* 20
`Print`	RngIntElt	*Default :* 0

These parameters define the defaults used for the Tietze operations. Each of the various procedures described below allows some or all of these control parameters to be overridden.

For the meanings of the parameters, see the description under `Simplify` above.

`ShowOptions(~P : parameters)`

Display the defaults associated with the Tietze process P. The current status of all the control parameters may be viewed by using this function.

`SetOptions(~P : parameters)`

Change the defaults associated with the Tietze process P. All of the control parameters may be overridden permanently by using this function.

`Simplify(~P : parameters)`

`SimplifyPresentation(~P : parameters)`

Use the default strategy to simplify the presentation as much as possible. The transformation process is terminated when no more eliminations of generators and no more length reducing substring replacements are possible. All the control parameters may be overridden for this function.

`SimplifyLength(~P : parameters)`

Use the default strategy to simplify the presentation as much as possible. The transformation process is terminated when the total length of the presentation starts to increase with the elimination of further generators. All the control parameters may be overridden for this function.

`Eliminate(~P: parameters)`

`EliminateGenerators(~P: parameters)`

Eliminate generators in the presentation defined by the Tietze process P under the control of the parameters. First any relators of length one are used to eliminate trivial generators. Then, if there are any non-involutory relators of length two, the generator with the higher number is eliminated. Of the control parameters, only `EliminationLimit, ExpandLimit, GeneratorsLimit` and `LengthLimit` may be overridden by this function.

`Relator` RngIntElt *Default :* 0

If $n > 0$, try to eliminate a generator using the n-th relator. If no generator is specified by the parameter `Generator` below, then the generator which is eliminated will be the one occurring once in the relator that produced the smallest total relator length.

`Generator` RngIntElt *Default :* 0

If $n > 0$, try to eliminate the n-th generator. If no relation is specified by the parameter `Relator` above, then the shortest relator in which the n-th generator occurs exactly once (if any) is used.

`Search(~P: parameters)`

Simplifies the presentation by repeatedly searching for common substrings in pairs of relators where the length of the substring is greater than half the length of the shorter relator and making the corresponding transformations. Relators of length 1 or 2 are also used to generate simplifications. The control parameters `SaveLimit` and `SearchSimultaneous` can be overridden.

`SearchEqual(~P: parameters)`

Modifies the presentation by repeatedly searching for common substrings in pairs of relators where the length of the substring is exactly half the length of the shorter relator and making the corresponding transformations. The control parameter `SearchSimultaneous` can be overridden.

`Group(P)`

Extract the group G defined by the current presentation associated with the Tietze process P, together with the isomorphism between the original group and G. G is returned as a subgroup of the original group underlying P.

`NumberOfGenerators(P)`

`Ngens(P)`

The number of generators for the presentation currently stored by the Tietze process P.

`NumberOfRelations(P)`

`Nrels(P)`

The number of relations in the presentation currently stored by the Tietze process P.

`PresentationLength(P)`

The sum of the lengths of the relators in the presentation currently stored by the Tietze process P.

Example H70E69

The Fibonacci group $F(n)$ is generated by $\{x_1, \ldots, x_n\}$ with defining relations

$$x_i x_{i+1} = x_{i+2}, i \in \{1, \ldots, n\},$$

where the subscripts are taken modulo n. Consider the Fibonacci group $F(7)$, which is defined in terms of the presentation

$$< x_1, x_2, x_3, x_4, x_5, x_6, x_7 \mid x_1x_2 = x_3, x_2x_3 = x_4, x_3x_4 = x_5, \\ x_4x_5 = x_6, x_5x_6 = x_7, x_6x_7 = x_1, x_7x_1 = x_2 > .$$

The following code will produce a 2-generator, 2-relator presentation for $F(7)$:

```
> F<x1, x2, x3, x4, x5, x6, x7> := FreeGroup(7);
> F7<x1, x2, x3, x4, x5, x6, x7> :=
>    quo< F | x1*x2=x3, x2*x3=x4, x3*x4=x5, x4*x5=x6,
>             x5*x6=x7, x6*x7=x1, x7*x1=x2 >;
> P := TietzeProcess(F7);
> for i := 7 to 3 by -1 do
>    Eliminate(~P: Generator := i);
> end for;
> Search(~P);
> H<x, y>, f := Group(P);
> H;
Finitely presented group H on 2 generators
Generators as words in group F7
    x = x1
    y = x2
Relations
    x^-1 * y^-1 * x^-1 * y^-2 * x^-1 * y * x^-1 * y * x^-1 = Id(H)
    x * y^3 * x^-1 * y * x^-1 * y^2 * x * y * x * y^-1 = Id(H)
```

The resulting presentation is

$$< a, b \mid a^{-1}b^{-1}a^{-1}b^{-2}a^{-1}ba^{-1}ba^{-1}, ab^3a^{-1}ba^{-1}b^2abab^{-1} > .$$

We can use the isomorphism f returned by the function `Group` to express arbitrary words in the original generators of $F(7)$ in terms of the new generators x and y:

```
> f;
Mapping from: GrpFP: F7 to GrpFP: H
> f(x7);
x * y^2 * x * y^2 * x * y * x * y^2 * x * y
```

Alternatively, a similar effect may be obtained using the `Simplify` function:

```
> F<x1, x2, x3, x4, x5, x6, x7> := FreeGroup(7);
> F7<x1, x2, x3, x4, x5, x6, x7> :=
>    quo< F | x1*x2=x3, x2*x3=x4, x3*x4=x5, x4*x5=x6,
```

```
>       x5*x6=x7, x6*x7=x1, x7*x1=x2>;
> H<x, y>, f := Simplify(F7: Iterations := 5);
> H;
Finitely presented group H on 2 generators
Generators as words in group F7
    x = x2
    y = x3
Relations
    x * y^-1 * x * y^2 * x * y * x^2 * y^-1 = Id(H)
    y * x * y^2 * x^-1 * y * x^-2 * y * x^-2 = Id(H)
```

Again, we can use the isomorphism f returned by the function `Simplify` to express arbitrary words in the original generators of $F(7)$ in terms of the new generators x and y:

```
> f;
Mapping from: GrpFP: F7 to GrpFP: H
> f(x7);
y * x * y * x * y^2 * x * y
```

Example H70E70

In a situation where some proper subset S of the original generating set of a finitely group G is sufficient to generate G, the function `Simplify` can also be used to rewrite words in the original generators in terms of the elements of S. Consider again one of the Fibonacci groups, say $F(8)$.

```
> F<x1, x2, x3, x4, x5, x6, x7, x8> := FreeGroup(8);
> F8<x1, x2, x3, x4, x5, x6, x7, x8> :=
>     quo< F | x1*x2=x3, x2*x3=x4, x3*x4=x5, x4*x5=x6,
>        x5*x6=x7, x6*x7=x8, x7*x8=x1, x8*x1=x2>;
```

Obviously, $F(8)$ is generated by x_1 and x_2. We utilise the function `Simplify` to obtain a presentation H of $F(8)$ on x_1 and x_2, using the parameter `Preserve` to indicate that x_1 and x_2 – i.e. the first and the second generator – are to be retained in the new presentation. We also compute the isomorphism $f : F(8) \to H$.

```
> H<x, y>, f := Simplify(F8: Preserve := [1,2]);
```

Mapping elements of $F(8)$ to H using the map f basically means to rewrite these elements in terms of the generators $x = x_1$ and $y = x_2$. Since H is returned as a subgroup of $F(8)$, the resulting words can be coerced from H back into $F(8)$, yielding words explicitly in x_1 and x_2.

```
> F8 ! f(x5*x6);
x1 * x2^2 * x1 * x2 * x1^2 * x2^-1 * x1 * x2^-1
```

Example H70E71

The finiteness of the last of the Fibonacci groups, $F(9)$, was settled in 1988 by M.F. Newman using the following result:

Theorem. *Let G be a group with a finite presentation on b generators and r relations, and suppose p is an odd prime. Let d denote the rank of the elementary abelian group $G_1 = [G, G]G^p$ and let e denote the rank of $G_2 = [G_1, G]G^p$. If*

$$r - b < d^2/2 - d/2 - d - e$$

or

$$r - b \leq d^2/2 - d/2 - d - e + (e + d/2 - d^2/4)d/2,$$

then G has arbitrary large quotients of p-power order.

We present a proof that $F(9)$ is infinite using this result.

```
> Left := func< b, r | r - b >;
> Right := func< d, e | d^2 div 2 - d div 2 - d - e +
>                       (e + d div 2 - d^2 div 4)*(d div 2) >;
>
>
> F< x1,x2,x3,x4,x5,x6,x7,x8,x9 > :=
>  ΨGroup< x1, x2, x3, x4, x5, x6, x7, x8, x9 |
>              x1*x2=x3, x2*x3=x4, x3*x4=x5, x4*x5=x6, x5*x6=x7,
>              x6*x7=x8, x7*x8=x9, x8*x9=x1, x9*x1=x2 >;
>
> F;
Finitely presented group F on 9 generators
Relations
       x1 * x2 = x3
       x2 * x3 = x4
       x3 * x4 = x5
       x4 * x5 = x6
       x5 * x6 = x7
       x6 * x7 = x8
       x7 * x8 = x9
       x8 * x9 = x1
       x9 * x1 = x2
> AbelianQuotientInvariants(F);
[ 2, 38 ]
```

Thus the nilpotent quotient of F is divisible by 2 and 19. We examine the 2- and 19-quotients of F.

```
> Q1 := pQuotient(F, 2, 0: Print := 1);
Class limit set to 127.
Lower exponent-2 central series for F
Group: F to lower exponent-2 central class 1 has order 2^2
Group: F to lower exponent-2 central class 2 has order 2^3
Group completed. Lower exponent-2 central class = 2, Order = 2^3
> Q2 := pQuotient(F, 19, 0: Print := 1);
Class limit set to 127.
Lower exponent-19 central series for F
```

```
Group: F to lower exponent-19 central class 1 has order 19^1
Group completed. Lower exponent-19 central class = 1, Order = 19^1
```

Thus, the nilpotent residual of F has index 152. We try to locate this subgroup. We first take a 2-generator presentation for F.

```
> G := Simplify(F);
> G;
Finitely presented group G on 2 generators
Generators as words in group F
   G.1 = x4
   G.2 = x5
Relations
   G.2 * G.1 * G.2 * G.1 * G.2^2 * G.1 * G.2^2 * G.1^-1 * G.2 * G.1^-2 * G.2 *
      G.1^-2 = Id(G)
   G.1 * G.2^2 * G.1 * G.2 * G.1^2 * G.2^-1 * G.1^2 * G.2^-1 * G.1 * G.2^-1 *
      G.1^2 * G.2^-1 * G.1 * G.2^-1 = Id(G)
> H := ncl< G | (G.1, G.2) >;
> H;
Finitely presented group H
Index in group G is 76 = 2^2 * 19
Subgroup of group G defined by coset table
```

We haven't got the full nilpotent residual yet, so we try again.

```
> H := ncl< G | (G.1*G.1, G.2) >;
> H;
Finitely presented group H
Index in group G is 152 = 2^3 * 19
Subgroup of group G defined by coset table
```

Now, we have it.

```
> AbelianQuotientInvariants(H);
[ 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5, 5 ]
```

The nilpotent residual H has a 5-quotient. We construct a presentation for H and then calculate d and e for its 5-quotient.

```
> K := Rewrite(G, H: Simplify := false);
> KP := pQuotientProcess(K, 5, 1);
> d := FactoredOrder(ExtractGroup(KP))[1][2];
> NextClass(~KP);
> e := FactoredOrder(ExtractGroup(KP))[1][2] - d;
> "D = ", d, "e = ", e;
d =  18 e =  81
> "Right hand side = ", Right(d, e);
Right hand side =  135
> "Left hand side = ", Left(Ngens(K), #Relations(K));
```

```
Left hand side =  151
```

Since `Left` is greater than `Right`, this presentation for H doesn't work. Thus we start eliminating generators.

```
> K := Simplify(K: Iterations := 1);
> "Left hand side = ", Left(Ngens(K), #Relations(K));
Left hand side =  136
> K := Simplify(K: Iterations := 1);
> "Left hand side = ", Left(Ngens(K), #Relations(K));
Left hand side =  123
```

Got it! By Newman's theorem, H has an infinite 5-quotient and so F must be infinite.

Example H70E72

In this example, we consider a – quite unpleasant – presentation for some group G. In fact, it is a presentation for the group $\mathrm{PSL}_3(7)$:2, but we assume that we do not know this and want to compute the order of the finitely presented group G using coset enumeration.
We note in passing that the strategy outlined in this example is, together with other approaches, applied by the function `Order`.

```
> F<a,b,c> := FreeGroup(3);
> rels := [ a^4, b^2, (a,b)^3, (a*b)^8, ((a*b)^2*(a^-1*b)^3)^2,
>  c^2, (c*a*c*a^2)^2, (c*a)^3*(c*a^-1)^3,
>  c*a*b*c*a^-1*b*a^-1*c*a*b*c*a^2*a*b*a^-1,
>  c*a*b*c*b*a*c*a*c*a^-1*b*c*b*a^-1*c*a^-1,
>  c*a*b*a^-1*c*a*b*a^-1*c*a*b*a^-1*c*a*b*a^-1,
>  c*b*a^2*b*c*b*c*a^2*c*b*c*b*a^2*b,
>  c*a^2*c*b*a*c*b*a*c*b*a*c*a^-1*c*a*b*a^-1,
>  c*a^-1*b*a*c*a^-1*b*a*c*b*a*b*a^2*b*a^-1*b,
>  c*a*b*a^-1*b*c*b*a^-1*b*c*a^-1*b*a*b*a*c*b*c*b,
>  c*a*c*b*a*b*c*a*c*b*a*b*c*a*c*b*a*b,
>  c*b*a^-1*b*c*a^-1*c*a^-1*b*a*b*c*b*c*a^2*b*a*b*a^-1,
>  c*b*a^-1*b*a*b*c*b*a^-1*b*a*b*c*b*a^-1*b*a*b,
>  c*a^2*b*a^-1*b*c*b*c*b*a^-1*b*a*c*b*a^2*b*a^-1*b
> ];
> G<a,b,c> := quo< F | rels >;
```

As it happens, trying to determine the order of G by enumerating the cosets of the trivial subgroup is quite hard. – Even the predefined enumeration strategy `"Hard"` (cf. `ToddCoxeter` and `CosetEnumerationProcess`) does not give a finite result.

```
>  time ToddCoxeter(G, sub<G|> : Strategy := "Hard");
0
Time: 199.620
```

Of course we could try to increase the workspace for the coset enumeration, but we decide to be more clever. Trying random words in the generators of G, we easily find some subgroup S of G with pretty small index in G.

```
> S := sub< G | b, c*a*c*b*a*b >;
```

```
> time Index(G, S);
114
Time: 0.120
```

We now have to compute the order of S. In order to be able to do this using coset enumeration, we have to construct a presentation for S by rewriting S w.r.t. G.

```
> time R := Rewrite(G, S : Simplify := false);
Time: 0.030
```

However, the presentation obtained by Reidemeister-Schreier rewriting without any simplification is not suitable for coset enumeration: it contains too many generators and its total length is quite high.

```
> NumberOfGenerators(R);
133
> PresentationLength(R);
14384
```

An enumeration with the predefined enumeration strategy `"Hard"` does not produce a finite result. (Note that in consideration of the high total relator length, we select a coset table based enumeration style; cf. `CosetEnumerationProcess` in Chapter 71.)

```
> time ToddCoxeter(R, sub<R|> : Strategy := "Hard", Style := "C");
0
Time: 4.330
```

On the other hand, simplifying the presentation by reducing the number of generators as much as possible is not a good idea either, since the total relator length grows massively.

```
> time Rs := Simplify(R);
Time: 43.900
> NumberOfGenerators(Rs);
3
> PresentationLength(Rs);
797701
```

Again, an enumeration with the predefined enumeration strategy `"Hard"` does not produce a finite result.

```
>  time ToddCoxeter(Rs, sub<Rs|> : Strategy := "Hard", Style := "C");
0
Time: 22015.849
```

The best strategy is, to simplify the presentation obtained from the Reidemeister-Schreier procedure by eliminating generators until the total length of the relators starts to grow.

```
> time Rsl := SimplifyLength(R);
Time: 0.330
> NumberOfGenerators(Rsl);
48
> PresentationLength(Rsl);
```

```
7152
```

A coset enumeration for this presentation produces a finite result in a reasonable amount of time.

```
> time ToddCoxeter(Rsl, sub<Rsl|> : Strategy := "Hard", Style := "C");
32928
Time: 289.410
```

This finally proves that G is finite and has order $32928 * 114 = 3753792$.

70.10 Representation Theory

This section describes some functions for creating $R[G]$-modules for a finitely presented group G, which are unique for this category or have special properties when called for fp-groups. For a complete description of the functions available for creating and working with $R[G]$-modules we refer to chapter 89.

Note that the function GModuleAction can be used to extract the matrix representation associated to an $R[G]$-module.

All operations described in this subsection may require a closed coset table for at least one subgroup of an fp-group. If a closed coset table is needed and has not been computed, a coset enumeration will be invoked. If the coset enumeration does not produce a closed coset table, a runtime error is reported.

Experienced users can control the behaviour of such indirectly invoked coset enumeration with a set of global parameters. These global parameters can be changed using the function SetGlobalTCParameters. For a detailed description of the available parameters and their meanings, we refer to Chapter 71.

GModulePrimes(G, A)

Let G be a finitely presented group and A a normal subgroup of G of finite index. Given any prime p, the maximal p-elementary abelian quotient of A can be viewed as a $\mathbf{F}_p[G]$-module M_p. This function determines all primes p such that M_p is not trivial (i.e. zero-dimensional) and the dimensions of the corresponding modules M_p. The return value is a multiset S. If $0 \notin S$, the maximal abelian quotient of A is finite and the multiplicity of p is the dimension of M_p. If S contains 0 with multiplicity m, the maximal abelian quotient of A contains m copies of $\mathbf{Z}$. In this case, M_p is non-trivial for every prime p. The rank of M_p in this case is the sum of m and the multiplicity of p in S.

`GModulePrimes(G, A, B)`

Let G be a finitely presented group, A a normal subgroup of finite index in G and B a normal subgroup of G contained in A. Given any prime p, the maximal p-elementary abelian quotient of A/B can be viewed as a $\mathbf{F}_p[G]$-module M_p. This function determines all primes p such that M_p is not trivial (i.e. zero-dimensional) and the dimensions of the corresponding modules M_p. The return value is a multiset S. If $0 \notin S$, the maximal abelian quotient of A/B is finite and the multiplicity of p is the dimension of M_p. If S contains 0 with multiplicity m, the maximal abelian quotient of A/B contains m copies of $\mathbf{Z}$. In this case, M_p is non-trivial for every prime p. The rank of M_p in this case is the sum of m and the multiplicity of p in S.

`GModule(G, A, p)`

Given a finitely presented group G, a normal subgroup A of finite index in G and a prime p, create the $\mathbf{F}_p[G]$-module M corresponding to the conjugation action of G on the maximal p-elementary abelian quotient of A. The function also returns the epimorphism $\pi : A \to M$.

Note that normality of A in G is not checked. The results for invalid input data are undefined.

`GModule(G, A, B, p)`

`GModule(G, A, B)`

Given a finitely presented group G, a normal subgroup A of G of finite index, a normal subgroup B of G contained in A and a prime p, create the $\mathbf{F}_p[G]$-module M corresponding to the conjugation action of G on the maximal p-elementary abelian quotient of A/B.

p can be omitted, if the maximal elementary abelian quotient of A/B is a p-group for some prime p. Note, however, that the computation is much faster, if a prime is specified.

The function also returns the epimorphism $\pi : A \to M$.

Note that normality of A and B in G is not checked. The results for invalid input data are undefined.

`Pullback(f, N)`

Given a map $f : A \to M$ from a normal subgroup A of an fp-group G onto a $\mathbf{F}_p[G]$-module M and a submodule N of M, try to compute the preimage of N under f using a fast pullback method. If successful, the preimage is returned as subgroup of A.

If the pullback works, it is in general faster than a direct computation of the preimage using the preimage operator and it produces a more concise generating set for the preimage; see the following example. In cases where the pullback fails, a runtime error is reported and a preimage construction should be used instead.

Example H70E73

Consider the group G defined by the presentation

$$\langle a, b, c, d, e \mid a^4, b^{42}, c^6, e^3, b^a = b^{-1}, [a, c], [a, d], [a, e], \\ c^b = ce, d^b = d^{-1}, e^b = e^2, d^c = de, e^c = e^2, [d, e] \rangle.$$

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> := quo< F | a^4, b^42, c^6, e^3,
>                         b^a=b^-1, (a,c), (a,d), (a,e),
>                         c^b=c*e, d^b=d^-1, e^b=e^2,
>                         d^c=d*e, e^c=e^2,
>                         (d,e) >;
```

The finite index subgroup H of G generated by c, d, e is normal in G.

```
> H := sub< G | c,d,e >;
> Index(G, H);
168
> IsNormal(G, H);
true
```

We check, for which characteristics the action of G on H yields non-trivial modules.

```
> GModulePrimes(G, H);
{* 0, 2, 3 *}
```

We construct the $\mathbf{F}_3[G]$-module M given by the action of G on the maximal 3-elementary abelian quotient of H and the natural epimorphism π from H onto the additive group of M.

```
> M, pi := GModule(G, H, 3);
> M;
GModule M of dimension 2 over GF(3)
```

Using the function Submodules, we obtain the submodules of M. Their preimages under π are precisely the normal subgroups of G which are contained in H and contain $\ker(\pi)$.

```
> submod := Submodules(M);
> time nsgs := [ m @@ pi : m in submod ];
Time: 11.640
> [ Index(G, s) : s in nsgs ];
[ 1512, 504, 504, 168 ]
```

The generating sets for the normal subgroups obtained in this way, contain in general many redundant generators. (E.g. each will contain a generating set for $\ker(\pi)$.)

```
> [ NumberOfGenerators(s) : s in nsgs ];
[ 19, 20, 20, 21 ]
```

Optimised generating sets can be obtained using the function ReduceGenerators.

```
> nsgs_red := [ ReduceGenerators(s) : s in nsgs ];
> [ NumberOfGenerators(s) : s in nsgs_red ];
```

```
[ 2, 2, 3, 2 ]
```

Alternatively, and in fact this is the recommended way, we can use the function Pullback to compute the preimages of the submodules under π. Note that the generating sets for the preimages computed this way contain fewer redundant generators.

```
> time nsgs := [ Pullback(pi, m) : m in submod ];
Time: 8.560
> [ Index(G, s) : s in nsgs ];
[ 1512, 504, 504, 168 ]
> [ NumberOfGenerators(s) : s in nsgs ];
[ 4, 4, 3, 2 ]
```

Example H70E74

Consider the group defined by the presentation

$$< a, b, c, d, e \mid a^5, b^5, c^6, d^5, e^3, b^a = bd, \\ (a,c), (a,d), (a,e), (b,c), (b,d), (b,e), (c,d), (c,e), (d,e) > .$$

```
> G<a,b,c,d,e> := Group< a,b,c,d,e |
>                            a^5, b^5, c^6, d^5, e^3, b^a = b*d,
>                            (a,c), (a,d), (a,e), (b,c), (b,d), (b,e),
>                            (c,d), (c,e), (d,e) >;
```

Obviously the subgroup of G generated by b, c, d, e is normal in G.

```
> H := sub< G | b,c,d,e >;
> IsNormal(G, H);
true
```

We use the function GModulePrimes to determine the set of primes p for which the action of G on the maximal p-elementary abelian quotient of H induces a nontrivial $\mathbf{F}_p[G]$-module.

```
> P := GModulePrimes(G, H);
> 0 in P;
false
```

0 is not contained in P, i.e. the maximal free abelian quotient of H is trivial. Hence, there are only finitely many primes, satisfying the condition above.

We loop over the distinct elements of P and for each element p we construct the induced $\mathbf{F}_p[G]$-module, print its dimension and check whether it is decomposable. Note that the dimension of the module for p must be equal to the multiplicity of p in P.

```
> for p in MultisetToSet(P) do
>     M := GModule(G, H, p);
>     dim := Dimension(M);
>     decomp := IsDecomposable(M);
>
>     assert dim eq Multiplicity(P, p);
```

```
>
>    print "prime", p, ": module of dimension", dim;
>    if decomp then
>       print "  has a nontrivial decomposition";
>     else
>       print "  is indecomposable";
>    end if;
> end for;
prime 2 : module of dimension 1
  is indecomposable
prime 3 : module of dimension 2
  has a nontrivial decomposition
prime 5 : module of dimension 2
  is indecomposable
```

70.11 Small Group Identification

This section describes some special issues arising with the identification of a finitely presented group using the database of small groups described in Section 66.2.

`IdentifyGroup(G)`

Locate the pair of integers $\langle o, n \rangle$ so that `SmallGroup(o, n)` is isomorphic to G. If the construction of a permutation representation for G fails or if there is no group isomorphic to G in the database, then an error will result.

When trying to look up a finitely presented group G in the database of small groups, MAGMA tries to construct a permutation representation of G by enumerating the cosets of the trivial subgroup in G. Assuming that a group isomorphic to G is contained in the database, the resulting coset table will be fairly small. Hence for performance reasons, a coset limit of $100 \cdot o$ is imposed, where o is the maximal order of groups in the database, unless the order of G is *known* to be less or equal to o. If, on the other hand, $|G| \leq o$ is known, the global set of parameters for implicitly invoked coset enumerations applies. This set of parameters can be changed using the function SetGlobalTCParameters.

If the coset enumeration for G fails with the coset limit $100 \cdot o$, this can be seen as a reasonable indication that G is probably too large to be contained in the database of small groups.

To deal with cases where the coset enumeration fails although G is known or suspected to be small enough, it is recommended to attempt to compute the order of G using the function Order before the actual group identification. If G that way can be shown to be small enough to be contained in the database, the function SetGlobalTCParameters can be used to control the behaviour of coset enumerations in a subsequent call to `IdentifyGroup`. The following example illustrates this.

Example H70E75

Consider the group defined by the presentation

$$\langle\, a, b \,|\, (ba^{-1})^3,\ (ba^{-1}b)^2,\ a^{12}b^2a^7b^2ab^2 \,\rangle.$$

```
> G := Group<a,b | (b*a^-1)^3, (b*a^-1*b)^2,
>                  a^12*b^2*a^7*b^2*a*b^2 >;
```

We suspect (for some reason) that G is a small group and want to identify its isomorphism type in the database of small groups.

```
>  IdentifyGroup(G);
IdentifyGroup(
    G: GrpFP: G
)
In file "/home/magma/package/Group/Grp/smallgps2.m", line 220,
column 25:
>>     res := IdentifyGroup(db, G);
                           ^
Runtime error in 'IdentifyGroup': Coset enumeration failed; group
may be too large (see handbook entry for details)
```

The group couldn't be identified, because it was not possible to obtain a permutation representation with the default value of the coset limit.
Since we still think the group should be small, we try to prove this using the function Order.

```
> Order(G : Print := true);
INDEX = 6 (a=6 r=66709 h=999999 n=999999; l=1247 c=1.56; m=969169
t=999998)
6
```

We were correct; the group is in fact very small. However, we can see from the output of the `Order` command that this wasn't that easy to find out: almost one million cosets were used in the coset enumeration.
Since the order of G is now known to the system, a subsequent call to `IdentifyGroup` will now use the global parameters for implicitly invoked coset enumerations. To be on the safe side, we tell the system to be prepared to work a little harder using the function `SetGlobalTCParameters` and try again to identify G.

```
> SetGlobalTCParameters( : Strategy := "Hard");
>
> IdentifyGroup(G);
<6, 1>
```

Now G can be identified.

70.11.1 Concrete Representations of Small Groups

When an finitely-presented group is known to small, it may be useful to write it concretely as a permutation or PC-group. There are two utilities provided for this purpose.

`PermutationGroup(G)`

Construct a faithful permutation representation of G, and the isomorphism from G to the representation. The algorithm first computes the order of G, then takes the regular representation of G, and reduces the degree. Thus the command is restricted to small groups.

`PCGroup(G)`

Construct a faithful PC-group representation of G, and the isomorphism from G to the representation. The algorithm first computes the order of G, then computes the soluble quotient of G with the order found. Thus the command is restricted to small soluble groups.

71 FINITELY PRESENTED GROUPS: ADVANCED

Chapter 71
FINITELY PRESENTED GROUPS: ADVANCED

71.1 Introduction

This section presents some more advanced techniques available for computing with finitely-presented groups (fp-groups for short) within MAGMA. The features considered here are regarded as more advanced, either because they are technically or theoretically more complex and they are therefore expected to be used mainly by specialists, or because their efficient (and in a few cases even their merely correct) use requires some more detailed knowledge on the user's part.

Trying to summarise the expected main purpose of the functions described in this section, one could think of two main situations: On the one hand, user written functions, which may benefit from low-level tools for manipulating presentations or words, or which make use of interruptible process versions of some standard MAGMA functions for fp-groups. On the other hand, the solution of very hard problems, which require careful fine-tuning of the strategy employed or for which some iterative approach, using feedback of information obtained during the computation, is necessary.

The following topics are discussed in detail. First, some rather low-level operations on presentations and elements of fp-groups (words) are described. Then, the features for interactive coset enumeration in MAGMA are presented. This section also contains the complete description of all the parameters available for controlling the execution of the Todd-Coxeter procedure, which also applies to the appropriate standard functions documented in Chapter 70. After that, we describe the process version of the p-quotient algorithm. Note that some care has to be taken when interpreting results obtained with this interactive p-quotient computation; incorrect use of the existing functions may result in incomplete or wrong answers. The chapter ends with a treatise of the soluble quotient algorithm available in MAGMA. This final section contains a brief review of the theory underlying the soluble quotient algorithm, a description of the parameters available for functions computing soluble quotients, and the documentation of the interactive soluble quotient facilities.

71.2 Low Level Operations on Presentations and Words

In this section, we describe some rather low level operations on presentations and on elements of fp-groups. The main purpose of the functions described here, is to provide some efficient machinery for manipulating presentations and elements of fp-groups for user written functions.

71.2.1 Modifying Presentations

The functions described in this section construct a new fp-group from an existing one by adding or deleting a generator or by adding, deleting or changing a relation. The new group is created without any relationship to the existing group.

`AddGenerator(G)`

Given an fp-group G with presentation $\langle X \mid R \rangle$, create a new fp-group with presentation $\langle X \cup \{z\} \mid R \rangle$, where z is a symbol not in X.

`AddGenerator(G, w)`

Given an fp-group G with presentation $\langle X \mid R \rangle$, and given also a word w in the generators X, create a new fp-group having the presentation $\langle X \cup \{z\} \mid R \cup \{z = w\} \rangle$, where z is a symbol not in X.

`AddRelation(G, r)`

Given an fp-group G, and a relation r on the generators of G, create a new fp-group whose presentation consists of the relations of G together with the relation r.

`AddRelation(G, g)`

Given an fp-group G, and an element g of G, create a new fp-group whose presentation consists of the relations of G together with the relation $g = \mathrm{Id}(G)$.

`AddRelation(G, r, i)`

Given an fp-group G, and a relation r on the generators of G, create a new fp-group which has as its presentation the relations of G together with the relation r inserted after the i-th existing relation of G.

`AddRelation(G, g, i)`

Given an fp-group G, and an element g of G, create a new fp-group which has as its presentation the relations of G together with the relation $g = \mathrm{Id}(G)$ inserted after the i-th existing relation of G.

`DeleteGenerator(G, x)`

Given an fp-group G with presentation $\langle X \mid R \rangle$, and given also an element z in X, create a new fp-group with presentation $\langle X \setminus \{z\} \mid R' \rangle$, where the relations R' are obtained from R by deleting all relations containing an occurrence of z.

`DeleteRelation(G, r)`

Given an fp-group G, which includes the relation r amongst its relations, create a new fp-group which has as its presentation the relations of G with relation r omitted.

`DeleteRelation(G, g)`

Given an fp-group G, which includes the relation $g = \mathrm{Id}(G)$ amongst its relations, create a new fp-group which has as its presentation the relations of G with this relation omitted.

`DeleteRelation(G, i)`

Given an fp-group G, create a new fp-group which has as its presentation the relations for G with the i-th relation deleted.

`ReplaceRelation(G, s, r)`

`ReplaceRelation(G, h, r)`

`ReplaceRelation(G, s, g)`

`ReplaceRelation(G, h, g)`

Given an fp-group G, which includes the relation s or $h = \mathrm{Id}(G)$ amongst its relations, create a new fp-group which has as its presentation the relations for G with the relation s replaced by the relation r or $g = \mathrm{Id}(G)$.

`ReplaceRelation(G, i, r)`

Given an fp-group G and a relation r in the generators of G, create a new fp-group which has as its presentation the relations for G with relation number i replaced by the relation r.

`ReplaceRelation(G, i, g)`

Given an fp-group G and an element g of G, create a new fp-group which has as its presentation the relations for G with relation number i replaced by the relation $g = \mathrm{Id}(G)$.

Example H71E1

We use the function `ReplaceRelation` to vary a particular relation in a presentation. The order of the resulting group together with the index of a particular subgroup is determined.

```
> G<x,y,z,h,k,a> := Group< x, y, z, h, k, a |
>    x^2, y^2, z^2, (x,y), (y,z), (x,z), h^3, k^3, (h,k),
>    (x,k), (y,k), (z,k), x^h*y, y^h*z, z^h*x, a^2, a*x*a*y,
>    a*y*a*x, (a,z), (a,k), (a*h)^2 >;
> for i := 0 to 1 do
>     for j := 0 to 1 do
>         for k := 0 to 1 do
>              for l := 0 to 2 do
>                 rel := G.1^i*G.2^j*G.3^k*G.5^l*(G.6*G.4)^2 = Id(G);
>                 K := ReplaceRelation(G, 21, rel);
>                 print Order(K), Index(K, sub< K | K.6, K.4>);
>             end for;
>         end for;
```

```
>     end for;
> end for;
<0, 0, 0, 0> 144 24
<0, 0, 0, 1> 144 8
<0, 0, 0, 2> 144 8
<0, 0, 1, 0> 18 3
<0, 0, 1, 1> 18 1
<0, 0, 1, 2> 18 1
<0, 1, 0, 0> 72 3
<0, 1, 0, 1> 72 1
<0, 1, 0, 2> 72 1
<0, 1, 1, 0> 36 6
<0, 1, 1, 1> 36 2
<0, 1, 1, 2> 36 2
<1, 0, 0, 0> 18 3
<1, 0, 0, 1> 18 1
<1, 0, 0, 2> 18 1
<1, 0, 1, 0> 144 6
<1, 0, 1, 1> 144 2
<1, 0, 1, 2> 144 2
<1, 1, 0, 0> 36 6
<1, 1, 0, 1> 36 2
<1, 1, 0, 2> 36 2
<1, 1, 1, 0> 72 12
<1, 1, 1, 1> 72 4
<1, 1, 1, 2> 72 4
```

71.2.2 Low Level Operations on Words

The functions described in this section perform low level string operations like substitution, elimination or substring matching on elements of fp-groups.

`Eliminate(u, x, v)`

Given words u and v, and a generator x, all belonging to a group G, return the word obtained from u by replacing each occurrence of x by v and each occurrence of x^{-1} by v^{-1}.

`Eliminate(U, x, v)`

Given a set of words U, a word v, and a generator x, all belonging to a group G, return the set of words obtained by taking each element u of U in turn, and replacing each occurrence of x in u by v and each occurrence of x^{-1} by v^{-1}.

`Match(u, v, f)`

Suppose u and v are words belonging to the same group G, and that f is an integer such that $1 \leq f \leq \#u$. The function seeks the least integer l such that:

(a) $l \geq f$; and

(b) v appears as a subword of u, starting at the l-th letter of u.

If such an integer l is found `Match` returns the value true and l. If no such l is found, `Match` returns the value false.

`RotateWord(u, n)`

The word obtained by cyclically permuting the word u by n places. If n is positive, the rotation is from left to right, while if n is negative the rotation is from right to left. In the case where n is zero, the function returns u.

`Substitute(u, f, n, v)`

Given words u and v belonging to a group G, and non-negative integers f and n, this function replaces the substring of u of length n, starting at position f, by the word v. Thus, if $u = x_{i_1}^{e_1} \cdots x_{i_f}^{e_f} \cdots x_{i_{f+n-1}}^{e_{f+n-1}} \cdots x_{i_m}^{e_m}$ then the substring $x_{i_f}^{e_f} \cdots x_{i_{f+n-1}}^{e_{f+n-1}}$ is replaced by v. If the function is invoked with $v = \mathrm{Id(G)}$, then the substring $x_{i_f}^{e_f} \cdots x_{i_{f+n-1}}^{e_{f+n-1}}$ of u is deleted.

`Subword(u, f, n)`

The subword of the word u comprising the n consecutive letters commencing at the f-th letter of u.

Example H71E2

We demonstrate some of these operations in the context of the free group on generators x, y, and z.

```
> F<x, y, z> := FreeGroup(3);
> u := (x, y*z);
> w := u^(x^2*y);
> #w;
12
> w;
y^-1 * x^-3 * z^-1 * y^-1 * x * y * z * x^2 * y
```

We replace each occurrence of the generator x in w by the word $y * z^-1$.

```
> Eliminate(w, x, y*z^-1);
y^-1 * z * y^-1 * z * y^-1 * z * y^-1 * z^-2 * y * z * y * z^-1 * y * z^-1 * y
```

We count the number of occurrences of each generator in w.

```
> [ ExponentSum(w, F.i) : i in [1..Ngens(F)] ];
[ 0, 0, 0 ]
> GeneratorNumber(w);
```

```
-2
```

We locate the start of the word u in the word w.

```
> b, p := Match(w, u, 1);
> b, p;
true 4
```

We now replace the subword u in w by the word $y * x$.

```
> t := Substitute(w, p, #u, y*x);
> t;
y^-1 * x^-2 * y * x^3 * y
```

We create the set of all distinct cyclic permutations of the word u.

```
> rots := { RotateWord(u, i) : i in [1 ..#u] };
> rots;
{ y^-1 * x * y * z * x^-1 * z^-1,  x * y * z * x^-1 * z^-1 * y^-1,
x^-1 * z^-1 * y^-1 * x * y * z,  z * x^-1 * z^-1 * y^-1 * x * y,
z^-1 * y^-1 * x * y * z * x^-1,  y * z * x^-1 * z^-1 * y^-1 * x }
```

71.3 Interactive Coset Enumeration

71.3.1 Introduction

This section presents the interactive coset enumeration facility of MAGMA. This concept makes it possible to restart an enumeration after changing enumeration parameters or adding relators or subgroup generators, while making use of information obtained up to that point as much as possible. It is thus particularly suitable for very hard enumerations, requiring a careful and interactive choice of enumeration parameters or for series of similar enumerations.

The Todd-Coxeter implementation installed in MAGMA is based on the stand alone coset enumeration programme `ACE3` developed by George Havas and Colin Ramsay at the University of Queensland. The reader should consult [CDHW73] and [Hav91] for an explanation of the terminology and a general description of the algorithm. A manual for `ACE3` as well as the sources of `ACE3` can be found online [Ram].

In MAGMA an interactive coset enumeration is realised as an object of the category `GrpFPCosetEnumProc` which can be created and modified, allows starting and restarting of coset enumerations and provides access to internal data like the coset table and various status information.

71.3.2 Constructing and Modifying a Coset Enumeration Process

`CosetEnumerationProcess(G, H: parameters)`

This function creates a coset enumeration process for enumerating the cosets of the subgroup H of the finitely presented group G. Note that no actual coset enumeration is started for the created coset enumeration process. This can be done with the function `StartEnumeration`.

The user can control in detail the way a subsequent enumeration will be performed with the help of the following parameters. For a more thorough explanation of the parameters and of how they affect the coset enumeration, we refer to the `ACE3` manual.

`Compact` RngIntElt *Default :* 10

This parameter controls the compaction of the coset table during an enumeration. A compaction will be done if a new coset definition is required, there is no space for a new coset available in the coset table and the percentage of dead cosets exceeds the value of the parameter `Compact`.

`CosetLimit` RngIntElt *Default :* 0

If `CosetLimit` is set to n, where n is a positive integer, then the coset table may have at most n rows. In other words, a maximum of n cosets can be defined at any instant during the enumeration. It is ensured in this case, that enough memory is allocated to store the requested number of cosets, regardless of the value of the parameter `Workspace`.

If `CosetLimit` is set to 0 (default), the maximal number of active cosets is determined by the size of the coset table (cf. parameter `Workspace`) and the number of columns of the coset table (i.e. the number of group generators).

`Workspace` RngIntElt *Default :* 4000000

The number of words allocated for the coset table. Note that if `CosetLimit` is set, at least as much memory is allocated as is necessary to store the requested number of cosets.

`FillFactor` RngIntElt *Default :* 0

In certain situations it is necessary to ensure that a certain proportion, the *fill fraction* (see Havas (1991)), of the coset table is always kept filled, even if *preferred definitions* are made. The parameter `FillFactor` allows the user to specify the fill fraction which is the reciprocal of `FillFactor`. The default value of 0 selects a fill factor of $\lfloor (5 * (c + 2))/4 \rfloor$, where c is the number of columns in the coset table.

`CTFactor` RngIntElt *Default :* 1000

`RTFactor` RngIntElt *Default :* $2000/l$

`Style` MonStgElt *Default :* "*R_CR*"

These parameters control the enumeration style and the balance between coset table style definitions (C-style, Felsch style) and relator table style definitions (R-style, HLT style).

The parameters `CTFactor` and `RTFactor` set the number of C-style coset definitions and R-style coset applications, respectively, which are performed in every step of the appropriate type. The default value for `RTFactor` is $2000/l$, where l is the total length of the relators.

The possible arguments to the parameter `Style` are `"R"`, `"C"`, `"R_CR"`, `"Rc"`, `"Cr"`, `"Rt"` and `"CR"`.

In style R all definitions are made via relator scans, i.e. this is HLT mode.

In style C all definitions are made by filling the next empty position in the coset table and testing the new coset in all essentially different positions in the relators, i.e. this is Felsch mode.

In style R_CR we run in style R until an overflow occurs, perform a lookahead on the entire table and then switch to style CR (see below).

The styles Rc and Cr are like the styles R and C, except that a single style C or style R pass is done after the initial R or style C pass, respectively.

In style Rt definitions are made as in style R, but the new cosets are tested in all essentially different positions in the relators as in style C.

In style CR alternate passes of style C and style R are performed, with all definitions tested in all essentially different positions in the relators as in style C.

`Lookahead` RngIntElt *Default :* 0

In HLT style enumerations, possible implications of new definitions or deductions made while tracing relators may not be detected until much later. One possible solution to this problem is to perform lookaheads occasionally, i.e. to process the coset table, looking for deductions or coincidences. A lookahead can be done using the entire table (*complete*) or only that part of the table above the current coset (*partial*) and it can be done in R-style (scanning cosets from the beginning of relators) or in C-style (testing all definitions in all essentially different relator positions). The following lookahead modes are supported.

For `Lookahead := 0` (default) no lookahead is done.
For `Lookahead := 1` a partial R-style lookahead is done.
For `Lookahead := 2` a complete C-style lookahead is done.
For `Lookahead := 3` a complete R-style lookahead is done.
For `Lookahead := 4` a partial C-style lookahead is done.

`Mendelsohn` BoolElt *Default :* `false`

If `Mendelsohn` is set, coset applications are done at all cyclic permutations of the relators. This is usually very expensive but may nevertheless be helpful in certain cases.

`RelationsInSubgroup` RngIntElt *Default :* -1

This parameter controls, whether relators are treated as additional subgroup generators, i.e. whether they are applied to coset 1 at the start of an enumeration. An argument of -1 (default) includes all relators, an argument of 0 turns this feature off and a positive argument includes the appropriate number of relators, in order.

`RowFilling` BoolElt *Default :* `true`

In R-style it is usual to scan each row of the table after its coset has been applied to all relators, and to make definitions to fill any holes encountered. Failure to do so can cause even simple enumerations to overflow. To switch row filling off, set the parameter `RowFilling` to false.

`PrefDefMode` RngIntElt *Default :* 3

If the argument is 0, then Felsch style definitions are made using the next empty position in the coset table. Otherwise, gaps of length one found during relator scans are preferentially filled. If the argument is 1, they are filled immediately, and if it is 2, the consequent deduction is also made immediately. If the argument is 3, then the gaps are noted in the preferred definition queue and the next coset definition will be made to fill the oldest gap of length one.

`PrefDefSize` RngIntElt *Default :* 8

This parameter controls the size of the preferred definition queue, which is implemented as a ring buffer, dropping earliest entries. Setting `PrefDefSize` to n allocates a buffer of size 2^n.

`DeductionMode` RngIntElt *Default :* 4

A completed table is only valid if every table entry has been tested in all essentially different relator positions. Untested deductions are stored on a stack. This parameter allows the user to specify how deductions should be handled. The possible actions are:

For `DeductionMode := 0` : discard deductions if there is no stack space left.

For `DeductionMode := 1` : as 0, but redundant cosets are purged off the top of the stack whenever a coincidence is found.

For `DeductionMode := 2` : as 0, but all redundant cosets are purged from the stack whenever a coincidence is found.

For `DeductionMode := 3` : discard the entire stack if it overflows.

For `DeductionMode := 4` : if the stack overflows, then double the stack size and purge all redundant cosets from the stack.

If deductions are discarded for any reason during an enumeration, then a final relator application pass will be done at the end of the enumeration automatically to check the result.

`DeductionSize` RngIntElt *Default :* 1000

Sets the (initial) size of the deduction stack in words, with one deduction taking two words. A value of 0 selects the default size of 1000 words.

`PathCompression` BoolElt *Default :* `false`

Switching this option on reduces the amount of data movement during coincidence processing at the expense of tracing and compressing coincidence paths, which involves many coset table accesses. The value of this parameter has no effect on the result but may influence the running time.

`TimeLimit` RngIntElt *Default :* -1

This parameter puts a time limit in seconds on the length of an enumeration. A value of -1 (default) means no limit. A value of 0 performs exactly one pass through the main enumeration loop.

`LoopLimit` RngIntElt *Default :* 0

The core enumerator is organised as a state machine, with each step performing an action (e.g. lookahead, compaction) or a block of actions (e.g. `CTFactor` coset definitions or `RTFactor` coset applications). Using this parameter, a limit on the total number of steps can be imposed. A value of 0 (default) turns this feature off.

`LowerBound` RngIntElt *Default :* 1

This may be set to any known lower bound for the index. Should it happen that the coset table has no holes, and the number of active cosets is equal to the given bound, the enumeration will terminate. When the given bound is equal to the index, this will save tracing relators at many cosets when there is no possibility of finding coincidences.

`Print` BoolElt *Default :* `false`

If this parameter is set to true, the enumerator prints a single message at the end of an enumeration and possibly some progress messages during an enumeration (cf. parameter `Messages`).

`Messages` RngIntElt *Default :* 0

If the argument n of this parameter is non-zero (and `Print` is set to true), then a progress message is printed after every $|n|$ "actions" (i.e. coset definitions, deductions, coincidences, etc.) A negative value of n turns hole monitoring on.

`Strategy` MonStgElt *Default :*

Using this parameter one of several predefined strategies can be selected. The effect is equivalent to selecting an appropriate combination of arguments for some of the parameters explained above. Any predefined strategy can be modified by explicitly overriding parameter values.

The following predefined strategies exist: "Default", "Easy", "Hard", "Felsch", "HLT", "CT", "RT", "Sims1", "Sims3", "Sims5", "Sims7", "Sims9".

All predefined strategies set `PrefDefSize := 8`, `DeductionSize := 1000`, `PathCompression := false` and `LoopLimit := 0`. For the remaining parameter settings see Table 1 on page 2215, Table 2 on page 2215 and Table 3 on page 2216.

`AddRelator(~P, w)`

Add a word w in the generators of the group G underlying the coset enumeration process P to the defining relations of G. This means that a coset enumeration process P for the cosets of H in G is transformed into a coset enumeration process for the cosets of $\pi(H)$ in $\pi(G)$, where $\pi : G \to \pi(G)$ is an epimorphism with kernel $\langle w \rangle^G$. (Here $\langle w \rangle^G$ denotes the normal closure in G of the subgroup of G generated by w.)

	Default	Easy	Hard	Felsch	HLT

`PrefDefMode`	0	0	0	0	0
`DeductionMode`	4	0	0	4	0

Table 2: Strategies (continued)

`AddSubgroupGenerator(~P, w)`

Add an element w of the group G underlying the coset enumeration process P to the generators of the subgroup. This means that a coset enumeration process P for the cosets of H in G is transformed into a coset enumeration process for the cosets of $\langle H, w\rangle$ in G, where $\langle H, w\rangle$ denotes the subgroup of G generated by H and w.

	Sims7	Sims9

PrefDefMode	0	0
DeductionMode	4	4

Table 3: Strategies (continued)

`SetProcessParameters(~P: parameters)`

Change enumeration parameters of the coset enumeration process P. The set of parameters accepted by this function is the same as for the function CosetEnumerationProcess; see there for a description.

All parameters which are not explicitly changed or modified by selecting one of the predefined strategies retain their old values.

It should be noted that it is not possible to decrease the workspace allocated by a coset enumeration process, once an enumeration has been started. However the workspace can be extended without invalidating any information contained in the process.

71.3.3 Starting and Restarting an Enumeration

There are several ways of starting and restarting an enumeration for a coset enumeration process, which retain information from previous enumerations to a varying extent.

`StartEnumeration(~P: parameters)`

Start a new enumeration for P. All information in P is discarded. This function can be called at any time for an existing coset enumeration process. The enumeration parameters for P can be modified by passing parameters to this function. (This is equivalent to calling the function SetProcessParameters before calling StartEnumeration.) The set of parameters accepted by this function is the same as for the function CosetEnumerationProcess; see there for a description.

`RedoEnumeration(~P: parameters)`

Restart an enumeration for P. All information in P is retained and the enumeration is restarted at coset number 1. This function can be called for any coset enumeration process, which contains a valid coset table. (If P does not contain a valid coset table, a call to `RedoEnumeration` causes a runtime error. Use the function `CanRedoEnumeration` to check whether a call to `RedoEnumeration` is legal for a certain coset enumeration process.) Note that the coset table of P need not be complete to use this function.

This function is intended for the case where additional relators and/or subgroup generators have been introduced. The coset table contained in P is still valid. However, the additional data may allow the enumeration to compete, or cause a collapse to a smaller index.

The enumeration parameters for P can be modified by passing parameters to this function. (This is equivalent to calling the function `SetProcessParameters` before calling `RedoEnumeration`.) The set of parameters accepted by this function is the same as for the function `CosetEnumerationProcess`; see there for a description.

`CanRedoEnumeration(P)`

Returns `true`, if a call to `RedoEnumeration` is legal for the coset enumeration process P.

`ContinueEnumeration(~P: parameters)`

Continue an enumeration for P, which has been interrupted because some limit was exceeded. All information in P is retained and the enumeration is restarted at the coset where the previous enumeration was stopped. This function can only be called for a coset enumeration process, if the previous enumeration produced a valid coset table and the subgroup underlying P has not been changed since then. (Otherwise, a call to `ContinueEnumeration` causes a runtime error. Use the function `CanContinueEnumeration` to check whether a call to `ContinueEnumeration` is legal for a certain coset enumeration process.) Note that the coset table of P need not be complete to use this function.

This function is intended for the case where an enumeration stopped without producing a finite index. This function allows to continue the enumeration with modified enumeration parameters with the minimal possible overhead.

The enumeration parameters for P can be modified by passing parameters to this function. (This is equivalent to calling the function `SetProcessParameters` before calling `ContinueEnumeration`.) The set of parameters accepted by this function is the same as for the function `CosetEnumerationProcess`; see there for a description.

`CanContinueEnumeration(P)`

Returns `true`, if a call to `ContinueEnumeration` is legal for the coset enumeration process P.

`ResumeEnumeration(~P: parameters)`

Resume or start an enumeration for P in the "cheapest" way permitted by the state of the coset enumeration process P. The call

```
ResumeEnumeration(~P : parameters);
```

is equivalent to

```
if CanContinueEnumeration(P) then
   ContinueEnumeration(~P : parameters);
elif CanRedoEnumeration(P) then
   RedoEnumeration(~P : parameters);
else
   StartEnumeration(~P : parameters);
end if;
```

The enumeration parameters for P can be modified by passing parameters to this function. (This is equivalent to calling the function `SetProcessParameters` before calling `ResumeEnumeration`.) The set of parameters accepted by this function is the same as for the function `CosetEnumerationProcess`; see there for a description.

71.3.4 Accessing Information

`CosetsSatisfying(P : parameters)`

`CosetSatisfying(P : parameters)`

Given a coset enumeration process P with underlying group G and subgroup H, which contains a valid coset table, these functions return a set of words representing cosets which satisfy the conditions defined in the parameters.

A call to `CosetSatisfying` is equivalent to calling `CosetsSatisfying` with `Limit` set to 1 and `First` set to 2 (unless a higher value for `First` is specified explicitly), i.e. the function returns when the first coset, other than H, satisfying the specified conditions has been found.

`First` RngIntElt *Default :* 1

This parameter determines at which coset the search for coset representatives satisfying the designated conditions is started. The coset H always is coset number 1, i.e. setting `First` to 2 restricts the search to non-trivial cosets.

For the function `CosetSatisfying`, the minimal possible value for this parameter is 2; setting it to 1 does not cause an error but will be ignored.

`Last` RngIntElt *Default :* 0

This parameter determines at which coset the search for coset representatives satisfying the designated conditions is stopped. If it is set to 0 (default), all active cosets (starting from `First`) are searched.

`Limit` RngIntElt *Default :* 0

If this parameter is set to $l > 0$, the search for coset representatives is aborted as soon as l cosets satisfying the designated condition have been found. If it is set to 0 (default for `CosetsSatisfying`), no limit is in force.

This parameter is not available for the function `CosetSatisfying`.

`Normalizing` BoolElt *Default :* `false`

If true, select coset representatives x such that $x^{-1}h_ix$ is known to be contained in H from the information in the coset table of P for every generator h_i of H. (I.e. x is recognised as an element of the normaliser of H in G.)

`Order` RngIntElt *Default :* 0

Select coset representatives x such that x^n is known to be contained in H from the information in the coset table of P.

`Print` RngIntElt *Default :* 0

If the value of this parameter is positive, print the coset representatives found to satisfy the designated conditions.

These functions can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to any of these functions causes a runtime error. You can use the function `HasValidCosetTable` to check whether a call to these functions is legal for a certain coset enumeration process.

`CosetTable(P)`

The current coset table of P as a map $f : \{1, \ldots, r\} \times G \to \{0, \ldots, r\}$, where G and H are the finitely presented group and the subgroup underlying P, respectively, and r is number of active cosets. $f(i, x)$ is the coset to which coset i is mapped under the action of $x \in G$. The value 0 is only included in the codomain if the coset table is not complete, and it denotes that the image of i under x is not known.

This function can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to `CosetTable` causes a runtime error. Use the function `HasValidCosetTable` to check whether a call to `CosetTable` is legal for a certain coset enumeration process. Note that the coset table of P need not be complete to use this function.

`HasValidCosetTable(P)`

Returns `true`, if P contains a valid (but not necessarily closed) coset table, i.e. if a call to `CosetTable` is legal for the coset enumeration process P.

`HasClosedCosetTable(P)`

`HasCompleteCosetTable(P)`

Returns `true`, if P contains a closed, valid coset table.

Note that if `HasClosedCosetTable` returns `true` for a coset enumeration process P, then in particular a call to `CosetTable` is legal for P.

`ExcludedConjugate(P)`

`ExcludedConjugates(P)`

Given a coset enumeration process P with underlying group G and subgroup H, which contains a valid coset table, these functions return a set E containing either at most one word (`ExcludedConjugate`) or all words (`ExcludedConjugates`) of the form $g_i^{-1}h_jg_i$, where g_i is a generator of G and h_j is a generator of H, such that $g_i^{-1}h_jg_i$ is not known to lie in H from the information contained in the coset table of P.

If E is empty, then H is a normal subgroup of G. Otherwise the addition of elements of E to the generators of H may yield a larger subgroup of the normal closure of H in G. In the case of a non-complete coset table it may happen, however, that excluded conjugates are found which actually lie in H.

These functions can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to `ExcludedConjugate` or `ExcludedConjugates` causes a runtime error. You can use the function `HasValidCosetTable` to check whether a call to these functions is legal for a certain coset enumeration process.

`ExistsCosetSatisfying(P :` *parameters*`)`

Given a coset enumeration process P with underlying group G and subgroup H, which contains a valid coset table, return whether or not there exists a coset other than H, which satisfies the conditions defined in the parameters. If such a coset exists, a representing word is returned as second return value. This function accepts the same set of parameters as the function `CosetSatisfying`; see there for a description.

This function can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to `ExistsCosetSatisfying` causes a runtime error. You can use the function `HasValidCosetTable` to check whether a call to `ExistsCosetSatisfying` is legal for a certain coset enumeration process.

`ExistsExcludedConjugate(P)`

Given a coset enumeration process P with underlying group G and subgroup H, which contains a valid coset table, return whether or not there exists a word of the form $g_i^{-1}h_jg_i$, where g_i is a generator of G and h_j is a generator of H, such that $g_i^{-1}h_jg_i$ is not known to lie in H from the information contained in the coset table of P. If the answer is positive, such a word is returned as second return value.

This function can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to `ExistsExcludedConjugate` causes a runtime error. You can use the function `HasValidCosetTable` to check whether a call to `ExistsExcludedConjugate` is legal for a certain coset enumeration process.

Note that the coset table of P need not be complete to call this function. A negative result of `ExistsExcludedConjugate` always implies that H is a normal subgroup of G, even if the coset table of P is not complete. In the case of a non-complete coset table it may happen, however, that excluded conjugates are found which actually lie in H.

`ExistsNormalisingCoset(P)`

`ExistsNormalizingCoset(P)`

Returns `true`, if an element of $G \setminus H$ which normalises H can be found from the coset table contained in P. (Here, G and H are the finitely presented group and the subgroup underlying P, respectively.) If the answer is positive, such an element is returned as second return value.

This function can be called for any coset enumeration process, which contains a valid coset table. If P does not contain a valid coset table, a call to `ExistsNormalisingCoset` causes a runtime error. You can use the function `HasValidCosetTable` to check whether a call to `ExistsNormalisingCoset` is legal for a certain coset enumeration process.

Note that the coset table of P need not be complete to call this function. However, no conclusion can be drawn from a negative result in the case of a non-complete coset table.

`Group(P)`

Returns the group underlying P as a finitely presented group.

`Index(P)`

Returns the index of H in G. (Here, G and H denote the finitely presented group and the subgroup underlying P, respectively.)

This function can only be called, if the last enumeration done for P has completed successfully with a finite index. Otherwise, a call to `Index` will cause a runtime error. Use the function `HasValidIndex` to check whether a call to `Index` is legal for a certain coset enumeration process.

`HasValidIndex(P)`

Returns `true`, if the last enumeration done for P has completed successfully with a finite index, i.e., if a call to `Index` is legal for the coset enumeration process P.

`MaximalNumberOfCosets(P)`

Returns the maximal number of cosets which were simultaneously active during the last enumeration done for P, or 1 if no enumeration has been done for P.

This function may be useful for assessing the performance of a certain set of enumeration parameters.

`Subgroup(P)`

Returns the subgroup H underlying the coset enumeration process P. H is returned as a subgroup of G, where G is the finitely presented group underlying P.

`TotalNumberOfCosets(P)`

Returns the total number of cosets defined during the last enumeration done for P, or 1 if no enumeration has been done for P.

This function may be useful for assessing the performance of a certain set of enumeration parameters.

Example H71E3

In the Harada-Norton sporadic simple group

$$\begin{aligned} < x, a, b, c, d, e, f, g \mid\ & x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2, \\ & (x, a), (x, g), \\ & (bc)^3, (bd)^2, (be)^2, (bf)^2, (bg)^2, \\ & (cd)^3, (ce)^2, (cf)^2, (cg)^2, \\ & (de)^3, (df)^2, (dg)^2, \\ & (ef)^3, (eg)^2, \\ & (fg)^3, \\ & (b, xbx), \\ & (a, edcb), (a, f)dcbdcd, (ag)^5, \\ & (cdef, xbx), (b, xcdefx), (cdef, xcdefx) > \end{aligned}$$

we want to construct the coset table for the subgroup generated by x, b, c, d, e, f, g interactively. First, we create a coset enumeration process. Since the index of the chosen subgroup is 1 140 000, we request a coset limit of 1 200 000. Then we start the enumeration.

