PREFACE

The computer algebra system MAGMA is designed to provide a software environment for computing with the structures which arise in areas such as algebra, number theory, algebraic geometry and (algebraic) combinatorics. MAGMA enables users to define and to compute with structures such as groups, rings, fields, modules, algebras, schemes, curves, graphs, designs, codes and many others. The main features of MAGMA include:

- *Algebraic Design Philosophy:* The design principles underpinning both the user language and system architecture are based on ideas from universal algebra and category theory. The language attempts to approximate as closely as possible the usual mathematical modes of thought and notation. In particular, the principal constructs in the user language are set, (algebraic) structure and morphism.

- *Explicit Typing:* The user is required to explicitly define most of the algebraic structures in which calculations are to take place. Each object arising in the computation is then defined in terms of these structures.

- *Integration:* The facilities for each area are designed in a similar manner using generic constructors wherever possible. The uniform design makes it a simple matter to program calculations that span different classes of mathematical structures or which involve the interaction of structures.

- *Relationships:* MAGMA provides a mechanism that manages "relationships" between complex bodies of information. For example, when substructures and quotient structures are created by the system, the natural homomorphisms that arise are always stored. These are then used to support automatic coercion between parent and child structures.
- *Mathematical Databases:* MAGMA has access to a large number of databases containing information that may be used in searches for interesting examples or which form an integral part of certain algorithms. Examples of current databases include factorizations of integers of the form $p^n \pm 1$, p a prime; modular equations; strongly regular graphs; maximal subgroups of simple groups; integral lattices; $K3$ surfaces; best known linear codes and many others.

- *Performance:* The intention is that MAGMA provide the best possible performance both in terms of the algorithms used and their implementation. The design philosophy permits the kernel implementor to choose optimal data structures at the machine level. Most of the major algorithms currently installed in the MAGMA kernel are state-of-the-art and give performance similar to, or better than, specialized programs.

The theoretical basis for the design of MAGMA is founded on the concepts and methodology of modern algebra. The central notion is that of an *algebraic structure*. Every object created during the course of a computation is associated with a unique parent algebraic structure. The *type* of an object is then simply its parent structure.

Algebraic structures are first classified by *variety*: a variety being a class of structures having the same set of defining operators and satisfying a common set of axioms. Thus, the collection of all rings forms a variety. Within a variety, structures are partitioned into *categories*. Informally, a family of algebraic structures forms a category if its members all share a common *representation*. All varieties possess an *abstract* category of structures (the finitely presented structures). However, categories based on a concrete representation are as least as important as the abstract category in most varieties. For example, within the variety of algebras, the family of finitely presented algebras constitutes an abstract category, while the family of matrix algebras constitutes a concrete category.

MAGMA comprises a novel user programming language based on the principles outlined above together with program code and databases designed to support computational research in those areas of mathematics which are algebraic in nature. The major areas represented in MAGMA V2.19 include group theory, ring theory, commutative algebra, arithmetic fields and their completions, module theory and lattice theory, finite dimensional algebras, Lie theory, representation theory, homological algebra, general schemes and curve schemes, modular forms and modular curves, L-functions, finite incidence structures, linear codes and much else.

This set of volumes (known as the Handbook) constitutes the main reference work on MAGMA. It aims to provide a comprehensive description of the MAGMA language and the mathematical facilities of the system, In particular, it documents every function and operator available to the user. Our aim (not yet achieved) is to list not only the functionality of the MAGMA system but also to show how the tools may be used to solve problems in the various areas that fall within the scope of the system. This is attempted through the inclusion of tutorials and sophisticated examples. Finally, starting with the edition corresponding to release V2.8, this work aims to provide some information about the algorithms and techniques employed in performing sophisticated or time-consuming operations. It will take some time before this goal is fully realised.

We give a brief overview of the organization of the Handbook.

- Volume 1 contains a terse summary of the language together with a description of the central datatypes: sets, sequences, tuples, mappings, etc. An index of all intrinsics appears at the end of the volume.

- Volume 2 deals with basic rings and linear algebra. The rings include the integers, the rationals, finite fields, univariate and multivariate polynomial rings as well as real and complex fields. The linear algebra section covers matrices and vector spaces.

- Volume 3 covers global arithmetic fields. The major topics are number fields, their orders and function fields. More specialised topics include quadratic fields , cyclotomic fields and algebraically closed fields.

- Volume 4 is concerned with local arithmetic fields. This covers p-adic rings and their extension and power series rings including Laurent and Puiseux series rings,

- Volume 5 describes the facilities for finite groups and, in particular, discusses permutation groups, matrix groups and finite soluble groups defined by a power-conjugate presentation. A chapter is devoted to databases of groups.

- Volume 6 describes the machinery provided for finitely presented groups. Included are abelian groups, general finitely presented groups, polycyclic groups, braid groups and automatic groups. This volume gives a description of the machinery provided for computing with finitely presented semigroups and monoids.

- Volume 7 is devoted to aspects of Lie theory and module theory. The Lie theory includes root systems, root data, Coxeter groups, reflection groups and Lie groups.

- Volume 8 covers algebras and representation theory. Associative algebras include structure-constant algebras, matrix algebras, basic algebras and quaternion algebras. Following an account of Lie algebras there is a chapter on quantum groups and another on universal enveloping algebras. The representation theory includes group algebras, $K[G]$-modules, character theory, representations of the symmetric group and representations of Lie groups.

- Volume 9 covers commutative algebra and algebraic geometry. The commutative algebra material includes constructive ideal theory, affine algebras and their modules, invariant rings and differential rings. In algebraic geometry the main topics are schemes, sheaves and toric varieties. Also included are chapters describing specialised machinery for curves and surfaces.

- Volume 10 describes the machinery pertaining to arithmetic geometry. The main topics include the arithmetic properties of low genus curves such as conics, elliptic curves and hyperelliptic curves. The volume concludes with a chapter on L-series.

- Volume 11 is concerned with modular forms.

- Volume 12 covers various aspects of geometry and combinatorial theory. The geometry section includes finite planes, finite incidence geometry and convex polytopes. The combinatorial theory topics comprise enumeration, designs, Hadamard matrices, graphs and networks.

- Volume 13 is primarily concerned with coding theory. Linear codes over both fields and finite rings are considered at length. Further chapters discuss machinery for AG-codes, LDPC codes, additive codes and quantum error-correcting codes. The volume concludes with short chapters on pseudo-random sequences and on linear programming.