```
> HN<x, a, b, c, d, e, f, g> :=
>     Group< x, a, b, c, d, e, f, g |
>               x^2, a^2, b^2, c^2, d^2, e^2, f^2, g^2,
>               (x, a), (x, g),
>               (b*c)^3, (b*d)^2, (b*e)^2, (b*f)^2, (b*g)^2,
>               (c*d)^3, (c*e)^2, (c*f)^2, (c*g)^2,
>               (d*e)^3, (d*f)^2, (d*g)^2,
>               (e*f)^3, (e*g)^2,
>               (f*g)^3,
>               (b, x*b*x), (a, e*d*c*b), (a, f)*d*c*b*d*c*d,
>               (a*g)^5, (c*d*e*f, x*b*x), (b, x*c*d*e*f*x),
>               (c*d*e*f, x*c*d*e*f*x)
>           >;
> H := sub<HN | x,b,c,d,e,f,g >;
> P := CosetEnumerationProcess(HN, H : CosetLimit := 1200000, Print := true);
```

```
> StartEnumeration(~P);
Overflow
 (a=1110331 r=58605 h=101193 n=1200001;
  l=5444 c=105.36;
  m=1110331 t=2001537)
```

The enumeration could not be completed successfully. Though P does contain a valid coset table, but this coset table fails to be closed.

```
> HasValidCosetTable(P);
true
> HasClosedCosetTable(P);
false
```

We extract the coset table map, check its domain and its codomain, and determine the position of the first "hole" in the coset table.

```
> ct := CosetTable(P);
> Domain(ct) : Minimal;
Cartesian Product<{ 1 .. 1110331 }, GrpFP: HN>
> Codomain(ct);
{ 0 .. 1110331 }
> row := 1;
> while forall(col){ gen : gen in {x, a, b, c, d, e, f, g}
>                        | ct(<row, gen>) ne 0 } do
>    row +:= 1;
> end while;
> row;
41881
> col;
x
```

We change the enumeration parameters for the process P, selecting the predefined strategy `Hard`. Since this predefined strategy sets a workspace of 10 000 000, we must expressly override this, if we want the old value to be retained. Because the workspace size never is decreased once an enumeration has been started, we can retain the old value simply by setting `Workspace` to 0; this overrides the setting done by selecting the predefined strategy, but actually doesn't change the process' workspace. We then continue the enumeration with the new set of parameters, after checking that this is legal.

```
> SetProcessParameters(~P : Strategy := "Hard",
>                           Workspace := 0);
> CanContinueEnumeration(P);
true
> ContinueEnumeration(~P);
INDEX = 1140000
 (a=1140000 r=58512 h=1144534 n=1144534;
  l=70 c=6.50;
```

```
  m=1140000 t=2035739)
```

We have obtained a closed coset table. Note that the codomain of the new coset table map does not contain 0.

```
> HasClosedCosetTable(P);
true
> ct := CosetTable(P);
> Domain(ct) : Minimal;
Cartesian Product<{ 1 .. 1140000 }, GrpFP: HN>
> Codomain(ct);
{ 1 .. 1140000 }
```

Example H71E4

First, we create a coset enumeration process for the trivial subgroup of the finite group $G := \langle a, b \mid a^8, b^7, (a*b)^2, (a^{-1}*b)^3 \rangle$ and start the enumeration.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | x^8, y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | >;
> P := CosetEnumerationProcess(G, H : Print := true);
> StartEnumeration(~P);
INDEX = 10752
 (a=10752 r=57263 h=1 n=57263;
  l=292 c=0.11;
  m=47825t=57262)
```

We want to enumerate the cosets of the two non-trivial subgroups of G generated by $a^{-1}*b$ and a^2, respectively. To do this, we create two copies of the coset enumeration process `P` and use the function `AddSubgroupGenerator` for each of them. Since the copies inherit all information contained in `P`, we then can call the function `RedoEnumeration` to enumerate the cosets of the two non-trivial subgroups, making use of the existing coset table.

```
> P1 := P;
> AddSubgroupGenerator(~P1, a^-1*b);
> Subgroup(P1);
Finitely presented group on 2 generators
Generators as words in group G
    $.1 = Id(G)
    $.2 = a^-1 * b
> CanRedoEnumeration(P1);
true
> RedoEnumeration(~P1);
INDEX = 3584
 (a=3584 r=57263 h=1 n=57263;
  l=49 c=0.02;
  m=47825 t=57262)
>
> P2 := P;
```

```
> AddSubgroupGenerator(~P2, a^2);
> Subgroup(P2);
Finitely presented group on 2 generators
Generators as words in group G
    $.1 = Id(G)
    $.2 = a^2
> CanRedoEnumeration(P2);
true
> RedoEnumeration(~P2);
INDEX = 2688
 (a=2688 r=57263 h=1 n=57263;
  l=37 c=0.02;
  m=47825 t=57262)
```

Finally, we are interested in the quotient of G by the normal closure of the subgroup generated by a^4 and want to enumerate the cosets of the image of the subgroup generated by a^2 in this quotient. Since this is the subgroup used in `P2`, we create a copy of `P2` and add the relation a^4. Again, we are able to make use of information obtained earlier, by continuing the inherited enumeration.

```
> P3 := P2;
> AddRelator(~P3, a^4);
> CanContinueEnumeration(P3);
true
> ContinueEnumeration(~P3);
INDEX = 84
 (a=84 r=57263 h=1 n=57263;
 l=2 c=0.00;
 m=47825 t=57262)
```

We extract the quotient and its subgroup from the process `P3`, using the appropriate access functions.

```
> G3<a3,b3> := Group(P3);
> G3;
Finitely presented group G3 on 2 generators
Relations
    a3^8 = Id(G3)
    b3^7 = Id(G3)
    (a3 * b3)^2 = Id(G3)
    (a3^-1 * b3)^3 = Id(G3)
    a3^4 = Id(G3)
> H3<u3, v3> := Subgroup(P3);
> H3;
Finitely presented group H3 on 2 generators
Generators as words in group G3
    u3 = Id(G3)
    v3 = a3^2
```

Example H71E5

Consider the subgroup H of the (infinite) group $G := \langle a, b \mid b^7, (a*b)^2, (a^{-1}*b)^3 \rangle$ generated by a. We create a coset enumeration process and start an enumeration with the default parameters.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | a>;
> P := CosetEnumerationProcess(G, H);
> StartEnumeration(~P : Print := true);
Overflow
 (a=957026 r=415230 h=415230 n=999999;
  l=3553 c=2.38;
  m=960050 t=999998)
```

The enumeration produces a valid (albeit not complete) coset table.

```
> HasValidCosetTable(P);
true
> HasCompleteCosetTable(P);
false
```

Even the partial coset table is sufficient to find an element in the normaliser of H in G.

```
> found, elt := ExistsNormalisingCoset(P);
> found;
true
> elt;
b^-4 * a * b^-2
```

Example H71E6

Consider again the subgroup H of the (infinite) group $G := \langle a, b \mid b^7, (a*b)^2, (a^{-1}*b)^3 \rangle$ generated by a. We create a coset enumeration process and start an enumeration with the default parameters.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | a>;
> P := CosetEnumerationProcess(G, H);
> StartEnumeration(~P : Print := true);
Overflow
 (a=957026 r=415230 h=415230 n=999999;
  l=3553 c=2.38;
  m=960050 t=999998)
```

We check, whether the coset table exhibits excluded conjugates.

```
> ExistsExcludedConjugate(P);
```

```
true a^b
```

It does. This means in particular, that H is not normal in G. We create a copy `P1` of the coset enumeration process `P`, extend the subgroup of `P1` by the excluded conjugates found in the previous step and restart the enumeration for `P1`.

```
> P1 := P;
> for c in ExcludedConjugates(P) do
>   AddSubgroupGenerator(~P1, c);
> end for;
> RedoEnumeration(~P1);
INDEX = 1 (a=1 r=2 h=2 n=2; l=2 c=0.94; m=960050 t=999998)
```

The new subgroup is equal to G. In particular, the normal closure of H in G is the whole of G. We return to the coset enumeration process `P` and check whether we can find a non-trivial element $x \in \mathbf{N}_G(H)$ such that $x^2 \in H$.

```
> ExistsCosetSatisfying(P : Order := 2, Normalizing := true);
true b^-4 * a * b^-2
```

We can. In fact, $b^{-4} \cdot a \cdot b^{-2}$ is the only non-trivial coset which is known to satisfy this condition...

```
> CosetsSatisfying(P : Order := 2, Normalizing := true);
{ Id(G), b^-4 * a * b^-2 }
```

...and we can't find in a similar way a non-trivial element $x \in \mathbf{N}_G(H)$ such that $x^3 \in H$.

```
> ExistsCosetSatisfying(P : Order := 3, Normalizing := true);
false
```

Note the difference in the output of `CosetSatisfying` and `CosetsSatisfying`: The former takes into account only cosets other than H, whereas the latter (unless we set the parameter `First`) includes the coset H, which obviously satisfies the specified conditions.

```
> CosetSatisfying(P : Order := 3, Normalizing := true);
{}
> CosetsSatisfying(P : Order := 3, Normalizing := true);
{ Id(G) }
```

71.3.5 Induced Permutation Representations

Given a finite index subgroup H of a group G, the action of G on the set of right cosets of H in G by right multiplication defines a permutation representation $\rho : G \to S$ of G onto a suitable subgroup S of the symmetric group on $[G : H]$ letters. The kernel of ρ is the core of H in G, the maximal normal subgroup of G contained in H.

`CosetAction(P)`

Given a coset enumeration process P with underlying group G and subgroup H for which a valid finite index has been obtained, this function returns

(a) The permutation representation ρ of G, induced by the action of G on the set of right cosets of H in G.

(b) The image group $\rho(G)$.

(c) (if possible) the kernel of ρ.

This function can only be called, if the last enumeration done for P has completed successfully with a finite index. Otherwise, a call to `CosetAction` will cause a run-time error. Use the function `HasValidIndex` to check whether a call to `CosetAction` is legal for a certain coset enumeration process.

`CosetImage(P)`

Given a coset enumeration process P with underlying group G and subgroup H for which a valid finite index has been obtained, this function returns the image of the permutation representation ρ of G induced by the action of G on the set of right cosets of H in G as a permutation group on $[G : H]$ digits.

This function can only be called, if the last enumeration done for P has completed successfully with a finite index. Otherwise, a call to `CosetImage` will cause a runtime error. Use the function `HasValidIndex` to check whether a call to `CosetImage` is legal for a certain coset enumeration process.

`CosetKernel(P)`

Given a coset enumeration process P with underlying group G and subgroup H for which a valid finite index has been obtained, this function returns the kernel of the permutation representation ρ of G induced by the action of G on the set of right cosets of H in G. This function is only available if the index of H in G is sufficiently small.

This function can only be called, if the last enumeration done for P has completed successfully with a finite index. Otherwise, a call to `CosetKernel` will cause a run-time error. Use the function `HasValidIndex` to check whether a call to `CosetKernel` is legal for a certain coset enumeration process.

71.3.6 Coset Spaces and Transversals

The (right) indexed coset space V of the subgroup H of the group G is a G-set consisting of the set of integers $\{1, ..., m\}$, where i represents some right coset c_i of H in G. The action of G on this G-set is that induced by the natural G-action

$$f : V \times G \to V$$

where

$$f : \langle c_i, x \rangle = c_k \quad \Longleftrightarrow \quad c_i * x = c_k,$$

for $c_i \in V$ and $x \in G$. If certain of the products $c_i * x$ are unknown, the corresponding images under f are undefined, and V is called an *incomplete coset space* for H in G.

`CosetSpace(P)`

The coset space defined by the current state of the coset enumeration process P.

This function can be called for any coset enumeration process, which contains a valid coset table. (If P does not contain a valid coset table, a call to `CosetSpace` causes a runtime error. Use the function `HasValidCosetTable` to check whether a call to `CosetSpace` is legal for a certain coset enumeration process.) Note that the coset table of P need not be complete to use this function.

`RightCosetSpace(P)`

`LeftCosetSpace(P)`

The explicit right coset space of a subgroup H of some group G is a G-set containing the set of right cosets of H in G. The elements of this G-set are the pairs $\langle H, x\rangle$, where x runs through a transversal for H in G. Similarly, the explicit left coset space of H is a G-set containing the set of left cosets of H in G, represented as the pairs $\langle x, H\rangle$.

These functions return the explicit right (left) coset space defined by the current state of the coset enumeration process P.

This function can be called for any coset enumeration process, which contains a valid coset table. (If P does not contain a valid coset table, a call to any of these functions causes a runtime error. Use the function `HasValidCosetTable` to check whether a call to these functions is legal for a certain coset enumeration process.) Note that the coset table of P need not be complete to use these functions.

`Transversal(P)`

`RightTransversal(P)`

Given a coset enumeration process P with underlying group G and subgroup H for which a valid finite index has been obtained, these functions return

(a) An indexed set T of elements of G forming a right transversal for H in G; and

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = \{@\ t_1, \ldots, t_r\ @\}$ and $g \in G$, then ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

These functions can only be called, if the last enumeration done for P has completed successfully with a finite index. Otherwise, a call to any of these functions will cause a runtime error. Use the function `HasValidIndex` to check whether a call to these functions is legal for a certain coset enumeration process.

Example H71E7

We construct a coset enumeration process for the subgroup $H = \langle a^2, a^{-1}b\rangle$ in the group $G = \langle a, b \mid a^8, b^7, (ab)^2, (a^{-1}b)^3\rangle$ and start an enumeration.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | x^8, y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | a^2,a^-1*b>;
```

```
> P := CosetEnumerationProcess(G, H);
> StartEnumeration(~P);
```

After checking that a finite index has been obtained, we extract a transversal and the corresponding transversal map from P.

```
> HasValidIndex(P);
true
> T, f := Transversal(P);
> #T;
448
> f;
Mapping from: GrpFP: G to SetIndx: T
```

Finally, we construct the permutation representation of G on the cosets of H in G, its image and its kernel.

```
> r, S, K := CosetAction(P);
> r : Minimal;
Homomorphism of GrpFP: G into GrpPerm: S, Degree 448, Order 2^9 *
3 * 7
> S;
Permutation group S acting on a set of cardinality 448
Order = 10752 = 2^9 * 3 * 7
> K;
Finitely presented group K
Index in group G is 10752 = 2^9 * 3 * 7
Subgroup of group G defined by coset table
```

The kernel turns out to be trivial, i.e. the permutation representation is faithful.

```
> Order(K);
1
```

Example H71E8

Consider the subgroup H of the (infinite) group $G := \langle a, b \mid b^7, (a*b)^2, (a^{-1}*b)^3 \rangle$ generated by a. We create a coset enumeration process and start an enumeration with the default parameters.

```
> F<x, y> := FreeGroup(2);
> G<a, b> := quo<F | y^7, (x*y)^2, (x^-1*y)^3>;
> H := sub<G | a>;
> P := CosetEnumerationProcess(G, H);
> StartEnumeration(~P : Print := true);
Overflow
 (a=957026 r=415230 h=415230 n=999999;
  l=3553 c=2.38;
  m=960050 t=999998)
```

The enumeration produces a valid (albeit not complete) coset table.

```
> HasValidCosetTable(P);
```

```
true
> HasCompleteCosetTable(P);
false
```

We extract the incomplete coset space from the process.

```
> V := CosetSpace(P);
> #V;
957026
> IsComplete(V);
false
```

71.4 p-Quotients (Process Version)

Let F be a finitely presented group, p a prime and c a positive integer. A p-quotient algorithm constructs a consistent power-conjugate presentation for the largest p-quotient of F having lower exponent-p class at most c. For details of this algorithm, see [NO96].

Assume that the p-quotient has order p^n, Frattini rank d, and that its generators are $a_1, \ldots, a_n$. Then the power-conjugate presentation constructed has the following additional structure. The set $\{a_1, \ldots, a_d\}$ is a generating set for G. For each a_k in $\{a_{d+1}, \ldots, a_n\}$, there is at least one relation whose right hand side is a_k. One of these relations is taken as the *definition* of a_k. (The list of definitions is also returned by `pQuotient`.) The power-conjugate generators also have a *weight* associated with them: a generator is assigned a weight corresponding to the stage at which it is added and this weight is extended to all normal words in a natural way.

The p-quotient process and its associated commands allows the user to construct a power-conjugate presentation (pcp) for a p-group.

71.4.1 The p-Quotient Process

`pQuotientProcess(F, p, c`: *parameters*`)`

Given an fp-group F, a prime p and a positive integer c, create a p-quotient process for the group F with the indicated arguments. As part of the initialisation of the process, a pcp for the largest p-quotient of F having class at most c will be constructed. If c is given as 0, then the limit 127 is placed on the class. This function supports the same parameters as `pQuotient` and returns a process P.

`NextClass(~P : parameters)`

`NextClass(~P, k : parameters)`

`Exponent`	RngIntElt	*Default :*
`Metabelian`	BoolElt	*Default :*
`Print`	RngIntElt	*Default :*
`MaxOccurrence`	[RngIntElt]	*Default :* []

Assumes that a pcp has already been constructed for the class c quotient of F. It seeks to construct a pcp for the class $c+1$ p-quotient of F. If `k` is supplied, continue to construct until the pcp for the largest quotient of class k is constructed.

The parameters `Exponent`, `Print`, and `Metabelian` are used as before. If `MaxOccurrence := Q`, then the sequence Q has length equal to the rank of the class 1 quotient of F; its entries are integers which specify the maximum number of occurrences of the class 1 generators in the definitions of pcp generators of F. An entry of 0 for a particular generator indicates that no limit is placed on the number of occurrences of this generator.

Care should be exercised when supplying values for parameters. Once set, they retain their values until explicitly reassigned.

71.4.2 Using p-Quotient Interactively

We assume that we have constructed a pcp for the largest class c p-quotient of F and now seek to construct a pcp for the largest class $c+1$ p-quotient.

The following options allow the user to construct a pcp for the next class of the group interactively. The steps are laid out in one of a number of natural sequences in which they may be executed. Some of them may be interleaved; however, the user should pay particular attention to the assumptions mentioned below. The procedures that drive the process do not verify that the assumptions are satisfied.

`StartNewClass(~P: parameters)`

If P is a process for a class c p-quotient, commence construction of class $c+1$.

`Tails(~P: parameters)`

`Tails(~P, k: parameters)`

`Metabelian`	BoolElt	*Default :* `false`

Add tails to the current pcp; default is to add all tails for this class. If `k` is supplied, then tails for weight k only are added; in this case, it is assumed that the tails for each of weight $c+1, c, \ldots, k+1$ have already been added. The valid range of k is $2, \ldots, c+1$. The one valid parameter is `Metabelian`; if `true`, then only the tails for the metabelian p-quotient are inserted.

`Consistency(~P: parameters)`

`Consistency(~P, k: parameters)`

`Metabelian` BoolElt *Default :* `false`

Apply the consistency algorithm to the pcp to compute any redundancies among the tails already added. Default is to apply it to all tails; in this case, it is assumed that all tails have been added. If `k` is supplied, it is assumed that tails for weight k have been added; in this case, the tails added for weight k only are checked. The range of k is $3, \ldots, c+1$. The one valid parameter is `Metabelian`; if `true`, we assume that the tails inserted were those for a metabelian p-quotient and hence invoke the (less expensive) metabelian consistency algorithm.

`CollectRelations(~P)`

Collect the defining relations (if any) in the current pcp. If the tails operation is not complete, then the relations may be evaluated incorrectly.

`ExponentLaw(~P : parameters)`

`ExponentLaw(~P, Start, Fin: parameters)`

Enforce the supplied exponent law on the current pcp. If `Start` and `Fin` are supplied, then enforce the law for those weights between `Start` and `Fin`; otherwise, enforce the law for all weights. It is assumed that the tails operation is complete. If the display parameter `DisplayLevel` (which may be set using `SetDisplayLevel`) has value 2, those words whose powers are collected and give redundancies among the pcp generators are printed out. If `DisplayLevel` has value 3, all words whose powers are collected are printed out. The following additional parameters are available:

`Exponent` RngIntElt *Default :* 0

If `Exponent := m`, enforce the exponent law, $x^m = 1$, on the group.

`Print` RngIntElt *Default :* 1

As for `pQuotient`.

`Trial` BoolElt *Default :* `false`

Generate the list of words used to enforce the exponent law and print out statistics but do not power words or echelonise the results.

`ShortList` BoolElt *Default :* `false`

Generate the list of enforcement words whose entries have the form w or $1 * w$ where w is an element of the Frattini subgroup of F.

`DisplayList` BoolElt *Default :* `false`

Display the list of all enforcement words generated – not just those which are collected.

`IdentifyFilters` BoolElt *Default :* `false`

Identify filters used to eliminate words from list.

`InitialSegment` [<GrpFPElt, RngIntElt>] *Default :* []

If `InitialSegment := w`, generate only those enforcement words which have w as an initial segment, where w is supplied as a sequence of generator-exponent pairs.

`Report` RngIntElt *Default :* 0

If `Report := n`, report after computing the powers of each collection of n enforcement words.

`EliminateRedundancy(~P)`

Eliminate all redundant generators from the pcp defined by process P. This operation may be performed at any time.

We now list the remaining functions which can be applied to a pQuotient process.

`Display(P)`

`Display(P, DisplayLevel)`

Display the pcp for the p-quotient G of the fp-group F. The argument `DisplayLevel` may be 1, 2, or 3, and is used to control the amount of information given:

`1` : Display order and class of G;

`2` : Display non-trivial relations for G;

`3` : Display the structure of pcp generators of G, non-trivial relations of G, and the map from the defining generators of F to the pcp generators of G.

The presentation displayed by this function is in power-commutator form. If `DisplayLevel` is not supplied, the information displayed is determined by its existing (or default) value.

`RevertClass(~P)`

Given a pcp for the class $c+1$ p-quotient of F, this procedure reverts to the pcp for the class c p-quotient of F. Note that this command can be applied only **once** during construction of a single class.

`pCoveringGroup(~P)`

`pCoveringGroup(`G`)`

Given a process or a pcp for a p-group, this procedure computes a pcp for the p-covering group of this group. In the process case, it is equivalent to `Tails(~P); Consistency(~P); EliminateRedundancy(~P)`.

`GeneratorStructure(P)`

`GeneratorStructure(P, Start, Fin)`

Display the structure of the generators in the pcp. If `Start` and `Fin` are given, then print out the structure of those pcp generators numbered from `Start` to `Fin`.

`Jacobi(~P, c, b, a, ~r)`

`Jacobi(~P, c, b, a)`

Calculate the Jacobi c, b, a and echelonise the resulting relation against the current pcp. If a redundant generator results from the echelonisation, the optional variable r is the number of that generator; otherwise r has value 0.

`Collect(P, Q)`

The sequence Q, consisting of generator-exponent pairs, defines a word w in the pcp generators of the group defined by the process P. Collect this word and return the resulting normal word as an exponent vector.

`EcheloniseWord(~P, ~r)`

`EcheloniseWord(~P)`

Echelonise the word most recently collected using `Collect` against the relations of the pcp. If a redundant generator results from the echelonisation, the optional variable r is the number of that generator; otherwise r has value 0. This function must be called immediately after `Collect`.

`SetDisplayLevel(~P, Level)`

This procedure alters the display level for the process to the supplied value, `Level`.

`ExtractGroup(P)`

Extract the group G defined by the pcp associated with the process P, as a member of the category `GrpPC` of finite soluble groups. The function also returns the natural homomorphism π from the original group F to G, a sequence S describing the definitions of the pc-generators of G and a flag indicating whether G is the maximal p-quotient of F.

The k-th element of S is a sequence of two integers, describing the definition of the k-th pc-generator $G.k$ of G as follows.

- If $S[k] = [0, r]$, then $G.k$ is defined via the image of $F.r$ under π.
- If $S[k] = [r, 0]$, then $G.k$ is defined via the power relation for $G.r$.
- If $S[k] = [r, s]$, then $G.k$ is defined via the conjugate relation involving $G.r^{G.s}$.

`Order(P)`

The order of the group defined by the pcp associated with the process P.

`FactoredOrder(P)`

The factored order of the group defined by the pcp associated with the process P.

`NumberOfPCGenerators(P)`

The number of pc-generators of the group defined by the pcp associated with the process P.

pClass(P)

The lower exponent-p class of the group defined by the pcp associated with the process P.

NuclearRank(G)

NuclearRank(P)

Return the rank of the p-multiplicator of the p-group G, where G may be supplied or defined by the process P.

pMultiplicatorRank(G)

pMultiplicatorRank(P)

Return the rank of the p-multiplicator of the p-group G, where G may be supplied or defined by the process P.

Example H71E9

Starting with an exponent 9 group having two generators of order 3, we set up the largest class 4 quotient and then interactively compute two more classes.

```
> G<a, b> := Group<a, b | a^3, b^3>;
> q := pQuotientProcess(G, 3, 4: Exponent := 9, Print :=1);

Lower exponent-3 central series for G

Group: G to lower exponent-3 central class 1 has order 3^2

Group: G to lower exponent-3 central class 2 has order 3^3

Group: G to lower exponent-3 central class 3 has order 3^5

Group: G to lower exponent-3 central class 4 has order 3^7
> Display(q, 2);

Group: G to lower exponent-3 central class 4 has order 3^7

Non-trivial powers:
 .3^3 = .6^2

Non-trivial commutators:
[ .2, .1 ] = .3
[ .3, .1 ] = .4
[ .3, .2 ] = .5
[ .4, .1 ] = .6
[ .4, .2 ] = .7
[ .5, .1 ] = .7
```

```
[ .5, .2 ] = .6
```

We construct the class 5 quotient using the function NextClass.

```
> NextClass(~q);
```

```
Group: G to lower exponent-3 central class 5 has order 3^9
```

We now construct the class 6 quotient step by step. For this, we set the output level to 1.

```
> SetDisplayLevel(~q, 1);
```

Now we start the next class.

```
> StartNewClass(~q);
```

The first step is to add the tails.

```
> Tails(~q);
```

After that, we apply the consistency algorithm,...

```
> Consistency(~q);
```

... collect the defining relations,...

```
> CollectRelations(~q);
```

... and enforce the exponent law.

```
> ExponentLaw(~q);
```

Finally, we eliminate redundant generators.

```
> EliminateRedundancy(~q);
```

This results in the following presentation for class 6 quotient.

```
> Display(q, 2);
```

```
Group: G to lower exponent-3 central class 6 has order 3^11

Non-trivial powers:
 .3^3 = .6^2 .8^2 .10 .11

Non-trivial commutators:
[ .2, .1 ] = .3
[ .3, .1 ] = .4
[ .3, .2 ] = .5
[ .4, .1 ] = .6
[ .4, .2 ] = .7
[ .4, .3 ] = .8 .10^2 .11^2
[ .5, .1 ] = .7 .8 .9^2 .10^2 .11^2
[ .5, .2 ] = .6 .8 .9^2 .10^2
[ .5, .3 ] = .9^2 .11
[ .5, .4 ] = .10 .11
```

```
[ .6, .2 ] = .10^2
[ .7, .1 ] = .8
[ .7, .2 ] = .9
[ .7, .3 ] = .10^2 .11
[ .8, .2 ] = .10
[ .9, .1 ] = .11
```

Example H71E10

Starting with the free product of two cyclic groups of order 5, we bound the number of occurrences of pcp generators of the class 1 quotient in definitions of new pcp generators.
We start with setting up the class 1 quotient of the group.

```
> G := Group<a, b | a^5, b^5>;
> q := pQuotientProcess(G, 5, 1);
> Display(q, 1);
Group: G to lower exponent-5 central class 1 has order 5^2
```

Now we start the next class, setting bounds on the number of occurrences of the pcp generators of the class 1 quotient in the definitions of new pcp generators.

```
> NextClass(~q, 6: MaxOccurrence := [3, 2]);
Group: G to lower exponent-5 central class 2 has order 5^3
Group: G to lower exponent-5 central class 3 has order 5^5
Group: G to lower exponent-5 central class 4 has order 5^7
Group: G to lower exponent-5 central class 5 has order 5^9
> Display(q, 2);
Group: G to lower exponent-5 central class 5 has order 5^9
Non-trivial powers:
Non-trivial commutators:
[ .2, .1 ] = .3
[ .3, .1 ] = .4
[ .3, .2 ] = .5
[ .4, .1 ] = .6
[ .4, .2 ] = .7
[ .4, .3 ] = .8^4 .9
[ .5, .1 ] = .7 .8^4 .9
[ .6, .2 ] = .8
[ .7, .1 ] = .9
```

Example H71E11

We construct the class 6 quotient q of $R(2,5)$ and then partially construct the class 7 quotient interactively to find out how many normal words having initial segment $q.1^2$ need to be considered when imposing the exponent law.

```
> F := FreeGroup(2);
> q := pQuotientProcess(F, 5, 6: Exponent := 5);
Lower exponent-5 central series for F
```

```
Group: F to lower exponent-5 central class 1 has order 5^2
Group: F to lower exponent-5 central class 2 has order 5^3
Group: F to lower exponent-5 central class 3 has order 5^5
Group: F to lower exponent-5 central class 4 has order 5^8
Group: F to lower exponent-5 central class 5 has order 5^10
Group: F to lower exponent-5 central class 6 has order 5^14
> StartNewClass(~q);
> Tails(~q);
> Consistency(~q);
> SetDisplayLevel(~q, 3);
> ExponentLaw(~q, 1, 6: InitialSegment := [<1, 2>], Trial := true);
0 Relations of class 1 will be collected
0 Relations of class 2 will be collected
Will collect power 5 of the following word: 1^2 2^1
1 Relation of class 3 will be collected
Will collect power 5 of the following word: 1^2 2^2
1 Relation of class 4 will be collected
Will collect power 5 of the following word: 1^2 2^3
Will collect power 5 of the following word: 1^2 5^1
2 Relations of class 5 will be collected
Will collect power 5 of the following word: 1^2 2^4
Will collect power 5 of the following word: 1^2 2^1 4^1
2 Relations of class 6 will be collected
```

Example H71E12

We demonstrate several of the remaining procedures in the course of interactively extending the class 6 quotient of the group

$$< a, b, c, d \mid (bc^{-1}d)^7, (cd^{-1})^7, (b, a) = c^{-1}, (c, a) = 1, (c, b) = d^{-1} >$$

to class 7.

```
> G := Group<a, b, c, d | (b * c^-1 * d)^7, (c * d^-1)^7, (b,a) = c^-1,
>                         (c,a) = 1, (c,b) = d^-1>;
> q := pQuotientProcess(G, 7, 6);
Lower exponent-7 central series for G
Group: G to lower exponent-7 central class 1 has order 7^2
Group: G to lower exponent-7 central class 2 has order 7^4
Group: G to lower exponent-7 central class 3 has order 7^6
Group: G to lower exponent-7 central class 4 has order 7^8
Group: G to lower exponent-7 central class 5 has order 7^11
Group: G to lower exponent-7 central class 6 has order 7^14
> StartNewClass(~q);
> Tails(~q);
> GeneratorStructure(q, 15, 34);
Class 7
15 is defined on [12, 1] = 2 1 2 2 1 2 1
```

```
16 is defined on [12, 2] = 2 1 2 2 1 2 2
17 is defined on [13, 1] = 2 1 2 2 2 2 1
18 is defined on [13, 2] = 2 1 2 2 2 2 2
19 is defined on [14, 1] = 1 1 1 1 1 1 1
20 is defined on [14, 2] = 1 1 1 1 1 1 2
21 is defined on 14^7 = 1 1 1 1 1 1 1
22 is defined on [9, 1] = 2 1 2 2 1 1
23 is defined on [10, 1] = 2 1 2 2 2 1
24 is defined on [11, 1] = 1 1 1 1 1 1
25 is defined on [11, 2] = 1 1 1 1 1 2
26 is defined on [8, 1] = 1 1 1 1 1
27 is defined on [8, 2] = 1 1 1 1 2
28 is defined on [5, 1] = 2 1 2 1
29 is defined on [6, 1] = 1 1 1 1
30 is defined on [6, 2] = 1 1 1 2
31 is defined on [3, 1] = 2 1 1
32 is defined on [4, 1] = 1 1 1
33 is defined on [4, 2] = 1 1 2
34 is defined on 2^7 = 2 2
> Jacobi(~q, 6, 6, 1);
Generator 26 is trivial
Jacobi was 6 6 1
> Jacobi(~q, 3, 2, 1);
Generator 28 is redundant
Jacobi was 3 2 1
> v := Collect(q,  [<29, 2>, <26, -3>]);
> v;
[ 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
    0, 0, 0, 4, 0, 0, 2, 0, 0, 0, 0, 0 ]
> EcheloniseWord(~q, ~redgen);
Generator 29 is trivial
> Display(q, 1);
Group: G to lower exponent-7 central class 7 has order 7^34
```

Now we enforce the relations...

```
> CollectRelations(~q);
```

...and apply the consistency algorithm.

```
> Consistency(~q);
> Display(q, 1);
Group: G to lower exponent-7 central class 7 has order 7^36
> EliminateRedundancy(~q);
> Display(q, 1);
Group: G to lower exponent-7 central class 7 has order 7^19
```

71.5 Soluble Quotients

71.5.1 Introduction

This section presents a short overview towards the theory of the soluble quotient algorithm, the functions designed for computing soluble quotients and the functions designed for dealing with soluble quotient processes.

71.5.2 Construction

For a finite group G, the property of being soluble means that the derived series $G = G^{(0)} > G^{(1)} > ... > G^{(n)}$ terminates with $G^{(n)} = \langle 1 \rangle$. Each section $G^{(i)}/G^{(i+1)}$ is a finite abelian group, hence it can be identified with a $\mathbf{Z}G/G^{(i)}$-module M, where the action of $G/G^{(i)}$ on M is given by the conjugation action on $G^{(i)}/G^{(i+1)}$.

From module theory we see that there exists a series $M = M^{(0)} > M^{(1)} > ... > M^{(r_i)}$, where each section is an irreducible $GF(p)$ $G/G(i)$-module for some prime p. Using these series we obtain a refinement $G = G_{(0)} > G_{(1)} > ... > G_{(n)} = \langle 1 \rangle$ of the commutator series with the properties:

- The series is normal,
- Each section $G_{(i)}/G_{(i+1)}$ is elementary abelian of prime power order, and is irreducible as a $G/G_{(i)}$-module.
- If $G = H_{(0)} > H_{(1)} > ... > H_{(t)} = \langle 1 \rangle$ is another series with these properties, then $n = t$ and there exists a permutation $\pi \in S_n$ such that $G_{(i)}/G_{(i+1)}$ is isomorphic to $H_{(i\pi)}/H_{(i\pi+1)}$ (as $GF(p)$ modules).

Note: A PC-presentation defined by a further refinement of this series leads to a "conditioned" presentation. The converse is not always true, because the irreducibility of the sections is not required for a conditioned presentation.

The soluble quotient algorithm uses these series to construct soluble groups. Starting with the trivial group $G/G_{(0)}$, it successively chooses irreducible $G/G_{(i)}$ modules M_i and extensions

$$\zeta_i \in H^2(G/G_{(i)}, M_i)$$

which give rise to exact sequences

$$1 \to M_i \to G/G_{(i+1)} = G/G_{(i)}.M_i \to G/G_{(i)} \to 1.$$

To describe the algorithmic approach, we consider the following situation. Let G be a finite soluble group, M a normal elementary abelian subgroup of G such that M is a $H = G/M$ irreducible module. (The action of H on M is identified with the conjugation action of G/M on the subgroup M.) Then the relations of the group G have the shape

$$g_i^{p_i} = w_i m_i \text{ resp. } g_j^{g_i} = w_{ij} m_{ij}, m_i, m_{ij} \in M$$

where w_i, w_{ij} are the canonical representatives of H in G. Then $\bar{g_i}^{p_i} = \bar{w_i}$ resp. $\bar{g_j}^{\bar{g_i}} = \bar{w_{ij}}$ is a PC-presentation of H and the set of images $\left((g_i^{p_i-1}, g_i) \to m_i, (g_j, g_i) \mapsto m_{ij}\right)$ determines a unique element of the cocycle space $C^2(H, M)$.

According to the p-group situation, we call the system $t = (m_i, m_{ij})$, the tail defining $G = H.M_t$ as an extension of M by H.

Not every choice of a system $t = (m_i, m_{ij})$ defines an extension. To make sure that t corresponds to an element s of $C^2(G, M)$ it must satisfy a certain equation system, the so-called consistency equations (see Vaughan-Lee). These are linear homogeneous equations in M, so the solution space can be determined.

For the construction of soluble quotients we also have to find the epimorphism $\varepsilon : F \twoheadrightarrow G$. The existence of the epimorphism is obviously a restriction of the possible images G, and it can be checked simultaneously with constructing G. Let G be an extension $G = H.M$, where M is a H-module and H is a known soluble quotient $\delta : F \twoheadrightarrow H$. Then δ is uniquely determined by the images $\delta(f_i) = h_i, 1 \leq i \leq r$, where $\{f_1, \ldots, f_r\}$ is a generating set of F. We want to find a lift ε of δ, i.e. $\varepsilon(f) = \delta(f) \bmod M$ for all $f \in F$. This means that $\varepsilon(f_i) = h_i x_i$ for all $i \leq r$, where $x_i \in M$ are to be determined. Since ε will be a homomorphism, we require $\varepsilon(r_j(f_1, \ldots, f_r)) = 1_G$ for the defining relations r_j of F. This leads to a linear equation system for the variables $(x_1, \ldots, x_r) \in M^r$. We solve this equation system together with the consistency equations, hence we find a subspace S of $M^r \times H^2(H, M)$ of those extensions for which the epimorphism δ has a lift. Let us call an element of S an extended tail.

Let K be the minimal splitting field of M, i.e. the character field of the unique character of H which corresponds to M. Then M is obviously a KH-module and S is also a K-space. The space S has a K-subspace S_S of split extensions, i.e. the projection of S_S into $H^2(H, M)$ is only the trivial element. For any element $t \in S/S_S$ the corresponding map $\varepsilon_t : F \to H.M_t$ is necessarily surjective, hence defines a soluble quotient. Let s_1, s_2 be two elements of S/S_S and let $\varepsilon_i : F \twoheadrightarrow H.M_{s_i} =: G_i$ denote the corresponding soluble quotients. If s_1 and s_2 are K-linear dependent, the groups G_1 and G_2 will be isomorphic. Unfortunately, the converse is not true, even K-linear independent elements may lead to isomorphic groups. Nevertheless, if s_1 and s_2 are independent, the kernels of the epimorphisms will be different, hence one can iterate the lifting to

$$\varepsilon_{1,2} : F \twoheadrightarrow (G_1).M_{s_2} = (H.M_{s_1}).M_{s_2} = H.(M \oplus M)_{s_1 \cdot s_2}.$$

(The last equality can be read as a definition of $s_1 \cdot s_2$ in the righthand side term.)

The dimension $a = dim_K(S/S_S)$ is therefore characterised as the maximal multiplicity

$$a = max\left\{z \in \mathbf{Z}^+ \mid \exists \varepsilon : F \twoheadrightarrow H, M^z\right\}.$$

S_S itself also has a K-subspace S_C, for which the map

$$\varepsilon_s : F \to H.M_s, s \in S_C$$

is not surjective. The K-dimension $b = dim_K(S_S/S_C)$ is again characterised as the maximal multiplicity

$$b = \max\left\{z \in \mathbf{Z}^+ \mid \exists \varepsilon : F \twoheadrightarrow H, M^z\right\}.$$

Moreover, after taking a maximal extension $\varepsilon : F \twoheadrightarrow H.M^b$, M never has to be considered for split extensions again.

71.5.3 Calculating the Relevant Primes

A crucial step in finding finite soluble quotients $\varepsilon : F \twoheadrightarrow G$ is the calculation of the relevant primes, i.e. the prime divisors of $|G|$. This is the most time consuming part of the algorithm, so it is crucial to apply it as efficiently as possible, and any other information about possible prime divisors is very helpful. We do not explain this calculation in detail. However, to use the functions and options provided by MAGMA in a correct manner, we outline the idea of the calculation.

Let $\varepsilon : F \twoheadrightarrow G$ be a finite soluble quotient and let N denote the kernel of ε. If a module M allows an extension $\bar{\varepsilon} : F \twoheadrightarrow G.M$, then M must be a constituent of N/N', and the relevant primes are the prime divisors of N/N'. Again N/N' can be viewed as an F/N-module, hence an H-module. Therefore it is a direct sum $N/N' \cong M_{p_1} \oplus M_{p_2} \oplus \ldots \oplus \mathbf{Z}^d$, where the M_{p_i} are finite modules of order a power of the prime p_i. Let p not divide $|H|$. Then by Zassenhaus the extension $H.M_p$ must split. We consider an irreducible module M in the head of M_p, i.e. there is an H-epimorphism $M_p \twoheadrightarrow M$. Then there is a valid soluble quotient $\varepsilon : F \twoheadrightarrow H.M$ and the extension $H.M$ splits.

Now there exists an irreducible $\mathbf{Z}H$- module L such that M is a $GF(p)$-modular constituent of L/pL. Moreover, $\Delta : H \to GL(L)$ is the corresponding representation of H and any Δ-module will have this property.

Now using the theory of space groups, one can construct homomorphisms $\varepsilon_1 : F \twoheadrightarrow H.L$ and $\varepsilon_2 : H.L \twoheadrightarrow H.M$ such that the composition is surjective. Hence p can be detected in Δ. Let P_Δ denote the set of primes obtained from Δ. To find these primes, we have to know a set D of representatives of the irreducible rational representations of F/N, hence of H. The set of prime divisors of K/K' is a subset of

$$P = \bigcup_{\Delta \in D} P_\Delta \cup \{p \mid p \text{ prime}, p \mid |G|\}.$$

We want to point out the following:

- Usually the set of primes dividing $|K/K'|$ is a proper subset of P, because the primes dividing $|G|$ may or may not divide $|K/K'|$.

  Conversely, if p does not divide $|G|$, then there certainly exists a module M in characteristic p such that there is a soluble quotient $F \twoheadrightarrow G.M$, and the extension splits.
- The algorithm can also recognise infinite abelian sections. This means that already $\varepsilon_1 : F \twoheadrightarrow H.L$ is surjective. All primes are relevant and no maximal finite soluble quotient exists.
- Let $\phi : F \twoheadrightarrow H$ be a lift of $\varepsilon : F \twoheadrightarrow G$, i.e. G is a quotient of H: $\phi : H \twoheadrightarrow G$. If the relevant primes of G are known, these are also relevant primes of H, and only those representations Δ of H must be considered for which $\ker \phi \not\subset \ker \Delta$ is valid.

71.5.4 The Functions

MAGMA provides two different ways to calculate finite soluble quotients: a main function for the whole calculation, and a process which gives control over each individual step.

Let F be a finitely presented group.

`SolubleQuotient(F, n : parameters)`
`SolvableQuotient(F, n : parameters)`
`SolubleQuotient(F : parameters)`
`SolvableQuotient(F : parameters)`
`SolubleQuotient(F, P : parameters)`
`SolvableQuotient(F, P : parameters)`

Find a soluble quotient $\varepsilon : F \twoheadrightarrow G$ with a specified order. n must be a nonnegative integer. P must be a set of primes.

The three forms reflect possible information about the order of an expected soluble quotient. In the first form the order of G is given by n, if n is greater than zero. If n equals zero, nothing about the order is known and the relevant primes will be calculated completely.

The second form, with no n argument, is equivalent to the first with $n = 0$. This is a standard argument, and usually it is the most efficient way to calculate soluble quotients.

Note that, if $n > 0$ is not the order of the maximal finite soluble quotient, it may happen that no group of order n can be found, since an epimorphic image of size n may not be exhibited by the chosen series.

In the third form a set P of relevant primes is given. The algorithm calculates the biggest quotient such that the order has prime divisors only in P. P may have a zero as element, this is just for consistency reasons. It is equivalent to the first form with n equal zero.

The returned values are the group G and the epimorphism $\varepsilon : F \twoheadrightarrow G$. The third returned value is a sequence describing the series and modules by which G has been constructed.

The fourth value is a string which explain the reason for termination. The following list gives the termination conditions. The algorithm terminates normally if:

1. A quotient of the given order has been constructed.
2. A maximal quotient (with respect to the conditions given on the order) has been constructed.

The algorithm will be aborted and returns a warning if:

3. A bound on the length of a series or subseries has been hit.
4. A limit on the size of the quotient or a section has been hit.
5. The algorithm detects a free abelian section.

With the following options one can define abort conditions corresponding to the third and fourth item. The idea of all these conditions is to control the occurrence of infinite soluble quotients.

`SeriesLength` RngIntElt *Default :* 0

Limits the length of the chief series to r. For sag-series it is the nilpotent length of the series, for derived series it is the derived length. The default value of zero means no limit.

If the algorithm hits the limit, it gives a warning message and returns the last soluble quotient.

`SubseriesLength` RngIntElt *Default :* 0

Limits the length of a series in a section. If the sag-series is used, it is the length of the lower descending series. For the derived series, the limit is applied to the exponent of an element of a section with maximal prime power order. For example, if the limit is set to 3, the limit would be hit by a section of type C_8, but not by C_2^3 and not even by C_4^2.

`#QuotientSize` RngIntElt *Default :* 0

If the value n is bigger than zero, the algorithm returns if a quotient of order bigger or equal to n has been found. A warning message will be printed.

`#SectionSize` RngIntElt *Default :* 0

If the value s is bigger than zero, the algorithm returns if the order of a section is bigger than or equal to s. A warning message will be printed.

Note: Since an additive bound on a group order is not as meaningful as a multiplicative bound, the latter options are only useful as break conditions when the quotient gets too big for further calculations. The return quotient which hits such a bound is somewhat randomly chosen, since only a change in the order of checking modules may lead to other quotients.

With the following options the strategy of the algorithm and some subalgorithms can be chosen.

`#MSQ_Series` MonStgElt *Default :* "*sag*"

Determines the series which is used for the construction of soluble groups.

The default value is `"sag"`, since it is usually the most efficient choice. Of course, there is a value `"derived"`, exhibiting the derived series.

Another choice is `"lowercentral"`, choosing the lower central series. This restricts the algorithm to finite nilpotent quotients. The choice `"pcentral"` only exhibits p-groups as quotients.

The nilpotent resp. p-quotient algorithms are usually more efficient, so these options may only be useful to obtain additional information needed for a SQ-process.

`MSQ_PrimeSearchModus` RngIntElt *Default :* 3

Defines at what status of the algorithm the relevant prime search is called.

The possible choices reflect the different intentions of constructing a soluble quotient; for the general situation, (i.e. finding a finite soluble quotient without any information about relevant primes and check its maximality) this option makes only little difference in runtime behaviour.

0: No calculation of relevant primes. This is the default value, if the second argument does not request a prime calculation, e.g. if the order of the quotient or its relevant primes are known.

1: The relevant primes will be calculated after the soluble quotient algorithm (with the given input) terminates normally. Possibly new relevant primes are returned in a message. If, for example, the second argument is a set S (so no limit on the exponent) and no new relevant primes have been found, the maximality of the soluble quotient is proved.

2: As 1, but continues the algorithm when finding new relevant primes.

3: Perform the relevant prime calculation after a "main" step in the series, i.e. after completing a nilpotent section in a sag-series resp. a commutator section for the derived series. This is the default value, if prime calculation is required by the second argument. It is a good choice if one wants to construct large finite quotients quickly.

Note: This option can cause problems in case of a sag-series when infinite soluble quotients exist. For finite quotients, it seems to be the best choice.

4: Perform the relevant prime calculation after calculating an elementary abelian layer. This option is preferable, if the sag-series is used and an infinite soluble quotient is possible.

5: Perform the relevant prime calculation after each successful lift of a quotient. This option is preferable when infinite sections shall be detected as soon as possible (with respect to the chosen series).

`MSQ_ModulCalcModus` RngIntElt *Default :* 0

In the construction of soluble quotients using a sag-series one can restrict the number of modules by using tensor products and skew symmetric products. This can improve the performance in the case of big soluble quotients, for small quotients the overhead may invalidate the improvement. For other series this option has no meaning. The possible values are:

0: Do not apply this technique (default).

1: Fast version, just apply those parts which can be calculated quickly.

2: Full version, this is only recommended for "big" soluble quotients, i.e. quotients with long descending series in nilpotent sections.

`MSQ_CollectorModus` RngIntElt *Default :* 2

Defines the setup modus for the symbolic collector, i.e. the ratio of precalculation to dynamic setup:

0: Full precalculation, preferable for small soluble groups.

1: Partial precalculation (test version).

2: Dynamic setup (default).

The function also provides a general print option determining the amount of timings status information during the function call. Additionally there are some

verbose flags which determine the amount of information given about various sub-algorithms. If both a general print value and a verbose flag are given, the verbose flag has higher preference.

`Print` RngIntElt *Default :* 0

Determines what timing information and status messages are given during the calculation (0 = no printing, 5 = maximal information).

Verbose `MSQ_Messages` *Maximum :* 2

If set to 1, the sizes of new soluble quotients are printed.

Verbose `MSQ_PrimeSearch` *Maximum :* 15

Bitflag for print levels during the calculation of relevant primes:

1: Timings and statistics about the calculation of rational representations.

2: Timings for transforming rational into integral representations.

4: Timing for finding the relevant primes.

8: Printing of new relevant primes.

Verbose `MSQ_RepsCheck` *Maximum :* 3

1: Timing for checking extensions of modules.

2: Statistics about the modules to be checked.

Verbose `MSQ_RepsCalc` *Maximum :* 3

1: Timing information about the module calculation.

2: Statistics about the module calculation.

Verbose `MSQ_Collector` *Maximum :* 1

If set to 1, the timing for the setup of the symbolic collector is printed.

Verbose `MSQ_TraceFunc` *Maximum :* 2

Give messages about the main function calls (1) resp. most function calls (2) in the Magma language during the algorithm.

72 POLYCYCLIC GROUPS

Chapter 72
POLYCYCLIC GROUPS

72.1 Introduction

In this chapter, we consider a class of finitely presented groups for which the word problem is solvable, the category of – possibly infinite – polycyclic groups. The corresponding MAGMA category is called `GrpGPC`. To distinguish this class from finite solvable groups described by a power-conjugate presentation (MAGMA category `GrpPC`, cf. Chapter 63), we use the term *general polycyclic group*.

An introduction to the theory of polycyclic groups and a collection of some basic algorithms can be found in [Sim94, ch. 9]. Unless otherwise mentioned, implementations of MAGMA functions are mostly based on ideas described in this reference.

72.2 Polycyclic Groups and Polycyclic Presentations

72.2.1 Introduction

A polycyclic group is a group G with a subnormal series $G = G_1 \triangleright G_2 \triangleright \ldots \triangleright G_{n+1} = 1$ in which each of the quotients G_i/G_{i+1} is cyclic. Every polycyclic group G has a presentation of the form

$$\begin{aligned} < a_1, \ldots, a_n \mid\ & a_i^{m_i} = w_{i,i} \quad (i \in I), \\ & a_j^{a_i} = w_{i,j} \quad (1 \leq i < j \leq n), \\ & a_j^{a_i^{-1}} = w_{-i,j} \quad (1 \leq i < j \leq n, i \notin I) > \end{aligned}$$

where

(i) $I \subseteq \{1, \ldots, n\}$,

(ii) $m_i > 1$ for $i \in I$, and

(iii) the words $w_{i,j}$ are of the form $w_{i,j} = a_{|i|+1}^{l(i,j,|i|+1)} \ldots a_n^{l(i,j,n)}$, with $0 \leq l(i,j,k) < m_k$ if $k \in I$.

Such a presentation is called a *polycyclic presentation* for G. For $1 \leq i \leq n$, let G_i be the subgroup of G generated by $a_i, \ldots, a_n$ and define G_{n+1} to be the trivial group. The presentation is called *consistent*, if $|G_i/G_{i+1}| = m_i$ whenever $i \in I$ and G_i/G_{i+1} is infinite whenever $i \notin I$. The generators $a_1, \ldots a_n$ are referred to as *polycyclic generators* (*pc-generators*) for G and the values m_i $(i \in I)$ are called the corresponding *pc-exponents*.

In MAGMA, the user can define a polycyclic group by providing a consistent polycyclic presentation or by using one of the existing category transfer functions.

Given a consistent polycyclic presentation for G, every element a of G can be written uniquely in the form $a = a_1^{e_1} \ldots a_n^{e_n}$, where the e_i are integers satisfying $0 \leq e_i < m_i$

if $i \in I$. This form is called *normal form*. There exists an algorithm (the *collection algorithm*), which given an arbitrary word in the generators $a_1, \ldots, a_n$, will determine the corresponding normal word. MAGMA uses a collection algorithm written by Volker Gebhardt. The cost of collection for this algorithm grows logarithmically in a bound on the absolute values of the exponents e_i occurring during the collection [Geb02].

Infinite polycyclic groups are a comparatively new topic in computational group theory and the number of available algorithms is much smaller than in the case of finite polycyclic groups. For this reason, the data type `GrpPC` (cf. Chapter 63) should be preferred for finite polycyclic groups.

72.2.2 Specification of Elements

Elements of polycyclic groups are words. A *word* is defined inductively as follows:

(i) A generator is a word;

(ii) The expression (u) is a word, where u is a word;

(iii) The product $u * v$ of the words u and v is a word;

(iv) The conjugate u^v of the word u by the word v is a word (u^v expands into the word $v^{-1} * u * v$);

(v) The power of a word u^n, where u is a word and n is an integer, is a word;

(vi) The commutator (u, v) of the words u and v is a word ((u, v) expands into the word $u^{-1} * v^{-1} * u * v$).

`G ! Q`

Given the polycyclic group G and a sequence Q of length n, containing integers $e_1 \ldots e_n$, where $0 \leq e_i < m_i$ if $i \in I$, construct the element x of G given by

$$x = a_1^{e_1} \ldots a_n^{e_n}.$$

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity element of the polycyclic group G.

72.2.3 Access Functions for Elements

Throughout this subsection, G will be a polycyclic group with pc-generators $a_1, \ldots, a_n$.

`ElementToSequence(x)`

`Eltseq(x)`

Given an element x belonging to the polycyclic group G, where $x = a_1^{e_1} \ldots a_n^{e_n}$ in normal form, return the sequence Q of n integers defined by $Q[i] = e_i$, for $i = 1, \ldots, n$.

`LeadingTerm(x)`

Given an element x of a polycyclic group G with n pc-generators, where x is of the form $a_1^{e_1} \dots a_n^{e_n}$, return $a_i^{e_i}$ for the smallest i such that $e_i > 0$. If x is the identity of G, then the identity is returned.

`LeadingGenerator(x)`

Given an element x of a polycyclic group G with n pc-generators, where x is of the form $a_1^{e_1} \dots a_n^{e_n}$, return a_i for the smallest i such that $e_i > 0$. If x is the identity of G, then the identity is returned.

`LeadingExponent(x)`

Given an element x of a polycyclic group G with n pc-generators, where x is of the form $a_1^{e_1} \dots a_n^{e_n}$, return e_i for the smallest i such that $e_i > 0$. If x is the identity of G, then 0 is returned.

`Depth(x)`

Given an element x of a polycyclic group G with n pc-generators, where x is of the form $a_1^{e_1} \dots a_n^{e_n}$, return the smallest i such that $e_i > 0$. If x is the identity of G, then $n + 1$ is returned.

`Depth` returns the maximal value of i, such that $x \in G_i$.

72.2.4 Arithmetic Operations on Elements

Throughout this subsection, G will be a polycyclic group with pc-generators $a_1, \dots, a_n$.

`g * h`

Product of the element g and the element h, where g and h belong to some common subgroup G of a polycyclic group U. If g and h are given as elements belonging to the same proper subgroup G of U, then the result will be returned as an element of G; if g and h are given as elements belonging to distinct subgroups H and K of U, then the product is returned as an element of G, where G is the smallest subgroup of U known to contain both elements.

`g *:= h`

Replace g with the product of element g and element h.

`g ^ n`

The n-th power of the element g, where n is a positive or negative integer.

`g ^:= n`

Replace g with the n-th power of the element g.

`g / h`

Quotient of the element g by the element h, i.e. the element $g * h^{-1}$. Here g and h must belong to some common subgroup G of a polycyclic group U. The rules for determining the parent group of g/h are the same as for $g * h$.

`g /:= h`

Replace g with $g * h^{-1}$.

`g ^ h`

Conjugate of the element g by the element h, i.e. the element $h^{-1} * g * h$. Here g and h must belong to some common subgroup G of a polycyclic group U. The rules for determining the parent group of g^h are the same as for $g * h$.

`g ^:= h`

Replace g with the conjugate of the element g by the element h.

`(g1, ..., gn)`

Given the n words $g_1, \ldots, g_n$ belonging to some common subgroup G of a polycyclic group U, compute the *left-normed* commutator of $g_1, \ldots, g_n$. This is defined inductively as follows: $(g_1, g_2) = g_1^{-1} * g_2^{-1} * g_1 * g_2$ and $(g_1, \ldots, g_n) = ((g_1, \ldots, g_{n-1}), g_n)$.

If $g_1, \ldots, g_n$ are given as elements belonging to the same proper subgroup G of U, then the result will be returned as an element of G; if $g_1, \ldots, g_n$ are given as elements belonging to distinct subgroups of U, then the product is returned as an element of G, where G is the smallest subgroup of U known to contain all elements.

72.2.5 Operators for Elements

`Order(x)`

The order of the element x.

`Parent(x)`

The parent group G of the element x.

72.2.6 Comparison Operators for Elements

`g eq h`

Given elements g and h belonging to a common polycyclic group, return `true` if g and h are the same element, `false` otherwise.

`g ne h`

Given elements g and h belonging to a common polycyclic group, return `true` if g and h are distinct elements, `false` otherwise.

`IsIdentity(g)`

`IsId(g)`

Returns `true` if g is the identity element, `false` otherwise.

72.2.7 Specification of a Polycyclic Presentation

`quo< GrpGPC : F | R : parameters >`

`Check` BoolElt *Default :* `true`

Given a free group F of rank n with generating set X, and a collection R of polycyclic relations on X, construct the polycyclic group G defined by the polycyclic presentation $< X|R >$.

The construct R denotes a list of polycyclic relations. Thus, an element of R must be one of:

(a) A *power relation* $a_i^{m_i} = w_{i,i}$, $i \in I \subseteq \{1, \ldots, n\}$, where $m_i > 1$ is an integer, and $w_{i,i}$ is $Id(F)$ or a word in the generators $a_{i+1}, \ldots, a_n$ for $i < n$, and $w_{i,i} = Id(F)$ for $i = n$.

(b) A *conjugate relation* $a_j^{a_i^e} = w_{e\cdot i,j}$, $1 \leq i < j \leq n$, where $w_{e\cdot i,j}$ is a word in the generators $a_{i+1}, \ldots, a_n$, $e = 1$ if $i \in I$ and $e \in \{-1, 1\}$ if $i \notin I$.

(c) A *power* $a_i^{m_i}$, $i \in I \subseteq \{1, \ldots, n\}$, where $m_i > 1$ is an integer, which is treated as the *power relation* $a_i^{m_i} = Id(F)$.

(d) A set of (a) – (c).

(e) A sequence of (a) – (c).

Note the following points:

(i) If there is no power relation for some generator a_i, $i = 1, \ldots, n$ (i.e. $i \notin I$), conjugate relations $a_j^{a_i^{-1}} = w_{-i,j}$ must be present for $i < j \leq n$ (except for pairs of commuting generators). If there is a power relation for a_i, on the other hand, conjugate relations involving a_i^{-1} are not permitted.

(ii) Conjugate relations for pairs of commuting generators may be omitted. If no conjugate relations are given for a certain pair of generators, the corresponding generators are assumed to commute.

(iii) The words $w_{i,j}$ must be in normal form.

(iv) The presentation must be consistent. In particular, right hand sides of conjugate relations must not be the empty word.

This constructor returns a polycyclic group because the category `GrpGPC` is stated. If no category were stated, it would return an fp-group.

The parameter `Check` may be used to indicate whether or not the presentation should be checked for consistency. Disabling this check can be useful for avoiding runtime errors if the constructor is called in user written loops or functions. The boolean valued function `IsConsistent` is provided to check presentations obtained

with disabled consistency check. It should be noted that the results of working with an inconsistent presentation are undefined, hence it is strongly advised to enable the consistency check in the constructor or to use the function IsConsistent.

The natural homomorphism from $F \to G$ is returned as second return value.

PolycyclicGroup< x$_1$, ..., x$_n$ | R : *parameters* >

Check	BoolElt	*Default :* true
Class	MonStgElt	*Default :*

Construct the polycyclic group G defined by the consistent polycyclic presentation $< x_1, \ldots, x_n | R >$.

The construct $x_1, \ldots, x_n$ defines names for the generators of G that are local to the constructor, i.e. they are used when writing down the relations to the right of the bar. However, no assignment of names to these generators is made. If the user wants to refer to the generators by these (or other) names, then the *generators assignment* construct must be used on the left hand side of an assignment statement.

The construct R denotes a list of polycyclic relations. The syntax and semantics for the relations clause is identical to that appearing in the quo-constructor above.

A map f from the free group on $x_1, \ldots, x_n$ to G is returned as second return value.

The parameter Check may be used as described for the quo-constructor.

If R is both, a valid power-conjugate presentation for a finite soluble group (cf. Chapter 63) and a consistent polycyclic presentation, this constructor by default returns a group in the category GrpPC. To force creation of a group in the category GrpGPC, the parameter Class must be set to "GrpGPC" in these situations.

Example H72E1

(1) Consider the infinite polycyclic group defined by the presentation

$$< a, b, c \mid b^a = b * c, (a, c), (b, c) > .$$

Starting from a free group and giving the relations in the form of a sequence, this presentation would be specified as follows:

```
> F<a,b,c> := FreeGroup(3);
> rels := [ b^a = b*c, b^(a^-1) = b*c^-1 ];
> G<a,b,c> := quo< GrpGPC : F | rels >;
> G;
GrpGPC : G of infinite order on 3 PC-generators
PC-Relations:
    b^a = b * c,
    b^(a^-1) = b * c^-1
```

Note, that the relation $b^{a^{-1}} = b * c^{-1}$ has to be included, although it can be derived from the relations $b^a = b * c$ and (a, b).

(2) The infinite dihedral group is obtained as epimorphic image of the free group of rank two as follows:

```
> F<a,b> := FreeGroup(2);
> D<u,v>, pi := quo<GrpGPC: F | a^2, b^a = b^-1>;
> D;
GrpGPC : D of infinite order on 2 PC-generators
PC-Relations:
    u^2 = Id(D),
    v^u = v^-1
> pi;
Mapping from: GrpFP: F to GrpGPC: D
```

(3) We create an element e of the group D defined above from a sequence of coefficients and extract both its leading generator and its leading exponent.

```
> e := D ! [1,42];
> e;
u * v^42
> gen := LeadingGenerator(e);
> gen;
u
> Parent(gen);
GrpGPC : D of infinite order on 2 PC-generators
PC-Relations:
    u^2 = Id(D),
    v^u = v^-1
> exp := LeadingExponent(e);
> exp;
1
```

We obtain an element of depth 2 from e, by replacing e with its quotient by the appropriate power of the leading generator.

```
> e /:= gen^exp;
> Depth(e);
2
> e;
v^-42
> ElementToSequence(e);
[ 0, -42 ]
```

Example H72E2

Using the constructor PolycyclicGroup with different values of the parameter Class, we construct the dihedral group of order 10 first as a finite soluble group given by a power-conjugate presentation (GrpPC) and next as a general polycyclic group (GrpGPC). Note that the presentation $\langle a, b \mid a^2, b^5, b^a = b^4 \rangle$ is both a valid power-conjugate presentation and a consistent polycyclic

presentation, so we have to set the parameter `Class` to `"GrpGPC"` if we want to construct a group in the category `GrpGPC`.

```
> G1<a,b> := PolycyclicGroup< a,b | a^2, b^5, b^a=b^4 >;
> G1;
GrpPC : G1 of order 10 = 2 * 5
PC-Relations:
    a^2 = Id(G1),
    b^5 = Id(G1),
    b^a = b^4
> G2<a,b> := PolycyclicGroup< a,b | a^2, b^5, b^a=b^4 : Class := "GrpGPC">;
> G2;
GrpGPC : G2 of order 10 = 2 * 5 on 2 PC-generators
PC-Relations:
    a^2 = Id(G2),
    b^5 = Id(G2),
    b^a = b^4
```

We construct the infinite dihedral group as a group in the category `GrpGPC` from a consistent polycyclic presentation. We do not have to use the parameter `Class` in this case.

```
> G3<a,b> := PolycyclicGroup< a,b | a^2, b^a=b^-1>;
> G3;
GrpGPC : G3 of infinite order on 2 PC-generators
PC-Relations:
    a^2 = Id(G3),
    b^a = b^-1
```

The presentation $\langle a, b \,|\, a^2, b^4, b^a = b^3 \rangle$ is not a valid power-conjugate presentation for the dihedral group of order 8, since the exponent of b is not prime. However, it is a consistent polycyclic presentation. Consequently, the constructor `PolycyclicGroup` without specifying a value for the parameter `Class` returns a group in the category `GrpGPC`.

```
> G4<a,b> := PolycyclicGroup< a,b | a^2, b^4, b^a=b^3 >;
> G4;
GrpGPC : G4 of order 2^3 on 2 PC-generators
PC-Relations:
    a^2 = Id(G3),
    b^4 = Id(G3),
    b^a = b^3
```

72.2.8 Properties of a Polycyclic Presentation

`IsConsistent(G)`

Returns `true` if the stored presentation for G is consistent, `false` otherwise.

`IsIdenticalPresentation(G, H)`

Returns `true` if the polycyclic presentations for G and H are identical, `false` otherwise.

`PresentationIsSmall(G)`

Returns `true` if only small integers occur in the presentation of G, `false` otherwise. The category transfer functions `FPGroup` and `PCGroup` currently support only groups with a small presentation.

72.3 Subgroups, Quotient Groups, Homomorphisms and Extensions

72.3.1 Construction of Subgroups

`sub< G | L >`

Construct the subgroup H of the polycyclic group G generated by the elements specified by the terms of the *generator list* L.
A term $L[i]$ of the generator list may consist of any of the following objects:

(a) An element liftable to G;

(b) A sequence of integers representing an element of G;

(c) A subgroup of G;

(d) A set or sequence of (a), (b), or (c). The collection of words and groups specified by the list must all belong to the group G and H will be constructed as a subgroup of G.

The generators of H consist of the words specified directly by terms of $L[i]$ together with the stored generating words for any groups specified by terms of $L[i]$. Repetitions of an element and occurrences of the identity element are removed.

The inclusion map from H to G is returned as a second value.

`ncl< G | L >`

Construct the subgroup N of the polycyclic group G as the normal closure of the subgroup generated by the elements specified by the terms of the *generator list* L.

The possible forms of a term $L[i]$ of the generator list are the same as for the `sub`-constructor.

The inclusion map from N to G is returned as a second value.

72.3.2 Coercions Between Groups and Subgroups

`G ! g`

Given an element g belonging to the subgroup H of the group G, rewrite g as an element of G.

`H ! g`

Given an element g belonging to the group G, and given a subgroup H of G containing g, rewrite g as an element of H.

`K ! g`

Given an element g belonging to the group H, and a group K, such that H and K are subgroups of G, and both H and K contain g, rewrite g as an element of K.

`InclusionMap(G, H)`

The map from the subgroup H of G to G.

Example H72E3

Consider again the infinite polycyclic group G defined by the polycyclic presentation

$$< a, b, c \mid b^a = b * c, (a, c), (b, c) > .$$

```
> F<a,b,c> := FreeGroup(3);
> rels := [ b^a = b*c, b^(a^-1) = b*c^-1 ];
> G<a,b,c> := quo< GrpGPC : F | rels >;
> G;
GrpGPC : G of infinite order on 3 PC-generators
PC-Relations:
    b^a = b * c,
    b^(a^-1) = b * c^-1
```

Using the function PCGenerators which is described later, the groups $G_1, \ldots, G_4$ and the corresponding inclusion maps can be defined as follows:

```
> G_ := []; incl_ := [ PowerStructure(Map) | ];
> for i := 1 to #PCGenerators(G)+1 do
>   G_[i], incl_[i] := sub< G | [ g : g in PCGenerators(G) |
>                                       Depth(g) ge i ] >;
> end for;
> for i := 1 to #G_ do
>   printf "G_%o = <%o>", i, {@ G!x : x in
>                   PCGenerators(G_[i]) @}; print "";
> end for;
G_1 = <{@ a, b, c @}>
G_2 = <{@ b, c @}>
G_3 = <{@ c @}>
```

```
G_4 = <{@ @}>
```

Note that we must set the universe of the sequence `incl_` to `PowerStructure(Map)` manually, since we want to store maps which do not have a common domain. If we failed to do this, the universe would be chosen automatically to be the set of all maps from G_1 to G when the first map is inserted into the sequence. Inserting the second map, which does not have the domain G_1, would then cause a runtime error.

72.3.3 Construction of Quotient Groups

`quo< G | L >`

Construct the quotient Q of the polycyclic group G by the normal subgroup N, where N is the smallest normal subgroup of G containing the elements specified by the terms of the *generator list* L.

The possible forms of a term $L[i]$ of the generator list are the same as for the `sub`-constructor.

The quotient group Q and the corresponding natural homomorphism $f : G \to Q$ are returned.

`G / N`

Given a normal subgroup N of the polycyclic group G, construct the quotient of G by N.

72.3.4 Homomorphisms

For a general description of homomorphisms, we refer to Chapter 16. This section describes some special aspects of homomorphisms the domain of which is a polycyclic group.

72.3.4.1 General remarks

The kernel of a homomorphism with a domain of type `GrpGPC` can be computed using the function `Kernel`, if the codomain is of one of the types `GrpGPC`, `GrpPC` (cf. Chapter 63), `GrpAb` (cf. Chapter 69), `GrpPerm` (cf. Chapter 58), `ModAlg` or `ModGrp` (cf. Chapter 89) or if the codomain is of the type `GrpMat` (cf. Chapter 59) and the image is finite.

In particular, preimages of substructures can be computed in these situations. The kernel of a map will be computed automatically, if the preimage of a substructure of the codomain is to be computed.

The kernel (and hence preimages of substructures) may also be computable, if the codomain is of the type `GrpFP` (cf. Chapter 70) and the domain is nilpotent.

72.3.4.2 Construction of Homomorphisms

`hom< P -> G | S : parameters >`

Returns the homomorphism from the polycyclic group P to the group G defined by the assignment S. S can be the one of the following:

(i) A list, sequence or indexed set containing the images of the n polycyclic generators $P.1, \ldots, P.n$ of P. Here, the i-th element of S is interpreted as the image of $P.i$, i.e. the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing r tuples $< x_i, y_i >$ or arrow pairs $x_i -> y_i$, where $x_i \in P$, $y_i \in G$ $(i = 1, \ldots, r)$ and the set $\{x_1, \ldots, x_r\}$ is a generating set for P. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important. Note that the preimages x_i need not be the polycyclic generators of P.

If the data type of the codomain supports element arithmetic and element comparison, by default the constructed homomorphism is checked by verifying that the would-be images of the polycyclic generators satisfy the defining relations of P and that this assignment is consistent with the assignments made by the user. In this case, it is assured that the returned map is a well-defined homomorphism with the desired images. The most important situation in which it is not possible to perform checking is the case in which the domain is a finitely presented group (`FPGroup`; cf. Chapter 70) which is not free. Checking may be disabled using the parameter `Check`.

`Check` BoolElt *Default :* `true`

If `Check` is set to `false`, checking of the homomorphism is disabled.

72.3.5 Construction of Extensions

`DirectProduct(G, H)`

The direct product K of the polycyclic groups G and H. The second value returned is a sequence containing the inclusion maps $I_G : G \to K$ and $I_H : H \to K$. The third value returned is a sequence containing the projection maps $P_G : K \to G$ and $P_H : K \to H$.

72.3.6 Construction of Standard Groups

A number of functions are provided which construct polycyclic presentations for various standard groups.

`AbelianGroup(GrpGPC, Q)`

Construct the abelian group defined by the sequence $Q = [n_1, \ldots, n_r]$ as a polycyclic group. The entries n_i may be either zero, indicating an infinite cyclic factor, or integers greater than 1. The function returns the polycyclic group which is the direct product of the cyclic groups $Z_1 \times \cdots \times Z_r$, where Z_i is a cyclic group of infinite order if $n_i = 0$, or a cyclic group of order n_i if $n_i > 1$.

`CyclicGroup(GrpGPC, n)`

For $n > 0$, the cyclic group of order n is returned, while for $n = 0$, the infinite cyclic group is returned as a polycyclic group.

`DihedralGroup(GrpGPC, n)`

For $n \geq 3$, the dihedral group of order $2n$ is returned, while for $n = 0$, the infinite dihedral group is returned as a polycyclic group.

`ElementaryAbelianGroup(GrpGPC, p, n)`

Given a prime p and a positive integer n, construct the elementary abelian group of order p^n as a polycyclic group.

`ExtraSpecialGroup(GrpGPC, p, n : parameters)`

Given a prime p and a small positive integer n, construct an extra-special group G of order p^{2n+1} as a polycyclic group. The isomorphism type of G can be selected using the parameter `Type`.

`Type` MonStgElt *Default :* "+"

Possible values for this parameter are "+" (default) and "−".

If `Type` is set to "+", the function returns for $p = 2$ the central product of n copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p.

If `Type` is set to "−", the function returns for $p = 2$ the central product of a quaternion group of order 8 and $n - 1$ copies of the dihedral group of order 8, and for $p > 2$ it returns the unique extra-special group of order p^{2n+1} and exponent p^2.

`FreeAbelianGroup(GrpGPC, n)`

Given a positive integer n, construct the free abelian group of rank n as a polycyclic group.

`FreeNilpotentGroup(r, e)`

The free nilpotent group of rank r and class e is returned as a polycyclic group.

Example H72E4

Consider the dihedral group D_4.

```
> G<a,b> := DihedralGroup(GrpGPC, 4);
```

We obtain a well-defined homomorphism f of G onto a group $A = \mathbf{Z}_2 \times \mathbf{Z}_2$, by assigning two generators of A as the images of a and ab, respectively. Note that in the definition of f we can use the generating set $\{a, ab\}$ of G, instead of the defining polycyclic generating sequence of G.

```
> A<u,v> := AbelianGroup([2,2]);
```

```
> f := hom< G->A | a->u, a*b->v >;
```

We compute the kernel K of f and express the generators of K as elements of G, using the function PCGenerators described later.

```
> K := Kernel(f);
> PCGenerators(K, G);
{@ b^2 @}
```

Example H72E5

A polycyclic representation for the group $D_3 \times D_\infty$ may be obtained as follows:

```
> G1<a,b> := DihedralGroup(GrpGPC, 3);
> G2<u,v> := DihedralGroup(GrpGPC, 0);
> D, incl, proj := DirectProduct(G1, G2);
> D;
GrpGPC : D of infinite order on 4 PC-generators
PC-Relations:
    D.1^2 = Id(D),
    D.2^3 = Id(D),
    D.3^2 = Id(D),
    D.2^D.1 = D.2^2,
    D.4^D.3 = D.-4
```

Using the inclusion maps returned by DirectProduct, we define a subgroup and compute the quotient by its normal closure:

```
> S := sub<D| incl[1](a)*incl[2](u), incl[1](b)*incl[2](v)>;
> S;
GrpGPC : S of infinite order on 3 PC-generators
PC-Relations:
    S.1^2 = Id(S),
    S.2^3 = S.3,
    S.2^S.1 = S.2^2 * S.-3,
    S.3^S.1 = S.-3
> Q, pi := quo<D|S>;
> Q;
GrpGPC : Q of order 2 on 1 PC-generators
PC-Relations:
    Q.1^2 = Id(Q)
> Q.1 @@ pi;
D.3
```

72.4 Conversion between Categories

This section describes category transfers from polycyclic groups to other MAGMA categories of groups. For category transfers to permutation groups (cf. Chapter 58) the functions CosetAction and CosetImage can be used. For category transfers to matrix groups (cf. Chapter 59) we refer to section 72.12.

AbelianGroup(G)

A GrpAb (cf. Chapter 69) representation A of the abelian polycyclic group G and the isomorphism from G to A.

FPGroup(G)

A GrpFP (cf. Chapter 70) representation F of G and the isomorphism from F to G. This category transfer is currently only possible provided that all exponents occurring in the presentation of G are small integers. This can be checked by means of the function PresentationIsSmall.

PCGroup(G)

A GrpPC (cf. Chapter 63) representation F of the finite polycyclic group G and the isomorphism from G to F.

This category transfer is currently only possible provided that all exponents occurring in the presentation of G are small integers. This can be checked by means of the function PresentationIsSmall.

GPCGroup(G)

A GrpGPC representation P of the solvable group G and the isomorphism from G to P. The group G can be of one of the following types: GrpPerm (cf. Chapter 58), GrpMat (cf. Chapter 59), GrpAb (cf. Chapter 69), GrpPC (cf. Chapter 63). Currently G must be finite, if it is of type GrpMat.

Example H72E6

We define a finite, solvable matrix group and convert it to a (general) polycyclic group G.

```
> a := GL(2,3) ! [1,1,0,1];
> b := GL(2,3) ! [0,1,1,0];
> M := sub<Parent(a)|a,b>;
> IsSolvable(M);
true
> IsFinite(M);
true
> G, f := GPCGroup(M);
```

We now compute the direct product D of G and the infinite dihedral group H, define a subgroup S of D, its normal closure N and construct the quotient Q of D by N.

```
> H<u,v> := DihedralGroup(GrpGPC, 0);
> D, incl, proj := DirectProduct(G, H);
```

```
> S := sub<D | incl[1](f(a*b)), incl[2]((u,v)^2)>;
> N := ncl<D|S>;
> Q := D/N;
> Q;
GrpGPC : Q of order 2^3 on 2 PC-generators
PC-Relations:
    Q.1^2 = Id(Q),
    Q.2^4 = Id(Q),
    Q.2^Q.1 = Q.2^3
```

Since Q is finite, it can be transformed into a group of type `GrpPC` using the function `PCGroup`. This should (in non-trivial examples) be done, if further computations with it are intended.

```
> Q_ := PCGroup(Q);
> Q_;
GrpPC : Q_ of order 8 = 2^3
PC-Relations:
    Q_.2^2 = Q_.3,
    Q_.2^Q_.1 = Q_.2 * Q_.3
```

72.5 Access Functions for Groups

The functions described here provide access to basic information stored for a polycyclic group G.

`G . i`

The i-th polycyclic generator for G if $i > 0$, the inverse of the $|i|$-th polycyclic generator for G if $i < 0$ and the identity element of G if $i = 0$.

`Generators(G)`
`PCGenerators(G)`

An indexed set containing the polycyclic generators of G.

`Generators(H, G)`
`PCGenerators(H, G)`

An indexed set containing the polycyclic generators of H as elements of G.

`NumberOfGenerators(G)`
`Ngens(G)`
`NumberOfPCGenerators(G)`
`NPCgens(G)`

The number of polycyclic generators for the polycyclic group G.

`PCExponents(G)`

The orders of the cyclic factors in the polycyclic series defined by the polycyclic presentation of G. The orders are returned in a sequence Q. $|G_i/G_{i+1}| = m_i = Q[i]$ if $Q[i] > 0$ and G_i/G_{i+1} is infinite (i.e. $i \notin I$) if $Q[i] = 0$.

`HirschNumber(G)`

The Hirsch number of G, i.e. the number of infinite cyclic factors in the polycyclic series defined by the polycyclic presentation of G.

The Hirsch number of G is equal to $n - |I|$, i.e. to the number of polycyclic generators of G for which there is no power relation. A polycyclic group G is finite if and only if its Hirsch number is 0.

72.6 Set-Theoretic Operations in a Group

72.6.1 Functions Relating to Group Order

`FactoredIndex(G, H)`

Given a group G and a subgroup H of G of finite index, return the factored index of H in G

`FactoredOrder(G)`

The factored order of the finite group G.

`Index(G, H)`

The index of the subgroup H in the group G, returned as an ordinary integer.

`Order(G)`
`#G`

The order of the group G, returned as an ordinary integer.

72.6.2 Membership and Equality

`g in G`

Given an element g and a group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given an element g and a group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given an group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a group G and a set S of elements belonging to a group H, where G and H have some covering group, return `true` if S is not a subset of G, `false` otherwise.

`H subset G`

Given groups G and H, having some covering group, return `true` if H is a subgroup of G, `false` otherwise.

`H notsubset G`

Given groups G and H, having some covering group, return `true` if H is not a subgroup of G, `false` otherwise.

`G eq H`

Given groups G and H, having some covering group, return `true` if G and H are the same group, `false` otherwise.

`G ne H`

Given groups G and H, having some covering group, return `true` if G and H are distinct groups, `false` otherwise.

72.6.3 Set Operations

`Representative(G)`

`Rep(G)`

A representative element of G.

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 100

Create a process to generate pseudo-randomly chosen elements from the group G. The process uses an 'expansion' procedure to construct a set of elements corresponding to fairly long words in the generators of G [CLGM+95]. At all times, N elements forming a generating set for G are stored. Here, N is the maximum of $n + 1$ and the specified value for `Slots`, where n is the number of generators of G. Initially, these are just the generators of G and products of pairs of generators of G. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses an element previously stored by the process as the new random element. The process then replaces this stored element with the product of this element and another one of the stored elements (on the left or the right). Setting `Scramble:= m` causes m such operations to be performed before the process is returned.

Care should be taken when trying to apply this function to infinite polycyclic groups. Firstly, the computations may take a considerable amount of time and secondly, the quality of the pseudo-random element generator may be extremely poor, depending on the required properties of the sequence of pseudo-random elements.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the group G, construct a pseudo-random element of G by forming a random product over the expanded generating set currently stored by the process. The remarks concerning random elements of infinite polycyclic groups given in the description of `RandomProcess` apply here.

`Random(G)`

`Random(G, max)`

An element, pseudo-randomly chosen, from the group G. An exponent vector in normal form is chosen at random. Exponents of polycyclic generators for which there is no power relation, are chosen to have absolute value less or equal to `max`. A default value for `max` is 10.

It should be kept in mind that the distribution of the elements returned by `Random` is uniform only in the case that G is finite.

72.7 Coset Spaces

`CosetTable(G, H)`

The (right) coset table for G over the subgroup H of finite index, relative to the polycyclic generators. This is defined to be a map

$$\{1, \ldots, |G : H|\} \times G \to \{1, \ldots, |G : H|\}$$

describing the action of G on the enumerated set of right cosets of H in G by right multiplication.

The underlying set of right coset representatives is identical to the right transversal returned by `Transversal` and `RightTransversal` and the same enumeration of the elements is used.

`Transversal(G, H)`

`RightTransversal(G, H)`

Given a group G and a subgroup H of G, this function returns:

(a) An indexed set of elements T of G forming a right transversal for G over H. The right transversal and its enumeration are identical to those internally used by the function `CosetTable`.

(b) The corresponding transversal mapping $\phi : G \to T$. If $T = [t_1, \ldots, t_r]$ and g in G, ϕ is defined by $\phi(g) = t_i$, where $g \in H * t_i$.

Example H72E7

We compute a right transversal of a subgroup H of the infinite dihedral group G.

```
> G<a,b> := DihedralGroup(GrpGPC, 0);
> H := sub<G|a*b, b^10>;
> Index(G, H);
10
> RT, transmap := Transversal(G, H);
> RT;
{@ Id(G), b^-1, b^-2, b^-3, b^-4, b^-5, b^-6, b^-7, b^-8, b^-9 @}
> transmap;
Mapping from: GrpGPC: G to SetIndx: RT
```

From this a left transversal is easily obtained:

```
> LT := {@ x^-1 : x in RT @};
> LT;
{@ Id(G), b, b^2, b^3, b^4, b^5, b^6, b^7, b^8, b^9 @}
```

We construct the coset table and define a function $RT \times G \to RT$, describing the action of G on the set of right cosets of H in G.

```
> ct := CosetTable(G, H);
> action := func< r, g | RT[ct(Index(RT, r), g)] >;
> action(Id(G), b);
b^-9
```

I.e. $H * b = Hb^{-9}$.

```
> action(b^-4, a*b);
b^-6
```

I.e. $Hb^{-4} * (ab) = Hb^{-6}$.

Note that the definition of the function `action` relies on the fact that the computed right transversal and its enumeration are identical to those internally used by the function `CosetTable`.

`CosetAction(G, H)`

Given a subgroup H of the group G of finite index, construct the permutation representation of G, induced by the action of G on the set of (right) cosets of H in G. The function returns:

(a) The permutation representation $f : G \to L \leq \mathrm{Sym}(|G : H|)$, induced by the action of G on the set of (right) cosets of H in G;

(b) The epimorphic image L of G under the representation f;

(c) The kernel K of the representation f.

`CosetImage(G, H)`

Given a subgroup H of the group G of finite index, construct the permutation group, induced by the action of G on the set of (right) cosets of H in G. The returned group is the epimorphic image L of G under the permutation representation $f : G \to L \leq \mathrm{Sym}(|G:H|)$, induced by the action of G on the set of (right) cosets of H in G.

`CosetKernel(G, H)`

Given a subgroup H of the group G of finite index, construct the kernel of the permutation representation $f : G \to L \leq \mathrm{Sym}(|G:H|)$, induced by the action of G on the set of (right) cosets of H in G.

Example H72E8

We use the function `CosetAction` to construct a (non-faithful) permutation representation of the group G defined by the polycyclic presentation

$$< a, b, c \mid b^a = b * c, (a, c), (b, c) > .$$

```
> F<a,b,c> := FreeGroup(3);
> rels := [ b^a=b*c, b^(a^-1)=b*c^-1 ];
> G<a,b,c> := quo<GrpGPC: F | rels>;
>
> S := sub<G|(a*b)^3, c^7, b^21>;
> Index(G, S);
441
> pi, P, K := CosetAction(G, S);
> P;
Permutation group P acting on a set of cardinality 441
> K;
GrpGPC : K of infinite order on 3 PC-generators
PC-Relations:
    K.2^K.1 = K.2 * K.3^63,
    K.2^(K.-1) = K.2 * K.-3^63
> Index(G, K);
3087
```

We express the generators of the kernel K in terms of the generators of G:

```
> {@ G!x : x in PCGenerators(K) @};
{@ a^21, b^21, c^7 @}
```

$pi(S)$ is a point stabiliser in the transitive permutation group P of degree 441 and hence should have index 441 in P:

```
> pi(S);
Permutation group acting on a set of cardinality 441
> Index(P, pi(S));
441
```

72.8 The Subgroup Structure

72.8.1 General Subgroup Constructions

The operators and functions which construct a subgroup of a polycyclic group always return the subgroup as a polycyclic group.

`H ^ g`

`Conjugate(H, g)`

Construct the conjugate $g^{-1} * H * g$ of the group H under the action of the element g. The group H and the element g must belong to a common group.

`H ^ G`

`ncl< G | H >`

`NormalClosure(G, H)`

Given a subgroup H of the group G, construct the normal closure of H in G.

`CommutatorSubgroup(G, H, K)`

`CommutatorSubgroup(H, K)`

Construct the commutator subgroup of groups H and K, where H and K are subgroups of a common group G.

72.8.2 Subgroup Constructions Requiring a Nilpotent Covering Group

The operators and functions described in this section require the existence of a nilpotent covering group. They are based on algorithms published in [Lo98]. Again, the constructed subgroup is returned as a polycyclic group.

`H meet K`

Given two groups H and K, contained in some common group G which is nilpotent, construct the intersection of H and K.

`H meet:= K`

Given two groups H and K, contained in some common group G which is nilpotent, replace H with the intersection of H and K.

`Centraliser(G, g)`

`Centralizer(G, g)`

The subgroup of G centralising g. Both g and G must be contained in some common nilpotent group.

`Centraliser(G, H)`
`Centralizer(G, H)`

The subgroup of G centralising H. Both H and G must be subgroups of some common nilpotent group.

`Core(G, H)`

The maximal normal subgroup of the nilpotent group G that is contained in the subgroup H of G.

`Normaliser(G, H)`
`Normalizer(G, H)`

The subgroup of G normalising H. Both H and G must be subgroups of some common nilpotent group.

72.9 General Group Properties

`IsAbelian(G)`

Returns `true` if the group G is abelian, `false` otherwise.

`IsCyclic(G)`

Returns `true` if the group G is cyclic, `false` otherwise.

`IsElementaryAbelian(G)`

Returns `true` if the group G is elementary abelian, `false` otherwise. The following definition is used:

A group G is called elementary abelian if it is an abelian p-group of exponent p for some prime p.

`IsFinite(G)`

Returns `true` if the group G is finite, `false` otherwise.

`IsNilpotent(G)`

Returns `true` if the group G is nilpotent, `false` otherwise. This function uses an algorithm described in [Lo98].

`IsPerfect(G)`

Returns `true` if the group G is perfect, `false` otherwise. A polycyclic group G is perfect, if and only if it is trivial.

`IsSimple(G)`

Returns `true` if the group G is simple, `false` otherwise. A polycyclic group is simple, if and only if it is cyclic of prime order.

IsSoluble(G)

IsSolvable(G)

Returns `true` if the group G is solvable, `false` otherwise. Every polycyclic group is solvable.

72.9.1 General Properties of Subgroups

IsCentral(G, H)

Returns `true` if the subgroup H of the group G lies in the centre of G, `false` otherwise.

IsNormal(G, H)

Returns `true` if the subgroup H of the group G is a normal subgroup of G, `false` otherwise.

72.9.2 Properties of Subgroups Requiring a Nilpotent Covering Group

The functions described in this section require the existence of a nilpotent covering group. The are based on algorithms published in [Lo98].

IsConjugate(G, H, K)

Given groups G, H and K with a nilpotent common covering group, return the value `true` if there exists $c \in G$ such that $H^c = K$. If so, the function returns such a conjugating element as second value.

IsSelfNormalising(G, H)

IsSelfNormalizing(G, H)

Returns `true` if the subgroup H of the nilpotent group G is self-normalising in G, `false` otherwise.

Example H72E9

We define a group G on 5 generators $a, \ldots, e$ of infinite order by fixing the commutators of the generators:

$$(b, a) = e^2, \quad (d, c) = e^3$$

All other pairs of generators commute.

```
> F<a,b,c,d,e> := FreeGroup(5);
> rels := [ b^a = b*e^2, b^(a^-1) = b*e^-2, d^c = d*e^3,
>           d^(c^-1) = d*e^-3 ];
> G<a,b,c,d,e> := quo< GrpGPC: F | rels >;
> IsNilpotent(G);
true
```

Since G is nilpotent, we can compute intersections of subgroups of G.

We define the subgroups generated by $a, \ldots, e$ and their nontrivial commutator groups as subgroups of G.

```
> H1 := sub<G|a>;
> H2 := sub<G|b>;
> H3 := sub<G|c>;
> H4 := sub<G|d>;
> H5 := sub<G|e>;
>
> C12 := CommutatorSubgroup(H1, H2);
> {@ G!x : x in PCGenerators(C12) @};
{@ e^2 @}
> C12 subset H5;
true
>
> C34 := CommutatorSubgroup(H3, H4);
> {@ G!x : x in PCGenerators(C34) @};
{@ e^3 @}
> C34 subset H5;
true
```

Finally, we compute the intersection C of $C12$ and $C13$.

```
> C := C12 meet C34;
> {@ G!x : x in PCGenerators(C) @};
{@ e^6 @}
```

This intersection C is cyclic and central in G.

```
> IsCyclic(C);
true
> IsCentral(G, C);
true
```

Example H72E10

Consider the nilpotent group $G := D_{16} \wr 2$ generated by the 5 generators a, b, c, d, t with the relations

$$a^2 = 1, \quad b^{16} = 1, \quad b^a = b^{15}$$

$$c^2 = 1, \quad d^{16} = 1, \quad d^c = d^{15}$$

$$t^2 = 1, \quad a^t = c, \quad b^t = d, \quad c^t = a, \quad d^t = b$$

(All other pairs of generators commute.)

```
> F<t, a,b, c,d> := FreeGroup(5);
> G<t, a,b, c,d> := quo<GrpGPC: F | a^2, b^16, b^a=b^15,
>                                   c^2, d^16, d^c=d^15,
>                      t^2, a^t=c, b^t=d, c^t=a, d^t=b>;
> IsNilpotent(G);
```

```
true
```

Since G is nilpotent, we can compute normalisers and centralisers in G.
We define the (dihedral) subgroup $D3$ of G generated by ac and bd and compute its normaliser in G and its centraliser in the (dihedral) subgroup $D2$ of G generated by c and d.

```
> D2 := sub<G|c,d>;
>
> D3<u,v> := sub<G|a*c, b*d>;
> D3;
GrpGPC : D3 of order 2^5 on 2 PC-generators
PC-Relations:
    u^2 = Id(D3),
    v^16 = Id(D3),
    v^u = v^15
>
> N3 := Normaliser(G, D3);
> PCGenerators(N3, G);
{@ t, a * c, b * d, d^8 @}
>
> C3 := Centraliser(D2, D3);
> PCGenerators(C3, G);
{@ d^8 @}
```

Finally we compute the centraliser of the element t in G.

```
> Ct := Centraliser(G, t);
> PCGenerators(Ct, G);
{@ t, a * c, b * d @}
```

72.10 Normal Structure and Characteristic Subgroups

72.10.1 Characteristic Subgroups and Subgroup Series

`Centre(G)`
`Center(G)`

The centre of the group G. For nilpotent groups the centre is computed using the centraliser algorithm [Lo98]. Otherwise, it is computed as the simultaneous fixed point space of the action of the generators of G on the centre of the Fitting subgroup of G [Eic01].

`DerivedLength(G)`

The derived length of the group G.

`DerivedSeries(G)`

The derived series of the group G. The series is returned as a sequence of subgroups.

`DerivedSubgroup(G)`

`DerivedGroup(G)`

The derived subgroup of the group G.

`EFASeries(G)`

Returns a normal series of G, the factors of which are either elementary abelian p-groups or free abelian groups.

`FittingLength(G)`

The Fitting length of the group G, i.e. the smallest integer k such that $F_k = G$ where the groups F_i are defined recursively by $F_0 := 1$ and $F_i/F_{i-1} := \mathrm{Fit}(G/F_{i-1})$ $(i > 0)$. Note that such a k exists for every polycyclic group G.

`FittingSeries(G)`

The Fitting series of the group G, where the groups F_i are defined recursively by $F_0 := 1$ and $F_i/F_{i-1} := \mathrm{Fit}(G/F_{i-1})$ $(i > 0)$. The series is returned as the sequence $[F_0, \ldots, F_k]$ of subgroups of G. Note that every polycyclic group G has a finite Fitting series ending in G.

`FittingSubgroup(G)`

`FittingGroup(G)`

The Fitting subgroup of the group G, i.e. the maximal nilpotent normal subgroup of G. This function uses an algorithm described in [Eic01].

`HasComputableLCS(G)`

This function returns the value `true` if the lower central series of G is computable, otherwise it returns the value `false`. This is useful to avoid runtime errors, when `LowerCentralSeries` is called in user written loops or functions.

`LowerCentralSeries(G)`

The lower central series for the group G. The series is returned as a sequence of subgroups. Since infinite polycyclic groups need not satisfy the descending chain condition for subgroups, computation of the lower central series may fail. To determine if the series can be computed and thereby avoid runtime errors, the function `HasComputableLCS` may be used. This function uses an algorithm described in [Lo98].

`NilpotencyClass(G)`

The nilpotency class of the group G. If G is not nilpotent, then -1 is returned.

`NilpotentPresentation(G)`

A polycyclic presentation is called *nilpotent*, if for all $i = 1, \ldots, n$, G_{i+1} is normal in G and G_i/G_{i+1} is central in G/G_{i+1}. Every nilpotent polycyclic group has a nilpotent polycyclic presentation. A suitable polycyclic series can be obtained by refining the lower central series.

The function `NilpotentPresentation` computes a group N isomorphic to G, given by a nilpotent polycyclic presentation and the isomorphism from G to N.

`SemisimpleEFASeries(G)`

Returns a normal series of G, the factors of which are either elementary abelian p-groups which are semisimple as $\mathbf{F}_p[G]$-modules or free abelian groups which are semisimple as $\mathbf{Q}[G]$-modules.

The normal series returned by the function `SemisimpleEFASeries` is a refinement of the normal series returned by the function `EFASeries`.

`UpperCentralSeries(G)`

The upper central series $[Z_0, \ldots, Z_k]$ of the group G, where the groups Z_k are defined recursively by $Z_0 := 1$ and $Z_i/Z_{i-1} := \mathrm{Z}(G/Z_{i-1})$ $(i > 0)$. The series is returned as a sequence of subgroups of G. Note that since polycyclic groups satisfy the ascending chain condition for subgroups, every polycyclic group G has a finite upper central series.

Example H72E11

The dihedral group of order 32 is nilpotent; we compute its lower central series.

```
> D16<a,b> := DihedralGroup(GrpGPC, 16);
> IsNilpotent(D16);
true
> NilpotencyClass(D16);
4
> L := LowerCentralSeries(D16);
```

The generators of the subgroups in the lower central series expressed as elements of $D16$ are:

```
> for i := 1 to 1+NilpotencyClass(D16) do
>   print i, ":", {@ D16!x : x in PCGenerators(L[i]) @};
> end for;
1 : {@ a, b @}
2 : {@ b^2 @}
3 : {@ b^4 @}
4 : {@ b^8 @}
5 : {@ @}
```

We compute a nilpotent presentation and express the new generators in terms of a and b:

```
> N<p,q,r,s,t>, f := NilpotentPresentation(D16);
> N;
```

```
GrpGPC : N of order 2^5 on 5 PC-generators
PC-Relations:
    p^2 = Id(N),
    q^2 = r,
    r^2 = s,
    s^2 = t,
    t^2 = Id(N),
    q^p = q * r * s * t,
    r^p = r * s * t,
    s^p = s * t
> {@ x@@f : x in PCGenerators(N) @};
{@ a, b, b^2, b^4, b^8 @}
```

The infinite dihedral group has an infinite, strictly descending, lower central series which cannot be computed:

```
> D := DihedralGroup(GrpGPC, 0);
> HasComputableLCS(D);
false
```

It is easy to see, that $b^{2^{i-1}}$ would be a generator of L_i.

The symmetric group on 3 letters is not nilpotent, but has a lower central series which becomes stationary and which can be computed:

```
> F2<a,b> := FreeGroup(2);
> rels := [ a^2 = F2!1, b^3 = F2!1, b^a = b^2 ];
> G<a,b> := quo<GrpGPC : F2 | rels>;
> G;
GrpGPC : G of order 6 = 2 * 3 on 2 PC-generators
PC-Relations:
    a^2 = Id(G),
    b^3 = Id(G),
    b^a = b^2
> IsNilpotent(G);
false
> HasComputableLCS(G);
true
> L := LowerCentralSeries(G);
> for i := 1 to #L do
>   print i, ":", {@ G!x : x in PCGenerators(L[i]) @};
> end for;
1 : {@ a, b @}
2 : {@ b @}
```

72.10.2 The Abelian Quotient Structure of a Group

`AbelianQuotient(G)`

The maximal abelian quotient G/G' of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism is returned as second return value.

`AbelianQuotientInvariants(G)`

`AQInvariants(G)`

Returns a sequence containing the invariants of the maximal abelian quotient G/G' of the group G. Each infinite cyclic factor of G/G' is represented by zero.

`ElementaryAbelianQuotient(G, p)`

The maximal p-elementary abelian quotient of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism is returned as second return value.

`FreeAbelianQuotient(G)`

The maximal free abelian quotient of the group G as `GrpAb` (cf. Chapter 69). The natural epimorphism is returned as second return value.

72.11 Conjugacy

The functions described in this section require the existence of a nilpotent covering group. They are based on algorithms published in [Lo98].

`IsConjugate(G, g, h)`

Given elements g and h and a group G, which are contained in some nilpotent common group, return the value `true` if there exists $c \in G$ such that $g^c = h$. If so, the function returns such a conjugating element as second value.

`IsConjugate(G, H, K)`

Given groups G, H and K with a nilpotent common covering group, return the value `true` if there exists $c \in G$ such that $H^c = K$. If so, the function returns such a conjugating element as second value.

Example H72E12

We again consider the nilpotent group $G := D_{16} \wr 2$.

```
> F<t, a,b, c,d> := FreeGroup(5);
> G<t, a,b, c,d> := quo<GrpGPC: F | a^2, b^16, b^a=b^15,
>                                   c^2, d^16, d^c=d^15,
>                      t^2, a^t=c, b^t=d, c^t=a, d^t=b>;
> IsNilpotent(G);
true
```

Since G is nilpotent, a test for conjugacy in G is available.

We define the following subgroups of G: $D1$ generated by a and b, $D2$ generated by c and d and $D3$ generated by ac and bd.

```
> D1 := sub<G|a,b>;
> D2 := sub<G|c,d>;
> D3<u,v> := sub<G|a*c, b*d>;
>
```

$D1$ and $D2$ are, of course, conjugate in G; t is a conjugating element.

```
> IsConjugate(G, D1, D2);
true t
```

The elements b and d^{-1} are conjugate in G; we compute a conjugating element.

```
> IsConjugate(G, b, d^-1);
true t * a * c
```

However, neither the subgroups $D1$ and $D2$ nor the elements b and d^{-1}, are conjugate in the subgroup $D3$.

```
> IsConjugate(D3, D1, D2);
false
> IsConjugate(D3, b, d^-1);
false
```

72.12 Representation Theory

This section describes some functions for creating $R[G]$-modules for a polycyclic group G, which are unique for this category or have special properties when called for polycyclic groups. For a complete description of the functions available for creating and working with $R[G]$-modules we refer to Chapter 89.

Note that the function GModuleAction can be used to extract the matrix representation associated to an $R[G]$-module.

`EFAModuleMaps(G)`

Every polycyclic group G has a normal series $G = N_1 \triangleright N_2 \triangleright \ldots \triangleright N_{r+1} = 1$, such that every quotient $M_i := N_i/N_{i+1}$ is either free abelian or p-elementary abelian for some prime p. The action of G by conjugation induces a $\mathbf{Z}[G]$-module structure on M_i if M_i is free abelian and an $\mathbf{F}_p[G]$-module structure if M_i is p-elementary abelian.

This function returns a sequence $[f_1, \ldots, f_r]$, where $f_i : N_i \to M_i$ is the natural epimorphism onto the additive group of an $R_i[G]$-module M_i ($R_i \in \{\mathbf{F}_p, \mathbf{Z}\}$), constructed as above.

The functions EFAModuleMaps and EFAModules use the normal series returned by the function EFASeries.

Note that the kernels of the epimorphisms f_i can be computed and hence it is possible to form preimages of submodules of M_i, which are normal subgroups of G contained in N_i and containing N_{i+1}.

`EFAModules(G)`

Every polycyclic group G has a normal series $G = N_1 \triangleright N_2 \triangleright \ldots \triangleright N_{r+1} = 1$, such that every quotient $M_i := N_i/N_{i+1}$ is either free abelian or p-elementary abelian for some prime p. The action of G by conjugation induces a $\mathbf{Z}[G]$-module structure on M_i if M_i is free abelian and an $\mathbf{F}_p[G]$-module structure if M_i is p-elementary abelian.

This function returns a sequence $[M_1, \ldots, M_r]$ of $R_i[G]$-modules (where $R_i \in \{\mathbf{F}_p, \mathbf{Z}\}$), constructed as above.

The functions `EFAModuleMaps` and `EFAModules` use the normal series returned by the function `EFASeries`.

`GModule(G, A, p)`

`GModule(G, A)`

Let A be a normal subgroup of the polycyclic group G. If $p = 0$, the function returns the $\mathbf{Z}[G]$-module corresponding to the conjugation action of G on the maximal free abelian quotient of A. If p is a prime, it returns the $\mathbf{F}_p[G]$-module corresponding to the conjugation action of G on the maximal p-elementary abelian quotient of A. The epimorphism $\pi : A \to M$ onto the additive group of the constructed module M is returned as second return value. Note that the kernel of π can be computed and hence it is possible to form preimages of submodules of M, which are normal subgroups of G contained in A.

If the maximal abelian quotient A/A' of A is either free abelian or p-elementary abelian for some prime p, p can be omitted in the function call.

Note that it is the user's responsibility to ensure that A is in fact normal in G.

`GModule(G, A, B, p)`

`GModule(G, A, B)`

Let A and $B < A$ be normal subgroups of the polycyclic group G. If $p = 0$, the function returns the $\mathbf{Z}[G]$-module corresponding to the conjugation action of G on the maximal free abelian quotient of A/B. If p is a prime, it returns the $\mathbf{F}_p[G]$-module corresponding to the conjugation action of G on the maximal p-elementary abelian quotient of A/B. The epimorphism $\pi : A \to M$ onto the additive group of the constructed module M is returned as second return value. Note that the kernel of π can be computed and hence it is possible to form preimages of submodules of M, which are normal subgroups of G contained in A and containing B.

If the maximal abelian quotient of A/B is either free abelian or p-elementary abelian for some prime p, p can be omitted in the function call.

Note that it is the user's responsibility to ensure that A and B are in fact normal in G.

`GModulePrimes(G, A)`

Let G be a polycyclic group and A a normal subgroup of G. Given any prime p, the maximal p-elementary abelian quotient of A can be viewed as an $\mathbf{F}_p[G]$-module M_p. The maximal free abelian quotient of A can be viewed as a $\mathbf{Z}[G]$-module M_0. This function determines those primes p for which the module M_p is non-trivial (i.e. not zero-dimensional) and the dimensions of the corresponding modules M_p. The return value is a multiset S. If $0 \notin S$, the maximal abelian quotient of A is finite and the multiplicity of p is the dimension of M_p. If S contains 0 with multiplicity m, the maximal abelian quotient of A contains m copies of $\mathbf{Z}$. In this case, the rank of M_0 is m and M_p is non-trivial for every prime p and its rank is the sum of m and the multiplicity of p in S.

`GModulePrimes(G, A, B)`

Let G be a polycyclic group, A a normal subgroup of G and B a normal subgroup of G contained in A. Given any prime p, the maximal p-elementary abelian quotient of A/B can be viewed as an $\mathbf{F}_p[G]$-module M_p. The maximal free abelian quotient of A/B can be viewed as a $\mathbf{Z}[G]$-module M_0. This function determines those primes p for which the module M_p is non-trivial (i.e. not zero-dimensional) and the dimensions of the corresponding modules M_p. The return value is a multiset S. If $0 \notin S$, the maximal abelian quotient of A/B is finite and the multiplicity of p is the dimension of M_p. If S contains 0 with multiplicity m, the maximal abelian quotient of A/B contains m copies of $\mathbf{Z}$. In this case, the rank of M_0 is m and M_p is non-trivial for every prime p and its rank is the sum of m and the multiplicity of p in S.

`SemisimpleEFAModuleMaps(G)`

Every polycyclic group G has a normal series $G = N_1 \triangleright N_2 \triangleright \ldots \triangleright N_{r+1} = 1$, such that every quotient $M_i := N_i/N_{i+1}$ is either free abelian and semisimple as a $\mathbf{Q}[G]$-module or p-elementary abelian and semisimple as an $\mathbf{F}_p[G]$-module for some prime p.

This function returns a sequence $[f_1, \ldots, f_r]$, where $f_i : N_i \to M_i$ is the natural epimorphism onto the additive group of an $R_i[G]$-module M_i ($R_i \in \{\mathbf{F}_p, \mathbf{Z}\}$), constructed as above.

The functions `SemisimpleEFAModules` and `SemisimpleEFAModuleMaps` use the normal series returned by the function `SemisimpleEFASeries`. Moreover, this normal series is a refinement of the normal series returned by the function `EFASeries`.

Note that the kernels of the epimorphisms f_i can be computed and hence it is possible to form preimages of submodules of M_i, which are normal subgroups of G contained in N_i and containing N_{i+1}.

`SemisimpleEFAModules(G)`

Every polycyclic group G has a normal series $G = N_1 \triangleright N_2 \triangleright \ldots \triangleright N_{r+1} = 1$, such that every quotient $M_i := N_i/N_{i+1}$ is either free abelian and semisimple as a $\mathbf{Q}[G]$-module or p-elementary abelian and semisimple as an $\mathbf{F}_p[G]$-module for some prime p.

This function returns a sequence $[M_1, \ldots, M_r]$ of $R_i[G]$-modules (where $R_i \in \{\mathbf{F}_p, \mathbf{Z}\}$), constructed as above.

The functions SemisimpleEFAModules and SemisimpleEFAModuleMaps use the normal series returned by the function SemisimpleEFASeries. Moreover, this normal series is a refinement of the normal series returned by the function EFASeries.

Example H72E13

Consider the group G defined by the polycyclic presentation

$$\langle a, b, c, d, e \,|\, c^6, e^3, d^c = de, e^c = e^2, b^a = b^{-1}, b^{a^{-1}} = b^{-1}, \\ c^b = ce, c^{b^{-1}} = ce, d^b = d^{-1}, d^{b^{-1}} = d^{-1}, e^b = e^2, e^{b^{-1}} = e^2 \rangle.$$

(Trivial commutator relations have been omitted.)

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> := quo< GrpGPC : F | c^6 = F!1, e^3 = F!1,
>                                   d^c=d*e, e^c=e^2,
>                                   b^a=b^-1,
>                                   b^(a^-1)=b^-1,
>                                   c^b=c*e,
>                                   c^(b^-1)=c*e,
>                                   d^b=d^-1,
>                                   d^(b^-1)=d^-1,
>                                   e^b=e^2,
>                                   e^(b^-1)=e^2 >;
```

The subgroup H of G generated by c, d, e is normal in G.

```
> H := sub< G | c,d,e >;
> IsNormal(G, H);
true
```

We determine the primes such that the action of G on H yields non-trivial modules.

```
> GModulePrimes(G, H);
{* 0, 2, 3 *}
```

We construct the $\mathbf{F}_3[G]$-module M given by the action of G on the maximal 3-elementary abelian quotient of H and the natural epimorphism π from H onto the additive group of M.

```
> M, pi := GModule(G, H, 3);
> M;
GModule M of dimension 2 over GF(3)
```

Using the function Submodules, we obtain the submodules of M. Their preimages under π are precisely the normal subgroups of G which are contained in H and contain $\ker(\pi)$.

```
> submod := Submodules(M);
> nsgs := [ m @@ pi : m in submod ];
> [ PCGenerators(s, G) : s in nsgs ];
```

```
[
    {@ c^3, d^3, e @},
    {@ c, d^3, e @},
    {@ c^3, d, e @},
    {@ c, d, e @}
]
```

Example H72E14

Consider the group defined by the polycyclic presentation

$$< a, b, c, d, e \mid a^5, b^5, c^6, d^5, e^3, b^a = bd > .$$

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> := quo< GrpGPC : F |
>                      a^5, b^5, c^6, d^5, e^3, b^a = b*d >;
```

Obviously the subgroup of G generated by b, c, d, e is normal in G.