Although the Handbook has been compiled with care, it is possible that the semantics of some facilities have not been described adequately. We regret any inconvenience that this may cause, and we would be most grateful for any comments and suggestions for improvement. We would like to thank users for numerous helpful suggestions for improvement and for pointing out misprints in previous versions.

The development of MAGMA has only been possible through the dedication and enthusiasm of a group of very talented mathematicians and computer scientists. Since 1990, the principal members of the MAGMA group have included: Geoff Bailey, Mark Bofinger, Wieb Bosma, Gavin Brown, John Brownie, Herbert Brückner, Nils Bruin, Steve Collins, Scott Contini, Bruce Cox, Brendan Creutz, Steve Donnelly, Willem de Graaf, Andreas-Stephan Elsenhans, Claus Fieker, Damien Fisher, Alexandra Flynn, Volker Gebhardt, Katharina Geißler, Sergei Haller, Michael Harrison, Emanuel Herrmann, Florian Heß, David Howden, Al Kasprzyk, David Kohel, Paulette Lieby, Graham Matthews, Scott Murray, Anne O'Kane, Catherine Playoust, Richard Rannard, Colva Roney-Dougal, Dan Roozemond, Andrew Solomon, Bernd Souvignier, Ben Smith, Allan Steel, Damien Stehlé, Nicole Sutherland, Don Taylor, Bill Unger, John Voight, Alexa van der Waall, Mark Watkins and Greg White.

John Cannon

ACKNOWLEDGEMENTS

The Magma Development Team

Current Members

Geoff Bailey, BSc (Hons) (Sydney), [1995-]: Main interests include elliptic curves (especially those defined over the rationals), virtual machines and computer language design. Has implemented part of the elliptic curve facilities especially the calculation of Mordell-Weil groups. Other main areas of contribution include combinatorics, local fields and the Magma system internals.

John Cannon, Ph.D. (Sydney), [1971-]: Research interests include computational methods in algebra, geometry, number theory and combinatorics; the design of mathematical programming languages and the integration of databases with Computer Algebra systems. Contributions include overall concept and planning, language design, specific design for many categories, numerous algorithms (especially in group theory) and general management.

Brendan Creutz, Ph.D. (Jacobs University Bremen) [2011-]: Primary research interests are in arithmetic geometry. Main contributions focus on descent obstructions to the existence of rational points on curves and torsors under their Jacobians. Currently developing a package for cyclic covers of the projective line.

Steve Donnelly, Ph.D. (Athens, Ga) [2005-]: Research interests are in arithmetic geometry, particularly elliptic curves and modular forms. Major contributions include descent methods for elliptic curves (including over function fields) and Cassels-Tate pairings, classical modular forms of half-integral weight, Hilbert modular forms and fast algorithms for definite quaternion algebras. Currently working on Hilbert modular forms, and elliptic curves over number fields.

Andreas-Stephan Elsenhans, Ph.D. (Göttingen) [2012-]: Main research interests are in the areas of arithmetic and algebraic geometry, particularly cubic and K3 surfaces. Main contributions focus on cubic surfaces from the arithmetic and algebraic points of view. Currently working on the computation of invariants.

Michael Harrison, Ph.D. (Cambridge) [2003-]: Research interests are in number theory, arithmetic and algebraic geometry. Implemented the p-adic methods for counting points on hyperelliptic curves and their Jacobians over finite fields including Kedlaya's algorithm and the modular parameter method of Mestre. Currently working on machinery for general surfaces and cohomology for projective varieties.

David Howden, Ph.D. (Warwick) [2012-]: Primary research interests are in computational group theory. Main contributions focus on computing automorphism groups and isomorphism testing for soluble groups.

Allan Steel, Ph.D. (Sydney), [1989-]: Has developed many of the fundamental data structures and algorithms in MAGMA for multiprecision integers, finite fields, matrices and modules, polynomials and Gröbner bases, aggregates, memory management, environmental features, and the package system, and has also worked on the MAGMA language interpreter. In collaboration, he has developed the code for lattice theory (with Bernd Souvignier), invariant theory (with Gregor Kemper) and module theory (with Jon Carlson and Derek Holt).

Nicole Sutherland, BSc (Hons) (Macquarie), [1999-]: Works in the areas of number theory and algebraic geometry. Developed the machinery for Newton polygons and lazy power series and contributed to the code for local fields, number fields, modules over Dedekind domains, function fields, schemes and has worked on aspects of algebras.

Don Taylor, D.Phil. (Oxford), [2010-] Research interests are in reflection groups, finite group theory, and geometry. Implemented algorithms for complex reflection groups and complex root data. Contributed to the packages for Chevalley groups and groups of Lie type. Currently developing algorithms for classical groups of isometries, Clifford algebras and spin groups.

Bill Unger, Ph.D. (Sydney), [1998-]: Main area of interest is computational group theory, with particular emphasis on algorithms for permutation and matrix groups. Implemented many of the current permutation and matrix group algorithms for MAGMA, in particular BSGS verification, solvable radical and chief series algorithms. Recently discovered a new method for computing the character table of a finite group.

Mark Watkins, Ph.D. (Athens, Ga), [2003, 2004-2005, 2008-]: Works in the area of number theory, particularly analytic methods for arithmetic objects. Implemented a range of analytic tools for the study of elliptic curves including analytic rank, modular degree, Heegner points and (general) point searching methods. Also deals with conics, lattices, modular forms, and descent machinery over the rationals.

Former Members

Wieb Bosma, [1989-1996]: Responsible for the initial development of number theory in MAGMA and the coordination of work on commutative rings. Also has continuing involvement with the design of MAGMA.

Gavin Brown, [1998-2001]: Developed code in basic algebraic geometry, applications of Gröbner bases, number field and function field kernel operations; applications of Hilbert series to lists of varieties.

Herbert Brückner, [1998–1999]: Developed code for constructing the ordinary irreducible representations of a finite soluble group and the maximal finite soluble quotient of a finitely presented group.

Nils Bruin, [2002–2003]: Contributions include Selmer groups of elliptic curves and hyperelliptic Jacobians over arbitrary number fields, local solubility testing for arbitrary projective varieties and curves, Chabauty-type computations on Weil-restrictions of elliptic curves and some algorithms for, and partial design of, the differential rings module.

Bruce Cox, [1990–1998]: A member of the team that worked on the design of the MAGMA language. Responsible for implementing much of the first generation MAGMA machinery for permutation and matrix groups.