```
> H := sub< G | b,c,d,e >;
> IsNormal(G, H);
true
```

We use the function GModulePrimes to determine the set of primes p for which the action of G on the maximal p-elementary abelian quotient of H induces a nontrivial $\mathbf{F}_p[G]$-module.

```
> P := GModulePrimes(G, H);
> 0 in P;
false
```

0 is not contained in P, i.e. the maximal free abelian quotient of H is trivial. Hence, there are only finitely many primes, satisfying the condition above.

We loop over the distinct elements of P and for each element p we construct the induced $\mathbf{F}_p[G]$-module, print its dimension and check whether it is decomposable. Note that the dimension of the module for p must be equal to the multiplicity of p in P.

```
> for p in MultisetToSet(P) do
>    M := GModule(G, H, p);
>    dim := Dimension(M);
>    decomp := IsDecomposable(M);
>
>    assert dim eq Multiplicity(P, p);
>
>    print "prime", p, ": module of dimension", dim;
>    if decomp then
>       print "  has a nontrivial decomposition";
>     else
>       print "  is indecomposable";
>    end if;
```

```
> end for;
prime 2 : module of dimension 1
  is indecomposable
prime 3 : module of dimension 2
  has a nontrivial decomposition
prime 5 : module of dimension 2
  is indecomposable
```

Example H72E15

The Fitting subgroup of a polycyclic group G can be characterised as the intersection of the centralisers in G of the semisimple G-modules defined by the action of G on the factors of a semisimple EFA-series of G. The centraliser in G of a G-module is just the kernel of the action map.
We illustrate this with the group G defined in the example above.

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> := quo< GrpGPC : F | c^6 = F!1, e^3 = F!1,
>                                   b^a = b * d,
>                                   b^(a^-1) = b * d^-1 >;
```

We first construct the G-modules defined by the action of G on the factors of a semisimple EFA-series of G.

```
> modules := SemisimpleEFAModules(G);
> modules;
[
    GModule of dimension 2 over Integer Ring,
    GModule of dimension 1 over Integer Ring,
    GModule of dimension 1 over GF(2),
    GModule of dimension 2 over GF(3)
]
```

Now, we compute the intersection of the kernels of the module action maps, which can be obtained using the function GModuleAction.

```
> S := G;
> for m in modules do
>    S meet:= Kernel(GModuleAction(m));
> end for;
```

Finally, we compare the result with the Fitting subgroup of G, returned by the Magma function FittingSubgroup.

```
> S eq FittingSubgroup(G);
true
```

Example H72E16

The functions EFAModuleMaps and SemisimpleEFAModuleMaps are useful whenever it is desired to refine an EFA-series or a semisimple EFA-series by computing the subgroups corresponding to submodules of the G-modules given by the factors of the series. Consider again the group defined above.

```
> F<a,b,c,d,e> := FreeGroup(5);
> G<a,b,c,d,e> := quo< GrpGPC : F | c^6 = F!1, e^3 = F!1,
>                                   b^a = b * d,
>                                   b^(a^-1) = b * d^-1 >;
```

We extract the map f from G (the first group in any EFA-series of G) onto the module given by the first factor of an EFA-series of G.

```
> f := EFAModuleMaps(G)[1];
> f;
Mapping from: GrpGPC: G to GModule of dimension 2 over Integer
Ring
```

The module itself can be accessed as the codomain of f.

```
> M := Codomain(f);
> M;
GModule M of dimension 2 over Integer Ring
```

Spinning up random elements, we try to construct a submodule S of M.

```
> repeat
>    S := sub<M|[Random(-1, 1): i in [1 .. Dimension(M)]]>;
>    until Dimension(S) gt 0 and S ne M;
> S;
GModule S of dimension 1 over Integer Ring
```

The preimage N of S under f is a normal subgroup of G, which lies between the first and the second subgroup of the original EFA-series for G.

```
> N := S @@ f;
> PCGenerators(N, G);
{@ a^2 * b^4, c, d, e @}
```

72.13 Power Groups

`Parent(G)`

The PowerStructure of category GrpGPC.

`PowerGroup(G)`

The set of all subgroups of G. This is very useful when constructing sets of polycyclic groups. If the user will be building a set of subgroups of a polycyclic group G, then it is best to specify the set's universe to be PowerGroup(G). If the set's universe is not specified it will be the parent structure of G as returned by Parent(G).

73 BRAID GROUPS

Chapter 73
BRAID GROUPS

73.1 Introduction

This chapter deals with another, quite specialised, class of finitely presented groups for which the word problem is solvable, the category of braid groups. The corresponding MAGMA category is called `GrpBrd`.

The notion of braid groups was introduced by Artin [Art47], who considered a sequence B_n $(n = 1, 2, \ldots)$ of groups, where B_n is presented on $n-1$ generators $\sigma_1, \ldots, \sigma_{n-1}$ with the defining relations

$$\begin{aligned} \sigma_i\sigma_j &= \sigma_j\sigma_i && (1 \leq i < j < n, \quad j - i > 1), \\ \sigma_i\sigma_{i+1}\sigma_i &= \sigma_{i+1}\sigma_i\sigma_{i+1} && (1 \leq i < n-1) \quad . \end{aligned}$$

B_n is called the *braid group on n strings*. In the sequel, we refer to the above presentation as *Artin presentation* and to $\sigma_1, \ldots, \sigma_{n-1}$ as *Artin generators* of B_n.

Birman, Ko and Lee introduced an alternative way of presenting braid groups [BKL98]. Here, B_n is presented on $n(n-1)/2$ generators $a_{r,t}$ $(n \geq r > t \geq 1)$ with the defining relations

$$\begin{aligned} &a_{t,s}a_{r,q} = a_{r,q}a_{t,s} \quad \text{for } n \geq t > s \geq 1,\ n \geq r > q \geq 1,\ (t-r)(t-q)(s-r)(s-q) > 0 \\ &a_{t,s}a_{s,r} = a_{t,r}a_{t,s} = a_{s,r}a_{t,r} \quad \text{for } n \geq t > s > r > 0 \quad . \end{aligned}$$

We refer to this presentation as *BKL presentation* and to $a_{r,t}$ $(n \geq r > t \geq 1)$ as *BKL generators* of B_n.

A possible choice for the BKL generators in terms of Artin generators is $a_{r,t} = (\sigma_{r-1} \cdots \sigma_{t+1})\sigma_t(\sigma_{t+1}^{-1} \cdots \sigma_{r-1}^{-1})$. This identification is used in MAGMA.

Recently, braid groups came under consideration as possible sources for public key cryptosystems [AAG99, KLC+00]. The features of braid groups which make them interesting for public key cryptography are the following.

- The basic group operations in braid groups can be implemented efficiently on a computer.
- The word problem in braid groups is solvable, that is, there is a normal form for elements of a braid group and elements can be compared. Moreover, there are algorithms which are able to compute the normal form of an element efficiently.
- There are several problems in braid groups which are believed to be mathematically hard and whose use for cryptographic purposes has been suggested. The most important examples are variations of the conjugacy problem.

However, both recent attacks on particular cryptosystems [GKT+02, HS03, Hug02, LL02, LP03] and advances in the analysis of the conjugacy problem [GM02, Geb03] in general shed some doubts on the security of braid group cryptosystems. At the time of this writing it is an open question whether braid group cryptosystems can be made secure by an appropriate choice of parameters and keys or whether they have to be considered as insecure. More research into these issues is necessary.

The MAGMA category `GrpBrd` was introduced mainly with these applications in mind. Focus was put on providing fast operations with elements and on giving the user as much control over the details of computations as possible.

73.1.1 Lattice Structure and Simple Elements

In this section we briefly recall the basic terminology used for describing elements of braid groups. More detailed descriptions can be found in [ECH+92] for the Artin presentation and in [BKL98] for the BKL presentation.

We remark that both Artin presentation and BKL presentation are special cases of so-called *Garside groups* [Deh02].

In the sequel, let M be either the Artin presentation or the BKL presentation of the braid group B on n strings, let X denote the generators of M and let R denote the relations of M. As the relations in R do not contain inverses of generators, we can interpret M as monoid presentation. We denote the finitely presented monoid defined by M by B^+. The natural homomorphism from B^+ to B can be shown to be injective. We identify its image with B^+ and call it the set of *positive* elements of B. Finally, we denote the identity of B by 1.

We can now define two partial orderings on B. For elements $u, v \in B$ we say $u \preceq v$, if there exists a positive element a such that $ua = v$, and we say $v \succeq u$, if there exists a positive element a such that $v = au$. Note that these partial orderings are different; $u \preceq v$ is not equivalent to $v \succeq u$.

B can be shown to be a lattice with respect to both partial orderings, that is, for elements $u, v \in B$ there are elements $d_l, m_l, d_r, m_r \in B$ such that

$$\begin{aligned}
d_l \preceq u,\ d_l \preceq v \quad &\text{and} \quad d \preceq u,\ d \preceq v \ \text{ implies } \ d \preceq d_l \ \text{ for all } \ d \in B \\
u \preceq m_l,\ v \preceq m_l \quad &\text{and} \quad u \preceq m,\ v \preceq m \ \text{ implies } \ m_l \preceq m \ \text{ for all } \ m \in B \\
u \succeq d_r,\ v \succeq d_r \quad &\text{and} \quad u \succeq d,\ v \succeq d \ \text{ implies } \ d_r \succeq d \ \text{ for all } \ d \in B \\
m_r \succeq u,\ m_r \succeq v \quad &\text{and} \quad m \succeq u,\ m \succeq v \ \text{ implies } \ m \succeq m_r \ \text{ for all } \ m \in B \quad .
\end{aligned}$$

We call d_l, m_l, d_r and m_r the *left-gcd*, the *left-lcm*, the *right-gcd* and the *right-lcm*, respectively, of u and v.

It can be shown that the left-lcm of the elements of X and the right-lcm of the elements of X are equal; we call this element the *fundamental element* of the presentation M and denote it by D. The fundamental element is crucial for the study of braid groups. One of its most important properties is that a certain power D^N of D generates the centre of B. ($N = 2$ for the Artin presentation and $N = n$ for the BKL presentation.) Moreover, $u \preceq D^k$ is equivalent to $D^k \succeq u$ and $D^k \preceq u$ is equivalent to $u \succeq D^k$ for all $k \in \mathbf{Z}, u \in B$.

In MAGMA, the partial ordering $\preceq$ is provided as operator `le` and the partial ordering $\succeq$ is provided as operator `ge`; see Section 73.4.4. For a description of the functions computing lcm and gcd of elements, see Section 73.4.5.

The positive elements c of B satisfying $c \preceq D$ are called *simple elements*; we denote the set of simple elements by C. simple elements can be uniquely described by permutations on n points. In MAGMA, a simple element c inducing a permutation π on the strings on which B is defined, is represented by the permutation π^{-1}.

If M is the Artin presentation, every permutation on n points corresponds to a simple element, that is, $|C| = n!$.

If M is the BKL presentation, $|C| = (2n)!/(n!(n+1)!)$ and only permutations on n points which are products of parallel, descending cycles correspond to simple elements. Here, a cycle $(i_1, \ldots, i_r)$ is called *descending* if $i_1 > \ldots > i_r$ and two descending cycles $(i_1, \ldots, i_r)$ and $(j_1, \ldots, j_s)$ are called *parallel* if $(i_k - j_l)(i_k - j_{l'})(i_{k'} - j_l)(i_{k'} - j_{l'}) > 0$ for all $1 \leq k, k' \leq r$ and $1 \leq l, l' \leq s$. The descending cycle $(i_1, \ldots, i_r)$ corresponds to the element $a_{i_1,i_2} a_{i_2,i_3} \cdots a_{i_{r-1},i_r}$ of B. It is obvious from the defining relations that the simple elements defined by two parallel descending cycles commute.

Every element u of B can be written in the form $u = D^l c_1 \cdots c_k$, where l is a suitable integer and $c_1, \ldots c_k$ are simple elements. We call representations of this form *simple element representations* or *canonical factor products* (CFP).

73.1.2 Representing Elements of a Braid Group

This section describes the ways in which elements of a braid group can be represented internally by MAGMA. From the user's point of view, this mainly affects input and printing of elements. This section is intended to be a concise overview; for a detailed description of functions and for examples we refer to Section 73.2, Section 73.3 and Section 73.4.1.

Since an element of a braid group B can be represented either as word in the generators or as product of simple elements (see Section 73.4.5) with respect to either the Artin presentation or the BKL presentation of B, there are four different ways of representing elements of B, which can be used for entering or printing elements and for computing with elements.

73.1.2.1 Automatic Conversions

MAGMA can work with all the above representations and conversions are done automatically when necessary, for example, when multiplying an element defined as word in the Artin generators with an element given as product of simple elements for the BKL presentation. Hence, the user normally does not have do give too much thought about how elements are represented. It should be noted, however, that automatic conversions can affect performance and that in time critical situations, the best results in general are obtained if automatic conversions are avoided.

73.1.2.2 Default Presentations

When creating a braid group B using the command `BraidGroup`, the user can specify whether the Artin presentation or the BKL presentation should be used as *default presentation* for B. Unless specified otherwise by the user, this presentation is used in all

subsequent operations with B or with elements of B. In particular, group operations and printing of elements are performed with respect to this presentation. It is possible to change the default presentation using the command SetPresentation. Certain commands accept a parameter Presentation, which can be used to perform that command with respect to a presentation other than the default presentation.

73.1.2.3 Representation Used for Group Operations

By default, group operations with elements of a braid group B are performed using representations of the elements as products of simple elements for the default presentation of B. Experienced users can change this behaviour using the command SetForceCFP. If this flag is set to false, arguments of a group operation are not automatically converted into CFP representation if both arguments are represented as words in the generators of the default presentation of B, but the operation is performed, if possible, using the word representations instead.

73.1.2.4 Printing of Elements

The default printing format for an element u of a braid group B is that both a representation of u as word in the generators of the default presentation of B and a representation of u as product of simple elements for the default presentation of B are printed.

Depending on the application, the user may wish to change the print format so that only one of the above representations of u is printed. This can be achieved using the command SetElementPrintFormat.

73.1.3 Normal Form for Elements of a Braid Group

This section briefly describes the normal form for elements of braid groups. For details we refer to [ECH+92] and [BKL98]. The MAGMA commands for computing normal forms are described in Section 73.4.2.

Let B be the braid group on n strings and fix a presentation M for B, either the Artin presentation or the BKL presentation. A product of simple elements $D^l c_1 \cdots c_k$ is said to be in *left normal form* with respect to M, if $c_1 \neq D$, $c_k \neq 1$ and $(c_i^{-1} D) \wedge_l c_{i+1} = 1$ for $i = 1, \ldots, k-1$, where $(c_i^{-1} D) \wedge_l c_{i+1}$ denotes the left-gcd of $c_i^{-1} D$ and c_{i+1} with respect to the presentation M.

Similarly, we define $c_1 \cdots c_k D^l$ to be in *right normal form* with respect to M, if $c_k \neq D$, $c_1 \neq 1$ and $c_i \wedge_r (D c_{i+1}^{-1}) = 1$ for $i = 1, \ldots, k-1$, where $\wedge_r$ denotes right-gcd with respect to the presentation M.

It can be shown that the numbers of simple elements and the powers of D in the left and right normal forms of an element are equal, that is, if $x \in B$ has left normal form $D^l c_1 \cdots c_k$ and right normal form $\bar{c}_1 \cdots \bar{c}_{k'} D^{l'}$ then $k' = k$ and $l' = l$. In this situation we call l the *infimum* of x, denoted by $\inf(x)$, k the *canonical length* of x, denoted by $\mathrm{len}(x)$, and $l + k$ the *supremum* of x, denoted by $\sup(x)$. l is the maximal integer d satisfying $D^d \preceq x$ and $l + k$ is the minimal integer d satisfying $x \preceq D^d$.

To bring a product $D^l c_1 \cdots c_k$ of simple elements into left normal form, we proceed by induction, assuming that $D^l c_1 \cdots c_{k-1}$ is in left normal form. For $i = k-1, \ldots, 1$ we now

compute $d = (c_i^{-1}D) \wedge_l c_{i+1}$ and, if $d \neq 1$, replace c_i by $c_i d$ and c_{i+1} by $d^{-1}c_{i+1}$. Finally, we delete trailing trivial simple elements and absorb simple elements equal to D into the leading power of D. The result can be shown to be in left normal form [ECH+92, BKL98].

Both the theoretical complexity of this algorithm and its performance in practice are determined by the gcd computations.

For the Artin presentation, the cost of computing the left-gcd of two simple elements is $O(n \log n)$ [ECH+92], whence the complexity of bringing a product of simple elements as above into left normal form is $O(k^2 n \log n)$.

For the Artin presentation, the cost of computing the left-gcd of two simple elements is $O(n)$ [BKL98], whence the complexity of bringing a product of simple elements as above into left normal form is $O(k^2 n)$.

Computing right normal forms is analogous.

73.1.4 Mixed Canonical Form and Lattice Operations

This section outlines the algorithms used for lattice operations in a braid group. Let u and v be elements of a braid group B and let M be either the Artin presentation or the BKL presentation of B. The MAGMA commands for computing mixed canonical forms are described in Section 73.4.2 and the commands providing lattice operations are described in Section 73.4.5.

Evaluating partial orderings for u and v with respect to M is straightforward. $u \preceq v$ if and only if $u^{-1}v$ is a positive element with respect to M. The latter can be decided by computing the left normal form $D^l c_1 \cdots c_k$ of $u^{-1}v$ with respect to M: $u^{-1}v$ is positive if and only if $l \geq 0$. Evaluating the partial ordering $\succeq$ is analogous.

We call the tuple $< a, b >$ the *left-mixed canonical form* of an element $x \in B$, if $a = a_1 \cdots a_k$ and $b = b_1 \cdots b_s$ are positive elements in left normal form ($a_1 = D$, $b_1 = D$ is permitted), $x = a^{-1}b$ and the left-gcd of a_1 and b_1 is trivial.

Similarly, we call the tuple $< a, b >$ the *right-mixed canonical form* of x, if $a = a_1 \cdots a_k$ and $b = b_1 \cdots b_s$ are positive elements in right normal form ($a_k = D$, $b_s = D$ is permitted), $x = ab^{-1}$ and the right-gcd of a_k and b_s is trivial.

It is not difficult to show that the left-gcd of u and v is given by ua^{-1}, where $< a, b >$ is the left-mixed canonical form of $u^{-1}v$, and that the right-gcd of u and v is given by $a^{-1}u$, where $< a, b >$ is the right-mixed canonical form of uv^{-1} [ECH+92].

Similarly, the left-lcm of u and v is given by ua, where $< a, b >$ is the right-mixed canonical form of $u^{-1}v$ and the right-lcm of u and v is given by au, where $< a, b >$ is the left-mixed canonical form of uv^{-1}

Computing the left-mixed canonical form of an element x can, after writing $x = a^{-1}b$ with two positive elements a and b, easily be reduced to computing repeatedly the left-normal forms of a and b and cancelling the left-gcd of the leading simple elements. Computing the right-mixed canonical form is analogous.

73.1.5 Conjugacy Testing and Conjugacy Search

Conjugacy testing, that is, deciding whether two given braids are conjugate, and conjugacy search, that is, computing a conjugating element for a pair of conjugate braids, are of particular importance to public key cryptosystems based on braid groups. Known algorithms for both conjugacy testing and conjugacy search require the (at least partial) computation of an invariant of the conjugacy classes of the elements in question, either the *super summit set* [Gar69, ERM94] or the *ultra summit set* [Geb03].

This section recalls the definition of these invariants and sketches the algorithms used for computing them, for conjugacy testing and for conjugacy search. The relevant MAGMA commands are described in Section 73.4.6.

For this section let B be a braid group and let M be either the Artin presentation or the BKL presentation of B.

73.1.5.1 Definition of the Class Invariants

We define two operations, the *cycling* operation $\mathbf{c}$ and the *decycling* operation $\mathbf{d}$, each mapping an arbitrary element $x \in B$ to a conjugate of x as follows. Let $x \in B$ be a braid with left normal form $x = D^l c_1 \cdots c_k$ as defined in Section 73.1.3. If $k = 0$, we define $\mathbf{c}(x) = x$ and $\mathbf{d}(x) = x$. Otherwise, we define $\mathbf{c}(x) = D^l c_2 \cdots c_k (c_1^{D^{-l}})$ and $\mathbf{d}(x) = D^l (c_k^{D^l}) c_1 \cdots c_{k-1}$.

We now fix an element $x \in B$ and consider the set C_x of all conjugates of x. Proofs for the following facts can be found in [ECH+92] or [BKL98].

- The set $\{\inf(y) : y \in C_x\}$ is bounded above; we denote its maximum by ss-inf(x).
- The set $\{\sup(y) : y \in C_x\}$ is bounded below; we denote its minimum by ss-sup(x).
- The maximum of inf on C_x and the minimum of sup on C_x can be achieved simultaneously.

We define three sets of conjugates of x as follows.

- The set $P_x = \{y \in C_x : y \in B^+\}$, containing the positive conjugates of x.
- The set $S_x = \{y \in C_x : \inf(y) = \text{ss-inf}(x), \sup(y) = \text{ss-sup}(x)\}$, called the *super summit set* of x.
- The set $U_x = \{y \in S_x : \exists\, i > 0 : \mathbf{c}^i(y) = y\}$, called the *ultra summit set* of x.

Clearly, the sets P_x, S_x and U_x only depend on the conjugacy class of x. Moreover, the set P_x is empty if ss-inf$(x) < 0$ and it contains S_x if ss-inf$(x) \geq 0$.

Proofs of the following properties can be found in [ECH+92] and [BKL98] for the sets P_x and S_x and in [Geb03] for the set U_x.

- The sets P_x, S_x and U_x are finite.
- The sets S_x and U_x are non-empty.
- Representatives of P_x, S_x and U_x, respectively, can be obtained from x by a finite number of cycling and decycling operations.

73.1.5.2 Computing the Class Invariants

The main tools for computing the class invariants introduced in Section 73.1.5.1 are the following "convexity" results established in [ERM94] and [FGM03] for the sets P_x and S_x and in [Geb03] for the set U_x. Let $I_x \in \{P_x, S_x, U_x\}$.

- For $y, z \in I_x$, there exists a finite sequence $y = y_0, \ldots, y_r = z$ such that for $i = 1, \ldots, r$, $y_i \in I_x$ and $y_i = y_{i-1}^{c_i}$ for a simple element c_i.
- For $y \in I_x$ and a simple element c, there exists a unique $\preceq$-minimal element $\iota_y(c)$ such that $c \preceq \iota_y(c)$ and $y^{\iota_y(c)} \in I_x$. Moreover, $\iota_y(c)$ is simple.

By the above results, any non-empty subset $I \subseteq I_x$ with the property that $y^{\iota_y(s)} \in I$ for all $y \in I$ and all generators s of the presentation M is equal to I_x. In particular, I_x can be computed, starting from a single representative, as closure under conjugation with minimal simple elements.

Algorithms for computing the minimal simple elements $\iota_y(c)$ are given in [FGM03] for the case $I_x \in \{P_x, S_x\}$ and in [Geb03] for the case $I_x = U_x$.

The MAGMA commands for computing the class invariants P_x, S_x and U_x as well as corresponding minimal simple elements $\iota_y(c)$ are described in Section 73.4.6.

73.1.5.3 Conjugacy Testing and Conjugacy Search

Testing conjugacy of two braids $x, y \in B$ can be performed using either super summit sets or ultra summit sets. It is obvious from the results cited in Section 73.1.5.1 that the following are equivalent.

- x and y are conjugate in B.
- $S_x = S_y$.
- $U_x = U_y$.
- $S_x \cap S_y \neq \emptyset$.
- $U_x \cap U_y \neq \emptyset$.

If x and y are conjugate, a conjugating element can be obtained by establishing an element $z \in S_x \cap S_y$ or $z \in U_x \cap U_y$ both as conjugate of x and of y and keeping track of the conjugating elements in each step.

The size of super summit sets grows rapidly with increasing values of braid index n and canonical length. In general, computing super summit sets is difficult or infeasible for braids on more than 5-10 strings, except for very short canonical lengths. Ultra summit sets, on the other hand tend to be much smaller and can frequently be computed for braids on up to 100 strings and canonical length up to 1000, provided sufficient memory is available [Geb03]. Conjugacy search may be successful even in situations where the entire class invariant is too large to be computed.

In MAGMA, conjugacy testing and conjugacy search based on ultra summit sets is provided by the function `IsConjugate`.

73.2 Constructing and Accessing Braid Groups

This section describes the facilities for creating a braid group and for accessing and changing its basic properties.

`BraidGroup(n: parameters)`

`BraidGroup(GrpBrd, n: parameters)`

Given a small integer $n > 0$, return the braid group on n strings, that is, $n-1$ Artin generators.

`Presentation` MonStgElt *Default :* "*Artin*"

The presentation can be selected using the parameter `Presentation`. Possible values for this parameter are `"Artin"` (default) and `"BKL"`.

`GetPresentation(B)`

Returns a string s indicating the presentation currently used for B. s is either `"Artin"` or `"BKL"`.

`SetPresentation(~B, s)`

Set the presentation used for B to the presentation indicated by s. Possible values for s are `"Artin"` and `"BKL"`.

`GetForceCFP(B)`

Returns whether arithmetic operations with elements of B are always done using representations of the elements as products of simple elements.

`SetForceCFP(~B, b)`

By default, arithmetic operations with elements of B are always done using representations of the elements as products of simple elements. If necessary, such representations are computed.

Experienced users can turn this feature off for a braid group B using the procedure `SetForceCFP` with b set to `false`.

`GetElementPrintFormat(B)`

Returns a string s indicating the format currently used for printing elements of B. s is one of `"Word"`, `"CFP"` or `"Both"`.

`SetElementPrintFormat(~B, s)`

When printing an element of a braid group B, by default both the representation as word in the generators and the representation as product of simple elements in the presentation selected for B are printed.

Experienced users can use the procedure `SetElementPrintFormat` for changing the print format. Possible values for s are `"Word"`, `"CFP"` and `"Both"`.

`NumberOfStrings(B)`

Given a braid group B, return the number of strings on which B is defined.

`NumberOfGenerators(B)`

`Ngens(B)`

Given a braid group B, return the number of Artin generators of B. Note that the number of Artin generators is returned regardless of the presentation selected for B.

73.3 Creating Elements of a Braid Group

This section describes the facilities for creating elements of a braid group.

`Representative(B)`

`Rep(B)`

Given a braid group B, return a representative of B.

`Identity(B)`

`Id(B)`

`B ! 1`

Given a braid group B, return the identity element of B.

`FundamentalElement(B: parameters)`

`Presentation` MonStgElt *Default :*

Return the fundamental element for the presentation of B indicated by the parameter `Presentation`. Possible values for this parameter are `"Artin"` and `"BKL"`. If the parameter `Presentation` is not used, the fundamental element for the presentation currently selected for B is returned.

`Generators(B: parameters)`

`Presentation` MonStgElt *Default :*

Return a sequence containing the generators for the presentation of B indicated by the parameter `Presentation`. Possible values for this parameter are `"Artin"` and `"BKL"`. If the parameter `Presentation` is not used, a sequence containing the generators for the presentation currently selected for B is returned.

`B . i`

Given a braid group B on n strings and an integer i, where $0 < |i| < n$, return the $|i|$-th Artin generator σ_i, if $i > 0$, or its inverse $\sigma_{|i|}^{-1}$, if $i < 0$.

`B . T`

Given a braid group B on n strings and an tuple $T =< r, t >$, where $1 \leq |t| < |r| \leq n$, return the BKL generator $a_{|r|,|t|}$, if $r, t > 0$, or its inverse $a^{-1}_{|r|,|t|}$ otherwise.

`B ! [ i1, ..., ik ]`

Given a braid group B on n strings and a sequence $[i_1, \cdots, i_k]$ of integers satisfying $0 < |i_j| < n$ $(j = 1, \ldots, k)$, return the element of B given by the product

$$\sigma_{|i_1|}^{\mathrm{sgn}(i_1)} \cdots \sigma_{|i_k|}^{\mathrm{sgn}(i_k)}.$$

`B ! [ T1, ..., Tk ]`

Given a braid group B on n strings and a sequence $[T_1, \cdots, T_k]$ of tuples satisfying $T_j =< r_j, t_j >$, $1 \leq |t_j| < |r_j| \leq n$ $(j = 1, \ldots, k)$, return the element of B given by the product

$$a_{|r_1|,|t_1|}^{e_1} \cdots a_{|r_k|,|t_k|}^{e_k}$$

where $e_j = 1$ if $r_j, t_j > 0$ and $e_j = -1$ otherwise $(j = 1, \ldots, k)$.

`B ! p`

Given a braid group B on n strings and a permutation p on n points, return the simple element defined by p in the presentation currently selected for B as new element of B.

Note that the result in general depends on the presentation selected for B. Note further that in the BKL presentation, only permutations which are products of parallel descending cycles correspond to simple elements; attempting to coerce an invalid permutation will result in a runtime error. The function `IsProductOfParallelDescendingCycles` can be used to test whether a given permutation corresponds to a BKL simple element.

`B ! [ p1, ...,pk ]`

Given a braid group B on n strings and a sequence $[p_1, \ldots, p_k]$ of permutations on n points, return the product $c_1 \cdots c_k$ as new element of B, where c_j is the simple element defined by p_j in the presentation currently selected for B $(j = 1, \ldots, k)$.

Note that the result in general depends on the presentation selected for B. Note further that in the BKL presentation, only permutations which are products of parallel descending cycles correspond to simple elements; attempting to coerce a sequence containing an invalid permutation will result in a runtime error. The function `IsProductOfParallelDescendingCycles` can be used to test whether a given permutation corresponds to a BKL simple element.

`B ! T`

Given a braid group B on n strings and an tuple $T =< s, l, S, r >$, where s is either the string `"Artin"` or the string `"BKL"`, l and r are integers and S is a sequence $[p_1, \ldots, p_k]$ of permutations on n points, return the product $D^l c_1 \cdots c_k D^r$ as new element of B, where D is the fundamental element and c_j is the simple element defined by p_j $(j = 1, \ldots, k)$ in the presentation indicated by s.

Note that in the BKL presentation, only permutations which are products of parallel descending cycles correspond to simple elements; if S contains an invalid permutation, a runtime error will result. Whether the elements of a given sequence S correspond to BKL simple elements can be tested using the function `IsProductOfParallelDescendingCycles`.

`IsProductOfParallelDescendingCycles(p)`

Given a permutation p on n points, return whether p is a product of parallel descending cycles, that is, whether p defines a simple element in the BKL monoid on n strings.

`Random(B, r, s, m, n:` *parameters*`)`

`RandomCFP(B, r, s, m, n:` *parameters*`)`

`Random(B:` *parameters*`)`

`RandomCFP(B:` *parameters*`)`

`Presentation` MONSTGELT *Default :*

Given a braid group B and integers r, s, m, n, satisfying $r \leq s$ and $0 \leq m \leq n$, a pseudo-random element of B is constructed as follows. Let D be the fundamental element and C the set of simple elements for the presentation indicated by the parameter `Presentation`. First, integers $e \in [r, s]$ and $l \in [m, n]$ are chosen using uniform distributions on these sets. Then, for $i = 1, \ldots, l$, $c_i \in C$ is chosen using a uniform distribution on C and the element $D^e c_1 \cdots c_l$ is returned.

If no value is given for the parameter `Presentation`, the presentation selected for B is used.

The versions with a single argument are short for `Random(B, 0, 0, 0, 42)`.

`Random(B, m, n:` *parameters*`)`

`RandomWord(B, m, n:` *parameters*`)`

`RandomWord(B:` *parameters*`)`

`Presentation` MONSTGELT *Default :*

Given a braid group B and two integers $0 \leq m \leq n$, `Random(B, m, n)` returns a pseudo-random element of B constructed as follows. First, a length $l \in [m, n]$ is chosen using a uniform distribution. Then, for $i = 1, \ldots, l$, $g_i \in X \cup X^{-1} \setminus \{g_{i-1}^{-1}\}$ is chosen using a uniform distribution on this set. Here, X is the set of generators of the presentation indicated by the parameter `Presentation` and X^{-1} is the set of generator inverses.

If no value is given for the parameter `Presentation`, the presentation selected for B is used.

The signature `RandomWord(B)` is short for `RandomWord(B, 0, 42)`.

Example H73E1

We construct the braid group B on 6 strings and the symmetric group S on 6 points.

```
> S := Sym(6);
> B := BraidGroup(6);
> B;
GrpBrd : B on 6 strings
```

By default, B is created using the Artin presentation.

```
> GetPresentation(B);
Artin
```

We now define the fundamental element with respect to the BKL presentation of B and print this element with respect to the presentation currently used for B, that is, with respect to the Artin presentation. Note that both a word in the Artin generators and a representation of the element in terms of Artin simple elements are printed.

```
> D_BKL := FundamentalElement(B : Presentation := "BKL");
> D_BKL;
B.5 * B.4 * B.3 * B.2 * B.1
<Artin, 0, [
    (1, 6, 5, 4, 3, 2)
], 0>
> GetElementPrintFormat(B);
Both
```

We print the BKL generator $a_{3,1}$.

```
> B.<3,1>;
B.2 * B.1 * B.2^-1
<Artin, 0, [
    (1, 3, 2),
    (1, 6)(2, 5, 3, 4)
], -1>
```

Next we change the format for printing elements of B using the function `SetElementPrintFormat` so that only a representation in terms of simple elements is printed.

```
> SetElementPrintFormat(~B, "CFP");
```

We now define and print several elements of B, illustrating the use of some of the functions described in the previous section.

First we create a pseudo-random element of B as product of 3 random simple elements for the Artin presentation.

```
> u := Random(B, 0, 0, 3, 3);
> u;
```

```
<Artin, 0, [
    (1, 6)(3, 5, 4),
    (1, 3)(2, 6)(4, 5),
    (2, 3)
], 0>
```

Next we define an element of B by a product of simple elements for the BKL presentation using the coercion operator '!'. Note that printing of this element is still done with respect to the Artin presentation.

```
> v := B ! <"BKL", 0, [ S | (1,6)(3,5,4), (1,3)(4,5)], 0>;
> v;
<Artin, 0, [
    (1, 6, 5, 4, 3, 2),
    (1, 2, 6)(3, 5),
    (2, 4, 5, 6),
    (1, 6)(2, 4, 3, 5)
], -2>
```

Finally, we look at the simple elements defined by the permutations $p = (1, 3)(4, 2)$ and $q = (1, 4, 3)$ on 6 points.

```
> p := S ! (1,3)(4,2);
> q := S ! (1,4,3);
```

Creating the simple elements for the Artin presentation defined by p and q is straightforward using the coercion operator '!'.

```
> p_Artin := B!p;
> p_Artin;
<Artin, 0, [
    (1, 3)(2, 4)
], 0>
```

```
> q_Artin := B!q;
> q_Artin;
<Artin, 0, [
    (1, 4, 3)
], 0>
```

We now change the presentation used for B to the BKL presentation. Note that this also changes the presentation with respect to which elements are printed.

```
> SetPresentation(~B, "BKL");
> GetPresentation(B);
BKL
```

The attempt to define a simple element for the BKL presentation using the permutation p fails.

```
>  p_BKL := B!p;

>> p_BKL := B!p;
             ^
```

```
Runtime error in '!': Illegal coercion
LHS: GrpBrd
RHS: GrpPermElt
```

We should have been more careful: using the function IsProductOfParallelDescendingCycles we see that p is not a product of parallel descending cycles and hence does not define a simple element for the BKL presentation.

```
> IsProductOfParallelDescendingCycles(p);
false
```

q, on the other hand, does define a simple element for the BKL presentation and we can coerce q to an element of B using the operator '!'.

```
> IsProductOfParallelDescendingCycles(q);
true
> q_BKL := B!q;
> q_BKL;
<BKL, 0, [
    (1, 4, 3)
], 0>
```

Note however, that the simple element for the BKL presentation defined by q and the simple element for the Artin presentation defined by q are different elements of B! (The comparison operator eq is described in Section 73.4.4.)

```
> q_BKL eq q_Artin;
false
```

The representations of the Artin simple elements defined by p and q in terms of BKL simple elements have no obvious connection to p and q, respectively.

```
> p_Artin;
<BKL, 0, [
    (1, 3, 2),
    (2, 4, 3)
], 0>

> q_Artin;
<BKL, 0, [
    (1, 4, 3, 2),
    (2, 3)
], 0>
```

73.4 Working with Elements of a Braid Group

73.4.1 Accessing Information

This sections describes how the internal representations of an element and a number of basic invariants can be accessed.

`Parent(u)`

Given an element u of a braid group B, return the parent group of u, that is B.

`#u`

Given an element u of a braid group B, return the length of the representing word in the generators corresponding to the presentation selected for B. Note that this is not an invariant of u.

`CanonicalFactorRepresentation(u: parameters)`

`CFP(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a tuple $T =< s, l, S, r >$ describing the representation in terms of simple elements for the presentation indicated by the value of the parameter `Presentation`. If no value for `Presentation` is given, the presentation selected for B is used.

The interpretation of the components of T is as follows: s is a string, either equal to `"Artin"` or equal to `"BKL"` indicating the presentation, l and r are integers and S is a sequence $[p_1, \ldots, p_k]$ of permutations on n points, such that

$$D^l c_1 \cdots c_k D^r$$

is the representation of u in terms of simple elements, where D is the fundamental element and c_j is the simple element defined by p_j $(j = 1, \ldots, k)$ in the presentation indicated by s.

`WordToSequence(u: parameters)`

`ElementToSequence(u: parameters)`

`Eltseq(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a sequence describing the representing word in the generators corresponding to the presentation indicated by the value of the parameter `Presentation`. If no value for `Presentation` is given, the presentation selected for B is used.

For a representing word

$$\sigma_{i_1}^{e_1} \cdots \sigma_{i_k}^{e_k}$$

in the Artin generators with $0 < i_j < n$ and $e_j \in \{-1, 1\}$ for $j = 1, \ldots, k$, the sequence of integers

$$[e_1 i_1, \ldots, e_k i_k]$$

is returned.

For a representing word

$$a_{r_1,t_1}^{e_1} \ldots a_{r_k,t_k}^{e_k}$$

in the BKL generators with $1 \leq t_j < r_j \leq n$ and $e_j \in \{-1, 1\}$ for $j = 1, \ldots, k$, the sequence of tuples

$$[< e_1 r_1, e_1 t_1 >, \ldots, < e_k r_k, e_k t_k >]$$

is returned.

`InducedPermutation(u)`

Given an element u of a braid group B on n strings, return the permutation on n points induced by u acting on the strings on which B is defined.

For the following description of the functions `CanonicalLength`, `Infimum` and `Supremum`, let D be the fundamental element and let $D^l c_1 \cdots c_k$ be the left normal form of the element u of the braid group B in the presentation indicated by the value of the parameter `Presentation`. If no value for `Presentation` is given, the presentation selected for B is used.

`CanonicalLength(u:` *parameters*`)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the canonical length k of u for the appropriate presentation of B. The argument is converted into left normal form.

`Infimum(u:` *parameters*`)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the infimum l of u for the appropriate presentation of B. The argument is converted into left normal form.

`Supremum(u:` *parameters*`)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the supremum $l + k$ of u for the appropriate presentation of B. The argument is converted into left normal form.

For the following description of the functions `SuperSummitCanonicalLength`, `SuperSummitInfimum` and `SuperSummitSupremum`, let D be the fundamental element and let $D^l c_1 \cdots c_k$ be the normal form of a representative of the super summit set the element u of the braid group B with respect to the presentation indicated by the value of the parameter `Presentation`. If no value for `Presentation` is given, the presentation selected for B is used.

`SuperSummitCanonicalLength(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the canonical length k of a representative of the super summit set of u with respect to the appropriate presentation of B, that is, the minimal canonical length among all conjugates of u. The argument is converted into left normal form.

`SuperSummitInfimum(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the infimum l of a representative of the super summit set of u with respect to the appropriate presentation of B, that is, the maximal infimum among all conjugates of u. The argument is converted into left normal form.

`SuperSummitSupremum(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the supremum $l+k$ of a representative of the super summit set of u with respect to the appropriate presentation of B, that is, the minimal supremum among all conjugates of u. The argument is converted into left normal form.

Example H73E2

We define the braid group B on 6 strings using the BKL presentation and create an element u as a random word of length between 5 and 10 in the BKL generators.

```
> B := BraidGroup(6 : Presentation := "BKL");
> u := RandomWord(B, 5, 10);
```

The parent group of u can be accessed using the function `Parent`.

```
> Parent(u);
GrpBrd : B on 6 strings
```

As word in the BKL generators, u has length 5. We define a sequence describing the representation of u as word in the BKL generators.

```
> #u;
5
> seq_BKL := WordToSequence(u);
> seq_BKL;
[ <5, 1>, <5, 2>, <5, 4>, <4, 1>, <2, 1> ]
```

When we ask for a representation as word in the Artin generators, such a representation is created automatically.

```
> seq_Artin := WordToSequence(u : Presentation := "Artin");
> seq_Artin;
```

```
[ 4, 3, 2, 1, 2, 1, -2, -3, 1 ]
```

We now define the permutation p induced by u on the strings on which B is defined.

```
> p := InducedPermutation(u);
> p;
(4, 5)
```

The representation of u in terms of simple elements for the Artin presentation can be obtained using the function CanonicalFactorRepresentation.

```
> CanonicalFactorRepresentation(u : Presentation := "Artin");
<Artin, 0, [
    (1, 5, 4, 3),
    (1, 2),
    (1, 6)(2, 5, 3),
    (5, 6)
], -1>
```

We now compute the canonical lengths of u with respect to the Artin presentation and with respect to the BKL presentation. Note that these lengths are different.

```
> CanonicalLength(u : Presentation := "Artin");
4
> CanonicalLength(u : Presentation := "BKL");
3
```

Finally, we compute for both presentations the canonical lengths of a super summit representative of u.

```
> SuperSummitCanonicalLength(u : Presentation := "Artin");
2
> SuperSummitCanonicalLength(u : Presentation := "BKL");
3
```

Obviously, u does not belong to its super summit set with respect to the Artin presentation. (We cannot tell for the BKL presentation from the information we have computed.)

73.4.2 Computing Normal Forms of Elements

This section describes functions and procedures for computing various normal forms of elements of a braid group B. All normal forms are defined in terms of representations of elements as products of simple elements and depend on the presentation of B which is used. The functions documented in this section all accept a parameter `Presentation` which can be used to specify the presentation of B with respect to which the computation should be performed. Possible values for this parameter are the strings `"Artin"` and `"BKL"` If no value is given for `Presentation`, the presentation selected for B is used.

`LeftNormalForm(u: parameters)`

`NormalForm(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a new element of B defined by the left normal form of u with respect to the indicated presentation.

`LeftNormalForm(~u: parameters)`

`NormalForm(~u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, bring u into left normal form with respect to the indicated presentation.

`RightNormalForm(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a new element of B defined by the right normal form of u with respect to the indicated presentation.

`RightNormalForm(~u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, bring u into right normal form with respect to the indicated presentation.

`LeftMixedCanonicalForm(u: parameters)`

`MixedCanonicalForm(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return two tuples T_1 and T_2 defining products $v_1 \cdots v_k$ and $w_1 \cdots w_l$, respectively, of simple elements for the indicated presentation, such that $v_1 \cdots v_k$ and $w_1 \cdots w_l$ are in left normal form, the left-gcd of v_1 and w_1 is trivial and

$$u = (v_1 \cdots v_k)^{-1}(w_1 \cdots w_l).$$

See the entry for `CanonicalFactorRepresentation` for a description of the tuple format. Note that the tuples can be coerced into elements of B using the coercion operator '`!`'.

`RightMixedCanonicalForm(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return two tuples T_1 and T_2 defining products $v_1 \cdots v_k$ and $w_1 \cdots w_l$, respectively, of simple elements for the indicated presentation, such that $v_1 \cdots v_k$ and $w_1 \cdots w_l$ are in right normal form, the right-gcd of v_1 and w_1 is trivial and

$$u = (v_1 \cdots v_k)(w_1 \cdots w_l)^{-1}.$$

See the entry for `CanonicalFactorRepresentation` for a description of the tuple format. Note that the tuples can be coerced into elements of B using the coercion operator '`!`'.

Example H73E3

We define the braid group B on 6 strings using the Artin presentation, set the print format for elements to `"CFP"` and define an element u of B.

```
> B := BraidGroup(6);
> SetElementPrintFormat(~B, "CFP");
>
> u := B ! <"Artin",
>          0,
>          [ Sym(6) | (1,6)(3,5,4), (1,3)(2,6)(4,5), (2,3)],
>          0>;
> u;
<Artin, 0, [
    (1, 6)(3, 5, 4),
    (1, 3)(2, 6)(4, 5),
    (2, 3)
], 0>
```

We compute and print the left normal form of u with respect to the Artin presentation of B.

```
> u_Artin := LeftNormalForm(u);
> u_Artin;
<Artin, 1, [
    (1, 2, 6, 5, 4, 3),
    (2, 3)
], 0>
```

We now compute the left normal form of u with respect to the BKL presentation of B. Since elements are printed with respect to the presentation selected for the parent group, that is, in the Artin presentation in our example, we use the function `CanonicalFactorRepresentation` to print the representation in terms of simple elements for the BKL presentation.

```
> u_BKL := LeftNormalForm(u : Presentation := "BKL");
> CFP(u_BKL : Presentation := "BKL");
<BKL, 2, [
    (2, 6, 5, 4, 3),
```

```
    (2, 6, 5, 4),
    (2, 6, 5),
    (2, 6),
    (2, 3)
], 0>
```

We define another element v of B in left normal form.

```
> v := LeftNormalForm(B.5*B.2^-2*B.4*B.3^-1*B.5^-1*B.3^-1*B.5);
> v;
<Artin, -3, [
    (1, 6)(2, 4, 3, 5),
    (1, 2, 6)(3, 5),
    (1, 6, 2, 5)(3, 4),
    (3, 5)(4, 6)
], 0>
```

As can easily be read off the representation of v in terms of simple elements which is in left normal form, v has infimum -3, canonical length 4 and supremum 1 with respect to the Artin presentation.

```
> Infimum(v);
-3
> CanonicalLength(v);
4
> Supremum(v);
1
```

Note that infimum, canonical length and supremum of an element can also be obtained from its right normal form.

```
> RightNormalForm(v);
<Artin, 0, [
    (4, 6, 5),
    (1, 6)(2, 5, 3, 4),
    (1, 6)(2, 4, 5),
    (1, 6)(2, 5)
], -3>
```

73.4.3 Arithmetic Operators and Functions for Elements

This section describes the basic arithmetic operations for elements of a braid group. Strictly speaking, all functions should be considered as functions on *representatives* of elements, that is, words in the generators or products of simple elements.

Unless stated otherwise, arithmetic operations with elements of a braid group B are performed using representations with respect to the presentation selected for B. This presentation can be changed using the function SetPresentation.

By default, arithmetic operations with elements of B are performed using representations in terms of simple elements; such representations are created if necessary. Experienced users can change this behaviour, if desired, using the function SetForceCFP.

The complexity of all basic arithmetic operations is linear in the length of the representations of the input elements. No normalisations are performed automatically, as doing so would restrict the user's control of operations with elements. It is, however, recommended to use the function NormalForm or its procedural version in time critical situations to limit the length of representations of elements; see Example H73E4.

`u * v`

Given elements u and v belonging to the same braid group B, return the product uv as a new element of B.

`u *:= v`

Given elements u and v belonging to the same braid group B, replace u with the product uv.

`u / v`

Given elements u and v belonging to the same braid group B, return the product uv^{-1} as a new element of B.

`u /:= v`

Given elements u and v belonging to the same braid group B, replace u with the product uv^{-1}.

`u ^ n`

Given an element u of a braid group B and an integer n, return the power u^n as a new element of B.

`u ^:= n`

Given an element u of a braid group B and an integer n, replace u with the power u^n.

`u ^ v`

Given elements u and v belonging to the same braid group B, return the conjugate $u^v = v^{-1}uv$ as a new element of B.

`u ^:= v`

Given elements u and v belonging to the same braid group B, replace u with the conjugate $u^v = v^{-1}uv$.

`Inverse(u)`

Given an element u of a braid group B, return its inverse u^{-1} as a new element of B.

`Inverse(~u)`

Given an element u of a braid group B, replace u with its inverse u^{-1}.

`LeftConjugate(u, v)`

Given elements u and v belonging to the same braid group B, return the "left conjugate" vuv^{-1} as a new element of B.

`LeftConjugate(~u, v)`

Given elements u and v belonging to the same braid group B, replace u with the "left conjugate" vuv^{-1}.

`LeftDiv(u, v)`

Given elements u and v belonging to the same braid group B, return the product $u^{-1}v$ as a new element of B.

`LeftDiv(u, ~v)`

Given elements u and v belonging to the same braid group B, replace v with the product $u^{-1}v$.

The following functions `Cycle` and `Decycle` accept a parameter `Presentation` which can be set either to `"Artin"` or to `"BKL"`. The results of the cycling and decycling operations are defined in terms of the left normal form $D^l c_1 \cdots c_k$ of the argument $u \in B$ in terms of simple elements for a presentation of B and the results in general depend on the presentation used. The results of these functions are returned in left normal form.

If no value for the parameter `Presentation` is given, the presentation selected for the parent group of the argument will be used.

`Cycle(u: parameters)`

`Presentation` MONSTGELT *Default :*

Given an element $u \in B$ with left normal form $D^l c_1 \cdots c_k$, return the result of a cycling operation on u, that is,

$$u^{(c_1^{D^{-l}})}$$

as new element of B in left normal form.

`Cycle(~u: parameters)`

`Presentation` MONSTGELT *Default :*

Given an element $u \in B$ with left normal form $D^l c_1 \cdots c_k$, replace u by the result of a cycling operation on u, that is, by

$$u^{(c_1^{D^{-l}})}$$

in left normal form.

`Decycle(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element $u \in B$ with left normal form $D^l c_1 \cdots c_k$, return the result of a decycling operation on u, that is,

$$u^{(c_k^{-1})}$$

as new element of B in left normal form.

`Decycle(~u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element $u \in B$ with left normal form $D^l c_1 \cdots c_k$, replace u by the result of a decycling operation on u, that is, by

$$u^{(c_k^{-1})}$$

in left normal form.

Example H73E4

We illustrate the importance of limiting the length of representations of elements using the function `NormalForm` when performing a sequence of arithmetic operations on an element.
Consider the following computation in the braid group B on 6 strings. Starting with an element w, we repeatedly replace w by the product ww^{σ_1} where σ_1 is the first Artin generator of B.
A naive way of implementing this computation would be as follows.

```
> B := BraidGroup(6);
> u := B.5*B.2^-2*B.4*B.3^-1;
> v := B.1;
> N := 14;
>
> T := Cputime();
> w := u;
> for i := 1 to N do
>    w := w * w^v;
> end for;
```

This, however, yields an extremely complicated representation for the result; the representation in terms of simple elements has the length 114686.

```
> #CFP(w)[3];
114686
```

Performing subsequent computations with the result, for example computing its normal form, is very expensive.

```
> NormalForm(~w);
> print "total time used: ", Cputime()-T;
```

```
total time used:  149.229
```

One might be tempted to solve this problem by working only with elements in normal form, that is, by bringing every result of an arithmetic operation into normal form after computing it.
Using this approach, computing the result of the above iteration is indeed much faster.

```
> T := Cputime();
> w := u;
> for i := 1 to N do
>    t := w^v;
>    NormalForm(~t);
>    w := w * t;
>    NormalForm(~w);
> end for;
> print "total time used: ", Cputime()-T;
total time used:  0.53
```

However, this strategy is not optimal either. For the above example, the optimal performance is obtained if the result is normalised every third pass through the iteration.

```
> T := Cputime();
> w := u;
> for i := 1 to N do
>    w := w * w^v;
>    if i mod 3 eq 0 then
>       NormalForm(~w);
>    end if;
> end for;
> NormalForm(~w);
> print "total time used: ", Cputime()-T;
total time used:  0.171
```

Unfortunately, the frequency of normalisation giving best results depends heavily on the situation, that is, both on the arithmetic operations and on the characteristics of the arguments.
As a rule of thumb, the effects of normalising results too frequently are less of a problem than normalising results not often enough or not at all.

73.4.4 Boolean Predicates for Elements

This section describes the tests for membership, equality and partial orderings which are available for elements of a braid group B.

Unless stated otherwise, all computations are performed in the presentation selected for B or in the presentation specified by the value of the parameter `Presentation`, either `"Artin"` or `"BKL"` if a value for this parameter is given.

`u in B`

Given an element u of a braid group and a braid group B, return `true` if $u \in B$ and `false` otherwise.

`u notin B`

Given an element u of a braid group and a braid group B, return `false` if $u \in B$ and `true` otherwise.

`IsEmptyWord(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group, return `true` if u is the represented by the empty word in the specified presentation and `false` otherwise.

`AreIdentical(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return `true` if u and v are represented by identical words in the specified presentation and `false` otherwise.

`IsSimple(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group, return `true` if u is a simple element with respect to the specified presentation and `false` otherwise. The argument is converted into normal form.

`IsSuperSummitRepresentative(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group, return `true` if u is an element of its super summit set with respect to the specified presentation and `false` otherwise. The argument is converted into normal form.

`IsUltraSummitRepresentative(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group, return `true` if u is an element of its ultra summit set with respect to the specified presentation and `false` otherwise. The argument is converted into normal form.

`IsIdentity(u: parameters)`

`IsId(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return `true` if u is the identity element of B and `false` otherwise. The argument is converted into normal form.

`u eq v`

Given elements u and v belonging to the same braid group B, return `true` if $u = v$ and `false` otherwise. Both arguments are converted into normal form.

`u ne v`

Given elements u and v belonging to the same braid group B, return `false` if $u = v$ and `true` otherwise. Both arguments are converted into normal form.

`u le v`

`IsLE(u, v: parameters)`

`IsLe(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return `true` if $u \preceq v$, that is, if $u^{-1}v$ is a positive element, with respect to the specified presentation and `false` otherwise.

Note that the parameter `Presentation` is not available for the operator version of this predicate.

`u ge v`

`IsGE(u, v: parameters)`

`IsGe(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return `true` if $u \succeq v$, that is, if uv^{-1} is a positive element, with respect to the specified presentation and `false` otherwise.

Note that the parameter `Presentation` is not available for the operator version of this predicate.

`IsConjugate(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return `true` and an element $c \in B$ satisfying $u^c = v$ if u and v are conjugate and return `false` otherwise.

The function first computes representatives u_s and v_s of the ultra summit sets of u and v, respectively, with respect to the specified presentation. If this does not prove that the elements are not conjugate, the function tries to compute elements of the ultra summit set of u until either the element v_s is found, proving that u and v are conjugate, or the ultra summit set of u is seen not to contain v_s, proving that u and v are not conjugate. See Example H73E8 for a more detailed description.

Note that testing elements for conjugacy is a hard problem and may require significant amounts of memory and CPU time.

Example H73E5

We define the braid group B on 6 strings using the Artin presentation and set the print format for elements to "CFP".

```
> B:= BraidGroup(6);
> SetElementPrintFormat(~B, "CFP");
```

(1) We create pseudo-random elements of B until we find an element u which is contained in its super summit set with respect to the Artin presentation of B.

```
> repeat
>    u := Random(B, 5, 10);
> until IsSuperSummitRepresentative(u);
> NormalForm(u);
<Artin, -2, [
    (1, 5)(2, 3, 6),
    (1, 5, 6, 3, 2, 4),
    (2, 6)(3, 4, 5)
], 0>
```

u is not contained in its super summit set with respect to the BKL presentation of B, showing that the super summit set of an element in general depends on the presentation with respect to which it is defined.

```
> IsSuperSummitRepresentative(u : Presentation := "Artin");
true
> IsSuperSummitRepresentative(u : Presentation := "BKL");
false
```

(2) This example shows that the Artin presentation and the BKL presentation give rise to distinct partial orderings on B.

$\sigma_1^{-1}\sigma_2\sigma_1$ has negative infimum with respect to the Artin presentation and hence is not a positive element with respect to this presentation.

```
> Infimum(B.1^-1*B.2*B.1 : Presentation := "Artin");
-1
```

Consequently, $\sigma_1 \not\preceq \sigma_2\sigma_1$ in the partial ordering defined with respect to the Artin presentation.

```
> B.1 le B.2*B.1;
false
```

We can also use the function version to check this.

```
> IsLE(B.1, B.2*B.1 : Presentation := "Artin");
false
```

However, $\sigma_1^{-1}\sigma_2\sigma_1$ is equal to the BKL generator $a_{3,1}$ and hence is, in particular, a positive element with respect to the BKL presentation. in the BKL generators.

```
> B.1^-1*B.2*B.1 eq B.<3,1>;
```

```
true
```

Hence, $\sigma_1 \preceq \sigma_2\sigma_1$ in the partial ordering defined with respect to the BKL presentation.

```
> IsLE(B.1, B.2*B.1 : Presentation := "BKL");
true
```

(3) We change the print format for elements of B so that only words in the Artin generators are printed.

```
> SetElementPrintFormat(~B, "Word");
```

Inducing permutations with different cycle structure, σ_1 and $\sigma_1\sigma_2$ cannot be conjugate in B.

```
> InducedPermutation(B.1);
(1, 2)
> InducedPermutation(B.2*B.1);
(1, 2, 3)
> IsConjugate(B.1, B.2*B.1);
false
```

σ_1 and σ_2, however, are conjugate in B. We compute a conjugating element c.

```
> res, c := IsConjugate(B.1, B.2);
> res;
true
> NormalForm(c);
B.2 * B.1
```

c, as desired, conjugates σ_1: s_1: to σ_2: s_2:.

```
> B.1^c eq B.2;
true
```

73.4.5 Lattice Operations

This section describes the functions available for computing lattice operations, least common multiple and greatest common divisor, for elements of a braid group B. The results of all lattice operations depend on the presentation used for B and on the partial ordering considered.

The functions documented in this section all accept a parameter `Presentation` which can be used to specify the presentation of B with respect to which the computation should be performed. Possible values for this parameter are the strings `"Artin"` and `"BKL"`. If no value is given for `Presentation`, the presentation selected for B is used.

`LeftGCD(u, v: parameters)`
`LeftGcd(u, v: parameters)`
`LeftGreatestCommonDivisor(u, v: parameters)`
`GCD(u, v: parameters)`
`Gcd(u, v: parameters)`
`GreatestCommonDivisor(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return the left-gcd of u and v, that is, the with respect to $\preceq$ maximal element d of B satisfying $d \preceq u$ and $d \preceq v$. Here, $\preceq$ is the partial ordering on B defined as follows: $a \preceq b$ iff $a^{-1}b$ is representable as a positive word in the specified presentation of B.

`RightGCD(u, v: parameters)`
`RightGcd(u, v: parameters)`
`RightGreatestCommonDivisor(u, v: parameters)`

`Presentation` MonStgElt *Default :*

Given elements u and v belonging to the same braid group B, return the right-gcd of u and v, that is, the with respect to $\succeq$ maximal element d of B satisfying $u \succeq d$ and $v \succeq d$. Here, $\succeq$ is the partial ordering on B defined as follows: $a \succeq b$ iff ab^{-1} is representable as a positive word in the specified presentation of B.

`LeftGCD(S: parameters)`
`LeftGcd(S: parameters)`
`LeftGreatestCommonDivisor(S: parameters)`
`GCD(S: parameters)`
`Gcd(S: parameters)`
`GreatestCommonDivisor(S: parameters)`

`Presentation` MonStgElt *Default :*

Given a set or a sequence S containing elements of a braid group B, return the left-gcd of the elements of S, that is, the with respect to $\preceq$ maximal element d of B satisfying $d \preceq s$ for all $s \in S$, where $\preceq$ is defined as above.

`RightGCD(S: parameters)`
`RightGcd(S: parameters)`
`RightGreatestCommonDivisor(S: parameters)`

`Presentation` MonStgElt *Default :*

Given a set or a sequence S containing elements of a braid group B, return the right-gcd of the elements of S, that is, the with respect to $\succeq$ maximal element d of B satisfying $s \succeq d$ for all $s \in S$, where $\succeq$ is defined as above.

`LeftLCM(u, v: parameters)`
`LeftLcm(u, v: parameters)`
`LeftLeastCommonMultiple(u, v: parameters)`
`LCM(u, v: parameters)`
`Lcm(u, v: parameters)`
`LeastCommonMultiple(u, v: parameters)`

`Presentation` MONSTGELT *Default :*

Given elements u and v belonging to the same braid group B, return the left-lcm of u and v, that is, the with respect to $\preceq$ minimal element d of B satisfying $u \preceq d$ and $v \preceq d$, where $\preceq$ is defined as above.

`RightLCM(u, v: parameters)`
`RightLcm(u, v: parameters)`
`RightLeastCommonMultiple(u, v: parameters)`

`Presentation` MONSTGELT *Default :*

Given elements u and v belonging to the same braid group B, return the right-lcm of u and v, that is, the with respect to $\succeq$ minimal element d of B satisfying $d \succeq u$ and $d \succeq v$, where $\succeq$ is defined as above.

`LeftLCM(S: parameters)`
`LeftLcm(S: parameters)`
`LeftLeastCommonMultiple(S: parameters)`
`LCM(S: parameters)`
`Lcm(S: parameters)`
`LeastCommonMultiple(S: parameters)`

`Presentation` MONSTGELT *Default :*

Given a set or a sequence S containing elements of a braid group B, return the left-gcd of the elements of S, that is, the with respect to $\preceq$ minimal element d of B satisfying $s \preceq d$ for all $s \in S$, where $\preceq$ is defined as above.

`RightLCM(S: parameters)`
`RightLcm(S: parameters)`
`RightLeastCommonMultiple(S: parameters)`

`Presentation` MonStgElt *Default :*

Given a set or a sequence S containing elements of a braid group B, return the right-lcm of the elements of S, that is, the with respect to $\succeq$ minimal element d of B satisfying $d \succeq s$ for all $s \in S$, where $\succeq$ is defined as above.

Example H73E6

We define the braid group B on 6 strings.

```
> B := BraidGroup(6);
> SetElementPrintFormat(~B, "CFP");
```

(1) For both Artin and BKL presentation, the fundamental element is the (left or right) least common multiple of the generators. We check this for the Artin presentation...

```
> D_Artin := LeftLCM({B.i : i in [1..NumberOfGenerators(B)]});
> D_Artin eq FundamentalElement(B);
true
> D_Artin eq RightLCM({B.i : i in [1..NumberOfGenerators(B)]});
true
```

...and for the BKL presentation.

```
> idx := { <r,t> : r,t in {1..NumberOfStrings(B)} | r gt t };
> D_BKL := LeftLCM({B.T : T in idx} : Presentation := "BKL");
> D_BKL eq FundamentalElement(B : Presentation := "BKL");
true
> D_BKL eq RightLCM({B.T : T in idx} : Presentation := "BKL");
true
```

In general, left and right least common multiple of elements are different.

```
> LeftLCM(B.1,B.1*B.2) eq RightLCM(B.1,B.1*B.2);
false
```

(2) For both Artin and BKL presentation, the following hold. Let D denote the fundamental element.

- The simple elements are those positive elements s satisfying $s \preceq D$ (or $D \succeq s$).
- A product $u_1 \cdots u_r$ of simple elements is in left normal form, if and only if the left greatest common divisor of $u_i^{-1}D$ and u_{i+1} is trivial for all $i = 1, \ldots, r-1$.

We illustrate this for the Artin presentation.

```
> D := FundamentalElement(B);
> forall{ s : s in Sym(6) | B!1 le B!s and B!s le D };
true
> forall{ s : s in Sym(6) | D ge B!s and B!s ge B!1 };
```

```
true
```

We create an element u as product of random simple elements.

```
> u := Random(B, 0, 0, 3, 5);
> u;
<Artin, 0, [
    (1, 5, 2)(3, 6),
    (1, 6, 5, 3),
    (1, 6, 5, 3, 2)
], 0>
```

We define a sequence of elements of B, containing the simple elements of the above representation of u using the function `CanonicalFactorRepresentation` and the coercion operator `!`.

```
> cfu := [ B!x : x in CFP(u)[3] ];
```

This representation is not in left normal form, as the above condition is violated for $i = 1$.

```
> IsId(LeftGCD(cfu[1]^-1*D, cfu[2]));
false
```

We now bring u into left normal form and extract again the sequence of simple elements.

```
> n := NormalForm(u);
> n;
<Artin, 0, [
    (1, 5, 3, 6, 2),
    (1, 6, 3, 2, 5)
], 0>
> cfn := [ B!x : x in CFP(n)[3] ];
```

This time, the above condition is satisfied.

```
> IsId(LeftGCD(cfn[1]^-1*D, cfn[2]));
true
```

73.4.6 Invariants of Conjugacy Classes

This section describes the functions for computing the set of positive conjugates, the super summit set and the ultra summit set for an element of a braid group B as defined in Section 73.1.5, as well as related MAGMA functions.

All the class invariants in general depend on the presentation of B used for their definition. Many functions documented in this section accept a parameter `Presentation` which can be used to specify the presentation of B with respect to which the computation should be performed. Possible values for this parameter are the strings `"Artin"` and `"BKL"`. If no value is given for `Presentation`, the presentation selected for B is used.

For any given element $u \in B$, all the invariants defined in Section 73.1.5 are finite and can be computed in principle. In practice, however, computations may fail because the sets can get very large with increasing canonical length of u or with increasin braid index of B. This is in particular the case for sets of positive conjuagtes and for super summit sets.

`PositiveConjugates(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return an indexed set containing the conjugates of u which can be represented as positive words in the specified presentation of B.

`SuperSummitRepresentative(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return an element u_s of the super summit set of u with respect to the specified presentation of B and an element c of B satisfying $u^c = u_s$.

Note that u_s is a positive conjugate of u, if u_s has non-negative infimum and that u does not have any positive conjugates if the infimum of u_s is negative.

`SuperSummitSet(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the super summit set of u with respect to the specified presentation as indexed set of elements of B.

`UltraSummitRepresentative(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return an element u_s of the ultra summit set of u with respect to the specified presentation of B and an element c of B satisfying $u^c = u_s$.

Note that u_s is an element of the super summit set of u, that u_s is a positive conjugate of u, if u_s has non-negative infimum and that u does not have any positive conjugates if the infimum of u_s is negative.

`UltraSummitSet(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return the ultra summit set of u with respect to the specified presentation as indexed set of elements of B.

Example H73E7

(1) In the braid group B on 4 strings we compute the sets of positive conjugates and the super summit sets of $u = \sigma_1\sigma_2\sigma_1$ with respect to both Artin presentation and BKL presentation.

```
> B := BraidGroup(4);
> u := B.1*B.2*B.1;
> p_Artin := PositiveConjugates(u : Presentation := "Artin");
> p_BKL := PositiveConjugates(u : Presentation := "BKL");
> s_Artin := SuperSummitSet(u : Presentation := "Artin");
```

```
> s_BKL := SuperSummitSet(u : Presentation := "BKL");
```

Since the Artin generators form a subset of the BKL generators, every element which is positive with respect to the Artin presentation is also positive with respect to the BKL presentation. In particular, p_Artin is a subset of p_BKL.

```
> p_Artin subset p_BKL;
true
```

The converse inclusion does not hold.

```
> #p_Artin;
10
> #p_BKL;
36
```

For both presentations the super summit set is a subset of the set of positive conjugates, as u is positive. The converse inclusions do not hold.

```
> s_Artin subset p_Artin;
true
> s_BKL subset p_BKL;
true
> #s_Artin;
2
> #s_BKL;
12
```

(2) As we have seen in Section 73.1.5, we can decide whether two braids are conjugate by checking whether their super summit sets are equal.

We illustrate this approach with two elements of B, using the Artin presentation of B.

```
> u := B.2 * B.1 * B.2^2 * B.1 * B.2;
> v := B.2^2 * B.1 * B.3 * B.1 * B.3;
```

Suppose we want to prove that u and v are not conjugate in B. We could start by checking the cycle structure of the induced permutations on the strings on which B acts.

```
> CycleStructure(InducedPermutation(u));
[ <1, 4> ]
> CycleStructure(InducedPermutation(v));
[ <1, 4> ]
```

This does not help. Next we can check the infima and the suprema of super summit representatives.

```
> SuperSummitInfimum(u) eq SuperSummitInfimum(v);
true
> SuperSummitSupremum(u) eq SuperSummitSupremum(v);
true
```

Again, we cannot conclude anything. We decide to compare the super summit sets of u and v.

```
> SuperSummitSet(u) eq SuperSummitSet(v);
```

```
false
```

Success! The super summit sets of u and v are different, proving that u and v are not conjugate. For a more efficient version of conjugacy testing see Example H73E8.

(3) Finally, we illustrate the significant difference in the sizes of super summit sets and ultra summit sets for slightly larger values of braid index and canonical length.

```
> B := BraidGroup(8);
```

We create a pseudo-random element of B as product of 5 simple elements independently chosen at random.

```
> x := B.4 * B.3 * B.2 * B.1 * B.5 * B.4 * B.5 *
> B.6 * B.7 * B.6 * B.5;
> x := x^2;
> Sx := SuperSummitSet(x);
> #Sx;
10972
> Ux := UltraSummitSet(x);
> #Ux;
36
```

The ultra summit set is much smaller than the super summit set. We try again.

```
> x := B.4 * B.3 * B.2 * B.1 * B.5 * B.4 * B.5;
> x := x^3;
> Sx := SuperSummitSet(x);
> #Sx;
882
> Ux := UltraSummitSet(x);
> #Ux;
18
```

The difference in sizes is still large. The behaviour exhibited by these examples is quite typical. In particular, the sizes of super summit sets for braids on a given number of strings and with a given canonical length show much larger fluctuations than the sizes of ultra summit sets. For a more detailed analysis we refer to [Geb03].

73.4.6.1 Computing Class Invariants Interactively

This section describes the functions relevant for interactive computation of the set of positive conjugates, the super summit set and the ultra summit set for a given element of a braid group B as defined in Section 73.1.5.

Process versions of the algorithms used by the functions PositiveConjugates, SuperSummitSet and UltraSummitSet are available for computing these invariants one element at a time.

`PositiveConjugatesProcess(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a process for constructing the conjugates of u which can be represented as positive words in the specified presentation of B.

The returned process contains the first positive conjugate of u if positive conjugates exist and is *empty* otherwise.

`SuperSummitProcess(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a process for constructing the super summit elements of u with respect to the specified presentation of B.

The returned process contains the first super summit element of u.

`UltraSummitProcess(u: parameters)`

`Presentation` MonStgElt *Default :*

Given an element u of a braid group B, return a process for constructing the ultra summit elements of u with respect to the specified presentation of B.

The returned process contains the first ultra summit element of u.

`BaseElement(P)`

Return the element used for the construction of the process P.

`#P`

Return the number of elements that have been found by the process P.

`Representative(P)`

`Rep(P)`

Given a non-empty process P, return the element most recently found by P.

If P is empty, a runtime error will occur. The function `IsEmpty` can be used for checking whether a process is empty, in order to avoid runtime errors in loops and user written functions.

`IsEmpty(P)`

Return `true` if P is empty and `false` otherwise.

This function can be used to check whether `Representative` can be called for a process P.

`Elements(P)`

Return an indexed set containing the elements found so far by the process P.

`u in P`

Given an element u of a braid group and a process P for computing positive conjugates or super summit elements of the element b, return `true` and an element c satisfying $b^c = u$ if u is one of the elements that have been constructed by P and `false` otherwise.

`u notin P`

Given an element u of a braid group and a process P, return `false` if u is one of the elements that have been constructed by P and `true` otherwise.

`NextElement(~P)`

Given a process P, continue searching for elements until the next element is found or the search completes without finding a new element.

If a new element if found, it can subsequently be accessed using the function `Representative`. If the search completes without finding a new element, P is marked as *empty*. Calling `NextElement` on an empty process has no effect.

`Complete(~P)`

Given a process P, complete the search for elements. After executing this procedure, P is *empty* and the set of all elements found by P can be accessed using the function `Elements`. Calling `Complete` on an empty process has no effect.

Example H73E8

We sketch how the functions described in the preceeding section could be used for testing whether two elements are conjugate and for computing a conjugating element if they are.

The approach outlined here is basically the algorithm used by the function `IsConjugate`.

```
> function MyIsConjugate(u, v)
>
>  // check obvious invariants
>  infu := SuperSummitInfimum(u);
>  infv := SuperSummitInfimum(v);
>  supu := SuperSummitSupremum(u);
>  supv := SuperSummitSupremum(v);
>  if infu ne infv or supu ne supv then
>     return false, _;
>  end if;
>
>  // compute an ultra summit element for v
>  sv, cv := UltraSummitRepresentative(v);
>
>  // set up a process for computing the ultra summit set of u
>  P := UltraSummitProcess(u);
>
>  // compute ultra summit elements of u until sv is found
>  //    or sv is seen not to be in the ultra summit set of u
```

```
>  while sv notin P and not IsEmpty(P) do
>     NextElement(~P);
>  end while;
>
>  print #P, "elements computed";
>  isconj, c := sv in P;
>  if isconj then
>     // return true and an element conjugating u to v
>     return true, c*cv^-1;
>  else
>     return false, _;
>  end if;
>
> end function;
```

We test our function using two pairs of elements of the braid group B on 4 strings.

```
> B := BraidGroup(4);
```

As we have seen in Example H73E7, the following elements u and v are not conjugate.

```
> u := B.2 * B.1 * B.2^2 * B.1 * B.2;
> v := B.2^2 * B.1 * B.3 * B.1 * B.3;
```

To prove this, our function has to compute the whole ultra summit set of u.

```
> MyIsConjugate(u,v);
2 elements computed
false
> #UltraSummitSet(u);
2
```

We try our function on another pair of elements.

```
> r := B.3*B.2*B.3*B.2^2*B.1*B.3*B.1*B.2;
> s := B.3^-1*B.2^-1*B.3*B.2*B.3*B.2^2*B.1*B.3*B.1*B.2^2*B.3;
> isconj, c := MyIsConjugate(r,s);
3 elements computed
> isconj;
true
> r^c eq s;
true
```

The ultra summit representative of s was the 3rd ultra summit element of r found. Note that the function did not have to compute the whole ultra summit set of r to find the answer.

```
> #UltraSummitSet(r);
6
```

In this small example, we could also have used super summit sets for conjugacy testing, as the super summit set of r is not much larger than its ultra summit set.

```
>  #SuperSummitSet(r);
```

```
22
```

A more challenging application of the function `MyIsConjugate` from above will be presented in Example H73E10.

73.4.6.2 Computing Minimal Simple Elements

This section describes the functions for computing minimal simple elements as introduced in Section 73.1.5.2 and functions for computing the *transport* and the *pullback* as defined in [Geb03].

All functions documented in this section accept two parameters, `Presentation` and `CheckArguments`. The parameter `Presentation` can be used to specify the presentation of a braid group B with respect to which the computation should be performed. Possible values for this parameter are the strings `"Artin"` and `"BKL"`. If no value is given for `Presentation`, the presentation selected for B is used. The parameter `CheckArguments` can be used to turn off argument checking for performance reasons. It should be noted that the results are undefined if functions are called with invalid arguments and argument checking is disabled.

`MinimalElementConjugatingToPositive(x, s: parameters)`

`Presentation`	MonStgElt	*Default :*
`CheckArguments`	BoolElt	*Default :* `true`

Given a positive element x of a braid group B and a simple element s, return the minimal simple element $r_x(s)$ satisfying $s \preceq r_x(s)$ and $x^{r_x(s)} \in B^+$.

`MinimalElementConjugatingToSuperSummit(x, s: parameters)`

`Presentation`	MonStgElt	*Default :*
`CheckArguments`	BoolElt	*Default :* `true`

Given an element x of a braid group B which is contained in its super summit set S_x and a simple element s, return the minimal simple element $\rho_x(s)$ satisfying $s \preceq \rho_x(s)$ and $x^{\rho_x(s)} \in S_x$.

`MinimalElementConjugatingToUltraSummit(x, s: parameters)`

`Presentation`	MonStgElt	*Default :*
`CheckArguments`	BoolElt	*Default :* `true`

Given an element x of a braid group B which is contained in its ultra summit set U_x and a simple element s, return the minimal simple element $c_x(s)$ satisfying $s \preceq c_x(s)$ and $x^{c_x(s)} \in U_x$.

`Transport(x, s: parameters)`

`Presentation`	MonStgElt	*Default :*
`CheckArguments`	BoolElt	*Default :* `true`

Given an element x of a braid group B and a simple element s such that both x and x^s are super summit elements, return the *transport* of s along $x \to \mathbf{c}(x)$, that is, the element $\phi_x(s) = (D \wedge_l xD^{-\inf(x)})^{-1} \cdot s \cdot (D \wedge_l x^s D^{-\inf(x)})$, where D is the fundamental element of B. The transport is a simple element satisfying $\mathbf{c}(x^s) = \mathbf{c}(x)^{\phi_x(s)}$ [Geb03].

`Pullback(x, s: parameters)`

`Presentation`	MonStgElt	*Default :*
`CheckArguments`	BoolElt	*Default :* `true`

Given an element x of a braid group B which is contained in its super summit set S_x and a simple element s, return the *pullback* of s along $x \to \mathbf{c}(x)$, that is, the unique $\preceq$-minimal element $\pi_x(s)$ satisfying $x^{\pi_x(s)} \in S_x$ and $s \preceq \phi_x(\pi_x(s))$ [Geb03].

Example H73E9

The following function uses the technique sketched in Section 73.1.5 for computing the ultra summit set of a given braid. This is basically the algorithm used by the Magma function `UltraSummitSet`.

```
> function MyUltraSummitSet(x)
>
> // create a subset of the ultra summit set of x
> U := {@ UltraSummitRepresentative(x) @};
> gens := Generators(Parent(x));
> pos := 1;
>
> // close U under conjugation with minimal simple elements
> while pos le #U do
>    y := U[pos];
>    // add missing conjugates of y
>    for z in { y^MinimalElementConjugatingToUltraSummit(y, s)
>                   : s in gens } do
>       if z notin U then
>          Include(~U, z);
>       end if;
>    end for;
>    pos +:= 1;
> end while;
>
> return U;
>
> end function;
```

73.5 Homomorphisms

For a general description of homomorphisms, we refer to Chapter 16. This section describes some special aspects of homomorphisms whose domain is in the category GrpBrd.

73.5.1 General Remarks

An important special case of homomorphisms with domain in the category GrpBrd is the following. A homomorphism $f : B \to G$, where B and B' are braid groups on n and m strings, respectively, and f is an embedding of B in G induced by

$$\sigma_i \to \sigma'_{k+\epsilon i} \quad (i = 1, \ldots, n-1)$$

where the σ_i are the Artin generators of B, the σ'_j are the Artin generators of B', $|\epsilon| = 1$ and k is a suitable constant.

The MAGMA implementation uses special optimisation techniques, if a homomorphism with domain in the category GrpBrd has the additional properties listed above. Compared to the general case, this results in faster evaluation of such homomorphisms, in particular in the case $\epsilon = 1$.

Computing preimages under homomorphisms with domain in the category GrpBrd currently is only supported for the special case described above. Moreover, computing the preimage of an element u under a map f may fail, even if u is contained in the image of f.

73.5.2 Constructing Homomorphisms

`hom< B -> G | S : parameters >`

`Check` BOOLELT *Default :* `true`

Returns the homomorphism from the braid group B to the group G defined by the assignment S. S can be the one of the following:

(i) A list, sequence or indexed set containing the images of all k Artin generators $B.1, \ldots, B.k$ of B. Here, the i-th element of S is interpreted as the image of $B.i$, that is, the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing k tuples $< x_i, y_i >$ or arrow pairs $x_i \text{ -> } y_i$, where x_i is a generator of B and $y_i \in G$ $(i = 1, \ldots, k)$ and the set $\{x_1, \ldots, x_k\}$ is the full set of Artin generators of B. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important.

Note, that it is currently not possible to define a homomorphism by assigning images to the elements of an arbitrary generating set of B.

If the category of the codomain supports element arithmetic and element comparison, by default the constructed homomorphism is checked by verifying that the would-be images of the Artin generators satisfy the braid relations of B. In this case, it is assured that the returned map is a well-defined homomorphism. The most important situation in which it is not possible to perform checking is the case in which the domain is a finitely presented group (`FPGroup`; cf. Chapter 70) which is not free. Checking may be disabled by setting the parameter `Check` to `false`.

73.5.3 Accessing Homomorphisms

`e @ f`
`f(e)`

Given a homomorphism whose domain is a braid group B and an element e of B, return the image of e under f as element of the codomain of f.

`B @ f`
`f(B)`

Given a homomorphism whose domain is a braid group B, return the image of B under f as a subgroup of the codomain of f.

This function is not supported for all codomain categories.

`u @@ f`

Given a homomorphism whose domain is a braid group B and an element u of the image of f, return the preimage of u under f as an element of B.

This function currently is only supported if f is an embedding of one braid group into another as described in Section 73.5.1. Note, moreover, that computing the preimage of u may fail, even if u is contained in the image of f.

`Domain(f)`

The domain of the homomorphism f.

`Codomain(f)`

The codomain of the homomorphism f.

`Image(f)`

The image or range of the homomorphism f as a subgroup of the codomain of f.

This function is not supported for all codomain categories.

Example H73E10

(1) The symmetric group on n letters is an epimorphic image of the braid group on n strings, where for $0 < i < n$ the image of the Artin generator σ_i is given by the transposition $(i, i+1)$. We construct this homomorphism for the case $n = 10$.

```
> Bn := BraidGroup(10);
> Sn := Sym(10);
> f := hom< Bn->Sn | [ Sn!(i,i+1) : i in [1..Ngens(Bn)] ] >;
```

Of course, the image of `f` is the full symmetric group.

```
> Image(f) eq Sn;
true
```

Now we compute the image of a pseudo-random element of `Bn` under `f`.

```
> f(Random(Bn));
```

```
(1, 5, 8)(2, 4, 9, 7, 6, 3)
```

(2) (Key exchange as proposed in [KLC+00])

Consider a collection of $l+r$ strings $t_1, \ldots, t_{l+r}$ and the braid group B acting on $t_1, \ldots, t_{l+r}$ with Artin generators $\sigma_1, \ldots, \sigma_{l+r-1}$. The subgroups of B fixing the strings $t_{l+1}, \ldots, t_{l+r}$ and $t_1, \ldots, t_l$ may be identified with braid groups L on l strings and R on r strings, respectively, with the Artin generators of L and R corresponding to $\sigma_1, \ldots, \sigma_{l-1}$ and $\sigma_{l+1}, \ldots, \sigma_{l+r-1}$, respectively.

We set up these groups for $l = 6$ and $r = 7$ using the BKL presentations.

```
> l := 6;
> r := 7;
> B := BraidGroup(l+r : Presentation := "BKL");
> L := BraidGroup(l   : Presentation := "BKL");
> R := BraidGroup(r   : Presentation := "BKL");
```

We now construct the embeddings $f : L \to B$ and $g : R \to B$.

```
> f := hom< L-> B | [ L.i -> B.i : i in [1..Ngens(L)] ] >;
> g := hom< R-> B | [ R.i -> B.(l+i) : i in [1..Ngens(R)] ] >;
```

To complete the preparatory steps, we choose a random element of B which is not too short.

```
> x := Random(B, 15, 25);
```

The data constructed so far is assumed to be publicly available. Each time two users A and B require a shared key, the following steps are performed.

(a) A chooses a random secret element $a \in L$ and sends the normal form of $y_1 := x^a$ to B.
(b) B chooses a random secret element $b \in R$ and sends the normal form of $y_2 := x^b$ to A.
(c) A receives y_2 and computes the normal form of y_2^a.
(d) B receives y_1 and computes the normal form of y_1^b.

Note the following.

• Transmitting y_1 and y_2 in normal form disguises their structure as products $a^{-1}xa$ and $b^{-1}xb$, provided the words used are long enough and prevents simply reading off the conjugating elements a and b.
• Since the subgroups L and R of B commute, we have $ab = ba$, which implies $y_2^a = x^{ba} = x^{ab} = y_1^b$. Thus, the normal forms computed by A and B in steps (c) and (d), respectively, must be identical and can be used to extract a secret shared key.

We illustrate this, using the groups set up above. For step (a):

```
> a := Random(L, 15, 25);
> y1 := NormalForm(x^f(a));
```

Now for step (b):

```
> b := Random(R, 15, 25);
> y2 := NormalForm(x^g(b));
```

We now verify that A and B arrive at the same information in steps (c) and (d).

```
> K_A := NormalForm(y2^f(a));
```

```
> K_B := NormalForm(y1^g(b));
> AreIdentical(K_A, K_B);
true
```

We see that the information computed by A and B in steps (c) and (d) is indeed identical and hence can be used (in suitable form) as a common secret. Note, however, that the number of strings and the lengths of the elements used in the example above are much smaller than the values suggested for real cryptographic purposes.

(3) (Attack on key exchange)

We now show an attack on the key exchange outlined above using conjugacy search based on ultra summit sets.

An eavesdropper can try to compute an element c conjugating x to y_1. While this is not guaranteed to reproduce the braid a, the chances for a successful key recovery are quite good.

We decide to change to the Artin presentation of B and use the function `MyIsConjugate` from Example H73E8 for computing a conjugating element c as above.

```
> SetPresentation(~B, "Artin");
> time _, c := MyIsConjugate(x, y1);
42 elements computed
Time: 0.020
```

Finding a conjugating element is no problem at all. Using the conjugating element, we can try to recover the shared secret. In this example we are lucky.

```
> NormalForm(y2^c) eq K_A;
true
```

In the conjugacy search above, a conjugating element was found after computing 42 ultra summit elements. The ultra summit set itself is larger, but can still be computed very easily.

```
> time Ux := UltraSummitSet(x);
Time: 3.150
> #Ux;
1584
```

The super summit set is, even in this small example, too large to be computed; conjugacy search based on super summit sets would quite likely fail.

```
>  time Sx := SuperSummitSet(x);
Current total memory usage: 4055.1MB
System error: Out of memory.
```

Finally, we show that the attack using conjugacy search based on ultra summit sets is also applicable to larger examples. We try to recover a key, which is generated using elements with canonical lengths between 500 and 1000 in a braid group on 100 strings.

```
> l := 50;
> r := 50;
> B := BraidGroup(l+r);
> L := BraidGroup(l);
```

```
> R := BraidGroup(r);
>
> f := hom< L-> B | [ L.i -> B.i : i in [1..Ngens(L)] ] >;
> g := hom< R-> B | [ R.i -> B.(l+i) : i in [1..Ngens(R)] ] >;
>
> x := Random(B, 0, 1, 500, 1000);
>
> a := Random(L, 0, 1, 500, 1000);
> y1 := NormalForm(x^f(a));
>
> b := Random(R, 0, 1, 500, 1000);
> y2 := NormalForm(x^g(b));
>
> K_A := NormalForm(y2^f(a));
> K_B := NormalForm(y1^g(b));
> AreIdentical(K_A, K_B);
true
```

We again try to recover the key by computing an element conjugating x to y_1. This time, we use the built-in MAGMA function for efficiency reasons.

```
> time _, c := IsConjugate(x, y1);
Time: 18.350
> K_A eq NormalForm(y2^c);
false
```

Bad luck. – We managed to compute a conjugating element, but this failed to recover the key. We try with an element conjugating x to y_2.

```
> time _, c := IsConjugate(x, y2);
Time: 3.800
> K_B eq NormalForm(y1^c);
true
```

Success! – Good that we didn't use this key to encrypt our credit card number!

73.5.4 Representations of Braid Groups

This section describes the functions available for creating a number of well known representations of braid groups.

`SymmetricRepresentation(B)`

Given a braid group B on n strings, return the natural epimorphism from B onto the symmetric group on n points, induced by the action of B on the strings by which B is defined.

`BurauRepresentation(B)`

Given a braid group B on n strings, return the Burau representation of B as homomorphism from B to the matrix algebra of degree n over the rational function field over the integers.

`BurauRepresentation(B, p)`

Given a braid group B on n strings and a prime p, return the p-modular Burau representation of B as homomorphism from B to the matrix algebra of degree n over the rational function field over the field with p elements.

Example H73E11

We construct the Burau representation of the braid group on 4 strings.

```
> B := BraidGroup(4);
> f := BurauRepresentation(B);
```

Its codomain is a matrix algebra of degree 4 over the rational function field over the integers.

```
> A := Codomain(f);
> A;
GL(4, FunctionField(IntegerRing()))
> F := BaseRing(A);
> F;
Univariate rational function field over Integer Ring
Variables: $.1
```

To obtain nicer printing, we assign the name t to the generator of the function field F.

```
> AssignNames(~F, ["t"]);
```

Now we can check easily whether we remembered the definition of the Burau representation correctly.

```
> f(B.1);
[-t + 1      t      0      0]
[     1      0      0      0]
[     0      0      1      0]
[     0      0      0      1]

> f(B.2);
[     1      0      0      0]
[     0 -t + 1      t      0]
[     0      1      0      0]
[     0      0      0      1]

> f(B.3);
[     1      0      0      0]
[     0      1      0      0]
[     0      0 -t + 1      t]
[     0      0      1      0]
```

74 GROUPS DEFINED BY REWRITE SYSTEMS

Chapter 74
GROUPS DEFINED BY REWRITE SYSTEMS

74.1 Introduction

The class of finitely presented groups defined by finite rewrite systems provide a Magma level interface to Derek Holt's KBMAG programs, and specifically to the Knuth–Bendix completion procedure for groups defined by a finite (monoid) presentation. Much of the material in this chapter is taken from the KBMAG documentation [Hol97]. Familiarity with the Knuth–Bendix completion procedure is assumed. Some familiarity with KBMAG would be beneficial.

74.1.1 Terminology

A rewrite group G is a finitely presented group in which equality between elements of G, called *words* or *strings*, may be decidable via a sequence of rewriting equations, called *reduction relations, rules, or equations*. In the interests of efficiency the reduction rules are codified into a finite state automaton called a *reduction machine*. The words in a rewrite group G are ordered, as are the reduction relations of G. Several possible orderings of words are supported, namely short-lex, recursive, weighted short-lex and wreath-product orderings. A rewrite group can be *confluent* or *non-confluent*. If a rewrite group G is confluent its reduction relations, or more specifically its reduction machine, can be used to reduce words in G to their irreducible normal forms under the given ordering, and so the word problem for G can be efficiently solved.

74.1.2 The Category of Rewrite Groups

The family of all rewrite groups forms a category. The objects are the rewrite groups and the morphisms are group homomorphisms. The MAGMA designation for this category of groups is `GrpRWS`. Elements of a rewrite group are designated as `GrpRWSElt`.

74.1.3 The Construction of a Rewrite Group

A rewrite group G is constructed in a three-step process:

(i) We construct a free group FG.

(ii) We construct a quotient F of FG.

(iii) We create a monoid presentation of F and then run a Knuth–Bendix completion procedure on this presentation to create a rewrite group G.

The Knuth–Bendix procedure may or may not succeed. If it fails the user may need to perform the above steps several times, manually adjusting the parameters to the Knuth–Bendix procedure. If it succeeds then the rewrite system constructed will be confluent.

74.2 Constructing Confluent Presentations

74.2.1 The Knuth-Bendix Procedure

`RWSGroup(F: parameters)`

Suppose F is a finitely presented group. Internally, the first step is to construct a presentation for a monoid M. By default, the generators of M are taken to be $g_1, g_1^{-1}, \ldots, g_n, g_n^{-1}$, where $g_1, \ldots, g_n$ are the generators of F. The relations for M are taken to be the relations of F together with the trivial relations $g_1 g_1^{-1} = g_1^{-1} g_1 = 1$. The Knuth–Bendix completion procedure for monoids is now applied to M. Regardless of whether or not the completion procedure succeeds, the result will be a rewrite monoid, M, containing a reduction machine and a sequence of reduction relations. If the procedure succeeds M will be marked as confluent, and the word problem for M is therefore decidable. If, as is very likely, the procedure fails then M will be marked as non-confluent. In this case M will contain both the reduction relations and the reduction machine computed up to the point of failure. Reductions made using these relations will be correct in F, but words that are equal in F are not guaranteed to reduce to the same word.

The Knuth–Bendix procedure requires ordering to be defined on both the generators and the words. The default generator ordering is that induced by the ordering of the generators of F while the default ordering on strings is the `ShortLex` order. We give a simple example and then discuss the parameters that allow the user to specify these two orderings.

As the Knuth–Bendix procedure will more often than not run forever, some conditions must be specified under which it will stop. These take the form of limits that are placed on certain variables, such as the number of reduction relations. If any of these limits are exceeded during a run of the completion procedure it will fail, returning a non-confluent rewrite monoid. The optimal values for these limits vary from example to example. The various parameters that allow the user to specify the limits for these variables will be described in a subsequent section.

Example H74E1

We construct the Von Dyck $(2, 3, 5)$ group. Since a string ordering is not specified the default `ShortLex` ordering is used. Similarly, since a generator ordering is not specified, the default generator ordering, in this case $[a, a^{-1}, b, b^{-1}]$, is used.

```
> FG<a,b> := FreeGroup(2);
> F := quo< FG | a*a=1, b*b=b^-1, a*b^-1*a*b^-1*a=b*a*b*a*b>;
> G := RWSGroup(F);
> G;
A confluent rewrite group.
Generator Ordering = [ a, a^-1, b, b^-1 ]
Ordering = ShortLex.
The reduction machine has 39 states.
The rewrite relations are:
```

```
a^2 = Id(F)
b * b^-1 = Id(F)
b^-1 * b = Id(F)
b^2 = b^-1
b * a * b * a * b = a * b^-1 * a * b^-1 * a
b^-2 = b
b^-1 * a * b^-1 * a * b^-1 = a * b * a * b * a
a^-1 = a
a * b^-1 * a * b^-1 * a * b = b * a * b * a * b^-1
b * a * b^-1 * a * b^-1 * a = b^-1 * a * b * a * b
a * b * a * b * a * b^-1 = b^-1 * a * b^-1 * a * b
b^-1 * a * b * a * b * a = b * a * b^-1 * a * b^-1
b * a * b * a * b^-1 * a * b * a = a * b^-1 * a * b * a * b^-1 * a * b^-1
b^-1 * a * b^-1 * a * b * a * b^-1 * a = a * b * a * b^-1 * a * b * a * b
b^-1 * a * b * a * b^-1 * a * b * a * b^-1 = b * a * b^-1 * a * b * a * b^-1
    * a * b
b * a * b^-1 * a * b * a * b^-1 * a * b^-1 = (b^-1 * a * b * a)^2
b^-1 * a * b * a * b^-1 * a * b * a * b = (b * a * b^-1 * a)^2
b * a * b^-1 * a * b * a * b^-1 * a * b * a = a * b * a * b^-1 * a * b * a *
    b^-1 * a * b
```

74.2.2 Defining Orderings

`RWSGroup(F:` *parameters*`)`

Attempt to construct a confluent presentation for the finitely presented group F using the Knuth-Bendix completion algorithm. In this section we describe how the user can specify the generator order and the ordering on strings.

`GeneratorOrder`	SeqEnum	*Default :*

Give an ordering for the generators. This ordering affects the ordering of words in the alphabet. If not specified the ordering defaults to the order induced by F's generators, that is $[g_1, \ldots, g_n]$ where $g_1, \ldots, g_n$ are the generators of F.

`Ordering`	MonStgElt	*Default :* "*ShortLex*"
`Levels`	SeqEnum	*Default :*
`Weights`	SeqEnum	*Default :*

`Ordering := "ShortLex"`: Use the short-lex ordering on strings. Shorter words come before longer, and for words of equal length lexicographical ordering is used, using the given ordering of the generators.
`Ordering := "Recursive" | "RtRecursive"`: Use a recursive ordering on strings. There are various ways to define this. Perhaps the quickest is as follows. Let u and v be strings in the generators. If one of u and v, say v, is empty, then $u \geq v$. Otherwise, let $u = u'a$ and $v = v'b$, where a and b are generators. Then $u > v$ if and only if one of the following holds:

(i) $a = b$ and $u' > v'$;

(ii) $a > b$ and $u > v'$;

(iii) $b > a$ and $u' > v$.

The `RtRecursive` ordering is similar to the `Recursive` ordering, but with $u = au'$ and $v = bv'$. Occasionally one or the other runs significantly quicker, but usually they perform similarly.

`Ordering := "WtLex"`: Use a weighted-lex ordering. `Weights` should be a sequence of non-negative integers, with the i-th element of `Weights` giving the weight of the i-the generator. The length of `Weights` must equal the number of generators. The length of words in the generators is then computed by adding up the weights of the generators in the words. Otherwise, ordering is as for short-lex.

`Ordering := "Wreath"`: Use a wreath-product ordering. `Levels` should be a sequence of non-negative integers, with the i-th element of `Levels` giving the level of the i-the generator. The length of `Levels` must equal the number of generators. In this ordering, two strings involving generators of the same level are ordered using short-lex, but all strings in generators of a higher level are larger than those involving generators of a lower level. That is not a complete definition; one can be found in [Sim94, pp. 46–50]. Note that the recursive ordering is the special case in which the level of generator number i is i.

Example H74E2

A confluent presentation is constructed for an infinite non-hopfian group using the `Recursive` ordering.

```
> F<a, b> := Group< a, b | b^-1*a^2*b=a^3>;
> G := RWSGroup(F : Ordering :="Recursive");
> G;
A confluent rewrite group.
Generator Ordering = [ a, a^-1, b, b^-1 ]
Ordering = Recursive.
The reduction machine has 7 states.
The rewrite relations are:
    a * a^-1 = Id(FG)
    a^-1 * a = Id(FG)
    b * b^-1 = Id(FG)
    b^-1 * b = Id(FG)
    a^3 * b^-1 = b^-1 * a^2
    a^2 * b = b * a^3
    a^-1 * b^-1 = a^2 * b^-1 * a^-2
    a^-1 * b = a * b * a^-3
```

Example H74E3

A confluent presentation of a free nilpotent group of rank 2 and class 2 is constructed by the following code. Note that the lower weight generators (in the sense of nilpotency class) need to come first in the ordering of generators.

```
> FG<a,b,c> := FreeGroup(3);
> F := quo< FG | b*a=a*b*c, c*a=a*c, c*b=b*c>;
> G := RWSGroup(F : Ordering :="Recursive",
>                 GeneratorOrder := [c,c^-1,b,b^-1,a,a^-1]);
> G;
A confluent rewrite group.
Generator Ordering = [ c, c^-1, b, b^-1, a, a^-1 ]
Ordering = Recursive.
The reduction machine has 7 states.
The rewrite relations are:
    c * c^-1 = Id(FG)
    c^-1 * c = Id(FG)
    b * b^-1 = Id(FG)
    b^-1 * b = Id(FG)
    a * a^-1 = Id(FG)
    a^-1 * a = Id(FG)
    b * a = a * b * c
    c * a = a * c
    c * b = b * c
    c^-1 * a = a * c^-1
    c * a^-1 = a^-1 * c
    c^-1 * b = b * c^-1
    c * b^-1 = b^-1 * c
    b^-1 * a = a * b^-1 * c^-1
    b^-1 * a^-1 = a^-1 * b^-1 * c
    c^-1 * a^-1 = a^-1 * c^-1
    c^-1 * b^-1 = b^-1 * c^-1
    b * a^-1 = a^-1 * b * c^-1
```

74.2.3 Setting Limits

In this section we introduce the various parameters used to control the execution of the Knuth-Bendix procedure.

`RWSMonoid(F: parameters)`

Attempt to construct a confluent presentation for the finitely presented group F using the Knuth-Bendix completion algorithm. We present details of the various parameters used to control the execution of the Knuth-Bendix.

`MaxRelations` RngIntElt *Default :* 32767

Limit the maximum number of reduction equations to `MaxRelations`.

`TidyInt` RngIntElt *Default :* 100

After finding `TidyInt` new reduction equations, the completion procedure interrupts the main process of looking for overlaps, to tidy up the existing set of equations. This will eliminate any redundant equations performing some reductions on their left and right hand sides to make the set as compact as possible. (The point is that equations discovered later often make older equations redundant or too long.)

`RabinKarp` Tup *Default :*

Use the Rabin-Karp algorithm for word-reduction on words having length at least l, provided that there are at least n equations, where `RabinKarp := <l, n>`. This uses less space than the default reduction automaton, but it is distinctly slower, so it should only be used when seriously short of memory. Indeed this option is only really useful for examples in which collapse occurs - i.e. at some intermediate stage of the calculation there is a very large set of equations, which later reduces to a much smaller confluent set. Collapse is not uncommon when analysing pathological presentations of finite groups, and this is one situation where the performance of the Knuth–Bendix algorithm can be superior to that of Todd-Coxeter coset enumeration. The best setting for `RabinKarp` varies from example to example - generally speaking, the smaller l is, the slower things will be, so set it as high as possible subject to not running out of memory. The number of equations n should be set to a value greater than the expected final number of equations.

`MaxStates` RngIntElt *Default :*

Limit the maximum number of states of the finite state automaton used for word reduction to `MaxStates`. By default there is no limit, and the space allocated is increased dynamically as required. The space needed for the reduction automaton can also be restricted by using the `RabinKarp` parameter. This limit is not usually needed.

`MaxReduceLen` RngIntElt *Default :* 32767

Limit the maximum allowed length that a word can reach during reduction to `MaxReduceLen`. It is only likely to be exceeded when using the recursive ordering on words. This limit is usually not needed.

`ConfNum` RngIntElt *Default :* 500

If `ConfNum` overlaps are processed and no new equations are discovered, then the overlap searching process is interrupted, and a fast check for confluence performed on the existing set of equations. Doing this too often wastes time, but doing it at the

right moment can also save a lot of time. If `ConfNum` = 0, then the fast confluence check is performed only when the search for overlaps is complete.

Warning: Changing the default setting on any of the following parameters may either cause the procedure to terminate without having found a confluent presentation or may change the underlying group.

`MaxStoredLen` TUP *Default :*

Only equations in which the left and right hand sides have lengths at most l and r, respectively, where `MaxStoredLen := <l, r>` are kept. Of course this may cause the overlap search to complete on a set of equations that is not confluent. In some examples, particularly those involving collapse (i.e. a large intermediate set of equations, which later simplifies to a small set), it can result in a confluent set being found much more quickly. It is most often useful when using a recursive ordering on words. Another danger with this option is that sometimes discarding equations can result in information being lost, and the monoid defined by the equations changes.

`MaxOverlapLen` RNGINTELT *Default :*

Only overlaps of total length at most `MaxOverlapLen` are processed. Of course this may cause the overlap search to complete on a set of equations that is not confluent.

`Sort` BOOLELT *Default :* `false`

`MaxOpLen` RNGINTELT *Default :* 0

If `Sort` is set to `true` then the equations will be sorted in order of increasing length of their left hand sides, rather than the default, which is to leave them in the order in which they were found. `MaxOpLen` should be a non-negative integer. If `MaxOpLen` is positive, then only equations with left hand sides having length at most `MaxOpLen` are output. If `MaxOpLen` is zero, then all equations are sorted by length. Of course, if `MaxOpLen` is positive, there is a danger that the monoid defined by the output equations may be different from the original.

```
SetVerbose("KBMAG", v)
```

Set the verbose printing level for the Knuth-Bendix completion algorithm. Setting this level allows a user to control how much extra information on the progress of the algorithm is printed. Currently the legal values for v are 0 to 3 inclusive. Setting v to 0 corresponds to the '-silent' option of KBMAG in which no extra output is printed. Setting v to 2 corresponds to the '-v' (verbose) option of KBMAG in which a small amount of extra output is printed. Setting v to 3 corresponds to the '-vv' (very verbose) option of KBMAG in which a huge amount of diagnostic information is printed.

74.2.4 Accessing Group Information

The functions in this group provide access to basic information stored for a rewrite group G.

`G . i`

The i-th defining generator for G. The integer i must lie in the range $[-r, r]$, where r is the number of group G.

`Generators(G)`

A sequence containing the defining generators for G.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for G.

`Relations(G)`

A sequence containing the defining relations for G. The relations will be given between elements of the free group of which G is a quotient. In these relations the (image of the) left hand side (in G) will always be greater than the (image of the) right hand side (in G) in the ordering on words used to construct G.

`NumberOfRelations(G)`

`Nrels(G)`

The number of relations in G.

`Ordering(G)`

The ordering of G.

Example H74E4

We illustrate the access operations using the following presentation of $\mathbf{Z} \wr C_2$.

```
> FG<a,b,t> := FreeGroup(3);
> F := quo< FG | t^2=1, b*a=a*b, t*a*t=b>;
> G<x,y,z> := RWSGroup(F);
> G;
A confluent rewrite group.
Generator Ordering = [ a, a^-1, b, b^-1, t, t^-1 ]
Ordering = ShortLex.
The reduction machine has 6 states.
The rewrite relations are:
    a * a^-1 = Id(F)
    a^-1 * a = Id(F)
    b * b^-1 = Id(F)
    b^-1 * b = Id(F)
    t^2 = Id(F)
    b * a = a * b
    t * a = b * t
    b^-1 * a = a * b^-1
    t * b = a * t
```

```
    b * a^-1 = a^-1 * b
    t * a^-1 = b^-1 * t
    t^-1 = t
    b^-1 * a^-1 = a^-1 * b^-1
    t * b^-1 = a^-1 * t
> G.1;
x
> G.1*G.2;
x * y
> Generators(G);
[ x, y, z ]
> Ngens(G);
3
> Relations(G);
[ a * a^-1 = Id(F), a^-1 * a = Id(F), b * b^-1 = Id(F), b^-1 * b = Id(F), t^2 =
Id(F), b * a = a * b, t * a = b * t, b^-1 * a = a * b^-1, t * b = a * t, b *
a^-1 = a^-1 * b, t * a^-1 = b^-1 * t, t^-1 = t, b^-1 * a^-1 = a^-1 * b^-1, t *
b^-1 = a^-1 * t ]
> Nrels(G);
14
> Ordering(G);
ShortLex
```

74.3 Properties of a Rewrite Group

`IsConfluent(G)`

Returns `true` if G is confluent, `false` otherwise.

`IsFinite(G)`

Given a confluent group G return `true` if G has finite order and `false` otherwise. If G does have finite order also return the order of G.

`Order(G)`

`#G`

The order of the group G as an integer. If the order of G is known to be infinite, the symbol ∞ is returned.

Example H74E5

We construct the Weyl group E_8.

```
> FG<a,b,c,d,e,f,g,h> := FreeGroup(8);
> Q := quo< FG | a^2=1, b^2=1, c^2=1, d^2=1, e^2=1, f^2=1, g^2=1,
>     h^2=1, b*a*b=a*b*a, c*a=a*c, d*a=a*d, e*a=a*e, f*a=a*f,
>     g*a=a*g, h*a=a*h, c*b*c=b*c*b, d*b=b*d, e*b=b*e, f*b=b*f,
>     g*b=b*g, h*b=b*h, d*c*d=c*d*c, e*c*e=c*e*c, f*c=c*f,
>     g*c=c*g, h*c=c*h, e*d=d*e, f*d=d*f, g*d=d*g, h*d=d*h,
>     f*e*f=e*f*e, g*e=e*g, h*e=e*h, g*f*g=f*g*f, h*f=f*h,
>     h*g*h=g*h*g>;
> G := RWSGroup(Q);
> IsConfluent(G);
true
> IsFinite(G);
true 696729600
```

So the group is finite of order $696,729,600$.

Example H74E6

We construct a 2-generator 2-relator group and use the order function to show that the group is infinite. The symbol `Infinity`, returned by `Order`, indicates that the group has infinite order.

```
> G := Group< x, y | x^2 = y^2, x*y*x = y*x*y >;
> R := RWSGroup(G);
> print Order(G);
Infinity
```

74.4 Arithmetic with Words

74.4.1 Construction of a Word

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity word in G.

`G ! [ i`$_1$`, ..., i`$_s$` ]`

Given a rewrite group G defined on r generators and a sequence $[i_1, \cdots, i_s]$ of integers lying in the range $[-r, r]$, excluding 0, construct the word

$$G.|i_1|^{\epsilon_1} * G.|i_2|^{\epsilon_2} * \cdots * G.|i_s|^{\epsilon_s}$$

where ϵ_j is $+1$ if i_j is positive, and -1 if i_j is negative. The resulting word is reduced using the reduction machine associated with G.

`Parent(w)`

The parent group G for the word w.

Example H74E7

We construct the Fibonacci group $F(2,7)$, and its identity.

```
> FG<a,b,c,d,e,f,g> := FreeGroup(7);
> F := quo< FG | a*b=c, b*c=d, c*d=e, d*e=f, e*f=g, f*g=a, g*a=b>;
> G := RWSGroup(F : TidyInt := 1000);
> Id(G);
Id(G)
> G!1;
Id(G)
> G![1,2];
G.3
```

74.4.2 Element Operations

Having constructed a rewrite group G one can perform arithmetic with words in G. Assuming we have $u, v \in G$ then the product $u * v$ will be computed as follows:

(i) the product $w = u * v$ is formed as a product in the appropriate free group.

(ii) w is reduced using the reduction machine associated with G.

If G is confluent, then w will be the unique minimal word that represents $u * v$ under the ordering of G. If G is not confluent, then there are some pairs of words which are equal in G, but which reduce to distinct words, and hence w will not be a unique normal form. Note that:

(i) reduction of w can cause an increase in the length of w. At present there is an internal limit on the length of a word – if this limit is exceeded during reduction an error will be raised. Hence any word operation involving reduction can fail.

(ii) the implementation is designed more with speed of execution in mind than with minimizing space requirements; thus, the reduction machine is always used to carry out word reduction, which can be space-consuming, particularly when the number of generators is large.

`u * v`

Given words w and v belonging to a common group, return their product.

`u / v`

Given words w and v belonging to a common group, return the product of the word u by the inverse of the word v, i.e. the word $u * v^{-1}$.

`u ^ n`

The n-th power of the word w.

`u ^ v`

Given words w and v belonging to a common group, return the conjugate of the word u by the word v, i.e. the word $v^{-1} * u * v$.

`Inverse(w)`

The inverse of the word w.

`(u, v)`

Given words w and v belonging to a common group, return the commutator of the words u and v, i.e., the word $u^{-1}v^{-1}uv$.

`(u`$_1$`, ..., u`$_r$`)`

Given r words $u_1, \ldots, u_r$ belonging to a common group, return their commutator. Commutators are *left-normed*, so they are evaluated from left to right.

`u eq v`

Given words w and v belonging to the same group, return `true` if w and v reduce to the same normal form, `false` otherwise. If G is confluent this tests for equality. If G is non-confluent then two words which are the same may not reduce to the same normal form.

`u ne v`

Given words w and v belonging to the same group, return `false` if w and v reduce to the same normal form, `true` otherwise. If G is confluent this tests for non-equality. If G is non-confluent then two words which are the same may reduce to different normal forms.

`IsId(w)`
`IsIdentity(w)`

Returns `true` if the word w is the identity word.

`#u`

The length of the word w.

`ElementToSequence(u)`
`Eltseq(u)`

The sequence Q obtained by decomposing the element u of a rewrite group into its constituent generators and generator inverses. Suppose u is a word in the rewrite group G. Then, if $u = G.i_1^{e_1} \cdots G.i_m^{e_m}$, with each $e_i = \pm 1$, then $Q[j] = i_j$ if $e_j = +1$ and $Q[j] = -i_j$ if $e_j = -1$, for $j = 1, \ldots, m$.