Claus Fieker, [2000-2011]: Formerly a member of the KANT project. Research interests are in constructive algebraic number theory and, especially, relative extensions and computational class field theory. Main contributions are the development of explicit algorithmic class field theory in the case of both number and function fields and the computation of Galois groups.

Damien Fisher, [2002-2006]: Implemented a package for p-adic rings and their extensions and undertook a number of extensions to the MAGMA language.

Alexandra Flynn, [1995–1998]: Incorporated various Pari modules into MAGMA, and developed much of the machinery for designs and finite planes.

Volker Gebhardt, [1999–2003]: Author of the MAGMA categories for infinite polycyclic groups and for braid groups. Other contributions include machinery for general finitely presented groups.

Katharina Geißler, [1999–2001]: Developed the code for computing Galois groups of number fields and function fields.

Willem de Graaf, [2004-2005]: Contributed functions for computing with finite-dimensional Lie algebras, finitely-presented Lie algebras, universal enveloping algebras and quantum groups.

Sergei Haller, [2004, 2006-2007]: Developed code for many aspects of Lie Theory. Of particular note was his work on the construction of twisted groups of Lie type and the determination of conjugacy classes of elements in the classical groups (jointly with Scott Murray (MAGMA)).

Emanuel Herrmann, [1999]: Contributed code for finding S-integral points on genus 1 curves (not elliptic curves).

Florian Heß, [1999–2001]: Developed a substantial part of the algebraic function field module in MAGMA including algorithms for the computation of Riemann-Roch spaces and class groups. His most recent contribution (2005) is a package for computing all isomorphisms between a pair of function fields.

Alexander Kasprzyk, [2009-2010]: Developed the toric geometry and polyhedra packages (along with Gavin Brown and Jaroslaw Buczynski).

David Kohel, [1999–2002]: Contributions include a model for schemes (with G Brown); algorithms for curves of low genus; implementation of elliptic curves, binary quadratic forms, quaternion algebras, Brandt modules, spinor genera and genera of lattices, modular curves, conics (with P Lieby), modules of supersingular points (with W Stein), Witt rings.

Paulette Lieby, [1999–2003]: Contributed to the development of algorithms for algebraic geometry, abelian groups and incidence structures. Developed datastructures for multigraphs and implemented algorithms for planarity, triconnectivity and network flows.

Graham Matthews, [1989–1993]: Involved in the design of the MAGMA semantics, user interface, and internal organisation.

Scott Murray, [2001-2002, 2004-2010]: Implemented algorithms for element operations in split groups of Lie type, representations of split groups of Lie type, split Cartan subalgebras of modular Lie algebras, and Lang's Theorem in finite reductive groups. More recently implemented solutions to conjugacy problems in the classical groups (with S. Haller and D. Taylor).

Catherine Playoust, [1989–1996]: Wrote extensive documentation and implemented an early help system. Contributed to system-wide consistency of design and functionality. Also pioneered the use of MAGMA for teaching undergraduates.

Richard Rannard, [1997–1998]: Contributed to the code for elliptic curves over finite fields including a first version of the SEA algorithm.

Colva M. Roney-Dougal, [2001–2003]: Completed the classification of primitive permutation groups up to degree 999 (with Bill Unger). Also undertook a constructive classification of the maximal subgroups of the classical simple groups.

Dan Roozemond, [2010-2012]: Research focused on the computational aspects of Lie theory. Ported algorithms for the Weight Multisets from LiE to Magma and developed a number of algorithms for reductive Lie algebras, particularly over fields of small characteristic.

Michael Slattery, [1987–2006]: Contributed a large part of the machinery for finite soluble groups including subgroup lattice and automorphism group.

Ben Smith, [2000–2003]: Contributed to an implementation of the Number Field Sieve and a package for integer linear programming.

Bernd Souvignier, [1996–1997]: Contributed to the development of algorithms and code for lattices, local fields, finite dimensional algebras and permutation groups.

Damien Stehlé, [2006, 2008-2010]: Implemented the proveably correct floating-point LLL algorithm together with a number of fast non-rigorous variants. Also developed a fast method for enumerating short vectors.

John Voight, [2005-2006]: Implemented algorithms for quaternion algebras over number fields, associative orders (with Nicole Sutherland), and Shimura curves.

Alexa van der Waall, [2003]: Implemented the module for differential Galois theory.

Paul B. van Wamelen, [2002–2003]: Implemented analytic Jacobians of hyperelliptic curves in MAGMA.

Greg White, [2000-2006]: Contributions include fast minimum weight determination, linear codes over Z/mZ, additive codes, LDPC codes, quantum error-correcting codes, and a database of best known linear codes (with Cannon and Grassl).

External Contributors

The MAGMA system has benefited enormously from contributions made by many members of the mathematical community. We list below those persons and research groups who have given the project substantial assistance either by allowing us to adapt their software for inclusion within MAGMA or through general advice and criticism. We wish to express our gratitude both to the people listed here and to all those others who participated in some aspect of the MAGMA development.

Algebraic Geometry

A major package for algebraic surfaces providing formal desingularization, the calculation of adjoints, and rational parameterization was developed by **Tobias Beck** (RICAM, Linz). He also implemented a package for computing with algebraic power series. This work was done while he was a student of **Josef Schicho**.

A package for working with divisors on varieties has been developed by **Martin Bright** (American University of Beirut), **Gavin Brown** (Loughborough), **Mike Harrison** (Magma) and **Andrew Wilson** (Edinburgh). The functionality includes decomposition into irreducible components, Riemann-Roch spaces, canonical divisors and (surface) intersection numbers.

Machinery for working with Hilbert series of polarised varieties and the associated databases of K3 surfaces and Fano 3-folds has been constructed by **Gavin Brown** (Warwick).

Jaroslaw Buczynski (Texas A&M), along with **Gavin Brown** (Loughborough) and **Alexander Kasprzyk** (Imperial College), developed the toric geometry and polyhedra packages.

Functions for computing Shioda invariants for genus 3 hyperelliptic curves, reconstructing models for a curve from such invariants and computing geometric automorphism groups have been contributed by **Reynald Lercier** (DGA, Rennes) and **Christophe Ritzenthaler** (Luminy).

Jana Pilnikova (Univerzita Komenskeho, Bratislava) (while a student of **Josef Schicho** in Linz) contributed code for the parameterization of degree 8 and 9 Del Pezzo surfaces, jointly written with **Willem de Graaf** (Trento).

Miles Reid (Warwick) has been heavily involved in the design and development of a database of $K3$ surfaces within MAGMA.