Example H74E8

We illustrate the word operations by applying them to elements of the Fibonacci group $F(2,5)$.

```
> FG<a,b,c,d,e> := FreeGroup(5);
> F := quo< FG | a*b=c, b*c=d, c*d=e, d*e=a, e*a=b>;
> G<a,b,c,d,e> := RWSGroup(F);
> a*b^-1;
e^-1
> a/b;
e^-1
> (c*d)^4;
a
> a^b, b^-1*a*b;
a a
> a^-2,
> Inverse(a)^2;
d d
> c^-1*d^-1*c*d eq (c,d);
true
> IsIdentity(a*b*c^-1);
true
> #(c*d);
1
```

74.5 Operations on the Set of Group Elements

`Random(G, n)`

A random word of length at most n in the generators of G.

`Random(G)`

A random word (of length at most the order of G) in the generators of G.

`Representative(G)`

`Rep(G)`

An element chosen from G.

`Set(G, a, b)`

`Search` MonStgElt *Default :* "*DFS*"

Create the set of reduced words, w, in G with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Set(G)`

`Search` MonStgElt *Default :* "*DFS*"

Create the set of reduced words that is the carrier set of G. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Seq(G, a, b)`

`Search` MonStgElt *Default :* "*DFS*"

Create the sequence S of reduced words, w, in G with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

`Seq(G)`

`Search` MonStgElt *Default :* "*DFS*"

Create a sequence S of reduced words in the carrier set of G. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

Example H74E9

We construct the group D_{22}, together with a representative word from the group, a random word and a random word of length at most 5 from the group, and the set of elements of the group.

```
> FG<a,b,c,d,e,f> := FreeGroup(6);
> Q := quo< FG | a*c^-1*a^-1*d=1, b*f*b^-1*e^-1=1, c*e*c^-1*d^-1=1,
>               d*f^-1*d^-1*a=1, e*b*e^-1*a^-1=1, f*c^-1*f^-1*b^-1=1>;
```

```
> G<a,b,c,d,e,f> := RWSGroup(Q);
> Representative(G);
Id(G)
> Random(G);
b
> Random(G, 5);
a * d * b
> Set(G);
{ a * d * b, a * b, a * b * e, a * c, a * d, d * b, b * e, a * b * a,
  a * b * d, b * a, a * c * e, Id(G), b * d, c * e, e, f, a, a * e, b,
  c, a * f, d }
> Seq(G : Search := "DFS");
[ Id(G), a, a * b, a * b * a, a * b * d, a * b * e, a * c, a * c * e,
  a * d, a * d * b, a * e, a * f, b, b * a, b * d, b * e, c, c * e, d,
  d * b, e, f ]
```

74.6 Homomorphisms

For a general description of homomorphisms, we refer to chapter 16. This section describes some special aspects of homomorphisms whose domain or codomain is a rewrite group.

74.6.1 General Remarks

Groups in the category `GrpRWS` currently are accepted as codomains only in some special situations. The most important cases in which a rewrite group can be used as a codomain are group homomorphisms whose domain is in one of the categories `GrpFP`, `GrpGPC`, `GrpRWS` or `GrpAtc`.

74.6.2 Construction of Homomorphisms

`hom< R -> G | S >`

Returns the homomorphism from the rewrite group R to the group G defined by the expression S which can be the one of the following:

(i) A list, sequence or indexed set containing the images of the n generators $R.1, \ldots, R.n$ of R. Here, the i-th element of S is interpreted as the image of $R.i$, i.e. the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing n tuples $< x_i, y_i >$ or arrow pairs $x_i \to y_i$, where x_i is a generator of R and $y_i \in G$ $(i = 1, \ldots, n)$ and the set $\{x_1, \ldots, x_n\}$ is the full set of generators of R. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important.

It is the user's responsibility to ensure that the provided generator images actually give rise to a well-defined homomorphism. No checking is performed by the constructor.

Note that it is currently not possible to define a homomorphism by assigning images to the elements of an arbitrary generating set of R.

74.7 Conversion to a Finitely Presented Group

There is a standard way to convert a rewrite group into a finitely presented group using the functions `Relations` and `Simplify`. This is shown in the following example.

Example H74E10

We construct a two generator free abelian group as a rewrite group and then convert it into a finitely presented group.

```
> FG<a,b> := FreeGroup(2);
> F := quo< FG | b^-1*a*b=a >;
> G := RWSGroup(F);
> print G;
A confluent rewrite group.
Generator Ordering = [ a, a^-1, b, b^-1 ]
Ordering = ShortLex.
The reduction machine has 5 states.
The rewrite relations are:
    a * a^-1 = Id(FG)
    a^-1 * a = Id(FG)
    b * b^-1 = Id(FG)
    b^-1 * b = Id(FG)
    b^-1 * a = a * b^-1
    b * a = a * b
    b^-1 * a^-1 = a^-1 * b^-1
    b * a^-1 = a^-1 * b
> P<x,y> := Simplify(quo< FG | Relations(G)>);
> print P;
Finitely presented group P on 2 generators
Generators as words
    x = $.1
    y = $.2
Relations
    (y, x^-1) = Id(P)
```

75 AUTOMATIC GROUPS

Chapter 75
AUTOMATIC GROUPS

75.1 Introduction

Automatic groups provide a Magma level interface to Derek Holt's KBMAG programs, and specifically to KBMAG's automatic groups program *autgroup*. Much of the material in this chapter is based on the KBMAG documentation [Hol97]. Familiarity with the Knuth–Bendix completion procedure and the automata associated with a short-lex automatic group is assumed. Some familiarity with KBMAG would be beneficial.

75.1.1 Terminology

An automatic group G is a finitely presented group in which various group operations, notably equality between words of G and word enumeration, are decidable through the use of various automata. The words in the automatic group G that can be computed in MAGMA are ordered using the short-lex ordering on words (shorter words come before longer, and for words of equal length lexicographical ordering is used, based on the given ordering of the generators).

75.1.2 The Category of Automatic Groups

The family of all automatic groups forms a category. The objects are the automatic groups and the morphisms are group homomorphisms. The MAGMA designation for this category of groups is `GrpAtc`. Elements of a automatic group are designated as `GrpAtcElt`.

75.1.3 The Construction of an Automatic Group

An automatic group G is constructed in a three-step process:

(i) We construct a free group FG.

(ii) We construct a quotient F of FG.

(iii) We create a monoid presentation for F and then run procedures which attempt to construct the automata associated with G and to prove them correct.

These procedures may or may not succeed. Of course, if G is not an automatic group then they have no chance of succeeding.

75.2 Creation of Automatic Groups

75.2.1 Construction of an Automatic Group

`AutomaticGroup(F: parameters)`

`IsAutomaticGroup(F: parameters)`

Internally a monoid presentation P of the group F is constructed. By default the generators of P are taken to be $g_1, {g_1}^{-1}, \ldots, g_n, {g_n}^{-1}$ where $g_1, \ldots, g_n$ are the generators of F. The relations of P are taken to be the relations of F. The trivial relations between the generators and their inverses are also added. The word ordering is the short-lex ordering. The Knuth–Bendix completion procedure for monoids is now run on P to calculate the word difference automata corresponding to the generated equations, which are then used to calculate the finite state automata associated with a short-lex automatic group. In successful cases these automata are proved correct in the final step.

If the procedure succeeds the result will be an automatic group, G, containing four automata. These are the first and second word-difference machines, the word acceptor, and the word multiplier. The form `AutomaticGroup` returns an automatic group while the form `IsAutomaticGroup` returns the boolean value *true* and the automatic group. If the procedure fails, the first form does not return a value while the second returns the boolean value *false*.

For simple examples, the algorithms work quickly, and do not require much space. For more difficult examples, the algorithms are often capable of completing successfully, but they can sometimes be expensive in terms of time and space requirements. Another point to be borne in mind is that the algorithms sometimes produce temporary disk files which the user does not normally see (because they are automatically removed after use), but can occasionally be very large. These files are stored in the */tmp* directory. If you interrupt a running automatic group calculation you must remove these temporary files yourself.

As the Knuth–Bendix procedure will more often than not run forever, some conditions must be specified under which it will stop. These take the form of limits that are placed on certain variables, such as the number of reduction relations. If any of these limits are exceeded during a run of the completion procedure it will fail, returning a non-confluent automatic group. The optimal values for these limits varies from example to example. Some of these limits may be specified by setting parameters (see the next section). In particular, if a first attempt to compute the automatic structure of a group fails, it should be run again with the parameter `Large` (or `Huge`) set to `true`.

Example H75E1

We construct the automatic structure for the fundamental group of the torus. Since a generator ordering is not specified, the default generator ordering, $[a, a^{-1}, b, b^{-1}, c, c^{-1}, d, d^{-1}]$, is used.

```
> FG<a,b,c,d> := FreeGroup(4);
```

```
> F := quo< FG | a^-1*b^-1*a*b=d^-1*c^-1*d*c>;
> f, G := IsAutomaticGroup(F);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#Halting with 118 equations.
#First word-difference machine with 33 states computed.
#Second word-difference machine with 33 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 36 states computed.
#General multiplier with 104 states computed.
#Validity test on general multiplier succeeded.
#General length-2 multiplier with 220 states computed.
#Checking inverse and short relations.
#Checking relation:  _8*_6*_7*_5 = _2*_4*_1*_3
#Axiom checking succeeded.
> G;
An automatic group.
Generator Ordering = [ a, a^-1, b, b^-1, c, c^-1, d, d^-1 ]
The second word difference machine has 33 states.
The word acceptor has 36 states.
```

75.2.2 Modifying Limits

In this section we describe the various parameters used to control the execution of the procedures employed to determine the automatic structure.

`AutomaticGroup(F: parameters)`

`IsAutomaticGroup(F: parameters)`

Attempt to construct an automatic structure for the finitely presented group F (see the main entry). We now present details of the various parameters used to control the execution of the procedures.

`Large` BoolElt *Default :* `false`

If `Large` is set to `true` large hash tables are used internally. Also the Knuth–Bendix algorithm is run with larger parameters, specifically `TidyInt` is set to 500, `MaxRelations` is set to 262144, `MaxStates` is set to unlimited, `HaltingFactor` is set to 100, `MinTime` is set to 20 and `ConfNum` is set to 0. It is advisable to use this option only after having first tried without it, since it will result in much longer execution times for easy examples.

`Huge` BoolElt *Default :* `false`

Setting `Huge` to `true` doubles the size of the hash tables and `MaxRelations` over the `Large` parameter. As with the `Large` parameter, it is advisable to use this option only after having first tried without it.

`MaxRelations` RngIntElt *Default :* 200

Limit the maximum number of reduction equations to `MaxRelations`.

`TidyInt` RngIntElt *Default :* 20

After finding n new reduction equations, the completion procedure interrupts the main process of looking for overlaps, to tidy up the existing set of equations. This will eliminate any redundant equations performing some reductions on their left and right hand sides to make the set as compact as possible. (The point is that equations discovered later often make older equations redundant or too long.) The word-differences arising from the equations are calculated after each such tidying and the number reported if verbose printing is on. The best strategy in general is to try a small value of `TidyInt` first and, if that is not successful, try increasing it. Large values such as 1000 work best in really difficult examples.

`GeneratorOrder` SeqEnum *Default :*

Give an ordering for the generators of P. This ordering affects the ordering of words in the alphabet. If not specified, the ordering defaults to $[g_1, {g_1}^{-1}, \ldots, g_n, {g_n}^{-1}]$ where $g_1, \ldots, g_n$ are the generators of F.

`MaxWordDiffs` RngIntElt *Default :*

Limit the maximum number of word differences to `MaxWordDiffs`. The default behaviour is to increase the number of allowed word differences dynamically as required, and so usually one does not need to set this option.

`HaltingFactor` RngIntElt *Default :* 100

`MinTime` RngIntElt *Default :* 5

These options are experimental halting options. `HaltingFactor` is a positive integer representing a percentage. After each tidying it is checked whether both the number of equations and the number of states have increased by more than `HaltingFactor` percent since the number of word-differences was last less than what it is now. If so the program halts. A sensible value seems to be 100, but occasionally a larger value is necessary. If the `MinTime` option is also set then halting only occurs if at least `MinTime` seconds of cpu-time have elapsed altogether. This is sometimes necessary to prevent very early premature halting. It is not very satisfactory, because of course the cpu-time depends heavily on the particular computer being used, but no reasonable alternative has been found yet.

`SetVerbose("KBMAG", v)`

Set the verbose printing level for the Knuth–Bendix completion algorithm. Setting this level allows a user to control how much extra information on the progress of the algorithm is printed. Currently the legal values for v are 0 to 3 inclusive. Setting v to 0 corresponds to the '-silent' option of KBMAG in which no extra output is

printed. Setting v to 2 corresponds to the '-v' (verbose) option of KBMAG in which a small amount of extra output is printed. Setting v to 3 corresponds to the '-vv' (very verbose) option of KBMAG in which a huge amount of diagnostic information is printed.

Example H75E2

We attempt to construct an automatic structure for one of Listing's knot groups.

```
> F := Group< d, f | f*d*f^-1*d*f*d^-1*f^-1*d*f^-1*d^-1=1>;
> b, G := IsAutomaticGroup(F);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#Maximum number of equations exceeded.
#Halting with 195 equations.
#First word-difference machine with 45 states computed.
#Second word-difference machine with 53 states computed.
> b;
false;
```

So this attempt has failed. We run the `IsAutomaticGroup` function again setting `Large` to `true`. This time we succeed.

```
> f, G := IsAutomaticGroup(F : Large := true);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 262144
MaxStates     = 0
TidyInt       = 500
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#Halting with 3055 equations.
#First word-difference machine with 49 states computed.
#Second word-difference machine with 61 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 101 states computed.
#General multiplier with 497 states computed.
#Multiplier incorrect with generator number 3.
#General multiplier with 509 states computed.
#Multiplier incorrect with generator number 3.
#General multiplier with 521 states computed.
#Multiplier incorrect with generator number 3.
#General multiplier with 525 states computed.
#Validity test on general multiplier succeeded.
```

```
#General length-2 multiplier with 835 states computed.
#Checking inverse and short relations.
#Checking relation:  _3*_1*_4*_1*_3 = _1*_3*_2*_3*_1
#Axiom checking succeeded.
> G;
An automatic group.
Generator Ordering = [ d, d^-1, f, f^-1 ]
The second word difference machine has 89 states.
The word acceptor has 101 states.
```

Example H75E3

We construct the automatic group corresponding to the fundamental group of the trefoil knot. A generator order is specified.

```
> F<a, b> := Group< a, b | b*a^-1*b=a^-1*b*a^-1>;
> f, G := IsAutomaticGroup(F: GeneratorOrder := [a,a^-1, b, b^-1]);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#Halting with 83 equations.
#First word-difference machine with 15 states computed.
#Second word-difference machine with 17 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 15 states computed.
#General multiplier with 67 states computed.
#Multiplier incorrect with generator number 4.
#General multiplier with 71 states computed.
#Validity test on general multiplier succeeded.
#General length-2 multiplier with 361 states computed.
#Checking inverse and short relations.
#Checking relation:  _3*_2*_3 = _2*_3*_2
#Axiom checking succeeded.
> G;
An automatic group.
Generator Ordering = [ a, a^-1, b, b^-1 ]
The second word difference machine has 21 states.
The word acceptor has 15 states.
```

75.2.3 Accessing Group Information

The functions in this group provide access to basic information stored for an automatic group G.

`G . i`

The i-th defining generator for G. The integer i must lie in the range $[-r, r]$, where r is the number of group G.

`Generators(G)`

A sequence containing the defining generators for G.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of defining generators for G.

Example H75E4

We illustrate the access operations using the Von Dyck (2,3,5) group (isomorphic to A_5).

```
> F<a,b> := FreeGroup(2);
> Q := quo< F | a*a=1, b*b=b^-1, a*b^-1*a*b^-1*a=b*a*b*a*b>;
> f, G<a,b> := IsAutomaticGroup(Q);
> G;
An automatic group.
Generator Ordering = [ a, a^-1, b, b^-1 ]
The second word difference machine has 33 states.
The word acceptor has 28 states.
> print G.1*G.2;
a * b
> print Generators(G);
[ a, b ]
> print Ngens(G);
2
> rels := Relations(G);
> print rels[1];
Q.2 * Q.2^-1 = Id(Q)
> print rels[2];
Q.2^-1 * Q.2 = Id(Q)
> print rels[3];
Q.1^2 = Id(Q)
> print rels[4];
Q.2^2 = Q.2^-1
> print Nrels(G);
18
> print Ordering(G);
ShortLex
```

`FPGroup(G)`

Returns the finitely presented group F used in the construction of G, and the isomorphism from F to G.

`WordAcceptor(G)`

A record describing the word acceptor automaton stored in G.

`WordAcceptorSize(G)`

The number of states of the word acceptor automaton stored in G, and the size of the alphabet of this automaton.

`WordDifferenceAutomaton(G)`

A record describing the word difference automaton stored in G.

`WordDifferenceSize(G)`

The number of states of the 2nd word difference automaton stored in G, and the size of the alphabet of this automaton.

`WordDifferences(G)`

The labels of the states of the word difference automaton stored in G. The result is a sequence of elements of the finitely presented group used in the construction of G.

`GeneratorOrder(G)`

The value of the `GeneratorOrder` parameter used in the construction of G. The result is a sequence of generators and their inverses from the finitely presented group used in the construction of G.

75.3 Properties of an Automatic Group

`IsFinite(G)`

Given an automatic group G return `true` if G has finite order and `false` otherwise. If G does have finite order also return the order of G.

`Order(G)`
`#G`

The order of the group G as an integer. If the order of G is known to be infinite, the symbol ∞ is returned.

Example H75E5

We construct the group $\mathbf{Z} \wr C_2$ and compute its order. The result of `Infinity` indicates that the group has infinite order.

```
> F<a,b,t> := FreeGroup(3);
> Q := quo< F | t^2=1, b*a=a*b, t*a*t=b>;
> f, G := IsAutomaticGroup(Q);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#System is confluent.
#Halting with 14 equations.
#First word-difference machine with 14 states computed.
#Second word-difference machine with 14 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 6 states computed.
#General multiplier with 27 states computed.
#Validity test on general multiplier succeeded.
#Checking inverse and short relations.
#Axiom checking succeeded.
> Order(G);
Infinity
```

Example H75E6

We construct a three fold cover of A_6 and check whether it has finite order.

```
> FG<a,b> := FreeGroup(2);
> F := quo< FG | a^3=1, b^3=1, (a*b)^4=1, (a*b^-1)^5=1>;
> f, G := IsAutomaticGroup(F : GeneratorOrder := [a,b,a^-1,b^-1]);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#System is confluent.
#Halting with 183 equations.
#First word-difference machine with 289 states computed.
#Second word-difference machine with 360 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 314 states computed.
#General multiplier with 1638 states computed.
```

```
#Multiplier incorrect with generator number 4.
#General multiplier with 1958 states computed.
#Multiplier incorrect with generator number 2.
#General multiplier with 2020 states computed.
#Multiplier incorrect with generator number 1.
#General multiplier with 2038 states computed.
#Validity test on general multiplier succeeded.
#General length-2 multiplier with 4252 states computed.
#Checking inverse and short relations.
#Checking relation:  _1*_2*_1*_2 = _4*_3*_4*_3
#Checking relation:  _1*_4*_1*_4*_1 = _2*_3*_2*_3*_2
#Axiom checking succeeded.
> IsFinite(G);
true 1080
> isf, ord := IsFinite(G);
> isf, ord;
true 1080
```

75.4 Arithmetic with Words

75.4.1 Construction of a Word

`G ! [ i`$_1$`, ..., i`$_s$` ]`

Given an automatic group G defined on r generators and a sequence $[i_1, \cdots, i_s]$ of integers lying in the range $[-r, r]$, excluding 0, construct the word

$$G.|i_1|^{\epsilon_1} * G.|i_2|^{\epsilon_2} * \cdots * G.|i_s|^{\epsilon_s}$$

where ϵ_j is $+1$ if i_j is positive, and -1 if i_j is negative. The word will be returned in reduced form.

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity word in the automatic group G.

`Parent(w)`

The parent group G for the word w.

Example H75E7

We construct some words in a two-generator two-relator group.

```
> F<a, b> := Group< a, b | a^2 = b^2, a*b*a = b*a*b >;
> f, G<a, b> := IsAutomaticGroup(F);
> G;
An automatic group.
Generator Ordering = [ $.1, $.1^-1, $.2, $.2^-1 ]
The second word difference machine has 11 states.
The word acceptor has 8 states.

> Id(G);
Id(G)
> print G!1;
Id(G)
> a*b*a*b^3;
a^4 * b * a
> G![1,2,1,2,2,2];
a^4 * b * a
```

75.4.2 Operations on Elements

Having constructed an automatic group G one can perform arithmetic with words in G. Assuming we have $u, v \in G$ then the product $u * v$ will be computed as follows:

(i) The product $w = u * v$ is formed as a product in the appropriate free group.

(ii) w is reduced using the second word difference machine associated with G.

Note that:

(i) Reduction of w can cause an increase in the length of w. At present there is an internal limit on the length of a word – if this limit is exceeded during reduction an error will be raised. Hence any word operation involving reduction can fail.

(ii) The implementation is designed more with speed of execution in mind than with minimizing space requirements; thus, the reduction machine is always used to carry out word reduction, which can be space-consuming, particularly when the number of generators is large.

`u * v`

Given words w and v belonging to a common group, return their product.

`u / v`

Given words w and v belonging to a common group, return the product of the word u by the inverse of the word v, i.e. the word $u * v^{-1}$.

`u ^ n`

The n-th power of the word w.

`u ^ v`

Given words w and v belonging to a common group, return the conjugate of the word u by the word v, i.e. the word $v^{-1} * u * v$.

`Inverse(w)`

The inverse of the word w.

`(u, v)`

Given words w and v belonging to a common group, return the commutator of the words u and v, i.e., the word $u^{-1}v^{-1}uv$.

`(u`$_1$`, ..., u`$_r$`)`

Given r words $u_1, \ldots, u_r$ belonging to a common group, return their commutator. Commutators are *left-normed*, so they are evaluated from left to right.

`u eq v`

Given words w and v belonging to the same group, return `true` if w and v reduce to the same normal form, `false` otherwise. If G is confluent this tests for equality. If G is non-confluent then two words which are the same may not reduce to the same normal form.

`u ne v`

Given words w and v belonging to the same group, return `false` if w and v reduce to the same normal form, `true` otherwise. If G is confluent this tests for non-equality. If G is non-confluent then two words which are the same may reduce to different normal forms.

`IsId(w)`
`IsIdentity(w)`

Returns `true` if the word w is the identity word.

`#u`

The length of the word w.

`ElementToSequence(u)`
`Eltseq(u)`

The sequence Q obtained by decomposing the element u of a rewrite group into its constituent generators and generator inverses. Suppose u is a word in the rewrite group G. Then, if $u = G.i_1^{e_1} \cdots G.i_m^{e_m}$, with each $e_i = \pm 1$, then $Q[j] = i_j$ if $e_j = +1$ and $Q[j] = -i_j$ if $e_j = -1$, for $j = 1, \ldots, m$.

Example H75E8

We illustrate the word operations by applying them to elements of the fundamental group of a 3-manifold.
We illustrate the word operations by applying them to elements of a free group of rank two (with lots of redundant generators).

```
> FG<a,b,c,d,e> := FreeGroup(5);
> F := quo< FG | a*d*d=1, b*d*d*d=1, c*d*d*d*d*d*e*e*e=1>;
> f, G<a,b,c,d,e> := IsAutomaticGroup(F);
> G;
An automatic group.
Generator Ordering = [ a, a^-1, b, b^-1, c, c^-1, d, d^-1, e, e^-1 ]
The second word difference machine has 41 states.
The word acceptor has 42 states.
> print a*d;
d^-1
> print a/(d^-1);
d^-1
> print c*d^5*e^2;
e^-1
> print a^b, b^-1*a*b;
a a
> print (a*d)^-2, Inverse(a*d)^2;
a^-1 a^-1
> print c^-1*d^-1*c*d eq (c,d);
true
> print IsIdentity(b*d^3);
true
> print #(c*d*d*d*d*d*e*e);
1
```

75.5 Homomorphisms

For a general description of homomorphisms, we refer to chapter 16. This section describes some special aspects of homomorphisms whose domain or codomain is an automatic group.

75.5.1 General Remarks

Groups in the category `GrpAtc` currently are accepted as codomains only in some special situations. The most important cases in which an automatic group can be used as a codomain are group homomorphisms whose domain is in one of the categories `GrpFP`, `GrpGPC`, `GrpRWS` or `GrpAtc`.

75.5.2 Construction of Homomorphisms

`hom< A -> G | S >`

Returns the homomorphism from the automatic group A to the group G defined by the expression S which can be the one of the following:

(i) A list, sequence or indexed set containing the images of the n generators $A.1, \ldots, A.n$ of A. Here, the i-th element of S is interpreted as the image of $A.i$, i.e. the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing n tuples $< x_i, y_i >$ or arrow pairs $x_i -> y_i$, where x_i is a generator of A and $y_i \in G$ $(i = 1, \ldots, n)$ and the set $\{x_1, \ldots, x_n\}$ is the full set of generators of A. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important.

It is the user's responsibility to ensure that the provided generator images actually give rise to a well-defined homomorphism. No checking is performed by the constructor.

Note that it is currently not possible to define a homomorphism by assigning images to the elements of an arbitrary generating set of A.

75.6 Set Operations

In this section we describe functions which allow the user to enumerate various sets of elements of an automatic group G.

`Random(G, n)`

A random word of length at most n in the generators of G.

`Random(G)`

A random word (of length at most the order of G) in the generators of G.

`Representative(G)`

`Rep(G)`

An element chosen from G.

`Set(G, a, b)`

`Search` MonStgElt *Default : "DFS"*

Create the set of words, w, in G with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Set(G)`

`Search` MonStgElt *Default :* "*DFS*"

Create the set of words that is the carrier set of G. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Seq(G, a, b)`

`Search` MonStgElt *Default :* "*DFS*"

Create the sequence S of words, w, in G with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

`Seq(G)`

`Search` MonStgElt *Default :* "*DFS*"

Create a sequence S of words from the carrier set of G. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

Example H75E9

We construct the group D_{22}, together with a representative word from the group, a random word and a random word of length at most 5 from the group, and the set of elements of the group.

```
> FG<a,b,c,d,e,f> := FreeGroup(6);
> F := quo< FG | a*c^-1*a^-1*d=1, b*f*b^-1*e^-1=1,
>                c*e*c^-1*d^-1=1, d*f^-1*d^-1*a=1,
>                e*b*e^-1*a^-1=1, f*c^-1*f^-1*b^-1=1 >;
> f, G<a,b,c,d,e,f> := IsAutomaticGroup(F);
Running Knuth-Bendix with the following parameter values
MaxRelations  = 200
MaxStates     = 0
TidyInt       = 20
MaxWdiffs     = 512
HaltingFactor = 100
MinTime       = 5
#System is confluent.
#Halting with 41 equations.
#First word-difference machine with 16 states computed.
```

```
#Second word-difference machine with 17 states computed.
#System is confluent, or halting factor condition holds.
#Word-acceptor with 6 states computed.
#General multiplier with 58 states computed.
#Validity test on general multiplier succeeded.
#Checking inverse and short relations.
#Axiom checking succeeded.
> Representative(G);
Id(G)
> Random(G);
a*c;
> Random(G, 5);
a * b
> Set(G);
{ a * d * b, a * b, a * b * e, a * c, a * d, d * b, b * e,
  a * b * a, a * b * d, b * a, a * c * e, Id(G), b * d, c * e,
  e, f, a, a * e, b, c, a * f, d }
> Seq(G : Search := "BFS");
[ Id(G), a, b, c, d, e, f, a * b, a * c, a * d, a * e, a * f,
  b * a, b * d, b * e, c * e, d * b, a * b * a, a * b * d,
  a * b * e, a * c * e, a * d * b ]
```

75.7 The Growth Function

`GrowthFunction(G)`

`Primes` SeqEnum *Default :* []

Compute the growth function of the word acceptor automaton associated with G. The growth function of a DFA, A, is the quotient of two integral polynomials in a single variable x. The coefficient of x^n in the Taylor expansion (about 0) of this quotient is equal to the number of words of length n accepted by A. That is, the result is a closed form for this generating function.

The algorithm is by Derek Holt. The `Primes` parameter is no longer used, but is kept for backward compatibility. It may be removed in future releases.

Example H75E10

We construct a dihedral group of order 10 and compute the growth function of its word acceptor. As the group is finite, the result will be a polynomial. Note here that the `R!f` is only necessary to get pretty printing, specifically to ensure that f is printed in the variable x.

```
> R<x> := RationalFunctionField(Integers());
> FG<a,b> := FreeGroup(2);
> Q := quo< FG | a^5, b^2, a^b = a^-1>;
> G := AutomaticGroup(Q);
> f := GrowthFunction(G);
```

```
> R!f;
2*x^3 + 4*x^2 + 3*x + 1
```

Now we take as example an infinite dihedral group. The group is infinite, so the result cannot be polynomial. We then extract the coefficients of the growth function for word lengths 0 to 14.

```
> FG2<d,e> := FreeGroup(2);
> Q2 := quo<FG2| e^2, d^e = d^-1>;
> G2 := AutomaticGroup(Q2);
> f2 := GrowthFunction(G2);
> R!f2;
(-x^2 - 2*x - 1)/(x - 1)
> PSR := PowerSeriesRing(Integers():Precision := 15);
> Coefficients(PSR!f2);
[ 1, 3, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
```

76 GROUPS OF STRAIGHT-LINE PROGRAMS

Chapter 76
GROUPS OF STRAIGHT-LINE PROGRAMS

76.1 Introduction

This Chapter describes the category of straight-line program groups (SLP-groups). A straight-line program is formally a sequence $[s_1, s_2, \ldots, s_n]$ such that each s_i is one of the following:

(i) A generator of the SLP-group;

(ii) A product $s_j s_k, \quad j < i, k < i$;

(iii) A power $s_j^n, \quad j < i$;

(iv) A conjugate $s_j^{s_k}, \quad j < i, k < i$.

Effectively, a straight-line program can be regarded as a word in the generators which is stored as an expression tree instead of a list of generator-exponent pairs.

The importance of such a category of groups is that storing a word as an expression tree allows much faster evaluation of homomorphisms given as the unique extension of a mapping of the generators into a group of any category, as common subexpressions may be computed once only, and powers or conjugates may be more efficiently computed in the target group than by a linear product of generators and their inverses.

The name in MAGMA for the category of SLP-groups is `GrpSLP`.

76.2 Construction of an SLP-Group and its Elements

76.2.1 Structure Constructors

`SLPGroup(n)`

Construct the free group F of straight-line programs on n generators, where n is a non-negative integer. The i-th generator may be referenced by the expression `F.i`, $i = 1, \ldots, n$.

Example H76E1

The statement

```
> F := SLPGroup(2);
```

creates the free group on two generators. Here the generators may be referenced using the standard names, `F.1` and `F.2`. Group operations on the elements will be stored as part of the result.

76.2.2 Construction of an Element

`Identity(G)`

`Id(G)`

`G ! 1`

Construct the identity element (the straight-line program [] of length 0) for the SLP-group G.

76.3 Arithmetic with Elements

`u * v`

Given straight-line programs $u = [u_1, \ldots, u_m]$ and $v = [v_1, \ldots, v_n]$ belonging to the same SLP-group G, return a straight-line program corresponding to the product of u and v. It is clear that the straight-line program $[u_1, \ldots, u_m, v_1, \ldots, v_n, u_m v_n]$ satisfies the formal definition. In practice, the u_i and v_i need not be distinct, so the resulting program may be shorter.

`u ^ m`

Given an integer m and a straight-line program u, return the straight-line program corresponding to the m-th power of u.

`u ^ v`

Given straight-line programs u and v, return the straight-line program corresponding to the conjugate of u by v.

`#u`

Given a straight-line program u, return the number of multiplication, power or conjugate operations required to evaluate a homomorphism on u.

76.3.1 Accessing the Defining Generators and Relations

The functions described here provide access to basic information stored for an SLP-group G.

`G . i`

The i-th generator for G.

`Generators(G)`

A set containing the generators for G.

`NumberOfGenerators(G)`

`Ngens(G)`

The number of generators for B.

`Parent(u)`

The parent group G of the straight-line program u.

76.4 Addition of Extra Generators

It is often the case that a particular expression in the original generators is important in some homomorphic image of the group in the sense that it will very often form a common subexpression of subsequent expression. For this reason, MAGMA provides facilities to build related SLP-groups in which particular words acquire generator status themselves.

`AddRedundantGenerators(G, Q)`

An SLP-group H on $n + q$ generators (where G has n generators and Q has q elements). Furthermore, the identification of $G.i$ with $H.i$ ($i \leq n$) and of $Q[i]$ with $H.(n + i)$ is maintained, allowing coercion between G and H and also simple definition of homomorphisms.

76.5 Creating Homomorphisms

Because SLP-groups exist primarily to allow the user to write efficient code for evaluating words under a homomorphism, there are some extra features in the homomorphism constructor which rely on the user providing correct input.

Whne evaluating single words, it may not be desirable to explicitly construct the homomorphism. The `Evaluate` function uses the same evaluation mechanism as the homomorphisms and may a useful alternative.

`hom< G -> H | L:` *parameters* `>`

`CheckCodomain` BOOLELT *Default :* `true`

Return the group homomorphism $\phi : G \to H$ defined by the list L. The list may contain:

(i) Elements of the codomain. This form can only be used when all the preceding entries have given the image of the corresponding generator of G;

(ii) Generator-image pairs of the form `G.i -> x` or `<G.i, x>`;

(iii) A homomorphism ψ from an SLP-group B to H where G has been defined as a result of adding redundant generators to B. If this item appears, it must appear first. After the remaining generators have been processed, any images which are not yet assigned are computed from ψ. If the parameter `CheckCodomain` has the value `false`, then it is assumed that the generator images lie in the codomain.

`Evaluate(u, Q)`

`Evaluate(u, G)`

`Evaluate(v, Q)`

`Evaluate(v, G)`

Evaluate the word u using the elements of Q as images of the generators of the parent of u. The sequence Q must contains at least as many group elements as the parent of u has generators.

The second form evaluates all the words in v simultaneously, which is usually quicker than doing individual evaluations.

When the second argument is a group G, Q is taken as the sequence of generators of G.

Example H76E2

An illustration of the use of `AddRedundantGenerators` and the homomorphism constructing machinery.

```
> G := SLPGroup(2);
> M := GeneralLinearGroup(19, 7);
> P := RandomProcess(G);
> x := Random(P);
> #x;
74
```

We evaluate x im M using the `Evaluate` function.

```
> m := Evaluate(x, [M.1, M.2]);
> Order(m);
118392315154200
```

If we wish to evaluate several different words, we may be better off using a homomorphism.

```
> Q := [x^G.1, x^G.2, x^(G.1*G.2)];
> phi := hom<G -> M | M.1, M.2>;
> time R1 := phi(Q);
Time: 0.129
```

We note that x has become important since it is now a common sub-expression of several straight-line programs. We can build a homomorphism which will store the image of x by adding x as a redundant generator and defining the same homomorphism from the resulting group.

```
> H := AddRedundantGenerators(G, [x]);
> QQ := [H | x: x in Q];
```

We will define psi as the unique map on H which matches phi.

```
> psi := hom<H -> M | phi>;
> time R2 := psi(QQ);
Time: 0.000
> R1 eq R2;
true
```

In fact, if we had looked at the expression lengths of the straight-line programs involved, we would have found the following, which explains the significant speed up:

```
> [#x: x in Q];
[ 75, 75, 75 ]
> [#x: x in QQ];
[ 1, 1, 2 ]
```

76.6 Operations on Elements

76.6.1 Equality and Comparison

`u eq v`

Reutrns `true` if and only if the straight-line programs u and v are identical. Identical here means they are identical as expression trees, not that they will always evaluate to the same word in the generators.

`u ne v`

Returns `true` if and only if the straight-line programs u and v are not identical. Identical here means they are identical as expression trees, not that they will always evaluate to the same word in the generators.

76.7 Set-Theoretic Operations

76.7.1 Membership and Equality

`g in G`

Given a straight-line program g and an SLP-group G, return `true` if g is an element of G, `false` otherwise.

`g notin G`

Given an straight-line program g and an SLP-group G, return `true` if g is not an element of G, `false` otherwise.

`S subset G`

Given an group G and a set S of elements belonging to a group H, where G and H are related, return `true` if S is a subset of G, `false` otherwise.

`S notsubset G`

Given a group G and a set S of elements belonging to a group H, where G and H are related, return `true` if S is not a subset of G, `false` otherwise.

76.7.2 Set Operations

`RandomProcess(G)`

`Slots`	RngIntElt	*Default :* 10
`Scramble`	RngIntElt	*Default :* 100

Create a process to generate randomly chosen elements from the group G. The process is based on the product-replacement algorithm of [CLGM$^+$95], modified by the use of an accumulator. At all times, N elements are stored where N is the maximum of the specified value for `Slots` and `Ngens`$(G)+1$. Initially, these are just the generators of G. As well, one extra group element is stored, the accumulator. Initially, this is the identity. Random elements are now produced by successive calls to `Random(P)`, where P is the process created by this function. Each such call chooses one of the elements in the slots and multiplies it into the accumulator. The element in that slot is replaced by the product of it and another randomly chosen slot. The random value returned is the new accumulator value. Setting `Scramble := m` causes m such operations to be performed before the process is returned.

It should be noted that this process is not suitable for infinite groups, since all elements produced are products of the generators only and not their inverses. However, as long as the homomorphic image of G that is being worked with is finite, there is no problem.

`Random(P)`

Given a random element process P created by the function `RandomProcess(G)` for the SLP-group G, construct a random element of G by forming a random product over the expanded generating set stored as part of the process. The expanded generating set stored with the process is modified by replacing an existing generator by the element returned.

`Rep(G)`

A representative element of G.

Example H76E3

As an illustration of the efficiency of computing homomorphisms from SLP-groups, we set up the same random expression as both a straight-line program and a linear word.

```
> G := SLPGroup(3);
> F := FreeGroup(3);
> M := GeneralOrthogonalGroup(7, 3);
> gf := hom<G -> F | F.1, F.2, F.3>;
> gm := hom<G -> M | M.1, M.2, M.3>;
> fm := hom<F -> M | M.1, M.2, M.3>;
> P := RandomProcess(G);
> x := Random(P);
> #x;
```

```
85
```

The evaluation of the straight-line program will take 85 operations in M.

```
> w := gf(x);
> #w;
52307
```

The evaluation of the word will take 52306 multiplications in M.

```
> time h1 := gm(x);
Time: 0.020
> time h2 := fm(w);
Time: 1.640
> h1 eq h2;
true
```

76.7.3 Coercions Between Related Groups

`G ! g`

Given an element g belonging to an SLP-group H related to the group G, rewrite g as an element of G.

76.8 Bibliography

[**CLGM+95**] Frank Celler, Charles R. Leedham-Green, Scott H. Murray, Alice C. Niemeyer, and E. A. O'Brien. Generating random elements of a finite group. *Comm. Algebra*, 23(13):4931–4948, 1995.

77 FINITELY PRESENTED SEMIGROUPS

Chapter 77
FINITELY PRESENTED SEMIGROUPS

77.1 Introduction

This Chapter presents the functions designed for computing with finitely-presented semigroups (fp-semigroups for short).

77.2 The Construction of Free Semigroups and their Elements

77.2.1 Structure Constructors

`FreeSemigroup(n)`

Construct the free semigroup F on n generators, where n is a positive integer. The i-th generator may be referenced by the expression `F.i`, $i = 1, \ldots, n$. Note that a special form of the assignment statement is provided which enables the user to assign names to the generators of F. In this form of assignment, the list of generator names is enclosed within angle brackets and appended to the variable name on the **left hand side** of the assignment statement.

`FreeMonoid(n)`

Construct the free monoid F on n generators, where n is a positive integer. The i-th generator may be referenced by the expression `F.i`, $i = 1, \ldots, n$. Note that a special form of the assignment statement is provided which enables the user to assign names to the generators of F. In this form of assignment, the list of generator names is enclosed within angle brackets and appended to the variable name on the **left hand side** of the assignment statement.

Example H77E1

The statement

```
> F := FreeSemigroup(2);
```

creates the free semigroup on two generators. Here the generators may be referenced using the standard names, $F.1$ and $F.2$.
The statement

```
> F<x, y> := FreeSemigroup(2);
```

defines F to be the free semigroup on two generators and assigns the names x and y to the generators.

77.2.2 Element Constructors

Suppose S is an fp-semigroup, not necessarily free, for which generators have already been defined. A *word* is defined inductively as follows:

(i) A generator is a word;

(ii) The product uv of the words u and v is a word;

(iii) The power of a word, u^n, where u is a word and n is an integer, is a word.

An element (word) of S may be constructed as an expression in the generators as outlined below.

`S ! [i1, ... is]`

Given a semigroup S defined on r generators and a sequence $Q = [i_1, \cdots, i_s]$ of integers lying in the range $[1, r]$, construct the word $G.i_1G.i_2 \cdots G.i_s$.

`Id(M)`

`M ! 1`

Construct the identity element (empty word) for the fp-monoid M.

77.3 Elementary Operators for Words

77.3.1 Multiplication and Exponentiation

The word operations defined here may be applied either to the words of a free semigroup or the words of a semigroup with non-trivial relations.

`u * v`

Given words u and v belonging to the same fp-semigroup S, return the product of u and v.

`u ^ n`

The n-th power of the word u, where n is a positive integer.

`G ! Q`

Given a sequence Q of words belonging to the fp-semigroup G, return the product $Q[1]Q[2]\cdots Q[n]$ of the terms of Q as a word in G.

77.3.2 The Length of a Word

`#u`

The length of the word u.

77.3.3 Equality and Comparison

The words of an fp-semigroup S are ordered first by length and then lexicographically. The lexicographic ordering is determined by the following ordering on the generators:

$$S.1 < S.2 < S.3 < S.4 < \cdots$$

Here, u and v are words belonging to some common fp-semigroup.

`u eq v`

Returns `true` if the words u and v are identical (as elements of the appropriate free semigroup), `false` otherwise.

`u ne v`

Returns `true` if the words u and v are not identical (as elements of the appropriate free semigroup), `false` otherwise.

`u lt v`

Returns `true` if the word u precedes the word v, with respect to the ordering defined above for elements of an fp-semigroup, `false` otherwise.

`u le v`

Returns `true` if the word u either precedes, or is equal to, the word v, with respect to the ordering defined above for elements of an fp-semigroup, `false` otherwise.

`u ge v`

Returns `true` if the word u either follows, or is equal to, the word v, with respect to the ordering defined above for elements of an fp-semigroup, `false` otherwise.

`u gt v`

Returns `true` if the word u follows the word v, with respect to the ordering defined above for elements of an fp-semigroup.

`IsOne(u)`

Returns `true` if the word u, belonging to the monoid M, is the identity word, `false` otherwise.

77.4 Specification of a Presentation

77.4.1 Relations

`w1 = w2`

Given words w_1 and w_2 over the generators of an fp-semigroup S, create the relation $w_1 = w_2$. Note that this relation is not automatically added to the existing set of defining relations R for S. It may be added to R, for example, through use of the `quo`-constructor (see below).

`LHS(r)`

Given a relation r over the generators of S, return the left hand side of the relation r. The object returned is a word over the generators of S.

`RHS(r)`

Given a relation r over the generators of S, return the right hand side of the relation r. The object returned is a word over the generators of S.

77.4.2 Presentations

A semigroup with non-trivial relations is constructed as a quotient of an existing semigroup, possibly a free semigroup.

`Semigroup< generators | relations >`

Given a *generators* clause consisting of a list of variables $x_1, \cdots, x_r$, and a set of relations *relations* over these generators, first construct the free semigroup F on the generators $x_1, \cdots, x_r$ and then construct the quotient of F corresponding to the ideal of F defined by *relations*.

The syntax for the *relations* clause is the same as for the `quo`-constructor. The function returns:

(a) The quotient semigroup S;

(b) The natural homomorphism $\phi : F \to S$.

Thus, the statement

```
S< y1, ..., yr > := Semigroup< x1, ..., xr | w1, ..., ws >;
```

is an abbreviation for

```
F< x1, ..., xr > := FreeSemigroup(r);
S< y1, ..., yr > := quo< F | w1, ..., ws >;
```

`Monoid< generators | relations >`

Given a *generators* clause consisting of a list of variables $x_1, \cdots, x_r$, and a set of relations *relations* over these generators, first construct the free monoid F on the generators $x_1, \cdots, x_r$ and then construct the quotient of F corresponding to the ideal of F defined by *relations*.

The syntax for the *relations* clause is the same as for the `quo`-constructor. The function returns:

(a) The quotient monoid M;

(b) The natural homomorphism $\phi : F \to M$.

Thus, the statement

```
M< y1, ..., yr > := Monoid< x1, ..., xr | w1, ..., ws >;
```

is an abbreviation for

```
F< x1, ..., xr > := FreeMonoid(r);
M< y1, ..., yr > := quo< F | w1, ..., ws >;
```

Example H77E2

We create the monoid defined by the presentation $< x, y \mid x^2, y^2, (xy)^2 >$.

```
> M<x,y> := Monoid< x, y | x^2, y^2, (x*y)^2 >;
> M;
Finitely presented monoid
Relations:
    x^2 = Id(M)
    y^2 = Id(M)
    (x * y)^2 = Id(M)
```

77.4.3 Accessing the Defining Generators and Relations

The functions in this group provide access to basic information stored for a finitely-presented semigroup G.

`S . i`

The i-th defining generator for S.

`Generators(S)`

A set containing the generators for S.

`NumberOfGenerators(S)`

`Ngens(S)`

The number of generators for S.

`Parent(u)`

The parent semigroup S of the word u.

`Relations(S)`

A sequence containing the defining relations for S.

77.5 Subsemigroups, Ideals and Quotients

77.5.1 Subsemigroups and Ideals

`sub< S | L`$_1$`, ..., L`$_r$ `>`

Construct the subsemigroup R of the fp-semigroup S generated by the words specified by the terms of the *generator list* $L_1,\ldots, L_r$.
A term L_i of the generator list may consist of any of the following objects:

(a) A word;

(b) A set or sequence of words;

(c) A sequence of integers representing a word;

(d) A set or sequence of sequences of integers representing words;

(e) A subsemigroup of an fp-semigroup;

(f) A set or sequence of subsemigroups.

The collection of words and semigroups specified by the list must all belong to the semigroup S, and R will be constructed as a subgroup of S.

The generators of R consist of the words specified directly by terms L_i together with the stored generating words for any semigroups specified by terms of L_i. Repetitions of an element and occurrences of the identity element are removed (unless R is trivial).

`ideal< S | L`$_1$`, ..., L`$_r$ `>`

Construct the two-sided ideal I of the fp-semigroup S generated by the words specified by the terms of the *generator list* $L_1,\ldots, L_r$.

The possible forms of a term L_i of the generator list are the same as for the `sub`-constructor.

`lideal< G | L`$_1$`, ..., L`$_r$ `>`

Construct the left ideal I of the fp-semigroup S generated by the words specified by the terms of the *generator list* $L_1,\ldots, L_r$.

The possible forms of a term L_i of the generator list are the same as for the `sub`-constructor.

`rideal< G | L`$_1$`, ..., L`$_r$ `>`

Construct the right ideal I of the fp-semigroup S generated by the words specified by the terms of the *generator list* $L_1,\ldots, L_r$.

The possible forms of a term L_i of the generator list are the same as for the `sub`-constructor.

77.5.2 Quotients

`quo< F | relations >`

Given an fp-semigroup F, and a list of relations *relations* over the generators of F, construct the quotient of F by the ideal of F defined by *relations*.

The expression defining F may be either simply the name of a previously constructed semigroup, or an expression defining an fp-semigroup.

Each term of the list *relations* must be a *relation*, a *relation list* or, if S is a monoid, a *word*.

A *word* is interpreted as a relator if S is a monoid.

A *relation* consists of a pair of words, separated by '='. (See above).

A *relation list* consists of a list of words, where each pair of adjacent words is separated by '=': $w_1 = w_2 = \cdots = w_r$. This is interpreted as the relations $w_1 = w_r, \ldots, w_{r-1} = w_r$.

Note that the relation list construct is only meaningful in the context of the `fp semigroup`-constructor.

In the context of the `quo`-constructor, the identity element (empty word) of a monoid may be represented by the digit `1`.

Note that this function returns:

(a) The quotient semigroup S;

(b) The natural homomorphism $\phi : F \to S$.

77.6 Extensions

`DirectProduct(R, S)`

Given two fp-semigroups R and S, construct the direct product of R and S.

`FreeProduct(R, S)`

Given two fp-semigroups R and S, construct the free product of R and S.

77.7 Elementary Tietze Transformations

`AddRelation(S, r)`

`AddRelation(S, r, i)`

Given an fp-semigroup S and a relation r in the generators of S, create the quotient semigroup obtained by adding the relation r to the defining relations of S. If an integer i is specified as third argument, insert the new relation after the i-th relation of S. If the third argument is omitted, r is added to the end of the relations that are carried across from S.

`DeleteRelation(S, r)`

Given an fp-semigroup S and a relation r that occurs among the given defining relations for S, create the semigroup T, having the same generating set as S but with the relation r removed.

`DeleteRelation(S, i)`

Given an fp-semigroup S and an integer i, $1 \leq i \leq m$, where m is the number of defining relations for S, create the semigroup T having the same generating set as S but with the i-th relation omitted.

`ReplaceRelation(S, r1, r2)`

Given an fp-semigroup S and relations r_1 and r_2 in the generators of S, where r_1 is one of the given defining relations for S, create the semigroup T having the same generating set as S but with the relation r_1 replaced by the relation r_2.

`ReplaceRelation(S, i, r)`

Given an fp-semigroup S, an integer i, $1 \leq i \leq m$, where m is the number of defining relations for S, and a relation r in the generators of S, create the semigroup T having the same generating set as S but with the i-th relation of S replaced by the relation r.

`AddGenerator(S)`

Given an fp-semigroup S with presentation $< X \mid R >$, create the semigroup T with presentation $< X \cup \{y\} \mid R >$, where y denotes a new generator.

`AddGenerator(S, w)`

Given an fp-semigroup S with presentation $< X \mid R >$ and a word w in the generators of S, create the semigroup T with presentation $< X \cup \{y\} \mid R \cup \{y = w\} >$, where y denotes a new generator.

`DeleteGenerator(S, y)`

Given an fp-semigroup S with presentation $< X \mid R >$ and a generator y of S such that either S has no relations involving y, or a single relation r containing a single occurrence of y, create the semigroup T with presentation $< X - \{y\} \mid R - \{r\} >$.

77.8 String Operations on Words

`Eliminate(u, x, v)`

Given words u and v, and a generator x, belonging to a semigroup S, return the word obtained from u by replacing each occurrence of x by v.

`Match(u, v, f)`

Suppose u and v are words belonging to the same semigroup S, and that f is an integer such that $1 \leq f \leq \#u$. If v is a subword of u, the function returns true, as well as the least integer l such that:

(a) $l \geq f$; and,

(b) v appears as a subword of u, starting at the l-th letter of u.

If no such l is found, `Match` returns only false.

`Random(S, m, n)`

A random word of length l in the generators of the semigroup S, where $m \leq l \leq n$.

`RotateWord(u, n)`

The word obtained by cyclically permuting the word u by n places. If n is positive, the rotation is from left to right, while if n is negative the rotation is from right to left. In the case where n is zero, the function returns u.

`Substitute(u, f, n, v)`

Given words u and v belonging to a semigroup S, and non-negative integers f and n, this function replaces the substring of u of length n, starting at position f, by the word v. Thus, if $u = x_{i_1} \cdots x_{i_f} \cdots x_{i_{f+n-1}} \cdots x_{i_m}$ then the substring $x_{i_f} \cdots x_{i_{f+n-1}}$ is replaced by v. If u and v belong to a monoid M and the function is invoked with $v =$`Id(M)`, then the substring $x_{i_f} \cdots x_{i_{f+n-1}}$ of u is deleted.

`Subword(u, f, n)`

The subword of the word u comprising the n consecutive letters commencing at the f-th letter of u.

`ElementToSequence(u)`

`Eltseq(u)`

The sequence obtained by decomposing u into the indices of its constituent generators. Thus, if $u = x_{i_1} \ldots x_{i_m}$, then the sequence constructed by `ElementToSequence` is $[i_1, i_2, \ldots, i_m]$.

78 MONOIDS GIVEN BY REWRITE SYSTEMS

Chapter 78
MONOIDS GIVEN BY REWRITE SYSTEMS

78.1 Introduction

The category of monoids defined by finite sets of rewrite rules provide a Magma level interface to Derek Holt's KBMAG programs, and specifically to KBMAG's Knuth–Bendix completion procedure on monoids defined by a finite presentation. As such much of the documentation in this chapter is taken from the KBMAG documentation [Hol97]. Familiarity with the Knuth–Bendix completion procedure is assumed. Some familiarity with KBMAG would be beneficial.

78.1.1 Terminology

A rewrite monoid M is a finitely presented monoid in which equality between elements of M, called *words* or *strings*, is decidable via a sequence of rewriting equations, called *reduction relations, rules, or equations*. In the interests of efficiency the reduction rules are codified into a finite state automaton called a *reduction machine*. The words in a rewrite monoid M are ordered, as are the reduction relations of M. Several possible orderings of words are supported, namely short-lex, recursive, weighted short-lex and wreath-product orderings. A rewrite monoid can be *confluent* or *non-confluent*. If a rewrite monoid M is confluent its reduction relations, or more specifically its reduction machine, can be used to reduce words in M to their irreducible normal forms under the given ordering, and so the word problem for M can be efficiently solved.

78.1.2 The Category of Rewrite Monoids

The family of all rewrite monoids forms a category. The objects are the rewrite monoids and the morphisms are monoid homomorphisms. The MAGMA designation for this category of monoids is `MonRWS`. Elements of a rewrite monoid are designated as `MonRWSElt`.

78.1.3 The Construction of a Rewrite Monoid

A rewrite monoid M is constructed in a three-step process:

(i) A free monoid F of the appropriate rank is defined.

(ii) A quotient Q of F is created.

(iii) The Knuth–Bendix completion procedure is applied to the monoid Q to produce a monoid M defined by a rewrite system.

The Knuth–Bendix procedure may or may not succeed. If it fails the user may need to perform the above steps several times, manually adjusting parameters that control the execution of the Knuth–Bendix procedure. If it succeeds then the rewrite systems constructed will be confluent.

78.2 Construction of a Rewrite Monoid

`RWSMonoid(Q: parameters)`

The Knuth–Bendix completion procedure for monoids is run, with the relations of Q taken as the initial reduction rules for the procedure. Regardless of whether or not the completion procedure succeeds, the result will be a rewrite monoid, M, containing a reduction machine and a sequence of reduction relations. If the procedure succeeds M will be marked as confluent, and the word problem for M is therefore decidable. If, as is very likely, the procedure fails then M will be marked as non-confluent. In this case M will contain both the reduction relations and the reduction machine computed up to the point of failure.

As the Knuth–Bendix procedure will more often than not run forever, some conditions must be specified under which it will stop. These take the form of limits that are placed on certain variables, such as the number of reduction relations. If any of these limits are exceeded during a run of the completion procedure it will fail, returning a non-confluent rewrite monoid. The optimal values for these limits varies from example to example.

`MaxRelations`	RngIntElt	*Default :* 32767

Limit the maximum number of reduction equations to `MaxRelations`.

`GeneratorOrder`	SeqEnum	*Default :*

Give an ordering for the generators. This ordering affects the ordering of words in the alphabet. If not specified the ordering defaults to the order induced by Q's generators, that is $[g_1, \ldots, g_n]$ where $g_1, \ldots, g_n$ are the generators of Q.

`Ordering`	MonStgElt	*Default :* "*ShortLex*"
`Levels`	SeqEnum	*Default :*
`Weights`	SeqEnum	*Default :*

`Ordering := "ShortLex"`: Use the short-lex ordering on strings. Shorter words come before longer, and for words of equal length lexicographical ordering is used, using the given ordering of the generators.
`Ordering := "Recursive" | "RTRecursive"`: Use a recursive ordering on strings. There are various ways to define this. Perhaps the quickest is as follows. Let u and v be strings in the generators. If one of u and v, say v, is empty, then $u \geq v$. Otherwise, let $u = u'a$ and $v = v'b$, where a and b are generators. Then $u > v$ if and only if one of the following holds:

(i) $a = b$ and $u' > v'$;

(ii) $a > b$ and $u > v'$;

(iii) $b > a$ and $u' > v$.

The `RTRecursive` ordering is similar to the `Recursive` ordering, but with $u = au'$ and $v = bv'$. Occasionally one or the other runs significantly quicker, but usually they perform similarly.

`Ordering := "WTShortLex"`: Use a weighted-lex ordering. `Weights` should be a sequence of non-negative integers, with the i-th element of `Weights` giving the weight of the i-the generator. The length of `Weights` must equal the number of generators. The length of words in the generators is then computed by adding up the weights of the generators in the words. Otherwise, ordering is as for short-lex.
`Ordering := "Wreath"`: Use a wreath-product ordering. `Levels` should be a sequence of non-negative integers, with the i-th element of `Levels` giving the level of the i-the generator. The length of `Levels` must equal the number of generators. In this ordering, two strings involving generators of the same level are ordered using short-lex, but all strings in generators of a higher level are larger than those involving generators of a lower level. That is not a complete definition; one can be found in [Sim94, pp. 46–50]. Note that the recursive ordering is the special case in which the level of generator number i is i.

`TidyInt` RngIntElt *Default :* 100

After finding `TidyInt` new reduction equations, the completion procedure interrupts the main process of looking for overlaps, to tidy up the existing set of equations. This will eliminate any redundant equations performing some reductions on their left and right hand sides to make the set as compact as possible. (The point is that equations discovered later often make older equations redundant or too long.)

`RabinKarp` Tup *Default :*

Use the Rabin-Karp algorithm for word-reduction on words having length at least l, provided that there are at least n equations, where `RabinKarp := <l, n>`. This uses less space than the default reduction automaton, but it is distinctly slower, so it should only be used when seriously short of memory. Indeed this option is only really useful for examples in which collapse occurs - i.e. at some intermediate stage of the calculation there is a very large set of equations, which later reduces to a much smaller confluent set. Collapse is not uncommon when analysing pathological presentations of finite groups, and this is one situation where the performance of the Knuth–Bendix algorithm can be superior to that of Todd-Coxeter coset enumeration. The best setting for `RabinKarp` varies from example to example - generally speaking, the smaller l is, the slower things will be, so set it as high as possible subject to not running out of memory. The number of equations n should be set higher than the expected final number of equations.

`MaxStates` RngIntElt *Default :*

Limit the maximum number of states of the finite state automaton used for word reduction to `MaxStates`. By default there is no limit, and the space allocated is increased dynamically as required. The space needed for the reduction automaton can also be restricted by using the `RabinKarp` parameter. This limit is not usually needed.

`MaxReduceLen` RngIntElt *Default :* 32767

Limit the maximum allowed length that a word can reach during reduction to `MaxReduceLen`. It is only likely to be exceeded when using the recursive ordering

on words. This limit is usually not needed.

`ConfNum` RngIntElt *Default :* 500

If `ConfNum` overlaps are processed and no new equations are discovered, then the overlap searching process is interrupted, and a fast check for confluence performed on the existing set of equations. Doing this too often wastes time, but doing it at the right moment can also save a lot of time. If `ConfNum` = 0, then the fast confluence check is performed only when the search for overlaps is complete.

Warning: Changing the default setting for any of the following parameters may either cause the procedure to terminate without having found a confluent presentation or change the monoid.

`MaxStoredLen` Tup *Default :*

Only equations in which the left and right hand sides have lengths at most l and r, respectively, where `MaxStoredLen := <l, r>` are kept. Of course this may cause the overlap search to complete on a set of equations that is not confluent. In some examples, particularly those involving collapse (i.e. a large intermediate set of equations, which later simplifies to a small set), it can result in a confluent set being found much more quickly. It is most often useful when using a recursive ordering on words. Another danger with this option is that sometimes discarding equations can result in information being lost, with the effect of changing the monoid defined by the equations.

`MaxOverlapLen` RngIntElt *Default :*

Only overlaps of total length at most `MaxOverlapLen` are processed. Of course this may cause the overlap search to complete on a set of equations that is not confluent.

`Sort` BoolElt *Default :* `false`

`MaxOpLen` RngIntElt *Default :* 0

If `Sort` is set to `true` then the equations will be sorted in order of increasing length of their left hand sides, rather than the default, which is to leave them in the order in which they were found. `MaxOpLen` should be a non-negative integer. If `MaxOpLen` is positive, then only equations with left hand sides having length at most `MaxOpLen` are output. If `MaxOpLen` is zero, then all equations are sorted by length. Of course, if `MaxOpLen` is positive, there is a danger that the monoid defined by the output equations may be different from the original.

`SetVerbose("KBMAG", v)`

Set the verbose printing level for the Knuth-Bendix completion algorithm. Setting this level allows a user to control how much extra information on the progress of the algorithm is printed. Currently the legal values for v are 0 to 3 inclusive. Setting v to 0 corresponds to the '-silent' option of KBMAG in which no extra output is printed. Setting v to 2 corresponds to the '-v' (verbose) option of KBMAG in which a small amount of extra output is printed. Setting v to 3 corresponds to the '-vv' (very verbose) option of KBMAG in which a huge amount of diagnostic information is printed.

Example H78E1

Starting with a monoid presentation for the alternating group A_4, we construct a rewrite system. Since we don't specify an ordering the default `ShortLex` ordering is used. Since we don't specify a generator ordering, the default generator ordering, in this case that from Q, is used.

```
> FM<g10,g20,g30> := FreeMonoid(3);
> Q := quo< FM | g10^2=1, g20*g30=1, g30*g20=1,
>         g20*g20=g30, g30*g10*g30=g10*g20*g10>;
> M := RWSMonoid(Q);
> print M;
A confluent rewrite monoid.
Generator Ordering = [ g10, g20, g30 ]
Ordering = ShortLex.
The reduction machine has 12 states.
The rewrite relations are:
    g10^2 = Id(FM)
    g20 * g30 = Id(FM)
    g30 * g20 = Id(FM)
    g20^2 = g30
    g30 * g10 * g30 = g10 * g20 * g10
    g30^2 = g20
    g20 * g10 * g20 = g10 * g30 * g10
    g30 * g10 * g20 * g10 = g20 * g10 * g30
    g10 * g20 * g10 * g30 = g30 * g10 * g20
    g20 * g10 * g30 * g10 = g30 * g10 * g20
    g10 * g30 * g10 * g20 = g20 * g10 * g30
```

Example H78E2

We construct the second of Bernard Neumann's series of increasingly complicated presentations of the trivial monoid. The example runs best with a large value of `TidyInt`. Again the default `ShortLex` ordering is used.

```
> FM<x,X,y,Y,z,Z> := FreeMonoid(6);
> Q := quo< FM |
>         x*X=1, X*x=1, y*Y=1, Y*y=1, z*Z=1, Z*z=1,
>         y*y*X*Y*x*Y*z*y*Z*Z*X*y*x*Y*Y*z*z*Y*Z*y*z*z*Y*Z*y=1,
>         z*z*Y*Z*y*Z*x*z*X*X*Y*z*y*Z*Z*x*x*Z*X*z*x*x*Z*X*z=1,
>         x*x*Z*X*z*X*y*x*Y*Y*Z*x*z*X*X*y*y*X*Y*x*y*y*X*Y*x=1>;
> M := RWSMonoid(Q : TidyInt := 3000);
> print M;
A confluent rewrite monoid.
Generator Ordering = [ x, X, y, Y, z, Z ]
Ordering = ShortLex.
The reduction machine has 1 state.
The rewrite relations are:
    Z = Id(FM)
    Y = Id(FM)
```

```
    z = Id(FM)
    X = Id(FM)
    y = Id(FM)
    x = Id(FM)
```

Example H78E3

We construct a confluent presentation of a submonoid of a nilpotent group.

```
> FM<a,b,c> := FreeMonoid(6);
> Q := quo< FM | b*a=a*b*c, c*a=a*c, c*b=b*c >;
> M := RWSMonoid(Q:Ordering:="Recursive", GeneratorOrder:=[c,b,a]);
> M;
A confluent rewrite monoid.
Generator Ordering = [ c, b, a ]
Ordering = Recursive.
The reduction machine has 3 states.
    b * a = a * b * c
    c * a = a * c
    c * b = b * c
> Order(M);
Infinity
```

Example H78E4

We construct a monoid presentation corresponding to the Fibonacci group $F(2,7)$. This is a very difficult calculation unless the parameters of `RWSMonoid` are selected carefully. The best approach is to run the Knuth-Bendix once using a `Recursive` ordering with a limit on the lengths of equations stored (`MaxStoredLen := <15,15>` works well). This will halt returning a non-confluent rewrite monoid M, and give a warning message that the Knuth-Bendix procedure only partly succeeded. The original equations should then be appended to the relations of M, and the Knuth-Bendix re-run with no limits on lengths. It will then quickly complete with a confluent set. This is typical of a number of difficult examples, where good results can be obtained by running more than once.

```
> FM<a,b,c,d,e,f,g> := FreeMonoid(7);
> I := [a*b=c, b*c=d, c*d=e, d*e=f, e*f=g, f*g=a, g*a=b];
> Q := quo<FM | I>;
> M := RWSMonoid(Q: Ordering := "Recursive", MaxStoredLen := <15,15>);
Warning: Knuth Bendix only partly succeeded
> Q := quo< FM | Relations(M) cat I>;
> M := RWSMonoid(Q: Ordering := "Recursive");
> print M;
A confluent rewrite monoid.
Generator Ordering = [ a, b, c, d, e, f, g ]
Ordering = Recursive.
The reduction machine has 30 states.
The rewrite relations are:
```

```
    c = a^25
    d = a^20
    e = a^16
    f = a^7
    g = a^23
    b = a^24
    a^30 = a
> Order(M);
30
```

It turns out that the non-identity elements of this monoid form a submonoid isomorphic to the Fibonacci group $F(2,7)$ which is cyclic of order 29.

78.3 Basic Operations

78.3.1 Accessing Monoid Information

The functions in this section provide access to basic information stored for a rewrite monoid M.

`M . i`

The i-th defining generator for M.

`Generators(M)`

A sequence containing the defining generators for M.

`NumberOfGenerators(M)`

`Ngens(M)`

The number of defining generators for M.

`Relations(M)`

A sequence containing the defining relations for M. The relations will be given between elements of the free monoid of which M is a quotient. In these relations the (image of the) left hand side (in M) will always be greater than the (image of the) right hand side (in M) in the ordering on words used to construct M.

`NumberOfRelations(M)`

`Nrels(M)`

The number of relations in M.

`Ordering(M)`

The ordering of M.

`Parent(w)`

The parent monoid M for the word w.

Example H78E5

We illustrate the access operations using the following presentation of S_4.

```
> FM<a,b> := FreeMonoid(2);
> Q := quo< FM | a^2=1, b^3=1, (a*b)^4=1 >;
> M<x,y> := RWSMonoid(Q);
> print M;
A confluent rewrite monoid.
Generator Ordering = [ a, b ]
Ordering = ShortLex.
The reduction machine has 12 states.
    a^2 = Id(FM)
    b^3 = Id(FM)
    b * a * b * a * b = a * b^2 * a
    b^2 * a * b^2 = a * b * a * b * a
    b * a * b^2 * a * b * a = a * b * a * b^2 * a * b
> print Order(M);
24
> print M.1;
x
> print M.1*M.2;
x * y
> print Generators(M);
[ x, y ]
> print Ngens(M);
2
> print Relations(M);
[ a^2 = Id(FM), b^3 = Id(FM), b * a * b * a * b = a * b^2 * a, b^2 * a * b^2 = a
* b * a * b * a, b * a * b^2 * a * b * a = a * b * a * b^2 * a * b ]
> print Nrels(M);
5
> print Ordering(M);
ShortLex
```

78.3.2 Properties of a Rewrite Monoid

`IsConfluent(M)`

Returns `true` if M is confluent, `false` otherwise.

`IsFinite(M)`

Given a confluent monoid M return `true` if M has finite order and `false` otherwise. If M does have finite order also return the order of M.

`Order(M)`
`#M`

Given a monoid M defined by a confluent presentation, this function returns the cardinality of M. If the order of M is known to be infinite ∞ is returned.

Example H78E6

We construct a threefold cover of A_6.

```
> FM<a,b> := FreeMonoid(2);
> Q := quo< FM | a^3=1, b^3=1, (a*b)^4=1, (a*b^2)^5 = 1 >;
> M := RWSMonoid(Q);
> print Order(M);
1080
> IsConfluent(M);
true
```

Example H78E7

We construct the 2-generator free abelian group and compute its order. The result `Infinity` indicates that the group has infinite order.

```
> FM<a,A,b,B> := FreeMonoid(4);
> Q := quo< FM | a*A=1, A*a=1, b*B=1, B*b=1, B*a*b=a>;
> M := RWSMonoid(Q);
> Order(M);
Infinity
```

Example H78E8

We construct the Weyl group E_8 and test whether or not it has finite order.

```
> FM<a,b,c,d,e,f,g,h> := FreeMonoid(8);
> Q := quo< FM | a^2=1, b^2=1, c^2=1, d^2=1, e^2=1, f^2=1, g^2=1,
>         h^2=1, b*a*b=a*b*a, c*a=a*c, d*a=a*d, e*a=a*e, f*a=a*f,
>         g*a=a*g, h*a=a*h, c*b*c=b*c*b, d*b=b*d, e*b=b*e, f*b=b*f,
>         g*b=b*g, h*b=b*h, d*c*d=c*d*c, e*c*e=c*e*c, f*c=c*f,
>         g*c=c*g, h*c=c*h, e*d=d*e, f*d=d*f, g*d=d*g, h*d=d*h,
>         f*e*f=e*f*e, g*e=e*g, h*e=e*h, g*f*g=f*g*f, h*f=f*h,
>         h*g*h=g*h*g>;
> M := RWSMonoid(Q);
> print IsFinite(M);
true
> isf, ord := IsFinite(M);
> print isf, ord;
true 696729600
```

78.3.3 Construction of a Word

`Identity(M)`

`Id(M)`

`M ! 1`

Construct the identity word in M.

`M ! [ i`$_1$`, ..., i`$_s$` ]`

Given a rewrite monoid M defined on r generators and a sequence $[i_1, \cdots, i_s]$ of integers lying in the range $[1, r]$, construct the word $M.i_1 * M.i_2 * \cdots * M.i_s$.

Example H78E9

We construct the Fibonacci group $F(2, 7)$, and it's identity.

```
> FM<a,A,b,B,c,C,d,D,e,E,f,F,g,G> := FreeMonoid(14);
> Q := quo< FM | a*A=1, A*a=1, b*B=1, B*b=1, c*C=1, C*c=1,
>                d*D=1, D*d=1, e*E=1, E*e=1, f*F=1, F*f=1, g*G=1, G*g=1,
>                a*b=c, b*c=d, c*d=e, d*e=f, e*f=g, f*g=a, g*a=b>;
> M := RWSMonoid(Q : TidyInt := 1000);
> print Id(M);
Id(M)
> print M!1;
Id(M)
> Order(M);
29
```

78.3.4 Arithmetic with Words

Having constructed a rewrite monoid M one can perform arithmetic with words in M. Assuming we have $u, v \in M$ then the product $u * v$ will be computed as follows:

(i) The product $w = u * v$ is formed as a product in the appropriate free monoid.

(ii) The word w is reduced using the reduction machine associated with M.

If M is confluent, then w will be the unique minimal word that represents $u * v$ under the ordering of M. If M is not confluent, then there are some pairs of words which are equal in M, but which reduce to distinct words, and hence w will not be a unique normal form. Note that:

(i) Reduction of w can cause an increase in the length of w. At present there is an internal limit on the length of a word – if this limit is exceeded during reduction an error will be raised. Hence any word operation involving reduction can fail.

(ii) The implementation is designed more with speed of execution in mind than with minimizing space requirements; thus, the reduction machine is always used to carry out word reduction, which can be space-consuming, particularly when the number of generators is large.

`u * v`

Product of the words w and v.

`u ^ n`

The n-th power of the word w, where n is a positive or zero integer.

`u eq v`

Given words w and v belonging to the same monoid, return true if w and v reduce to the same normal form, false otherwise. If M is confluent this tests for equality. If M is non-confluent then two words which are the same may not reduce to the same normal form.

`u ne v`

Given words w and v belonging to the same monoid, return false if w and v reduce to the same normal form, true otherwise. If M is confluent this tests for non-equality. If M is non-confluent then two words which are the same may reduce to different normal forms.

`IsId(w)`

`IsIdentity(w)`

Returns `true` if the word w is the identity word.

`#u`

The length of the word w.

`ElementToSequence(u)`

`Eltseq(u)`

The sequence Q obtained by decomposing the element u of a rewrite monoid into its constituent generators. Suppose u is a word in the rewrite monoid M. If $u = M.i_1 \cdots M.i_m$, then $Q[j] = i_j$, for $j = 1, \ldots, m$.

Example H78E10

We illustrate the word operations by applying them to elements of the Fibonacci monoid $FM(2, 5)$.

```
> FM<a,b,c,d,e> := FreeMonoid(5);
> Q:=quo< FM | a*b=c, b*c=d, c*d=e, d*e=a, e*a=b >;
> M<a,b,c,d,e> := RWSMonoid(Q);
> a*b*c*d;
b^2
> (c*d)^4 eq a;
true
> IsIdentity(a^0);
true
> IsIdentity(b^2*e);
false
```

78.4 Homomorphisms

For a general description of homomorphisms, we refer to Chapter 16. This section describes some special aspects of homomorphisms whose domain is a rewrite monoid.

78.4.1 General Remarks

Monoids in the category MonRWS currently are accepted as codomains only for monoid homomorphisms, whose codomain is a rewrite monoid as well.

78.4.2 Construction of Homomorphisms

`hom< M -> N | S >`

Returns the homomorphism from the rewrite group M to the monoid N defined by the expression S which must be the one of the following:

(i) A list, sequence or indexed set containing the images of the n generators $M.1, \ldots, M.n$ of M. Here, the i-th element of S is interpreted as the image of $M.i$, i.e. the order of the elements in S is important.

(ii) A list, sequence, enumerated set or indexed set, containing n tuples $< x_i, y_i >$ or arrow pairs $x_i -> y_i$, where x_i is a generator of M and $y_i \in N$ $(i = 1, \ldots, n)$ and the set $\{x_1, \ldots, x_n\}$ is the full set of generators of M. In this case, y_i is assigned as the image of x_i, hence the order of the elements in S is not important.

It is the user's responsibility to ensure that the provided generator images actually give rise to a well-defined homomorphism. No checking is performed by the constructor. Presently, N must be either a rewrite monoid or a group, and it is not possible to define a homomorphism by assigning images to the elements of an arbitrary generating set of M.

78.5 Set Operations

`Random(M, n)`

A random word of length at most n in the generators of M.

`Random(M)`

A random word (of length at most the order of M) in the generators of M.

`Representative(M)`

`Rep(M)`

An element chosen from M.

`Set(M, a, b)`

`Search` MonStgElt *Default :* "*DFS*"

Create the set of words, w, in M with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Set(M)`

`Search` MonStgElt *Default :* "*DFS*"

Create the set of words that is the carrier set of M. If `Search` is set to `"DFS"` (depth-first search) then words are enumerated in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words are enumerated in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker. Since the result is a set the words may not appear in the resultant set in the search order specified (although internally they will be enumerated in this order).

`Seq(M, a, b)`

`Search` MonStgElt *Default :* "*DFS*"

Create the sequence S of words, w, in M with $a \leq \text{length}(w) \leq b$. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

`Seq(M)`

`Search` MonStgElt *Default :* "*DFS*"

Create a sequence S of words from the carrier set of M. If `Search` is set to `"DFS"` (depth-first search) then words will appear in S in lexicographical order. If `Search` is set to `"BFS"` (breadth-first-search) then words will appear in S in lexicographical order for each individual length (i.e. in short-lex order). Depth-first-search is marginally quicker.

Example H78E11

We construct the group D_{22}, together with a representative word from the group, a random word and a random word of length at most 5 from the group, and the set of elements of the group.

```
> FM<a,b,c,d,e,f> := FreeMonoid(6);
> Q := quo< FM | a^2=1, f^2=1,
>                d*a=a*c, e*b=b*f, d*c=c*e, d*f=a*d, a*e=e*b, b*f*c=f >;
> M<a,b,c,d,e,f> := RWSMonoid(Q);
```

```
> print Order(M);
22
> print Representative(M);
Id(M)
> print Random(M);
c * e
> print Random(M, 5);
d
> Set(M);
{ a * c, e, a * d, f, a * e, a * f, Id(M), a * c * e, b * a,
  b * d, a * d * b, b * e, c * e, a * b * a, d * b, a * b * d,
  a, a * b * e, b, c, a * b, d }
> Seq(M : Search := "BFS");
[ Id(M), a, b, c, d, e, f, a * b, a * c, a * d, a * e, a * f,
  b * a, b * d, b * e, c * e, d * b, a * b * a, a * b * d,
  a * b * e, a * c * e, a * d * b ]
```

78.6 Conversion to a Finitely Presented Monoid

There is a standard way to convert a rewrite monoid into a finitely presented monoid using the function `Relations`. This is shown in the following example.

Example H78E12

We construct the Fibonacci monoid $FM(2,4)$ as a rewrite monoid, and then convert it into a finitely presented monoid.

```
> FM<a,b,c,d> := FreeMonoid(4);
> Q := quo< FM | a*b=c, b*c=d, c*d=a, d*a=b >;
> M := RWSMonoid(Q);
> Order(M);
11
> P<w,x,y,z> := quo < FM | Relations(M) >;
> P;
Finitely presented monoid
Relations
    w * x = y
    x * y = z
    y * z = w
    z * w = x
    y^2 = w * z
    z^2 = x * w
    z * y = x^2
    y * x = w^2
    x * w * z = x^2
    w^3 = w * z
    x * w^2 = x * z
```

```
x^2 * z = x
w^2 * y = w
x^3 = x * w
x^2 * w = z
z * x = x * z
y * w = w * y
w^2 * z = y
x * w * y = x
```

PART XI
ALGEBRAS

79 ALGEBRAS

Chapter 79
ALGEBRAS

79.1 Introduction

Algebras are viewed as free modules over a ring R with an additional multiplication. There are no a priori conditions imposed on the ring except that it must be unital, but some functions may require that an echelonization algorithm is available for modules over R and sometimes it is also required that R is a field. For example, quotients of algebras can only be constructed over fields, since otherwise the quotient module is not necessarily a free module over R.

The most general way to define an algebra is by structure constants, but for special types of algebras MAGMA uses more efficient representations.

79.1.1 The Categories of Algebras

At present, MAGMA contains seven main categories of algebras:

(1) General algebras represented by structure constants: category `AlgGen`;

(2) Associative algebras represented by structure constants: category `AlgAss`;

(3) Quaternion algebras as special types of associative algebras; category `AlgQuat`;

(4) Lie algebras represented by structure constants: category `AlgLie`;

(5) Group algebras: category `AlgGrp` with a special type `AlgGrpSub` for subalgebras of group algebras;

(6) Matrix algebras: category `AlgMat`;

(7) Finitely presented algebras: category `AlgFP`.

The hierarchy of these categories is such that `AlgGen` is on the top level and `AlgAss` and `AlgLie` are on the next level inheriting the functions available for `AlgGen`. The categories `AlgQuat`, `AlgGrp` and `AlgMat` are on a third level inheriting the functions available for `AlgAss`. Finitely presented algebras are independent of the other categories.

79.2 Construction of General Algebras and their Elements

79.2.1 Construction of a General Algebra

The construction of an algebra depends on its category. The chapters on the individual algebra categories describe this in detail. Here only an overview is given.

`Algebra< R, n | Q >`

Let R be ring, n an integer and Q a sequence of n^3 elements of R. This function creates an algebra A of dimension n over R with basis $e_1, \ldots, e_n$ such that Q contains the structure constants of A, i.e. $e_i * e_j = \sum a_{ij}^k e_k$, where a_{ij}^k is the element in position $(i-1) * n^2 + (j-1) * n + k$ of Q.

`AssociativeAlgebra< R, n | Q >`

`Check` BoolElt *Default :* `true`

This function creates the associative structure constant algebra A as returned by `Algebra< R, n | Q >`. By default, the algebra is checked on associativity, but this can be avoided by setting `Check := false`. The returned algebra is of type `AlgAss`.

`QuaternionAlgebra< K | a, b >`

This function creates the quaternion algebra A over the field K on generators x and y with relations $x^2 = a$, $y^2 = b$, and $xy = -yx$.

`LieAlgebra< R, n | Q >`

`Check` BoolElt *Default :* `true`

This function creates the Lie structure constant algebra A as returned by `Algebra< R, n | Q >`. By default, the algebra is checked to be a Lie algebra, but this can be avoided by setting `Check := false`. The returned algebra is of type `AlgLie`.

`LieAlgebra(A)`

Given an associative algebra A, create the Lie algebra generated by the elements in L using the induced Lie product $(x, y) \to x * y - y * x$.

`GroupAlgebra(R, G)`

Given a ring R and a group G construct the group algebra $R[G]$ of dimension $|G|$ over R.

`MatrixAlgebra(R, n)`

Given a positive integer n and a ring R, create the full matrix algebra $M_n(R)$ of dimension n^2 over R.

79.2.2 Construction of an Element of a General Algebra

The construction of a generic element of an algebra varies for the different types of algebras and is therefore explained in the corresponding chapters.

`Zero(A)`
`A ! 0`

Create the zero element of the algebra A.

`One(A)`
`A ! 1`

If it exists, create the identity element of the algebra A; otherwise an error occurs.

`Random(A)`

Given an algebra A defined over a finite ring, return a random element.

79.3 Construction of Subalgebras, Ideals and Quotient Algebras

79.3.1 Subalgebras and Ideals

If the coefficient ring R of an algebra A is a Euclidean domain then one may construct submodules and ideals of A in MAGMA.

`sub< A | L >`

Create the subalgebra S of the algebra A that is generated by the elements defined by L, where L is a list of one or more items of the following types:

(a) An element of A;

(b) A set or sequence of elements of A;

(c) A subalgebra or ideal of A;

(d) A set or sequence of subalgebras or ideals of A.

The constructor returns the subalgebra as an algebra of the same type as A. An exception are group algebras, where the subalgebra is either of type `AlgAss` or of the special type `AlgGrpSub`. As well as the subalgebra S itself, the constructor returns the inclusion homomorphism $f : S \to A$.

`lideal< A | L >`

Create the left ideal I of the algebra A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the left ideal as an algebra of the same type as A with the same exception for group algebras as for the `sub` constructor. As well as the left ideal I itself, the constructor returns the inclusion homomorphism $f : I \to A$.

`rideal< A | L >`

Create the right ideal I of the algebra A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the right ideal as an algebra of the same type as A with the same exception for group algebras as for the `sub` constructor. As well as the right ideal I itself, the constructor returns the inclusion homomorphism $f : I \to A$.

`ideal< A | L >`

Create the (two-sided) ideal I of the algebra A generated by the elements defined by L, where L is a list as for the `sub` constructor above.

The constructor returns the right ideal as an algebra of the same type as A with the same exception for group algebras as for the `sub` constructor. As well as the ideal I itself, the constructor returns the inclusion homomorphism $f : I \to A$.

79.3.2 Quotient Algebras

If the coefficient ring R of an algebra A is a field, then quotient algebras of A may also be constructed.

`quo< A | L >`

Create the quotient algebra $Q = A/I$, where I is the two-sided ideal of A generated by the elements of A specified by the list L, which should satisfy the same conditions as for the `sub` constructor above.

The constructor returns the quotient as a structure constant algebra with degree equal to its dimension. If A is known to be associative, then Q is of type `AlgAss`, otherwise Q is of type `AlgGen`. As well as the quotient Q itself, the constructor returns the natural homomorphism $f : A \to Q$.

`A / S`

The quotient of the algebra A by the (two-sided) ideal closure of its subalgebra S.

79.4 Operations on Algebras and Subalgebras

79.4.1 Invariants of an Algebra

`CoefficientRing(A)`

`BaseRing(A)`

The coefficient ring (or base ring) over which the algebra A is defined.

`Dimension(A)`

The dimension of the algebra A.

`#A`

The cardinality of the algebra A if both R and the dimension of A are finite. Note that this cannot be computed if the dimension of A is too large.

79.4.2 Changing Rings

`ChangeRing(A, S)`

Given an algebra A with base ring R, together with a ring S, construct the algebra B with base ring S obtained by coercing the coefficients of elements of A into S, together with the homomorphism from A to B.

This function can not be applied if A is of type `AlgGrpSub`, as the parent structure of elements of A is the full group algebra of which A is a subalgebra.

`ChangeRing(A, S, f)`

Given an algebra A with base ring R, together with a ring S and a map $f : R \to S$, construct the algebra B with base ring S obtained by mapping the coefficients of elements of A into S via f, together with the homomorphism from A to B.

As above, this function can not be applied if A is of type `AlgGrpSub`.

79.4.3 Bases

In general, every algebra comes with a basis, corresponding to its underlying module structure. The only exception for that are group algebras in the `"Terms"` representation, where the dimension of the algebra may be too large to create vectors of that degree.

`BasisElement(A, i)`

`A . i`

The i-th basis element of the algebra A.

`Basis(A)`

The basis of the algebra A, as a sequence of elements of A.

Note that if A is of type `AlgGrpSub` the returned elements will be elements of the full group algebra of which A is a subalgebra.

`IsIndependent(Q)`

Given a sequence Q of elements of the R-algebra A, this functions returns `true` if these elements are linearly independent over R; otherwise `false`.

`ExtendBasis(S, A)`

`ExtendBasis(Q, A)`

Given an algebra A and either a subalgebra S of dimension m of A or a sequence Q of m linearly independent elements of A, return a sequence containing a basis of A such that the first m elements are the basis of S resp. the elements in Q.

79.4.4 Decomposition of an Algebra

An algebra A can be regarded as a (left- or right-) module for itself. If A is defined over a finite field, the machinery to decompose modules over finite fields can be used to investigate the structure of the algebra A.

`CompositionSeries(A)`

Compute a composition series for the algebra A. The function has three return values:

(a) a sequence containing the composition series as an ascending chain of subalgebras such that the successive quotients are irreducible A-modules;

(b) a sequence containing the composition factors as structure constant algebras;

(c) a transformation matrix to a basis compatible with the composition series, that is, the first basis elements form a basis of the first term of the composition series, the next extend these to a basis for the second term etc.

`CompositionFactors(A)`

Compute the composition factors of a composition series for the algebra A. This function returns the same as the second return value of `CompositionSeries` above, but will often be very much quicker.

`MinimalLeftIdeals(A :` *parameters*`)`

`MinimalRightIdeals(A :` *parameters*`)`

`MinimalIdeals(A :` *parameters*`)`

`Limit` RngIntElt *Default :* ∞

Return the minimal left/right/two-sided ideals of A (in non-decreasing size). If `Limit` is set to n, at most n ideals are calculated and the second return value indicates whether all of the ideals were computed.

`MaximalLeftIdeals(A :` *parameters*`)`

`MaximalRightIdeals(A :` *parameters*`)`

`MaximalIdeals(A :` *parameters*`)`

`Limit` RngIntElt *Default :* ∞

Return the maximal left/right/two-sided ideals of A (in non-decreasing size). If `Limit` is set to n, at most n ideals are calculated and the second return value indicates whether all of the ideals were computed.

`JacobsonRadical(A)`

Construct the Jacobson (or nilpotent) radical of A, that is, the intersection of the maximal ideals of A (which is equal to the intersection of the maximal left or right ideals).

`IsSemisimple(A)`

Return `true` if the Jacobson radical of A is trivial; otherwise `false`.

`IsSimple(A)`

Return `true` if A has no non-trivial composition factor; otherwise `false`.

Example H79E1

We create a division algebra of dimension 4 over the rational field.

```
> Q := MatrixAlgebra< Rationals(), 4 |
>    [0,1,0,0, -1,0,0,0, 0,0,0,-1, 0,0,1,0],
>    [0,0,1,0, 0,0,0,1, -1,0,0,0, 0,-1,0,0]>;
> i := Q.1;
> j := Q.2;
> k := i*j;
> Dimension(Q);
4
> MinimalPolynomial( (1+i+j+k)/2 );
$.1^2 - $.1 + 1
```

Hence, the element `(1+i+j+k)/2` is integral. In fact, together with `1`, `i` and `j` it forms a $\mathbf{Z}$-basis of a maximal order in `Q`. We create this maximal order as a structure constant algebra over the integers.

```
> a := [ Q!1, i, j, (1+i+j+k)/2 ];
> T := MatrixAlgebra(Rationals(),4) ! &cat[ Coordinates(Q,a[i]) : i in [1..4] ];
> V := RSpace(Rationals(), 4);
> C := [ V ! Coordinates(Q, a[i]*a[j]) * T^-1 : j in [1..4], i in [1..4] ];
> A := ChangeRing( Algebra< V | C >, Integers() );
> IsAssociative(A);
true
> AA := AssociativeAlgebra(A);
> AA;
Associative Algebra of dimension 4 with base ring Integer Ring
> MinimalPolynomial(AA.4);
$.1^2 - $.1 + 1
```

The so constructed maximal order is ramified at 2 and ∞, hence it should be simple after reducing at odd primes.

```
> for p in [ i : i in [1..100] | IsPrime(i) ] do
>    if not IsSimple( ChangeRing( AA, GF(p) ) ) then
>       print p;
>    end if;
> end for;
2
> CS, CF, T := CompositionSeries( ChangeRing( AA, GF(2) ) );
> T;
[1 0 1 0]
```

```
[0 1 1 0]
[0 0 1 0]
[0 0 0 1]
```

A glance at the preimages of the basis of the irreducible submodule shows the ramification of AA at the prime 2.

```
> MinimalPolynomial(AA.1 + AA.3);
$.1^2 - 2*$.1 + 2
> MinimalPolynomial(AA.2 + AA.3);
$.1^2 + 2
```

79.4.5 Operations on Subalgebras

`IsZero(A)`

Returns `true` if the algebra A is trivial; otherwise `false`.

`A eq B`

Returns `true` if the algebras A and B (having a common superalgebra) are equal; otherwise `false`.

`A ne B`

Returns `true` if the algebras A and B are not equal; otherwise `false`.

`A subset B`

Returns `true` if A is a subalgebra of the algebra B; otherwise `false`.

`A notsubset B`

Returns `true` if A is not a subalgebra of the algebra B; otherwise `false`.

`A meet B`

The intersection of the algebras A and B, which must have a common superalgebra.

`A * B`

The algebra product $A * B$ of the algebras A and B, which must have a common superalgebra.

`A ^ n`

The (left-normed) n-th power of the algebra A, i.e. $((\ldots(A * A) * \ldots) * A)$.

`Morphism(A, B)`

The map giving the morphism from A to B. Either A is a subalgebra of B, in which case the embedding of A into B is returned, or B is a quotient algebra of A, in which case the natural epimorphism from A onto B is returned.

79.5 Operations on Elements of an Algebra

79.5.1 Operations on Elements

`a + b`

The sum of the elements a and b of an algebra A.

`-a`

The negation of the algebra element a.

`a - b`

The difference of the elements a and b of an algebra A.

`a * b`

The product of the elements a and b of an algebra A.

`a * r`
`r * a`

The product of the element a of the algebra A and the ring element $r \in R$, where R is the coefficient ring of A.

`a / r`

The product of the element a of the R-algebra A and the ring element $1/r \in R$, where R is a field.

`a ^ n`

If n is positive, form the (left-normed) n-th power $((\ldots((a * a) * a)\ldots) * a)$ of a; if the parent algebra A of a has an identity and n is zero, return the identity; if $n < 0$ and a has an inverse a^{-1} in A, form the n-th power of a^{-1}.

`MinimalPolynomial(a)`

If R is a field or the integer ring, return the minimal polynomial of the algebra element a.

`Parent(a)`

For an element a in an algebra A return A.

79.5.2 Comparisons and Membership

`a eq b`

Returns `true` if the elements a and b of an algebra A are equal; otherwise `false`.

`a ne b`

Returns `true` if the elements a and b of an algebra A are not equal; otherwise `false`.

`a in A`

Returns `true` if a is in the algebra A; otherwise `false`.

`a notin A`

Returns `true` if a is not in the algebra A; otherwise `false`.

79.5.3 Predicates on Elements

`IsZero(a)`

Returns `true` if the algebra element a is zero; otherwise `false`.

`IsOne(a)`

Returns `true` if the algebra element a is the identity; otherwise `false`.

`IsMinusOne(a)`

Returns `true` if the algebra element a is the negative of the identity element; otherwise `false`.

`IsUnit(a)`

Returns `true` if the element a is a unit, plus the inverse; otherwise `false`.

`IsRegular(a)`

Returns `true` if the element a is regular, that is, is not a zero divisor; otherwise `false`.

`IsZeroDivisor(a)`

Returns `true` if the algebra element a is a divisor of zero; otherwise `false`.

`IsIdempotent(a)`

Returns `true` if the element a is an idempotent, i.e. if $a^2 = a$; otherwise `false`.

`IsNilpotent(a)`

Returns `true` if the element a is nilpotent, i.e. if $a^n = 0$ for some $n \geq 0$; otherwise `false`. If `true`, the minimal n such that $a^n = 0$ is returned as a second value.

80 STRUCTURE CONSTANT ALGEBRAS

Chapter 80
STRUCTURE CONSTANT ALGEBRAS

80.1 Introduction

A structure constant algebra A of dimension n over a ring R can be defined in MAGMA by giving the n^3 *structure constants* $a_{ij}^k \in R (1 \leq i, j, k \leq n)$ such that, if $e_1, e_2, \ldots, e_n$ is the basis of A, $e_i * e_j = \sum_{k=1}^{n} a_{ij}^k * e_k$. Structure constant algebras may be defined over any unital ring R. However, many operations require that R be a Euclidean domain or even a field.

80.2 Construction of Structure Constant Algebras and Elements

80.2.1 Construction of a Structure Constant Algebra

There are three ways in MAGMA to specify the structure constants for a structure constant algebra A of dimension n. The first is to give n^3 ring elements, the second to identify A with the module $M = R^n$ and give the products $e_i * e_j$ as elements of M and the third to specify only the non-zero structure constants.

`Algebra< R, n | Q : parameters >`

`Algebra< M | Q : parameters >`

`Rep` MONSTGELT *Default : "Dense"*

This function creates the structure constant algebra A over the free module $M = R^n$, with standard basis $e_1, e_2, \ldots, e_n$, and with the structure constants a_{ij}^k being given by the sequence Q. The sequence Q can be of any of the following three forms. Note that in all cases the actual ordering of the structure constants is the same: it is only their division that varies.

(i) A sequence of n sequences of n sequences of length n. The j-th element of the i-th sequence is the sequence $[a_{ij}^1, \ldots, a_{ij}^n]$, or the element $(a_{ij}^1, \ldots, a_{ij}^n)$ of M, giving the coefficients of the product $e_i * e_j$.

(ii) A sequence of n^2 sequences of length n, or n^2 elements of M. Here the coefficients of $e_i * e_j$ are given by position $(i-1) * n + j$ of Q.

(iii) A sequence of n^3 elements of the ring R. Here the sequence elements are the structure constants themselves, with the ordering $a_{11}^1, a_{11}^2, \ldots, a_{11}^n, a_{12}^1, a_{12}^2, \ldots, a_{nn}^n$. So a_{ij}^k lies in position $(i-1) * n^2 + (j-1) * n + k$ of Q.

The optional parameter `Rep` can be used to select the internal representation of the structure constants. The possible values for `Rep` are `"Dense"`, `"Sparse"` and `"Partial"`, with the default being `"Dense"`. In the dense format, the n^3 structure

constants are stored as n^2 vectors of length n, similarly to (ii) above. This is the best representation if most of the structure constants are non-zero. The sparse format, intended for use when most structure constants are zero, stores the positions and values of the non-zero structure constants. The partial format stores the vectors, but records for efficiency the positions of the non-zero structure constants.

`Algebra< R, n | T : parameters >`

`Rep` MonStgElt *Default : "Sparse"*

This function creates the structure constant algebra A with standard basis $e_1, e_2, \ldots, e_n$ over R. The sequence T contains quadruples $< i, j, k, a_{ij}^k >$ giving the non-zero structure constants. All other structure constants are defined to be 0.

As above, the optional parameter `Rep` can be used to select the internal representation of the structure constants.

`ChangeBasis(A, B)`

`ChangeBasis(A, B)`

`ChangeBasis(A, B)`

`Rep` MonStgElt *Default : "Dense"*

Create a new structure constant algebra A', isomorphic to A, by recomputing the structure constants with respect to the basis B. The basis B can be specified as a set or sequence of elements of A, a set or sequence of vectors, or a matrix. The second returned value is the isomorphism from A to A'.

As above, the optional parameter `Rep` can be used to select the internal representation of the structure constants. Note that the default is dense representation, regardless of the representation used by A.

80.2.2 Construction of Elements of a Structure Constant Algebra

`elt< A | r_1, r_2, ..., r_n >`

Given a structure constant algebra A of dimension n over a ring R, and ring elements $r_1, r_2, \ldots, r_n \in R$ construct the element $r_1 * e_1 + r_2 * e_2 + \ldots + r_n * e_n$ of A.

`A ! Q`

Given a structure constant algebra A of dimension n and a sequence $Q = [r_1, r_2, \ldots, r_n]$ of elements of the base ring R of A, construct the element $r_1 * e_1 + r_2 * e_2 + \ldots + r_n * e_n$ of A.

`BasisProduct(A, i, j)`

Return the product of the i-th and j-th basis element of the algebra A.

`BasisProducts(A)`

`Rep` MonStgElt *Default : "Dense"*

Return the products of all basis elements of the algebra A.

The optional parameter `Rep` may be used to specify the format of the result. If `Rep` is set to "Dense", the products are returned as a sequence Q of n sequences of n elements of A, where n is the dimension of A. The element $Q[i][j]$ is the product of the i-th and j-th basis elements.

If `Rep` is set to "Sparse", the products are returned as a sequence Q containing quadruples (i, j, k, a_{ijk}) signifying that the product of the i-th and j-th basis elements is $\sum_{k=1}^{n} a_{ijk} b_k$, where b_k is the k-th basis element and $n = \dim(A)$.

80.3 Operations on Structure Constant Algebras and Elements

80.3.1 Operations on Structure Constant Algebras

`IsCommutative(A)`

Returns `true` if the algebra A is commutative; otherwise `false`.

`IsAssociative(A)`

Returns `true` if the algebra A is associative; otherwise `false`.

Note that for a structure constant algebra of dimension n this requires up to n^3 tests.

`IsLie(A)`

Returns `true` if the algebra A is a Lie algebra; otherwise `false`.

Note that for a structure constant algebra of dimension n this requires about $n^3/3$ tests of the Jacobi identity.

`DirectSum(A, B)`

Construct a structure constant algebra of dimension $n + m$ where n and m are the dimensions of the algebras A and B, respectively. The basis of the new algebra is the concatenation of the bases of A and B and the products $a * b$ where $a \in A$ and $b \in B$ are defined to be 0.

Example H80E1

We define a structure constant algebra which is a Jordan algebra.

```
> M := MatrixAlgebra( GF(3), 2 );
> B := Basis(M);
> C := &cat[Coordinates(M,(B[i]*B[j]+B[j]*B[i])/2) : j in [1..#B], i in [1..#B]];
> A := Algebra< GF(3), #B | C >;
> #A;
81
> IsAssociative(A);
false
> IsLie(A);
false
> IsCommutative(A);
true
```

This is a good start, as one of the defining properties of Jordan algebras is that they are commutative. The other property is that the identity $(x^2 * y) * x = x^2 * (y * x)$ holds for all $x, y \in A$. We check this on a random pair.

```
> x := Random(A); y := Random(A); print (x^2*y)*x - x^2*(y*x);
(0 0 0 0)
```

The algebra is small enough to check this identity on all elements.

```
> forall{<x, y>: x, y in A | (x^2*y)*x eq x^2*(y*x)};
true
```

So the algebra is in fact a Jordan algebra (which was clear by construction). We finally have a look at the structure constants.

```
> BasisProducts(A);
[
    [ (1 0 0 0), (0 2 0 0), (0 0 2 0), (0 0 0 0) ],
    [ (0 2 0 0), (0 0 0 0), (2 0 0 2), (0 2 0 0) ],
    [ (0 0 2 0), (2 0 0 2), (0 0 0 0), (0 0 2 0) ],
    [ (0 0 0 0), (0 2 0 0), (0 0 2 0), (0 0 0 1) ]
]
```

80.3.2 Indexing Elements

`a[i]`

If a is an element of a structure constant algebra A of dimension n and $1 \leq i \leq n$ is a positive integer, then the i-th component of the element a is returned (as an element of the base ring R of A).

`a[i] := r`

Given an element a belonging to a structure constant algebra of dimension n over R, a positive integer $1 \leq i \leq n$ and an element $r \in R$, the i-th component of the element a is redefined to be r.

80.3.3 The Module Structure of a Structure Constant Algebra

`Module(A)`

The module R^n underlying the structure constant algebra A.

`Degree(A)`

The degree (= dimension) of the module underlying the algebra A.

`Degree(a)`

Given an element belonging to the structure constant algebra A of dimension n, return n.

`ElementToSequence(a)`
`Eltseq(a)`

The sequence of coefficients of the structure constant algebra element a.

`Coordinates(S, a)`

Let a be an element of a structure constant algebra A and let S be a subalgebra of A containing a. This function returns the coefficients of a with respect to the basis of S.

`InnerProduct(a, b)`

The (Euclidean) inner product of the coefficient vectors of a and b, where a and b are elements of some structure constant algebra A.

`Support(a)`

The support of the structure constant algebra element a; i.e. the set of indices of the non-zero components of a.

80.3.4 Homomorphisms

`hom< A -> B | Q >`

Given a structure constant algebra A of dimension n over R and either a structure constant algebra B over R or a module B over R, construct the homomorphism from A to B specified by Q. The sequence Q may be of the form $[b_1, \ldots, b_n]$, $b_i \in B$, indicating that the i-th basis element of A is mapped to b_1 or of the form $[< a_1, b_1 >, \ldots, < a_n, b_n >]$ indicating that a_i maps to b_i, where the $a_i (1 \leq i \leq n)$ must form a basis of A.

Note that this is in general only a module homomorphism, it is not checked whether it is an algebra homomorphism.

Example H80E2

We construct the real Cayley algebra, which is a non-associative algebra of dimension 8, containing 7 quaternion algebras. If the basis elements are labelled $1, \ldots, 8$ and 1 corresponds to the identity, these quaternion algebras are spanned by $\{1, (n+1) \bmod 7+2, (n+2) \bmod 7+2, (n+4) \bmod 7+4\}$, where $0 \leq n \leq 6$. We first define a function, which, given three indices i, j, k constructs a sequence with the structure constants for the quaternion algebra spanned by $1, i, j, k$ in the quadruple notation.

```
> quat := func<i,j,k | [<1,1,1, 1>, <i,i,1, -1>, <j,j,1, -1>, <k,k,1, -1>,
>   <1,i,i, 1>, <i,1,i, 1>, <1,j,j, 1>, <j,1,j, 1>, <1,k,k, 1>, <k,1,k, 1>,
>   <i,j,k, 1>, <j,i,k, -1>, <j,k,i, 1>, <k,j,i, -1>, <k,i,j, 1>, <i,k,j, -1>]>;
```

We now define the sequence of non-zero structure constants for the Cayley algebra using the function `quat`. Some structure constants are defined more than once and we have to get rid of these when defining the algebra.

```
> con := &cat[quat((n+1) mod 7 +2, (n+2) mod 7 +2, (n+4) mod 7 +2):n in [0..6]];
> C := Algebra< Rationals(), 8 | Setseq(Set(con)) >;
> C;
Algebra of dimension 8 with base ring Rational Field
> IsAssociative(C);
false
> IsAssociative( sub< C | C.1, C.2, C.3, C.5 > );
true
```

The integral elements in this algebra are those where either all coefficients are integral or exactly 4 coefficients lie in $1/2 + \mathbf{Z}$ in positions i_1, i_2, i_3, i_4, such that i_1, i_2, i_3, i_4 are a basis of one of the 7 quaternion algebras or a complement of such a basis. These elements are called the integral Cayley numbers and form a $\mathbf{Z}$-algebra. The units in this algebra are the elements with either one entry ± 1 and the others 0 or with 4 entries $\pm 1/2$ and 4 entries 0, where the non-zero entries are in the positions as described above. This gives 240 units and they form (after rescaling with $\sqrt{2}$) the roots in the root lattice of type E_8.

```
> a := (C.1 - C.2 + C.3 - C.5) / 2;
> MinimalPolynomial(a);
$.1^2 - $.1 + 1
> MinimalPolynomial(a^-1);
$.1^2 - $.1 + 1
> MinimalPolynomial(C.2+C.3);
$.1^2 + 2
> MinimalPolynomial((C.2+C.3)^-1);
$.1^2 + 1/2
```

Tensoring the integral Cayley algebra with a finite field gives a finite Cayley algebra. As the $\mathbf{Z}$-algebra generated by the chosen basis for C has index 2^4 in the full integral Cayley algebra, we can get the finite Cayley algebras by applying the `ChangeRing` function for finite fields of odd characteristic. The Cayley algebra over $GF(q)$ has the simple group $G_2(q)$ as its automorphism group. Since the identity has to be fixed, every automorphism is determined by its image on the remaining 7 basis elements. Each of these has minimal polynomial $x^2 + 1$, hence one obtains a

permutation representation of $G_2(q)$ on the elements with this minimal polynomial. As $\pm$-pairs have to be preserved, this number can be divided by 2.

```
> C3 := ChangeRing( C, GF(3) );
> f := MinimalPolynomial(C3.2);
> f;
$.1^2 + 1
> #C3;
6561
> time Im := [ c : c in C3 | MinimalPolynomial(c) eq f ];
Time: 3.099
> #Im;
702
> C5 := ChangeRing( C, GF(5) );
> f := MinimalPolynomial(C5.2);
> f;
$.1^2 + 1
> #C5;
390625
> time Im := [ c : c in C5 | MinimalPolynomial(c) eq f ];
Time: 238.620
> #Im;
15750
```

In the case of the Cayley algebra over $GF(3)$ we obtain a permutation representation of degree 351, which is in fact the smallest possible degree (corresponding to the representation on the cosets of the largest maximal subgroup $U_3(3) : 2$). Over $GF(5)$, the permutation representation is of degree 7875, corresponding to the maximal subgroup $L_3(5) : 2$, the smallest possible degree being 3906.

81 ASSOCIATIVE ALGEBRAS

Chapter 81
ASSOCIATIVE ALGEBRAS

81.1 Introduction

Defining an algebra by structure constants gives a very general set-up, but many structural concepts are restricted to associative algebras. Therefore, MAGMA provides a special type for structure constant algebras which are known to be associative.

81.2 Construction of Associative Algebras

81.2.1 Construction of an Associative Structure Constant Algebra

The construction of an associative structure constant algebra is identical to that of a general structure constant algebra, with the exception that an additional parameter is provided which may be used to avoid checking that the algebra is associative.

`AssociativeAlgebra< R, n | Q : parameters >`

`AssociativeAlgebra< M | Q : parameters >`

`Check`	BOOLELT	*Default :* `true`
`Rep`	MONSTGELT	*Default :* "*Dense*"

This function creates the associative structure constant algebra A over the free module $M = R^n$, with standard basis $e_1, e_2, \ldots, e_n$, and with the structure constants a_{ij}^k being given by the sequence Q. The sequence Q can be of any of the following three forms. Note that in all cases the actual ordering of the structure constants is the same: it is only their division that varies.

(i) A sequence of n sequences of n sequences of length n. The j-th element of the i-th sequence is the sequence $[a_{ij}^1, \ldots, a_{ij}^n]$, or the element $(a_{ij}^1, \ldots, a_{ij}^n)$ of M, giving the coefficients of the product $e_i * e_j$.

(ii) A sequence of n^2 sequences of length n, or n^2 elements of M. Here the coefficients of $e_i * e_j$ are given by position $(i-1) * n + j$ of Q.

(iii) A sequence of n^3 elements of the ring R. Here the sequence elements are the structure constants themselves, $a_{11}^1, a_{11}^2, \ldots, a_{11}^n, a_{12}^1, a_{12}^2, \ldots, a_{nn}^n$. So a_{ij}^k lies in position $(i-1) * n^2 + (j-1) * n + k$ of Q.

By default the algebra is checked to be associative; this can be overruled by setting the parameter `Check` to `false`.

The optional parameter `Rep` can be used to select the internal representation of the structure constants. The possible values for `Rep` are `"Dense"`, `"Sparse"` and `"Partial"`, with the default being `"Dense"`. In the dense format, the n^3 structure

constants are stored as n^2 vectors of length n, similarly to (ii) above. This is the best representation if most of the structure constants are non-zero. The sparse format, intended for use when most structure constants are zero, stores the positions and values of the non-zero structure constants. The partial format stores the vectors, but records for efficiency the positions of the non-zero structure constants.

`AssociativeAlgebra< R, n | T : parameters >`

`Check`	BoolElt	*Default :* `true`
`Rep`	MonStgElt	*Default :* "*Sparse*"

This function creates the associative structure constant algebra A with standard basis $e_1, e_2, \ldots, e_n$ over R. The sequence T contains quadruples $< i, j, k, a_{ij}^k >$ giving the non-zero structure constants. All other structure constants are defined to be 0.

The optional parameters are as above.

`AssociativeAlgebra(A)`

Given a structure constant algebra A of type `AlgGen`, construct an isomorphic associative structure constant algebra of type `AlgAss`. If it is not known whether or not A is associative, this will be checked and an error occurs if it is not. The elements of the resulting algebra can be coerced into A and vice versa.

`ChangeBasis(A, B)`

`ChangeBasis(A, B)`

`ChangeBasis(A, B)`

`Rep`	MonStgElt	*Default :* "*Dense*"

Create a new associative structure constant algebra A', isomorphic to A, by recomputing the structure constants with respect to the basis B. The basis B can be specified as a set or sequence of elements of A, a set or sequence of vectors, or a matrix. The second returned value is the isomorphism from A to A'.

As above, the optional parameter `Rep` can be used to select the internal representation of the structure constants. Note that the default is dense representation, regardless of the representation used by A.

81.2.2 Associative Structure Constant Algebras from other Algebras

`Algebra(A)`

If A is either a group algebra of type `AlgGrp` given in vector representation or a matrix algebra of type `AlgMat`, construct the associative structure constant algebra B isomorphic to A together with the isomorphism $A \to B$.

`Algebra(F, E)`

Let E and F be either finite fields or algebraic number fields such that E is a subfield of F. This function returns the associative algebra A of dimension $[F : E]$ over E which is isomorphic to F, together with the isomorphism from F to A such that the $(i-1)$-th power of the generator of F over E is mapped to the i-th basis vector of A.

`AlgebraOverCenter(A)`

Given a simple algebra A of type `AlgMat` or `AlgAss` with center K, this function returns a K-algebra B which is K-isomorphic to A as well as an isomorphism from A to B.

81.3 Operations on Algebras and their Elements

81.3.1 Operations on Algebras

`Centre(A)`

The centre of the associative algebra A.

`Centralizer(A, S)`

`Centraliser(A, S)`

The centralizer of the subalgebra S of the associative algebra A, that is, the subalgebra of A commuting elementwise with S.

`Idealizer(A, B: parameters)`

`Idealiser(A, B: parameters)`

`Side` MonStgElt *Default : "Both"*

Given an associative algebra A and a subalgebra B of A, compute the idealizer of B in A, that is, the largest subalgebra of A in which B is an ideal. By default the two-sided idealizer, that is, the largest subalgebra in which B is a two-sided ideal, is found; the left- or right-idealizer can be found by setting the parameter `Side` to `"Left"` or `"Right"` respectively.

`LieAlgebra(A)`

For an associative structure constant algebra A, return the structure constant algebra L with product given by the Lie bracket $(a, b) \mapsto a * b - b * a$. As a second value the map identifying the elements of A and L is returned.

`CommutatorModule(A, B)`

Let A and B be subalgebras of an associative algebra with underlying module M. This function returns the submodule of M which is spanned by the elements $[a, b] = a * b - b * a$, $a \in A, b \in B$.

`CommutatorIdeal(A, B)`

For two subalgebras A and B of an associative algebra, return the ideal generated by all $[a, b] = a * b - b * a$, $a \in A, b \in B$.

`LeftAnnihilator(A, B)`

For two subalgebras A and B of an associative algebra, return the left annihilator of B in A; that is, the subalgebra of A consisting of all elements a such that $a * b = 0$ for all $b \in B$.

`RightAnnihilator(A, B)`

For two subalgebras A and B of an associative algebra, return the right annihilator of B in A; that is, the subalgebra of A consisting of all elements a such that $b * a = 0$ for all $b \in B$.