Josef Schicho (RICAM, Linz) has played a major role in the design and implementation of the algebraic surfaces package. In particular, Josef has also implemented several of the modules for rational surface parameterization.

A function that finds the intersection multiplicities for all intersection points of two plane curves was adapted into MAGMA from code provided by **Chris Smyth** (Edinburgh).

Andrew Wilson (Edinburgh) has contributed a package to compute the log canonical threshold for singular points on a curve.

Arithmetic Geometry Over Characteristic 0 Fields

The method of Chabauty for finding points on elliptic curves was originally implemented by **Nils Bruin** in 2003 while a member of the MAGMA group. In 2009 Nils improved it considerably by combining it with *Mordell-Weil sieving*.

Two-cover-descent has been implemented by **Nils Bruin** (Simon Fraser) for hyperelliptic curves. Given the Jacobian of a genus 2 curve, Nils has also provided code to compute all $(2,2)$-isogenous abelian surfaces.

The MAGMA facility for determining the Mordell-Weil group of an elliptic curve over the rational field is based on the MWRANK programs of **John Cremona** (Nottingham).

John Cremona (Nottingham) has contributed his code implementing Tate's algorithm for computing local minimal models for elliptic curves defined over number fields.

The widely-used database of all elliptic curves over Q having conductor up to 300,000 constructed by **John Cremona** (Warwick) is also included.

Tim Dokchitser (Durham) wrote code for computing root numbers of elliptic curves over number fields.

Andreas-Stephan Elsenhans (Bayreuth) has provided routines for performing minimisation and reduction for Del Pezzo surfaces of degrees 3 and 4.

Code for determining isomorphism of cubic surfaces has been contributed by **Andreas-Stephan Elsenhans** (Bayreuth).

A collection of tools that calculate information about the Picard rank of a surface has been developed by **Andreas-Stephan Elsenhans** (Bayreuth).

Code for calculating the invariants, covariants and contravariants of a cubic surface has been developed by **Andreas-Stephan Elsenhans** (Bayreuth).

A package contributed by **Tom Fisher** (Cambridge) deals with curves of genus 1 given by models of a special kind (genus one normal curves) having degree $2, 3, 4$ and 5.

The implementation of 3-descent on elliptic curves was mainly written by **Tom Fisher** (Cambridge). An earlier version as well as part of the current version were developed by **Michael Stoll** (Bremen).

The algorithms and implementations of $6-$ and 12-descent are due to **Tom Fisher** (Cambridge). The new alorithm/implementation of 8-descent is likewise by Tom Fisher; this partly incorporates and partly replaces the earlier one by **Sebastian Stamminger**.

Martine Girard (Sydney) has contributed her fast code for determining the heights of a point on an elliptic curve defined over a number field or a function field.

David Kohel (Singapore–NUS, MAGMA) has provided implementations of division polynomials and isogeny structures for elliptic curves.

Full and partial descents on cyclic covers of the projective line were implemented by **Michael Mourao** (Warwick).

A package for computing canonical heights on hyperelliptic curves has been contributed by **Steffan Müller** (Bayreuth).

David Roberts (Nottingham) contributed some descent machinery for elliptic curves over function fields.

David Roberts and **John Cremona** (Nottingham) implemented the Cremona-van Hoeij algorithm for parametrization of conics over rational function fields.

Jasper Scholten (Leuven) has developed much of the code for computing with elliptic curves over function fields.

Much of the initial development of the package for computing with hyperelliptic curves is due to **Michael Stoll** (Bayreuth). He also contributed many of the high level routines involving curves over the rationals and their Jacobians, such as Chabauty's method.

A database of $136,924,520$ elliptic curves with conductors up to 10^8 has been provided by **William Stein** (Harvard) and **Mark Watkins** (Penn State).

For elliptic curves defined over finite fields of characteristic 2, Kedlaya's algorithm for point counting has been implemented by **Frederick Vercauteren** (Leuven).

Tom Womack (Nottingham) contributed code for performing four-descent, from which the current implementation was adapted.

Arithmetic Geometry Over Finite Fields

Various point-counting algorithms for hyperelliptic curves have been implemented by **Pierrick Gaudry** (Ecole Polytechnique, Paris). These include an implementation of the Schoof algorithm for genus 2 curves.

An implementation of GHS Weil descent for ordinary elliptic curves in characteristic 2 has been provided by **Florian Heß** (TU, Berlin).

A MAGMA package for calculating Igusa and other invariants for genus 2 hyperelliptic curves was written by **Everett Howe** (CCR, San Diego) and is based on `gp` routines developed by **Fernando Rodriguez–Villegas** (Texas) as part of the Computational Number Theory project funded by a TARP grant.

Reynard Lercier (Rennes) provided much advice and assistance to the MAGMA group concerning the implementation of the SEA point counting algorithm for elliptic curves.

Reynard Lercier (Rennes) and **Christophe Ritzenthaler** provided extensions to the machinery for genus 2 curves defined over finite fields. These include the reconstruction of a curve from invariants which applies to every characteristic p (previously $p > 5$), the geometric automorphism group and the calculation of all twists (not just quadratic).

Frederik Vercauteren (Leuven) has produced efficient implementations of the Tate, Eta and Ate pairings in MAGMA.

Class fields over local fields and the multiplicative structure of local fields are computed using new algorithms and implementations due to **Sebastian Pauli** (TU Berlin).

The module for Lazy Power Series is based on the ideas of **Josef Schicho** (Linz).

Associative Algebras

Fast algorithms for computing the Jacobson radical and unit group of a matrix algebra over a finite field were designed and implemented by **Peter Brooksbank** (Bucknell) and **Eamonn O'Brien** (Auckland).

A package for computing with algebras equipped with an involution (*-algebras) has been contributed by **Peter Brooksbank** (Bucknell) and **James Wilson**.

An algorithm designed and implemented by **Jon Carlson** and **Graham Matthews** (Athens, Ga.) provides an efficient means for constructing presentations for matrix algebras.

For matrix algebras defined over a finite field, **Jon Carlson** (Athens, Ga.) designed and implemented algorithms for the Jacobson radical and unit group which are faster than the Brooksbank-O'Brien algorithms for larger examples.

A substantial package for working with substructures and homomorphisms of basic algebras, developed by **Jon Carlson** (Athens, Ga.), was released as part of V2.19. Among other things, the package can compute the automorphism group of a basic algebra and test pairs of basic algebras for isomorphism.

Markus Kirschmer (Aachen) has written a number of optimized routines for definite quaternion algebras over number fields.

Markus Kirschmer has also contributed a package for quaternion algebras defined over the function fields $F_q[t]$, for q odd. The package includes calculation of the normaliser of an order and an efficient algorithm for computing the two-sided ideal classes of an order in a definite quaternion algebra (over $\mathbf{Z}$ or $\mathbf{F}_q[t]$).

Quaternion algebras over the rational field Q were originally implemented by **David Kohel** (Singapore-NUS, MAGMA).

The vector enumeration program of **Steve Linton** (St. Andrews) provides an alternative to the use of Gröbner basis for constructing a matrix representation of a finitely presented associative algebra.

John Voight (Vermont) produced the package for quaternion algebras over number fields.

Coding Theory

A package for constructing linear codes associated with lattice points in a convex polytope has been contributed by **Gavin Brown** (Loughborough) and **Al Kasprzyk** (Imperial).

The PERM package developed by **Jeff Leon** (UIC) is used to determine automorphism groups of codes, designs and matrices.

The development of machinery for linear codes benefited greatly from the active involvement of **Markus Grassl** (Karlsruhe) over a long period. Of particular note is his contribution to the development of improved algorithms for computing the minimum weight and for the enumeration of codewords.

Routines implementing many different constructions for linear codes over finite fields were contributed by **Markus Grassl** (Karlsruhe).

Markus Grassl (Karlsruhe) played a key role in the design of MAGMA packages for Additive Codes and Quantum Error-Correcting Codes. The packages were implemented by Greg White (Magma).

The construction of a database of Best Known Linear Codes over GF(2) was a joint project with **Markus Grassl** (Karlsruhe, NUS). Other contributors to this project include: **Andries Brouwer**, **Zhi Chen**, **Stephan Grosse**, **Aaron Gulliver**, **Ray Hill**, **David Jaffe**, **Simon Litsyn**, **James B. Shearer** and **Henk van Tilborg**.

The databases of Best Known Linear Codes over GF(3), GF(4), GF(5), GF(7), GF(8) and GF(9) were constructed by **Markus Grassl** (IAKS, Karlsruhe).

A substantial collection of intrinsics for constructing and computing properties of Z_4 codes has been contributed by **Jaume Pernas**, **Jaume Pujol** and **Merc̀ Villanueva** (Universitat Autònoma de Barcelona).

Combinatorics

Michel Berkelaar (Eindhoven) gave us permission to incorporate his LP_SOLVE package for linear programming.

The first stage of the MAGMA database of Hadamard and skew-Hadamard matrices was prepared with the assistance of **Stelios Georgiou** (Athens), **Ilias Kotsireas** (Wilfrid Laurier) and **Christos Koukouvinos** (Athens). In particular, they made available their tables of Hadamard matrices of orders 32, 36, 44, 48 and 52. Further Hadamard matrices were contributed by Dragomir Djokovic.

The MAGMA machinery for symmetric functions is based on the Symmetrica package developed by **Abalbert Kerber** (Bayreuth) and colleagues. The MAGMA version was implemented by **Axel Kohnert** of the Bayreuth group.

The PERM package developed by **Jeff Leon** (UIC) is used to determine automorphism groups of designs and also to determine isomorphism of pairs of designs.

Automorphism groups and isomorphism of Hadamard matrices are determined by converting to a similar problem for graphs and then applying **Brendan McKay's** (ANU) program NAUTY. The adaption was undertaken by **Paulette Lieby** and **Geoff Bailey**.

The calculation of the automorphism groups of graphs and the determination of graph isomorphism is performed using **Brendan McKay's** (ANU) program NAUTY (version 2.2). Databases of graphs and machinery for generating such databases have also been made available by Brendan. He has also collaborated in the design of the sparse graph machinery.

The code to perform the regular expression matching in the `regexp` intrinsic function comes from the V8 regexp package written by **Henry Spencer** (Toronto).

Commutative Algebra

Gregor Kemper (TU München) has contributed most of the major algorithms of the Invariant Theory module of MAGMA, together with many other helpful suggestions in the area of Commutative Algebra.

Alexa van der Waall (Simon Fraser) has implemented the module for differential Galois theory.

Galois Groups

Jürgen Klüners (Kassel) has made major contributions to the Galois theory machinery for function fields and number fields. In particular, he implemented functions for constructing the subfield lattice and automorphism group of a field and also the subfield lattice of the normal closure of a field. In joint work with Claus Fieker (MAGMA), Jürgen has recently developed a new method for determining the Galois group of a polynomial of arbitary high degree.

Jürgen Klüners (Kassel) and **Gunter Malle** (Kassel) made available their extensive tables of polynomials realising all Galois groups over Q up to degree 15.

Galois Representations

Jeremy Le Borgne (Rennes) contributed his package for working with mod p Galois representations.

Code for constructing Artin representations of the Galois group of the absolute extension of a number field was developed by **Tim Dokchitser** (Cambridge).

Jared Weinstein (UCLA) wrote the package on admissible representations of $GL_2(\mathbf{Q}_p)$.

Geometry

The MAGMA code for computing with incidence geometries has been developed by **Dimitri Leemans** (Brussels).

Algorithms for testing whether two convex polytopes embedded in a lattice are isomorphic or equivalent have been implemented by **Al Kasprzyk** (Imperial College). Of particular note is Al's implementation of the PALP normal form algorithm.

Global Arithmetric Fields

Jean-Francois Biasse (Calgary) implemented a quadratic sieve for computing the class group of a quadratic field. He also developed a generalisation of the sieve for number fields having degree greater than 2.

Florian Heß (TU Berlin) has contributed a major package for determining all isomorphisms between a pair of algebraic function fields.

David Kohel (Singapore–NUS, MAGMA) has contributed to the machinery for binary quadratic forms and has implemented rings of Witt vectors.

Jürgen Klüners (Düsseldorf) and **Sebastian Pauli** (UNC Greensboro) have developed algorithms for computing the Picard group of non-maximal orders and for embedding the unit group of non-maximal orders into the unit group of the field.

The facilities for general number fields and global function fields in MAGMA are based on the KANT V4 package developed by **Michael Pohst** and collaborators, first at Düsseldorf and then at TU Berlin. This package provides extensive machinery for computing with maximal orders of number fields and their ideals, Galois groups and function fields. Particularly noteworthy are functions for computing the class and unit group, and for solving Diophantine equations.

The fast algorithm of Bosma and Stevenhagen for computing the 2-part of the ideal class group of a quadratic field has been implemented by **Mark Watkins** (Bristol).