Example H81E1

We create the Lie algebra $sl_3(\mathbf{Q})$ as a structure constant algebra. First, we construct $gl_3(\mathbf{Q})$ from the full matrix algebra $M_3(\mathbf{Q})$ and get $sl_3(\mathbf{Q})$ as the derived algebra of $gl_3(\mathbf{Q})$.

```
> gl3 := LieAlgebra(Algebra(MatrixRing(Rationals(), 3)));
> sl3 := gl3 * gl3;
> sl3;
Lie Algebra of dimension 8 with base ring Rational Field
```

Let's see how the first basis element acts.

```
> for i in [1..8] do
>     print sl3.i * sl3.1;
> end for;
(0 0 0 0 0 0 0 0)
( 0 -1  0  0  0  0  0  0)
( 0  0 -2  0  0  0  0  0)
(0 0 0 1 0 0 0 0)
(0 0 0 0 0 0 0 0)
( 0  0  0  0  0 -1  0  0)
(0 0 0 0 0 0 2 0)
(0 0 0 0 0 0 0 1)
```

Since it acts diagonally, this element lies in a Cartan subalgebra. The next candidate seems to be the fifth basis element.

```
> for i in [1..8] do
>     print sl3.i * sl3.5;
> end for;
(0 0 0 0 0 0 0 0)
(0 1 0 0 0 0 0 0)
( 0  0 -1  0  0  0  0  0)
( 0  0  0 -1  0  0  0  0)
(0 0 0 0 0 0 0 0)
```

```
( 0  0  0  0  0 -2  0  0)
(0 0 0 0 0 0 1 0)
(0 0 0 0 0 0 0 2)
```

This also acts diagonally and commutes with `sl3.1`, hence we have luckily found a full Cartan algebra in $sl_3(\mathbf{Q})$. We can now easily work out the root system. Obviously the root spaces correspond to the pairs `(sl3.2, sl3.4)`, `(sl3.3, sl3.7)` and `(sl3.6, sl3.8)`. The product of a positive root with its negative should lie in the Cartan algebra.

```
> sl3.2*sl3.4;
( 1  0  0  0 -1  0  0  0)
> sl3.3*sl3.7;
(1 0 0 0 0 0 0 0)
> sl3.6*sl3.8;
(0 0 0 0 1 0 0 0)
```

Clearly some choices have to be made and we fix `sl3.3` as the element e_α corresponding to the first fundamental root α, `sl3.7` as $e_{-\alpha}$ and get `sl3.1` as $h_\alpha = e_\alpha * e_{-\alpha}$. For the other fundamental root β we have to find an element e_β such that $e_\alpha * e_\beta$ is non-zero.

```
> sl3.3*sl3.2;
(0 0 0 0 0 0 0 0)
> sl3.3*sl3.4;
( 0  0  0  0  0 -1  0  0)
> sl3.3*sl3.6;
(0 0 0 0 0 0 0 0)
> sl3.3*sl3.8;
(0 1 0 0 0 0 0 0)
```

We choose `sl3.8` as e_β, `sl3.6` as $e_{-\beta}$ and consequently `-sl3.5` as h_β. This now determines $e_{\alpha+\beta}$ to be `sl3.2` and $e_{-\alpha-\beta}$ to be `sl3.4`.

81.3.2 Operations on Elements

`Centralizer(A, s)`

`Centraliser(A, s)`

The centralizer of the element s of the associative algebra A, that is, the subalgebra of A commuting with s.

`LieBracket(a, b)`

`(a, b)`

The Lie bracket $a * b - b * a$ of a and b, where a and b are elements of an associative algebra A.

`IsScalar(a)`

Returns `true` (and a coerced to F) iff a belongs to the base ring F of its parent algebra.

`RepresentationMatrix(a, M : parameters)`

`Side` MonStgElt *Default :* "*Right*"

Returns the matrix representation of `Side`-multiplication by the element a in the associative algebra A (which must have 1) on the A-module M.

81.3.3 Representations

`MatrixAlgebra(A)`

For an associative algebra A of dimension n return an isomorphic matrix algebra. If A contains the identity-element, the matrix algebra will be of degree n, otherwise it will be of degree $n + 1$.

`MatrixAlgebra(A, M : parameters)`

`Side` MonStgElt *Default :* "*Right*"

Given a finite-dimensional R-algebra A and a `Side` A-module M (both free as R-modules), return the matrix algebra of A-endomorphisms of M, and the R-algebra homomorphism from A into this endomorphism ring.

`RegularRepresentation(A : parameters)`

`Side` MonStgElt *Default :* "*Right*"

For an associative algebra A of dimension n over R return its regular representation. If $B = (e_1, e_2, \ldots, e_n)$ is the stored basis for A, an element $a \in A$ is mapped to the matrix in $R^{n\times n}$ which has as its i-th row the coordinates of $e_i * a$ with respect to B. As a second map, the homomorphism of A onto the regular representation is returned.

By default, the right-regular representation is computed. This can be changed to the left-regular representation (in which the i-th row of the image of a contains the coordinates of $a * e_i$) by setting the parameter `Side` to `"Left"`.

81.3.4 Decomposition of an Algebra

This section describes a few functions that can be used to obtain information on the structure of a finite-dimensional associative algebra.

`JacobsonRadical(A)`

`Al` MonStgElt *Default :* "*Default*"

This returns the largest nilpotent ideal of A. This function works for finite-dimensional associative algebras defined over a field of characteristic 0, or over a finite field.

The algorithm used by default is taken from [CIW97]. The meataxe algorithm can be used by setting `Al := "Meataxe"`.

Example H81E2

We compute the Jacobson radical of the group algebra over the field of three elements of a 3-group. In that case it is equal to the augmentation ideal.

```
> G:= SmallGroup( 27, 5 );
> A:= GroupAlgebra( GF(3), G );
> JacobsonRadical( A );
Ideal of dimension 26 of the group algebra A
```

`DirectSumDecomposition(A)`

`IndecomposableSummands(A)`

Given an associative algebra A, return the direct sum decomposition of L as a sequence of ideals of L whose sum is L and each of which cannot be further decomposed into a direct sum of ideals. The second sequence return contains the corresponding primitive central idempotents.

For a description of the algorithm we refer to [EG96].

`CentralIdempotents(A)`

Let Z be the centre of the associative algebra A, and let $J(Z)$ denote its Jacobson radical. This function returns a sequence of primitive orthogonal idempotents in Z such that their images in $Z/J(Z)$ span $J(Z)$. Each such idempotent generates a two-sided ideal in A. The second return value is the sequence of these ideals.

In particular, if A is a semisimple algebra, then this function returns a sequence of primitive orthogonal idempotents spanning Z. Furthermore, the ideals in the second sequence returned are simple algebras, and their direct sum equals A.

For a description of the algorithm we refer to [EG96].

Example H81E3

We compute the direct sum decomposition of a group algebra.

```
> G:= SmallGroup( 10, 2 );
> A:= GroupAlgebra( Rationals(), G );
> ee, II:= CentralIdempotents( A );
> ee[1];
1/10*Id(G) + 1/10*G.2 + 1/10*G.2^2 + 1/10*G.2^3 + 1/10*G.2^4 + 1/10*G.1 +
1/10*G.1 * G.2 + 1/10*G.1 * G.2^2 + 1/10*G.1 * G.2^3 + 1/10*G.1 * G.2^4
> II;
[
    Ideal of dimension 1 of the group algebra A
    Basis:
        Id(G) + G.2 + G.2^2 + G.2^3 + G.2^4 + G.1 + G.1 * G.2 + G.1 * G.2^2 +
        G.1 * G.2^3 + G.1 * G.2^4,
    Ideal of dimension 1 of the group algebra A
    Basis:
```

```
        Id(G) + G.2 + G.2^2 + G.2^3 + G.2^4 - G.1 - G.1 * G.2 - G.1 * G.2^2 -
        G.1 * G.2^3 - G.1 * G.2^4,
    Ideal of dimension 4 of the group algebra A
    Basis:
        Id(G) - G.2^4 + G.1 - G.1 * G.2^4
        G.2 - G.2^4 + G.1 * G.2 - G.1 * G.2^4
        G.2^2 - G.2^4 + G.1 * G.2^2 - G.1 * G.2^4
        G.2^3 - G.2^4 + G.1 * G.2^3 - G.1 * G.2^4,
    Ideal of dimension 4 of the group algebra A
    Basis:
        Id(G) - G.2^4 - G.1 + G.1 * G.2^4
        G.2 - G.2^4 - G.1 * G.2 + G.1 * G.2^4
        G.2^2 - G.2^4 - G.1 * G.2^2 + G.1 * G.2^4
        G.2^3 - G.2^4 - G.1 * G.2^3 + G.1 * G.2^4
]
```

We see that here the group algebra is the direct sum of two 1-dimensional and two 4-dimensional ideals. The first idempotent is the sum over all group elements divided by the group order.

81.4 Orders

Let F be a number field with ring of integers R, and let A be a associative algebra over F (finite-dimensional, with 1). An *associative order* O of A is a subring $O \subset A$ which is a projective R-module such that $O \cdot F = A$. We will also refer to an associative order simply as an *order*.

In MAGMA, associative orders have the type `AlgAssVOrd`, and may be declared for any associative algebra of type `AlgAssV`, namely, `AlgAss`, `AlgMat`, `AlgQuat` and `AlgGrp`. Orders have ideals of type `AlgAssVOrdIdl`, and elements of type `AlgAssVOrdElt`. In the special case where A is a quaternion algebra over the rationals, A has type `AlgQuat` and orders in A have type `AlgQuatOrd`.

Orders, like modules over Dedekind domains, are represented by a pseudobasis, see Section 55.10. Currently, only basic arithmetic functions and procedures are available for general associative orders. Most of the nontrivial functionality currently available is designed for orders in quaternion algebras (over the rationals or number fields). The specialised functions for quaternionic orders are described in Chapter 86.

IMPORTANT WARNING for algebras over the rationals: In MAGMA, the rationals are *not* considered to be a number field (the type `FldRat` is not a subtype of `FldNum`). Currently, much of the functionality here is designed primarily for algebras whose base field is a `FldNum` (while some of it, but not all, also works for algebras over the `FldRat`). To compute with algebras over $\mathbf{Q}$, in many cases the best solution is to create $\mathbf{Q}$ as a number field at the outset, using `RationalsAsNumberField()`, and create the algebra over this field instead of `Rationals()`.

81.4.1 Creation of Orders

`Order(R, S)`

Given a ring R and sequence S of elements of an associative algebra A, returns the order of A generated freely over R by the sequence S. The ring R must be a number ring or $\mathbf{Z}$.

`Order(S)`

Given a sequence of elements S of an associative algebra A, returns the order of A generated by the sequence S. The algebra A must be defined over a number field F.

`Order(S, I)`

Given a sequence of elements S of an associative algebra A and a sequence I of ideals of a number ring R, returns the order of A generated by the sequence S with coefficient ideals I. The algebra A must be defined over a number field F and have ring of integers R.

`Order(A, m, I)`

Given an associative algebra A, a matrix m, and a sequence I of ideals of a number ring R, returns the order of A generated by the sequence of elements specified by the rows of m in the basis of A with coefficient ideals I. The algebra A must be defined over a number field F and have ring of integers R.

`Order(A, pm)`

Given an associative algebra A and a pseudomatrix pm, returns the order of A specified by the pseudomatrix pm. The basis of the order is specified by the rows of pm which have coefficients with respect to the basis of A. The algebra A must be defined over a number field with ring of integers R which is the base ring of the pseudomatrix pm.

Example H81E4

We begin by illustrating three methods for creating an associative order.

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> A<alpha,beta,alphabeta> := QuaternionAlgebra<F | -3,b>;
```

First type of constructor takes an algebra, a matrix representing the basis elements, and coefficient ideals.

```
> M := MatrixAlgebra(F,4) ! 1;
> I := [ideal<Z_F | 1> : i in [1..4]];
> O := Order(A, M, I);
> O;
Order of Quaternion Algebra with base ring Field of Fractions of Z_F
```

```
with coefficient ring Maximal Equation Order with defining polynomial x^3 - 3*x
    - 1 over its ground order
```

The second type takes an algebra and a pseudomatrix.

```
> P := PseudoMatrix(I, M);
> O := Order(A, P);
> O;
Order of Quaternion Algebra with base ring Field of Fractions of Z_F
with coefficient ring Maximal Equation Order with defining polynomial x^3 - 3*x
    - 1 over its ground order
```

The third takes simply a sequence of elements.

```
> O := Order([alpha,beta]);
> O;
Order of Quaternion Algebra with base ring Field of Fractions of Z_F
with coefficient ring Maximal Equation Order with defining polynomial x^3 - 3*x
    - 1 over its ground order
```

Example H81E5

Here we give two other examples of order creation.

```
> F<w> := CyclotomicField(3);
> A := FPAlgebra<F, x,y | x^3-3, y^3+5, y*x-w*x*y>;
> Aass, f := Algebra(A);
> Aass;
Associative Algebra of dimension 9 with base ring F
> f;
Mapping from: AlgFP: A to AlgAss: Aass
> S := [f(A.i) : i in [1..2]];
> S;
[ (0 0 1 0 0 0 0 0 0), (0 1 0 0 0 0 0 0 0) ]
> O := Order(S);
> O;
Order of Associative Algebra of dimension 9 with base ring Field of Fractions of R
with coefficient ring Maximal Equation Order with defining polynomial x^2 + x +
    1 over its ground order
>
> A := GroupAlgebra(F, DihedralGroup(6));
> Aass := Algebra(A);
> O := Order([g : g in Generators(Aass)]);
> O;
Order of Associative Algebra of dimension 12 with base ring Field of Fractions
of R with coefficient ring Maximal Equation Order with defining polynomial
x^2 + x + 1 over its ground order
```

`MaximalOrder(A)`

Computes a maximal **Z**-order in the semisimple associative algebra A, which must be defined over the rational numbers. The algorithm can be found in [Fri00], §3.5. We refer to [IR93] for a very similar approach.

Example H81E6

First we define two 9×9-matrices that generate a 9-dimensional associative algebra. We check that its Jacobson radical is zero, and then we compute a maximal order.

```
> a1 := Matrix( [
> [-184174/80137, -325/80137, 71/2163699, 0, 0, 0, 0, 0, 0],
> [17713719/80137, 92087/80137, -325/80137, 0, 0, 0, 0, 0, 0],
> [-2189265975/80137, -16429806/80137, 92087/80137, 0, 0, 0, 0, 0, 0],
> [0, 0, 0, 64850/80137, 1472/240411, -25/2163699, 0, 0, 0],
> [0, 0, 0, -6237225/80137, -32425/80137, 1472/240411, 0, 0, 0],
> [0, 0, 0, 3305230272/80137, 45310743/80137, -32425/80137, 0, 0, 0],
> [0, 0, 0, 0, 0, 0, 119324/80137, -497/240411, -46/2163699],
> [0, 0, 0, 0, 0, 0, -11476494/80137, -59662/80137, -497/240411],
> [0, 0, 0, 0, 0, 0, -1115964297/80137, -28880937/80137, -59662/80137] ] );
> a2:= Matrix( [
> [0, 0, 0, 282469/240411, 956/2163699, -26/2163699, 0, 0, 0],
> [0, 0, 0, -6486714/80137, -21029/240411, 956/2163699, 0, 0, 0],
> [0, 0, 0, 238511484/80137, -2766918/80137, -21029/240411, 0, 0, 0],
> [0, 0, 0, 0, 0, 0, -85879/240411, -4894/2163699, 64/6491097],
> [0, 0, 0, 0, 0, 0, 5322432/80137, 163145/240411, -4894/2163699],
> [0, 0, 0, 0, 0, 0, -1220999166/80137, -13720122/80137, 163145/240411],
> [-1183167/80137, -11814/80137, -14/80137, 0, 0, 0, 0, 0, 0],
> [-94306842/80137, -2653965/80137, -11814/80137, 0, 0, 0, 0, 0, 0],
> [-79581502242/80137, -1335450240/80137, -2653965/80137, 0, 0, 0, 0, 0, 0] ] );
> M := MatrixAlgebra( Rationals(), 9 );
> A := sub< M | [ a1, a2 ] >;
> Dimension(A);
9
> JacobsonRadical( A );
Matrix Algebra [ideal of A] of degree 9 and dimension 0 with 0 generators over
Rational Field
> O := MaximalOrder( A );
> Discriminant( O );
1
> T :=MultiplicationTable(O);
> T[3][7];
[ -16583482050411285785256, 5672389828626293786946, 1059868937213366777403,

```

81.4.2 Attributes

`BaseRing(O)`

`CoefficientRing(O)`

The base ring of the associative order O.

`Algebra(O)`

The container algebra of the associative order O.

`Degree(O)`

`Dimension(O)`

Returns the dimension (or degree) of the order O, equivalently the dimension of its parent algebra as a vector space over its ground field.

`Discriminant(O)`

Returns the discriminant of the order O. If O is a quaternion order, returns the reduced discriminant which is the square root of the usual discriminant.

`FactoredDiscriminant(O)`

Returns the factorization of the discriminant of the order O. If O is a quaternion order, returns the factorization of the reduced discriminant which is the square root of the usual discriminant.

`MultiplicationTable(O)`

Returns the multiplication table of the maximal order O. This is a three dimensional table of structure constants. If T denotes this table, then $T[i][j]$ is a sequence of integers containing the coefficients of the product of the i-th and j-th basis elements with respect to the basis of the order.

`Module(O)`

Return the pseudo matrix describing the basis of the associative order O over a number ring.

`TraceZeroSubspace(O)`

Given an order O in a quaternion algebra, this computes the submodule of elements with trace 0. A basis or a pseudo-basis for this submodule is returned, depending whether the base field of the quaternion algebra is $\mathbf{Q}$ or a number field. (The base ring of O is, respectively, either $\mathbf{Z}$ or an order in that number field.)

81.4.3 Bases of Orders

`Basis(O)`

Returns a basis of the order O. All other elements of the order are integral linear combinations of elements of this basis. Note that the elements of a basis will only be elements of the parent algebra A and may not be elements of O because of the existence of coefficient ideals.

`PseudoBasis(O)`

Returns the pseudobasis of the associative order O over a number ring.

`PseudoMatrix(O)`

Returns the pseudomatrix describing the pseudobasis of the associative order O over a number ring.

`ZBasis(O)`

Returns a $\mathbf{Z}$-basis for the order O.

`Generators(O)`

Returns a sequence of generators of O as a module over its base ring.

Example H81E7

We compute an order and show how a basis and a pseudobasis can differ.

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> A := QuaternionAlgebra<F | -3,b>;
> O := Order([1/3*A.1, A.2], [ideal<Z_F | b^2+b+1>, ideal<Z_F | 1>]);
> O;
Order of Quaternion Algebra with base ring Field of Fractions of Z_F
with coefficient ring Maximal Equation Order with defining polynomial x^3 - 3*x
    - 1 over its ground order
> Basis(O);
[ Z_F.1, i, j, k ]
> PseudoBasis(O);
[
    <Principal Ideal of Z_F
    Generator:
        Z_F.1, Z_F.1>,
    <Fractional Principal Ideal of Z_F
    Generator:
        1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3, i>,
    <Principal Ideal of Z_F
    Generator:
        Z_F.1, j>,
    <Fractional Principal Ideal of Z_F
```

```
    Generator:
        1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3, k>
]
> PseudoMatrix(O);
Pseudo-matrix over Maximal Equation Order with defining polynomial x^3 - 3*x
     - 1 over its ground order
Principal Ideal of Z_F
Generator:
    Z_F.1 * ( Z_F.1 0 0 0 )
Fractional Principal Ideal of Z_F
Generator:
    1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3 * ( 0 Z_F.1 0 0 )
Principal Ideal of Z_F
Generator:
    Z_F.1 * ( 0 0 Z_F.1 0 )
Fractional Principal Ideal of Z_F
Generator:
    1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3 * ( 0 0 0 Z_F.1 )
> ZBasis(O);
[ Z_F.1, Z_F.2, Z_F.3, (1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3)*i, (1/3*Z_F.1 +
4/3*Z_F.2 + 1/3*Z_F.3)*i, (1/3*Z_F.1 + 4/3*Z_F.2 + 4/3*Z_F.3)*i, j, Z_F.2*j,
Z_F.3*j, (1/3*Z_F.1 + 1/3*Z_F.2 + 1/3*Z_F.3)*k, (1/3*Z_F.1 + 4/3*Z_F.2 +
1/3*Z_F.3)*k, (1/3*Z_F.1 + 4/3*Z_F.2 + 4/3*Z_F.3)*k ]
```

Note that the basis of O does not generate O—one needs to include the coefficient ideals.

81.4.4 Predicates

`O1 eq O2`

Return `true` if and only if the orders O_1 and O_2 are equal as subrings of the same algebra.

`x in O`

`x notin O`

Return `true` (respectively, `false`) if the element x of an associative algebra is in the associative order O.

81.4.5 Operations with Orders

`Adjoin(O, x)`

`Adjoin(O, x, I)`

Returns the order obtained by adjoining the element x to the order O, optionally with coefficient ideal I.

`O1 + O2`

Returns the sum of the orders O_1 and O_2.

`O1 meet O2`

Returns the intersection of the orders O_1 and O_2.

`O ^ x`

Returns the conjugate order $x^{-1}Ox$.

Example H81E8

```
> P<x> := PolynomialRing(Rationals());
> F<b> := NumberField(x^3-3*x-1);
> Z_F := MaximalOrder(F);
> F := FieldOfFractions(Z_F);
> A<alpha,beta,alphabeta> := QuaternionAlgebra<F | -3,b>;
> O := Order([alpha,beta]);
> O1 := Order([1/3*alpha,beta], [ideal<Z_F | b^2+b+1>, ideal<Z_F | 1>]);
> Discriminant(O1);
Principal Ideal of Z_F
Generator:
    4/1*F.1 + 12/1*F.2 + 8/1*F.3
> xi := (1 + alpha + (7+5*b+6*b^2)*beta + (3+b+6*b^2)*alphabeta)/2;
> zeta := (-6-25*b-5*b^2)*alpha - 3*beta;
> O2 := Adjoin(O, xi);
> O := O1+O2;
> Discriminant(O);
Ideal of Z_F
Basis:
[2 0 4]
[0 2 4]
[0 0 6]
```

81.5 Elements of Orders

81.5.1 Creation of Elements

`O ! 0`
`Zero(O)`

The zero element of the associative order O.

`O ! 1`
`One(O)`

The identity element of the associative order O.

`O . i`

Given an associative order O and an integer i, returns the ith basis element as an order over the base ring. Note that the element 1 may or may not be the first element of a basis. These basis elements are returned as elements of the algebra of O not as elements of O itself.

`O ! x`

Return an element of the associative order O described by x, where x may be a sequence, an element of an associative order, an element coercible into the coefficient ring of O or into the algebra of O.

`Random(O)`

Returns a "random" element of the associative order O with small coefficients.

81.5.2 Arithmetic of Elements

`x + y`

The sum of elements x and y of an order of an associative algebra.

`x - y`

The difference of elements x and y of an order of an associative algebra.

`-x`

The negation of element x of an order of an associative algebra.

`x * y`

The product of elements x and y of an associative algebra.

`u * c`
`c * u`

The product of the element u of an associative order by the scalar c.

`x / y`

The quotient of x by the unit y in the parent algebra.

`x div y`

The exact division of x by y in the order containing them.

`x ^ n`

The product of the element x of an associative order with itself n times.

81.5.3 Predicates on Elements

`x eq y`

Returns `true` if and only if the elements x and y are equal.

`x ne y`

Returns `true` if and only if the elements x and y are not equal.

`IsZero(x)`

Return `true` if the element x of an associative order is the zero element.

`IsUnit(a)`

Return `true` if the element x of an associative order is a unit in that order.

`IsScalar(x)`

Returns `true` if and only if x is an element of the base ring of the order containing it, and if so returns the coerced element.

81.5.4 Other Operations with Elements

`ElementToSequence(x)`

`Eltseq(x)`

Given an element x of an associative order O, returns the sequence of coordinates of x in terms of the basis of O.

`Norm(x)`

The norm of the element x of an order as an element of its parent algebra.

`Trace(x)`

The trace of the element x of an order as an element of its parent algebra.

`LeftRepresentationMatrix(e)`

`RightRepresentationMatrix(e)`

The representation matrix describing left (right) multiplication by the element e of an associative order.

`RepresentationMatrix(a)`

`Side` MonStgElt *Default : "Left"*

The representation matrix of the element a of an associative order. This describes left multiplication unless the parameter `Side` is set to `"Right"`.

`CharacteristicPolynomial(x)`

The characteristic polynomial of the element x of an order as an element of its parent algebra.

`MinimalPolynomial(x)`

The minimal polynomial of the element x of an order as an element of its parent algebra.

81.6 Ideals of Orders

81.6.1 Creation of Ideals

`lideal< O | E >`
`rideal< O | E >`
`ideal< O | E >`

For an associative order O, this constructs the left, right or two sided O-ideal generated by the elements in the given sequence E (these elements should be coercible into O).

`lideal< O | M >`
`rideal< O | M >`
`ideal< O | M >`

Constructs a left, right or two sided ideal of the associative order O whose basis is given by M, which may be either a matrix or a pseudo matrix.

`O * e`
`e * O`

The principal left (right) ideal of the associative order O generated by the element e.

`RandomRightIdeal(O)`

Returns a "random" right ideal of the order O, generated by elements with small coefficients.

81.6.2 Attributes of Ideals

`Algebra(I)`

The container algebra of the associative ideal I.

`Order(I)`

The associative order the associative ideal I was created as an ideal of.

`LeftOrder(I)`

`RightOrder(I)`

The order which maps the associative ideal I to itself under left (right) multiplication.

`Basis(I)`

`Basis(I, R)`

The basis of the associative ideal I. This will be returned as elements of the order or algebra R if this second argument is given, otherwise as elements of the algebra of I.

`BasisMatrix(I)`

`BasisMatrix(I, R)`

The basis matrix of the associative ideal I. This will be with respect to the basis of the order or algebra R if this second argument is given, otherwise with respect to the basis of the order I was created as an ideal of.

`PseudoBasis(I)`

`PseudoBasis(I, R)`

Return a sequence of tuples of the coefficient ideals and the basis elements of the associative ideal I. If a second argument is given, an order or algebra R, then the basis elements will be in R, otherwise the algebra of I.

`PseudoMatrix(I)`

`PseudoMatrix(I, R)`

Return a pseudo matrix describing the basis of the associative ideal I. If a second argument is given, an order or algebra R, then the basis matrix will be with respect to the basis of R, otherwise the order I was created as an ideal of.

`ZBasis(I)`

Returns a $\mathbf{Z}$-basis for the ideal I.

`Generators(I)`

Returns a sequence of generators for the ideal I as a module over its base ring.

`Denominator(I)`

Return the denominator of the ideal I. This is the minimal element d of the coefficient ring of O such that $d * I \subseteq O$ where O is the order I was created as an ideal of.

81.6.3 Arithmetic for Ideals

`I + J`

The sum of the ideals I and J, which are ideals which share a side in equal orders.

`I * J`

The product of the ideals I and J, where I is a right ideal and J is a left ideal of the same order O. Returns the product given the structure of left and right ideal.

`a * I`
`I * a`

Returns the product of a and I as an ideal.

`Colon(J, I)`

If I, J are left ideals, returns the colon $(J : I) = \{x \in A : xI \subset J\}$, similarly defined if I, J are right ideals.

`MultiplicatorRing(I)`

Returns the colon $(I : I)$ of the ideal I, the set of all elements which multiply I into I.

81.6.4 Predicates on Ideals

`IsLeftIdeal(I)`
`IsRightIdeal(I)`
`IsTwoSidedIdeal(I)`

Return `true` if the associative ideal I is a left, right or two sided ideal (respectively).

`I eq J`

Return `true` if the associative ideals I and J are equal.

`I subset J`

Returns `true` if and only if the ideal I is contained in the ideal J.

`a in I`
`a notin I`

Return `true` (`false`) if the element a of an associative algebra is contained in the associative ideal I.

81.6.5 Other Operations on Ideals

`Norm(I)`

Returns the norm of the ideal I, the ideal of the base number ring of I generated by the norms of the elements in I.

Example H81E9

```
> F<w> := CyclotomicField(3);
> R := MaximalOrder(F);
> A := Algebra(FPAlgebra<F, x, y | x^3-3, y^3+5, y*x-w*x*y>);
> O := Order([A.i : i in [1..9]]);
> MinimalPolynomial(O.2);
$.1^3 + 5/1*R.1

81.7 Quaternionic Orders

The following intrinsics which take an argument of type `AlgAssVOrd`, `AlgAssVOrdElt`, or `AlgAssVOrdIdl`, apply only to associative orders of quaternion algebras and are documented in that chapter, Chapter 86.

`MaximalOrder(O)` `pMaximalOrder(O, p)`
`IsMaximal(O)` `IspMaximal(O, p)`
`pMatrixRing(O, p)`
`Embed(Oc, O)`
`LeftIdealClasses(S)` `RightIdealClasses(S)`
`TwoSidedIdealClasses(S)`
`TwoSidedIdealClassGroup(S)`
`OptimizedRepresentation(O)` `OptimisedRepresentation(O)`
`Units(S)` `MultiplicativeGroup(S)` `UnitGroup(S)`
`Conjugate(x)`
`Enumerate(O, A, B)` `Enumerate(O, B)` `Enumerate(I, B)`
`ReducedBasis(O)` `ReducedBasis(I)`
`IsIsomorphic(I, J)` `IsLeftIsomorphic(I, J)`
`IsRightIsomorphic(I, J)` `IsPrincipal(I)`

82 FINITELY PRESENTED ALGEBRAS

Chapter 82
FINITELY PRESENTED ALGEBRAS

82.1 Introduction

This chapter describes finitely presented algebras (FPAs) in MAGMA. An FPA is a quotient of a free associative algebra by an ideal of relations. To compute with these ideals, one constructs *noncommutative* Gröbner bases (GBs), which have many parallels with the standard commutative GBs, discussed in Chapter 105. At the heart of the theory is a noncommutative version of the *Buchberger algorithm* which computes a GB of an ideal of an algebra starting from an arbitrary basis (generating set) of the ideal. One significant difference with the commutative case is that a noncommutative GB may not be finite for a finitely-generated ideal. For overviews of the theory and the basic algorithms, see [Mor94, Li02].

MAGMA also contains an implementation of a noncommutative generalization of the Faugere F_4 algorithm (due to Allan Steel), based on sparse linear algebra techniques, which usually performs dramatically better than the Buchberger algorithm, and so this is used by MAGMA by default.

82.2 Representation and Monomial Orders

Let A be the free algebra $K\langle x_1, \ldots, x_n\rangle$ of rank n over a field K. A word in the underlying monoid of A is simply an associative product of the letters (or variables) of A. For consistency with the commutative case, we will call these monoid words *monomials*. Elements of A, called noncommutative polynomials, are finite sums of terms, where a term is the product of a coefficient from K and a monomial. The terms are sorted with respect to an admissible order $<$, which satisfies, for monomials p, q, r, the following conditions:

(a) If $p < q$, then $pr < qr$ and $sp < sq$.

(b) If $p = qr$ then $p > q$ and $p > r$.

Currently MAGMA only supports the noncommutative graded-lexicographical order (*glex*), which first compares degrees and then uses a left-lexicographical comparison for degree-ties. There is no admissible lexicographic order in the noncommutative case.

82.3 Exterior Algebras

Since V2.15 (December 2008), MAGMA has a special type for *exterior algebras*. Such an algebra is skew-commutative and is a quotient of the free algebra $K\langle x_1, \ldots, x_n\rangle$ by the relations $x_i^2 = 0$ and $x_i x_j = -x_j x_i$ for $1 \leq i, j \leq n$, $i \neq j$. Because of these relations, elements of the algebra can be written in terms of commutative monomials in the variables (via a collection algorithm), and the associated algorithms are much more efficient than for the general noncommutative case. Also, a Gröbner basis of an ideal of an exterior algebra is always finite (in fact, the whole exterior algebra has dimension 2^n as a K-vector space).

Exterior algebras may be constructed with the `ExteriorAlgebra` function below, and all operations applicable to general FP algebras are also applicable to them (so will not be duplicated here). Furthermore, modules over exterior algebras are also allowed: see Chapter 109 for details.

82.4 Creation of Free Algebras and Elements

82.4.1 Creation of Free Algebras

Currently algebras may only be created over fields. Free algebras are objects of type `AlgFr` with elements of type `AlgFrElt`.

`FreeAlgebra(K, n)`

Create a free algebra in $n > 0$ variables over the field K. The angle bracket notation can be used to assign names to the indeterminates; e.g., `F<a,b,c> := FreeAlgebra(GF(2), 3);`.

`ExteriorAlgebra(K, n)`

Create an exterior algebra in $n > 0$ variables over the field K. The angle bracket notation can be used to assign names to the indeterminates; The angle bracket notation can be used to assign names to the indeterminates; e.g., `F<a,b,c> := ExteriorAlgebra(GF(2), 3);`.

82.4.2 Print Names

The `AssignNames` and `Name` functions can be used to associate names with the indeterminates of free algebras after creation.

`AssignNames(~F, s)`

Procedure to change the name of the indeterminates of a free algebra F. The i-th indeterminate will be given the name of the i-th element of the sequence of strings s (for $1 \leq i \leq \#s$); the sequence may have length less than the number of indeterminates of F, in which case the remaining indeterminate names remain unchanged.

This procedure only changes the name used in printing the elements of F. It does *not* assign to identifiers corresponding to the strings the indeterminates in F; to do this, use an assignment statement, or use angle brackets when creating the free algebra.

`Name(F, i)`

Given a free algebra F, return the i-th indeterminate of F (as an element of F).

82.4.3 Creation of Polynomials

The easiest way to create (noncommutative) polynomials in a given algebra is to use the angle bracket construction to attach variables to the indeterminates, and then to use these variables to create polynomials (see the examples). Below we list other options.

`F . i`

Return the i-th indeterminate for the free algebra F in n variables ($1 \leq i \leq n$) as an element of F.

`elt< R | a >`
`R ! s`
`elt< R | s >`

This element constructor can only be used for trivial purposes in noncommutative free algebras: given a free algebra $F = R[x_1, \ldots, x_n]$ and an element a that can be coerced into the coefficient ring R, the constant polynomial a is returned; if a is in F already it will be returned unchanged.

`One(F)` `Identity(F)` `Zero(F)` `Representative(F)`

82.5 Structure Operations

82.5.1 Related Structures

The main structure related to a free algebra is its coefficient ring. Multivariate free algebras belong to the MAGMA category `AlgFr`.

`BaseRing(F)`
`CoefficientRing(F)`

Return the coefficient ring of the free algebra F.

`Category(F)` `Parent(F)` `PrimeRing(F)`

82.5.2 Numerical Invariants

Note that the `#` operator only returns a value for finite (quotients of) free algebras.

`Rank(F)`

Return the number of indeterminates of free algebra F over its coefficient ring.

`Characteristic(F)` `# F`

82.5.3 Homomorphisms

In its most general form, a homomorphism taking a free algebra $K\langle x_1, \ldots, x_n\rangle$ as domain requires $n + 1$ pieces of information, namely, a map (homomorphism) telling how to map the coefficient ring K together with the images of the n indeterminates. The map for the coefficient ring is optional.

```
hom<  F -> S | f, y1, ..., yn  >
```

```
hom<  F -> S | y1, ..., yn  >
```

Given a free algebra $F = K\langle x_1, \ldots, x_n\rangle$, a ring or associative algebra S (including another FP-algebra or a matrix algebra), and a map $f : K \to S$ and n elements $y_1, \ldots, y_n \in S$, create the homomorphism $g : F \to S$ by applying the rules that $g(rx_1^{a_1} \cdots x_n^{a_n}) = f(r)y_1^{a_1} \cdots y_n^{a_n}$ for monomials and linearity, that is, $g(M + N) = g(M) + g(N)$.

The coefficient ring map may be omitted, in which case the coefficients are mapped into S by the coercion map.

No attempt is made to check whether the map defines a genuine homomorphism.

Example H82E1

In this example we map an algebra F first into F itself, and then into a matrix algebra.

```
> K := RationalField();
> F<x,y,z> := FreeAlgebra(K, 3);
> h := hom<F -> F | x*y, y*x, z*x>;
> h(x);
x*y
> h(y);
y*x
> h(x*y);
x*y^2*x
> h(x + y + z);
x*y + y*x + z*x
> A := MatrixAlgebra(K, 2);
> M := [A | [1,1,-1,1], [-1,3,4,1], [11,7,-7,8]];
> M;
[
    [ 1  1]
    [-1  1],

    [-1  3]
    [ 4  1],

    [11  7]
    [-7  8]
]
> h := hom<F -> A | M>;
> h(x);
```

```
[ 1  1]
[-1  1]
> h(y);
[-1  3]
[ 4  1]
> h(x*y - y*z);
[ 35 -13]
[-32 -38]
```

82.6 Element Operations

82.6.1 Arithmetic Operators

The usual unary and binary ring operations are available for noncommutative polynomials, noting that multiplication is associative but noncommutative, of course.

`+ a` `- a`

`a + b` `a - b` `a * b` `a ^ k` `a / b` `a div b`

`a +:= b` `a -:= b` `a *:= b` `a div:= b`

82.6.2 Equality and Membership

`a eq b` `a ne b`

`a in R` `a notin R`

82.6.3 Predicates on Algebra Elements

`IsZero(f)` `IsOne(f)` `IsMinusOne(f)`

`IsNilpotent(f)` `IsIdempotent(f)`

`IsUnit(f)` `IsZeroDivisor(f)` `IsRegular(f)`

`IsIrreducible(f)` `IsPrime(f)`

82.6.4 Coefficients, Monomials, Terms and Degree

The functions in this subsection allow one to access noncommutative polynomials.

`Coefficients(f)`

Given a noncommutative polynomial f with coefficients in R, this function returns a sequence of 'base' coefficients, that is, a sequence of elements of R occurring as coefficients of the monomials in f. Note that the monomials are ordered, and that the sequence of coefficients corresponds exactly to the sequence of monomials returned by `Monomials(f)`.

`LeadingCoefficient(f)`

Given a noncommutative polynomial f with coefficients in R, this function returns the leading coefficient of f as an element of R; this is the coefficient of the leading monomial of f, that is, the first among the monomials occurring in f with respect to the ordering of monomials used in F.

`TrailingCoefficient(f)`

Given a noncommutative polynomial f with coefficients in R, this function returns the trailing coefficient of f as an element of R; this is the coefficient of the trailing monomial of f, that is, the last among the monomials occurring in f with respect to the ordering of monomials used in F.

`MonomialCoefficient(f, m)`

Given a noncommutative polynomial f and a monomial m, this function returns the coefficient with which m occurs in f as an element of R.

`Monomials(f)`

Given a noncommutative polynomial $f \in F$, this function returns a sequence of the monomials (monoid words) occurring in f. Note that the monomials in F are ordered, and that the sequence of monomials corresponds exactly to the sequence of coefficients returned by `Coefficients(f)`.

`LeadingMonomial(f)`

Given a noncommutative polynomial $f \in F$ this function returns the leading monomial of f, that is, the first monomial element of F that occurs in f, with respect to the ordering of monomials used in F.

`Terms(f)`

Given a noncommutative polynomial $f \in F$, this function returns the sequence of (non-zero) terms of f as elements of F. The terms are ordered according to the ordering on the monomials in F. Consequently the i-th element of this sequence of terms will be equal to the product of the i-th element of the sequence of coefficients and the i-th element of the sequence of monomials.

`LeadingTerm(f)`

Given a noncommutative polynomial $f \in F$, this function returns the leading term of f as an element of F; this is the product of the leading monomial and the leading coefficient that is, the first among the monomial terms occurring in f with respect to the ordering of monomials used in F.

`TrailingTerm(f)`

Given a noncommutative polynomial $f \in F$, this function returns the trailing term of f as an element of F; this is the last among the monomial terms occurring in f with respect to the ordering of monomials used in F.

`Length(m)`

Given a noncommutative monomial (word) m, return the length of m, i.e., the number of letters of m. Note that this differs from the commutative case, where the number of terms in a polynomial is returned.

`m[i]`

Given a noncommutative monomial (word) m of length l, and an integer i with $1 \leq i \leq l$, return the i-th letter of m.

`TotalDegree(f)`

Given a noncommutative polynomial f, this function returns the total degree of f, which is the maximum of the lengths of all monomials that occur in f. If f is the zero polynomial, the return value is -1.

`LeadingTotalDegree(f)`

Given a noncommutative polynomial, this function returns the leading total degree of f, which is the length of the leading monomial of f.

Example H82E2

In this example we illustrate the above access functions.

```
> K := RationalField();
> F<x,y,z> := FreeAlgebra(K, 3);
> f := (3*x*y - 2*y*z)*(4*x - 7*z*y) + 23*x*y*z;
> f;
-21*x*y*z*y + 14*y*z^2*y + 12*x*y*x + 23*x*y*z - 8*y*z*x
> TotalDegree(f);
4
> Coefficients(f);
[ -21, 14, 12, 23, -8 ]
> Monomials(f);
[
    x*y*z*y,
    y*z^2*y,
```

```
    x*y*x,
    x*y*z,
    y*z*x
]
> Terms(f);
[
    -21*x*y*z*y,
    14*y*z^2*y,
    12*x*y*x,
    23*x*y*z,
    -8*y*z*x
]
> MonomialCoefficient(f, x*y*z);
23
> LeadingTerm(f);
-21*x*y*z*y
> LeadingCoefficient(f);
-21
> m := Monomials(f)[1];
> m;
x*y*z*y
> Length(m);
4
> m[1];
x
> m[2];
y
```

82.6.5 Evaluation

`Evaluate(f, s)`

Given an element f of a free algebra $F = R\langle x_1, \ldots, x_n \rangle$ and a sequence or tuple s of ring or algebra elements of length n, return the value of f at s, that is, the value obtained by substituting $x_i = s[i]$. This behaves in the same way as the `hom` constructor above.

If the elements of s lie in a ring and can be lifted into the coefficient ring R, then the result will be an element of R. If the elements of s cannot be lifted to the coefficient ring, then an attempt is made to do a generic evaluation of f at s. In this case, the result will be of the same type as the elements of s.

Example H82E3

In this example we illustrate the above access functions.

```
> K := RationalField();
> F<x,y,z> := FreeAlgebra(K, 3);
> g := x*y + y*z;
> g;
x*y + y*z
> Evaluate(g, [1,2,3]);
8
> Parent($1);
Rational Field
> Evaluate(g, [y,x,z]);
x*z + y*x
> Parent($1);
Finitely presented algebra of rank 3 over Rational Field
Non-commutative Graded Lexicographical Order
Variables: x, y, z
```

82.7 Ideals and Gröbner Bases

MAGMA supports left-sided, right-sided, and two-sided ideals of free algebras. In general, there are not many operations applicable to single-sided ideals: quotients are supported only in the case of two-sided ideals.

Within the general context of fp-algebras, the term "basis" will refer to an *ordered* sequence of polynomials which generate an ideal. (Thus a basis may contain duplicates and zero elements so it is dissimilar to a basis of a vector space.)

82.7.1 Creation of Ideals

`ideal< A | L >`

`lideal< A | L >`

`rideal< A | L >`

Given a free algebra A over a field K, return the two-sided (`ideal`), left-sided (`lideal`), or right-sided (`rideal`) of A generated by the elements of A specified by the list L. Each term of the list L must be an expression defining an object of one of the following types:

(a) An element of A;

(b) A set or sequence of elements of A;

(c) An ideal of A;

(d) A set or sequence of ideals of A.

`Basis(I)`

Given an ideal I, return the current basis of I. If a Gröbner basis of I has been computed, that is returned.

`BasisElement(I, i)`

Given an ideal I together with an integer i, return the i-th element of the current basis of I. This the same as `Basis(I)[i]`.

82.7.2 Gröbner Bases

Gröbner bases (GBs) may be computed for any kind of ideal (left-, right-, or two-sided), but for single-sided ideals, the GBs are generally weak (i.e., they rarely differ much from the original generators of the ideals).

Unfortunately, the GB of a given ideal may not be finite. Thus the Buchberger or F_4 algorithms below will run forever in such cases. One can interrupt any GB computation by pressing `Ctrl-C`. Alternatively, the function `GroebnerBasis(S,d)` below, which creates a truncated degree-d Gröbner basis, can be used to set a limit on the degrees of the pairs considered, so the computation will always terminate.

As in the commutative case, when MAGMA constructs a GB G of an ideal I, then G is always the unique sorted minimal reduced GB of I. Before this happens, an ideal will usually possess a basis which is not a Gröbner basis, but that will be changed into the unique Gröbner basis when the GB is computed. Thus the original basis will be discarded. See the procedure `Groebner` below for details on the algorithms available.

The unique Gröbner basis will be computed automatically when necessary; the `Groebner` procedure below simply allows control of the algorithms used to compute the Gröbner basis.

`Groebner(I: parameters)`

(Procedure.) Explicitly force a Gröbner basis (GB) for I to be constructed. This procedure is normally not necessary, as MAGMA will automatically compute the GB when needed, but it does allow one to control how the GB is constructed.

`Faugere` BOOLELT *Default :* `true`

MAGMA has two algorithms for computing noncommutative GBs:

(1) A noncommutative generalization (due to Allan Steel) of the Faugère F_4 algorithm [Fau99], which works by specialized sparse linear algebra and is applicable to two-sided ideals defined over a finite field or the rational field;

(2) The noncommutative Buchberger algorithm [CLO96, Chap. 2, §7] for ideals defined over any field.

If the parameter `Faugere` is set to `true`, then the Faugère F_4 algorithm will be used (if the field is a finite field or the rational field); otherwise the Buchberger algorithm is used.

The current implementation of the Faugère algorithm is usually very much faster than the Buchberger algorithm and usually does not take much more memory, so that it is why it is selected by default. However, there may be examples for which it

may be more desirable to use the Buchberger algorithm (particularly to save some memory).

`GroebnerBasis(I: parameters)`

Given an ideal I, force the Gröbner basis of I to be computed, and then return that. The parameters are the same as those for the procedure `Groebner`.

`GroebnerBasis(S: parameters)`

Given a set or sequence S of polynomials, return the unique Gröbner basis of the two-sided ideal generated by S as a sorted sequence. This function is useful for computing Gröbner bases without the need to construct ideals. The parameters are the same as those for the procedure `Groebner`. See also the function `GroebnerBasis(S,d)` below, which creates a truncated degree-d Gröbner basis.

`GroebnerBasis(S, d: parameters)`

Given a set or sequence S of polynomials, return the degree-d Gröbner basis of the ideal generated by S, which is the truncated Gröbner basis obtained by ignoring S-polynomial pairs whose total degree is greater than d.

If the ideal is homogeneous, then it is guaranteed that the result is equal to the set of all polynomials in the full Gröbner basis of the ideal whose total degree is less than or equal to d, and a polynomial whose total degree is less than or equal to d is in the ideal if and only if its normal form with respect to this truncated basis is zero. But if the ideal is not homogeneous, these last properties may not hold, but it may still be useful to construct the truncated basis.

The parameters are the same as those for the procedure `Groebner`.

82.7.3 Verbosity

This subsection describes the verbose flags available for the Gröbner basis algorithms. There are separate verbose flags for each algorithm (`Buchberger`, etc.), but the all-encompassing verbose flag `Groebner` includes all these flags implicitly.

For each procedure provided for setting one of these flags, the value `false` is equivalent to level 0 (nothing), and `true` is equivalent to level 1 (minimal verbosity). For each `Set-` procedure, there is also a corresponding `Get-` function to return the value of the corresponding flag.

`SetVerbose("Groebner", v)`

(Procedure.) Change the verbose printing level for all Gröbner basis algorithms to be v. This includes all of the algorithms whose verbosity is controlled by flags subsequently listed, as well as some other minor related algorithms. Currently the legal levels are 0, 1, 2, 3, or 4. One would normally set this flag to 1 for minimal verbosity for Gröbner basis-type computations, and possibly also set one or more of the following flags to levels higher than 1 for more verbosity.

`SetVerbose("Buchberger", v)`

(Procedure.) Change the verbose printing level for the Buchberger algorithm to be v. Currently the legal levels are 0, 1, 2, 3, or 4. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

`SetVerbose("Faugere", v)`

(Procedure.) Change the verbose printing level for the Faugère algorithm to be v. Currently the legal levels are 0, 1, 2, or 3. If the value w of the `Groebner` verbose flag is greater than v, then w is taken to be the current value of this flag.

82.7.4 Related Functions

The following functions and procedures perform operations related to Gröbner bases.

`MarkGroebner(I)`

(Procedure.) Given an ideal I, mark the current basis of I to be *the* Gröbner basis of the ideal with respect to the monomial order of the ideal. Note that the current basis must exactly equal the unique (reverse) sorted minimal reduced Gröbner basis for the ideal, as returned by the function `GroebnerBasis`. This procedure is useful when one creates an ideal with a basis known to be the Gröbner basis of the ideal from a previous computation or for other reasons. If the basis is not the unique Gröbner basis, the results are unpredictable.

`Reduce(S)`

Given a set or sequence S of polynomials, return the sequence consisting of the reduction of S. The reduction is obtained by reducing to normal form each element of S with respect to the other elements and sorting the resulting non-zero elements left. Note that all Gröbner bases returned by MAGMA are automatically reduced so that this function would usually only be used just to simplify a set or sequence of polynomials which is not a Gröbner basis.

Example H82E4

For a certain sequence B of noncommutative polynomials, we create the left-, right- and two-sided ideals generated by B. We note that for the first two cases, the GB is no different from B, but for the two-sided case, the GB contains several more elements.

```
> K := RationalField();
> F<x,y,z> := FreeAlgebra(K, 3);
> B := [x^2 - y*z, x*y - y*z, y*x - z^2, y^3 - x*z];
> I := lideal<F | B>;
> I;
Left ideal of Finitely presented algebra of rank 3 over Rational Field
Non-commutative Graded Lexicographical Order
Variables: x, y, z
Basis:
[
```

```
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2,
    y^3 - x*z
]
> GroebnerBasis(I);
[
    y^3 - x*z,
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2
]
> I := rideal<F | B>;
> GroebnerBasis(I);
[
    y^3 - x*z,
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2
]
> I := ideal<F | B>;
> Groebner(I);
> I;
Two-sided ideal of Finitely presented algebra of rank 3 over Rational Field
Non-commutative Graded Lexicographical Order
Variables: x, y, z
Groebner basis:
[
    y*z^2*y - y*z^2,
    y*z^3 - y*z^2,
    z*y*z^2 - y*z^2,
    z^2*y^2 - y*z^2,
    z^2*y*z - y*z^2,
    z^3*y - y*z^2,
    z^4 - y*z^2,
    x*z*x - y*z^2,
    x*z*y - z^3,
    x*z^2 - y*z^2,
    y^3 - x*z,
    y^2*z - z^2*y,
    y*z*x - y*z^2,
    y*z*y - y*z^2,
    z^2*x - z^2*y,
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2
]
> NormalForm(x*y, I);
```

```
y*z
> NormalForm(y*x, I);
z^2
```

Finally, we compute some truncated bases of the two-sided ideal. For degree 2, the truncated GB has no new polynomials while for degree 3, some are added. Only at degree 5 do we obtain the full GB.

```
> GroebnerBasis(B, 2);
[
    y^3 - x*z,
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2
]
> GroebnerBasis(B, 3);
[
    x*z^2 - y*z^2,
    y^3 - x*z,
    y^2*z - z^2*y,
    y*z*x - y*z^2,
    y*z*y - y*z^2,
    z^2*x - z^2*y,
    x^2 - y*z,
    x*y - y*z,
    y*x - z^2
]
> #GroebnerBasis(I);
18
> #GroebnerBasis(B, 4);
16
> #GroebnerBasis(B, 5);
18
> GroebnerBasis(B, 5) eq GroebnerBasis(I);
true
```

82.8 Basic Operations on Ideals

In the following, note that the free algebra F itself is a valid ideal (the ideal containing 1).

82.8.1 Construction of New Ideals

`I + J`

Given ideals I and J belonging to the same algebra F, return the sum of I and J, which is the ideal generated by the union of the generators of I and J.

`I * J`

Given ideals I and J belonging to the same algebra A, return the product of I and J, which is the ideal generated by the products of the generators of I with those of J.

`F / J`

Given an algebra F over a field and an ideal J of F, return the fp-algebra F/J (see below).

`Generic(I)`

Given an ideal I of a generic algebra A, return A.

82.8.2 Ideal Predicates

`I eq J`

Given two ideals I and J belonging to the same algebra F, return whether I and J are equal.

`I ne J`

Given two ideals I and J belonging to the same algebra F, return whether I and J are not equal.

`I notsubset J`

Given two ideals I and J belonging to the same algebra F return whether I is not contained in J.

`I subset J`

Given two ideals I and J belonging to the same algebra F return whether I is contained in J.

`IsZero(I)`

Given an ideal I of the algebra F, return whether I is the zero ideal (contains zero alone).

82.8.3 Operations on Elements of Ideals

`f in I`

Given a polynomial f from an algebra F, together with an ideal I of F, return whether f is in I.

`NormalForm(f, I)`

Given a polynomial f from an algebra F, together with an ideal I of F, return the unique normal form of f with respect to (the Gröbner basis of) I. The normal form of f is zero if and only if f is in I.

`NormalForm(f, S)`

Given a polynomial f from an algebra F, together with a set or sequence S of polynomials from F, return a normal form of f with respect to S. This is not unique in general. If the normal form of f is zero then f is in the ideal generated by S, but the converse is false in general. In fact, the normal form is unique if and only if S forms a Groëbner basis.

`f notin I`

Given a polynomial f from an algebra F, together with an ideal I of F, return whether f is not in I.

Example H82E5

We demonstrate the element operations with respect to an ideal of $\mathbf{Q}[x, y, z]$.

```
> F<x,y,z> := FreeAlgebra(RationalField(), 3);
> I := ideal<F | (x + y)^3, (y - z)^2, y^2*z + z>;
> NormalForm(y^2*z + z, I);
0
> NormalForm(x^3, I);
-x^2*y - x*y*x - x*y*z - x*z*y + x*z^2 - y*x^2 - y*x*y - y*z*x -
    y*z*y - z*y*x - z*y*z + z^2*x + z^3
> NormalForm(z^4 + y^2, I);
z^4 + y*z + z*y - z^2
> x + y in I;
false
```

82.9 Changing Coefficient Ring

The `ChangeRing` function enables the changing of the coefficient ring of an algebra or ideal.

`ChangeRing(I, S)`

Given an ideal I of an algebra $F = R[x_1, \ldots, x_n]$ of rank n with coefficient ring R, together with a ring S, construct the ideal J of the algebra $Q = S[x_1, \ldots, x_n]$ obtained by coercing the coefficients of the elements of the basis of I into S. It is necessary that all elements of the old coefficient ring R can be automatically coerced into the new coefficient ring S. If R and S are fields and R is known to be a subfield of S and the current basis of I is a Gröbner basis, then the basis of J is marked automatically to be a Gröbner basis of J.

82.10 Finitely Presented Algebras

A finitely presented algebra (fp-algebra) in MAGMA is simply the quotient ring of a free algebra $F = R\langle x_1, \ldots, x_n \rangle$ by an ideal J of F. It is an object of type `AlgFP` with elements of type `AlgFPElt`.

The elements of fp-algebras are simply noncommutative polynomials which are always kept reduced to normal form modulo the ideal J of "relations". Practically all operations which are applicable to noncommutative polynomials are also applicable in MAGMA to elements of fp-algebras (when meaningful).

If an fp-algebra A has finite dimension, considered as a vector space over its coefficient field, then extra special operations are available for A and its elements.

82.11 Creation of FP-Algebras

One can create an fp-algebra simply by forming the quotient of a free algebra by an ideal (`quo` constructor or `/` function). A special constructor `FPAlgebra` is also provided to remove the need to create the free algebra.

NOTE: When one creates an fp-algebra, the ideal of relations is left unchanged, but as soon as one does just about any operation with elements of the algebra (such as printing or multiplying), then the Gröbner basis of the underlying ideal will have to be computed to enable MAGMA to compute a unique form of each element of the algebra.

`quo< F | J >`

`quo< F | a`$_1$`, ..., a`$_r$ `>`

Given a free algebra F and a two-sided ideal J of F, return the fp-algebra (quotient algebra) F/J. The ideal J may either be specified as an ideal or by a list a_1, a_2, ..., a_r, of generators which all lie in F. The angle bracket notation can be used to assign names to the indeterminates: `A<q, r> := quo< I | I.1 + I.2, I.2^2 - 2, I.3^2 + I.4 >;`.

`F / J`

Given a free algebra F and an ideal J of F, return the fp-algebra F/J.

`FPAlgebra< K, X | L >`