Group Theory: Finitely-Presented Groups

See also the subsection *Group Theory: Soluble Groups*.

A new algorithm for computing all normal subgroups of a finitely presented group up to a specified index has been designed and implemented by **David Firth** and **Derek Holt** (Warwick).

The function for determining whether a given finite permutation group is a homomorphic image of a finitely presented group has been implemented in C by Volker Gebhardt (Magma) from a Magma language prototype developed by **Derek Holt** (Warwick). A variant developed by Derek allows one to determine whether a small soluble group is a homomorphic image.

A small package for working with subgroups of free groups has been developed by **Derek Holt** (Warwick). He has also provided code for computing the automorphism group of a free group.

Versions of MAGMA from V2.8 onwards employ the Advanced Coset Enumerator designed by **George Havas** (UQ) and implemented by **Colin Ramsay** (UQ). George has also contributed to the design of the machinery for finitely presented groups.

Derek Holt (Warwick) developed a modified version of his program, KBMAG, for inclusion within MAGMA. The MAGMA facilities for groups and monoids defined by confluent rewrite systems, as well as automatic groups, are supported by this code.

Derek Holt (Warwick) has provided a MAGMA implementation of his algorithm for testing whether two finitely presented groups are isomorphic.

An improved version of the Plesken-Fabianska algorithm for finding L2-quotients of a finitely presented group has been developed and implemented by **Sebastian Jambor** (Aachen).

The low index subgroup function is implemented by code that is based on a Pascal program written by **Charlie Sims** (Rutgers).

Group Theory: Finite Groups

A variation of the Product Replacement Algorithm for generating random elements of a group due to **Henrik Bäärnhielm** and **Charles Leedham-Green** has been coded with their assistance.

A Small Groups database containing all groups having order at most 2000, excluding order 1024 has been made available by **Hans Ulrich Besche** (Aachen), **Bettina Eick** (Braunschweig), and **Eamonn O'Brien** (Auckland). This library incorporates "directly" the libraries of 2-groups of order dividing 256 and the 3-groups of order dividing 729, which were prepared and distributed at various intervals by **Mike Newman** (ANU) and **Eamonn O'Brien** and various assistants, the first release dating from 1987.

Michael Downward and **Eamonn O'Brien** (Auckland) provided functions to access much of the data in the on-line Atlas of Finite Simple Groups for the sporadic groups. A function to select "good" base points for sporadic groups was provided by Eamonn and **Robert Wilson** (QMUL).

The Small Groups database was augmented in V2.14 by code that can enumerate all groups of any square-free order. This code was developed by **Bettina Eick** (Braunschweig) and **Eamonn O'Brien** (Auckland).

The calculation of automorphism groups (for permutation and matrix groups) and determining group isomorphism is performed by code written by **Derek Holt** (Warwick).

Lifting-style algorithms have been developed by **Derek Holt** (Warwick) for computing structural information in groups given in terms of the Composition Tree data structure. The operations include centralisers, conjugacy classes, normalizers, subgroup conjugacy and maximal subgroups.

Magma includes a database of almost-simple groups defined on standard generators. The database was originally conceived by **Derek Holt** (Warwick) with a major extension by **Volker Gebhardt** (Magma) and sporadic additions by **Bill Unger** (Magma).

The routine for computing the subgroup lattice of a group (as distinct from the list of all conjugacy classes of subgroups) is based on code written by **Dimitri Leemans** (Brussels).

Csaba Schneider (Lisbon) has implemented code which allows the user to write an arbitrary element of a classical group as an SLP in terms of its standard generators.

Robert Wilson (QMUL) has made available the data contained in the on-line *ATLAS of Finite Group Representations* for use in a MAGMA database of permutation and matrix representations for finite simple groups. See `http://brauer.maths.qmul.ac.uk/Atlas/`.

Group Theory: Matrix Groups

The Composition Tree (CT) package developed by **Henrik Bäärnhielm** (Auckland), **Derek Holt** (Warwick), **Charles Leedham-Green** (QMUL) and **Eamonn O'Brien** (Auckland), working with numerous collaborators, was first released in V2.17. This package is designed for computing structural information for large matrix groups defined over a finite field.

Constructive recognition of quasi-simple groups belonging to the Suzuki and two Ree families have been implemented by **Hendrik Bäärnhielm** (QMUL). The package includes code for constructing their Sylow p-subgroups and maximal subgroups.

The maximal subgroups of all classical groups having degree not exceeding 12 have been constructed and implemented in MAGMA by **John Bray** (QMUL), **Derek Holt** (Warwick) and **Colva Roney-Dougal** (St Andrews).

Peter Brooksbank (Bucknell) implemented a MAGMA version of his algorithm for performing constructive black-box recognition of low-dimensional symplectic and unitary groups. He also gave the MAGMA group permission to base its implementation of the Kantor-Seress algorithm for black-box recognition of linear groups on his GAP implementation.

Code which computes the normaliser of a linear group defined over a finite field, using a theorem of Aschbacher rather than backtrack search, has been provided by **Hannah Coutts** (St Andrews).

A package, "Infinite", has been developed by **Alla Detinko** (Galway), **Dane Flannery** (Galway) and **Eamonn O'Brien** (Auckland) for computing with groups defined over number fields, or (rational) function fields in zero or positive characteristic.

An algorithm for determining the conjugacy of any pair of matrices in $GL(2, Z)$ was developed and implemented by **D. Husert** (University of Paderborn). In particular, this allows the conjugacy of elements having infinite order to be determined.

Markus Kirschmer (RWTH, Aachen) has provided a package for computing with finite subgroups of $GL(n, \mathbf{Z})$. A MAGMA database of the maximal finite irreducible subgroups of $Sp_{2n}(\mathbf{Q})$ for $1 \leq i \leq 11$ has also been made available by Markus.

A much improved algorithm for computing the normaliser or centraliser of a finite subgroup of $GL(n, Z)$ has been implemented by **Markus Kirschmer** (Aachen). Markus has also implemented an algorithm that tests finite subgroups for conjugacy.

Procedures to list irreducible (soluble) subgroups of $GL(2, q)$ and $GL(3, q)$ for arbitrary q have been provided by **Dane Flannery** (Galway) and **Eamonn O'Brien** (Auckland).

A Monte-Carlo algorithm to determine the defining characteristic of a quasisimple group of Lie type has been contributed by **Martin Liebeck** (Imperial) and **Eamonn O'Brien** (Auckland).

A Monte-Carlo algorithm for non-constructive recognition of simple groups has been contributed by **Gunter Malle** (Kaiserslautern) and **Eamonn O'Brien** (Auckland). This

procedure includes an algorithm of Babai et al which identifies a quasisimple group of Lie type.

MAGMA incorporates a database of the maximal finite rational subgroups of $GL(n, \mathbf{Q})$ up to dimension 31. This database as constructed by **Gabriele Nebe** (Aachen) and **Wilhelm Plesken** (Aachen). A database of quaternionic matrix groups constructed by Gabriele is also included.

A function that determines whether a matrix group G (defined over a finite field) is the normaliser of an extraspecial group in the case where the degree of G is an odd prime uses the new Monte-Carlo algorithm of **Alice Niemeyer** (Perth) and has been implemented in MAGMA by **Eamonn O'Brien** (Auckland).

The package for recognizing large degree classical groups over finite fields was designed and implemented by **Alice Niemeyer** (Perth) and **Cheryl Praeger** (Perth). It has been extended to include 2-dimensional linear groups by **Eamonn O'Brien** (Auckland).

Eamonn O'Brien (Auckland) has contributed a MAGMA implementation of algorithms for determining the Aschbacher category of a subgroup of $\mathrm{GL}(n, q)$.

Eamonn O'Brien (Auckland) has provided implementations of constructive recognition algorithms for the matrix groups $(\mathrm{P})\mathrm{SL}(2, q)$ and $(\mathrm{P})\mathrm{SL}(3, q)$.

A fast algorithm for determining subgroup conjugacy based on Aschbacher's theorem classifying the maximal subgroups of a linear group has been designed and implemented by **Colva Roney-Dougal** (St Andrews).

A package for constructing the Sylow p-subgroups of the classical groups has been implemented by **Mark Stather** (Warwick).

Generators in the natural representation of a finite group of Lie type were constructed and implemented by **Don Taylor** (Sydney) with some assistance from **Leanne Rylands** (Western Sydney).

Group Theory: Soluble Groups

The soluble quotient algorithm in MAGMA was designed and implemented by **Herbert Brückner** (Aachen).

Code producing descriptions of the groups of order p^4, p^5, p^6, p^7 for $p > 3$ was contributed by **Boris Girnat, Robert McKibbin, Mike Newman, Eamonn O'Brien**, and **Mike Vaughan-Lee**.

A new approach to the more efficient calculation of the automorphism group of a finite soluble group has been developed and implemented **David Howden** (Warwick). A slight variation of the algorithm is used to test isomorphism.

Most of the algorithms for p-groups and many of the algorithms implemented in MAGMA for finite soluble groups are largely due to **Charles Leedham–Green** (QMUL, London).

The NQ program of **Werner Nickel** (Darmstadt) is used to compute nilpotent quotients of finitely presented groups. Version 2.2 of NQ was installed in MAGMA V2.14 by **Bill Unger** (Magma) and **Michael Vaughan-Lee** (Oxford).

The p-quotient program, developed by **Eamonn O'Brien** (Auckland) based on earlier work by **George Havas** and **Mike Newman** (ANU), provides a key facility for studying p-groups in MAGMA. Eamonn's extensions in MAGMA of this package for generating p-groups, computing automorphism groups of p-groups, and deciding isomorphism of p-groups are also included. He has contributed software to count certain classes of p-groups and to construct central extensions of soluble groups.

The package for classifying metacyclic p-groups has been developed by **Eamonn O'Brien** (Auckland) and **Mike Vaughan-Lee** (Oxford).

Group Theory: Permutation Groups

Derek Holt (Warwick) has implemented the MAGMA version of the Bratus/Pak algorithm for black-box recognition of the symmetric and alternating groups.

Alexander Hulpke (Colorado State) has made available his database of all transitive permutation groups of degree up to 30. This incorporates the earlier database of **Greg Butler** (Concordia) and **John McKay** (Concordia) containing all transitive groups of degree up to 15.

The PERM package developed by **Jeff Leon** (UIC) for efficient backtrack searching in permutation groups is used for most of the permutation group constructions that employ backtrack search.

A table containing all primitive groups having degree less than 2,500 has been provided by **Colva Roney-Dougal** (St Andrews). The groups of degree up to 1,000 were done jointly with **Bill Unger** (MAGMA).

A table containing all primitive groups having degrees in the range 2,500 to 4,095 has been provided by **Hannah Coutts**, **Martyn Quick** and **Colva Roney-Dougal** (all at St Andrews).

Colva Roney-Dougal (St Andrews) has implemented the Beals et al algorithm for performing black-box recognition on the symmetric and alternating groups.

Derek Holt (Warwick) has constructed a table of irreducible representations of quasisimple groups (up to degree 100). Some representations were contributed by **Allan Steel, Volker Gebhardt** and **Bill Unger** (all MAGMA).

A MAGMA database has been constructed from the permutation and matrix representations contained in the on-line Atlas of Finite Simple Groups with the assistance of its author **Robert Wilson** (QMUL).

Homological Algebra

The packages for chain complexes and basic algebras have been developed by **Jon F. Carlson** (Athens, GA).

Sergei Haller developed MAGMA code for computing the first cohomology group of a finite group with coefficients in a finite (not necessarily abelian) group. This formed the basis of a package for computing Galois cohomology of linear algebra groups.

Machinery for computing group cohomology and for producing group extensions has been developed by **Derek Holt** (Warwick). There are two parts to this machinery. The first part comprises Derek's older C-language package for permutation groups while the second part comprises a recent MAGMA language package for group cohomology.

In 2011, **Derek Holt** (Warwick) implemented an alternative algorithm for finding the dimension of the cohomology group $H^n(G, K)$, for G a finite group, and K a finite field. In this approach the dimension is found using projective covers and dimension shifting.

The code for computing A_∞-structures in group cohomology was developed by **Mikael Vejdemo Johansson** (Jena).

L-Functions

Tim Dokchitser (Cambridge) has implemented efficient computation of many kinds of L-functions, including those attached to Dirichlet characters, number fields, Artin representations, elliptic curves and hyperelliptic curves. **Vladimir Dokchitser** (Cambridge) has contributed theoretical ideas.

Anton Mellit has contributed code for computing symmetric powers and tensor products of L-functions.

Lattices and Quadratic Forms

The construction of the sublattice of an integral lattice is performed by code developed by **Markus Kirschmer** (Aachen).

A collection of lattices derived from the on-line tables of lattices prepared by **Neil Sloane** (AT&T Research) and **Gabriele Nebe** (Aachen) is included in MAGMA.

The original functions for computing automorphism groups and isometries of integral lattices are based on the AUTO and ISOM programs of **Bernd Souvignier** (Nijmegen). In V2.16 they are replaced by much faster versions developed by **Bill Unger** (MAGMA).

Coppersmith's method (based on LLL) for finding small roots of univariate polynomials modulo an integer has been implemented by **Damien Stehlé** (ENS Lyon).

Given a quadratic form F in an arbitrary number of variables, **Mark Watkins** (Bristol) has used Denis Simon's ideas as the basis of an algorithm he has implemented in MAGMA for finding a large (totally) isotropic subspace of F.

Lie Theory

The major structural machinery for Lie algebras has been implemented for MAGMA by **Willem de Graaf** (Utrecht) and is based on his ELIAS package written in GAP. He has also implemented a separate package for finitely presented Lie rings.

A database of soluble Lie algebras of dimensions 2, 3 and 4 over all fields has been implemented by **Willem de Graaf** (Trento). Willem has also provided a database of all nilpotent Lie algebras of dimension up to 6 over all base fields (except characteristic 2 when the dimension is 6).

More recent extensions to the Lie algebra package developed by **Willem de Graaf** (Trento) include quantum groups, universal enveloping algebras, the semisimple subalgebras of a simple Lie algebra and nilpotent orbits for simple Lie algebras.

A fast algorithm for multiplying the elements of Coxeter groups based on their automatic structure has been designed and implemented by **Bob Howlett** (Sydney). Bob has also contributed MAGMA code for computing the growth function of a Coxeter group.

Machinery for computing the W-graphs for Lie types A_n, E_6, E_7 and E_8 has been supplied by **Bob Howlett** (Sydney). Subsequently, Bob supplied code for working with directed W-graphs.

The original version of the code for root systems and permutation Coxeter groups was modelled, in part, on the Chevie package of GAP and implemented by **Don Taylor** (Sydney) with the assistance of **Frank Lübeck** (Aachen).

Functions that construct any finite irreducible unitary reflection group in C^n have been implemented by **Don Taylor** (Sydney). Extension to the infinite case was implemented by **Scott Murray** (Sydney).

The current version of Lie groups in MAGMA has been implemented by **Scott Murray** (Sydney) and **Sergei Haller** with some assistance from **Don Taylor** (Sydney).

An extensive package for computing the combinatorial properties of highest weight representations of a Lie algebra has been written by **Dan Roozemond** (Eindhoven). This code is based in the `LiE` package with permission of the authors.

Code has been contributed by **Robert Zeier** (Technical University of Munich) for determining the irreducible simple subalgebras of the Lie algebra $su(k)$.

Linear Algebra and Module Theory

Parts of the ATLAS (Automatically Tuned Linear Algebra Software) created by **R. Clint Whaley et al.** (UTSA) are used for some fundamental matrix algorithms over finite fields GF(p), where p is about the size of a machine integer.

Local Arithmetic Fields

Sebastian Pauli (TU Berlin) has implemented his algorithm for factoring polynomials over local fields within Magma. This algorithm may also be used for the factorization of ideals, the computation of completions of global fields, and for splitting extensions of local fields into towers of unramified and totally ramified extensions.

Modular Forms

Kevin Buzzard (Imperial College) made available his code for computing modular forms of weight one. The MAGMA implementation was developed using this as a starting point.

Lassina Dembélé (Warwick) wrote part of the code implementing his algorithm for computing Hilbert modular forms.

Enrique González-Jiménez (Madrid) contributed a package to compute curves over $\mathbf{Q}$, of genus at least 2, which are images of $X_1(N)$ for a given level N.

Matthew Greenberg (Calgary) and **John Voight** (Vermont) developed and implemented an algorithm for computing Hilbert modular forms using Shimura curves.

A new implementation (V2.19) of Brandt modules associated to definite quaternion orders, over $\mathbf{Z}$ and over function fields $\mathbf{F}_q[t]$, has been developed by **Markus Kirschmer** (Aachen) and **Steve Donnelly** (Magma).

David Kohel (Singapore-NUS, MAGMA) has provided implementations of division polynomials and isogeny structures for Brandt modules and modular curves. Jointly with **William Stein** (Harvard), he implemented the module of supersingular points.

Allan Lauder (Oxford) has contributed code for computing the characteristic polynomial of a Hecke operator acting on spaces of overconvergent modular forms.

MAGMA routines for constructing building blocks of modular abelian varieties were contributed by **Jordi Quer** (Cataluna).

A package for computing with modular symbols (known as HECKE) has been developed by **William Stein** (Harvard). William has also provided much of the package for modular forms.

In 2003–2004, **William Stein** (Harvard) developed extensive machinery for computing with modular abelian varieties within MAGMA.

A package for computing with congruence subgroups of the group $\mathrm{PSL}(2, \mathbf{R})$ has been developed by **Helena Verrill** (LSU).

John Voight (Vermont) produced the package for Shimura curves and arithmetic Fuchsian groups.

Dan Yasaki (UNC) provided the package for Bianchi modular forms.

Primality and Factorisation

The factorisation of integers of the form $p^n \pm 1$, for small primes p, makes use of tables compiled by **Richard Brent** that extend tables developed by the Cunningham project. In addition MAGMA uses Richard's intelligent factorization code FACTOR.

One of the main integer factorization tools available in MAGMA is due to **Arjen K. Lenstra** (EPFL) and his collaborators: a multiple polynomial quadratic sieve developed by Arjen from his "factoring by email" MPQS during visits to Sydney in 1995 and 1998.

The primality of integers is proven using the ECPP (Elliptic Curves and Primality Proving) package written by **François Morain** (Ecole Polytechnique and INRIA). The ECPP program in turn uses the BigNum package developed jointly by **INRIA** and **Digital PRL**.

MAGMA uses the **GMP-ECM** implementation of the Elliptic Curve Method (ECM) for integer factorisation. This was developed by **Pierrick Gaudry**, **Jim Fougeron**, **Laurent Fousse**, **Alexander Kruppa**, **Dave Newman**, and **Paul Zimmermann**. See `http://gforge.inria.fr/projects/ecm/`.

Real and Complex Arithmetic

The complex arithmetic in MAGMA uses the **MPC** package which is being developed by **Andreas Enge**, **Philippe Théveny** and **Paul Zimmermann**. (For more information see `www.multiprecision.org/mpc/`).

Xavier Gourdon (INRIA, Paris) made available his C implementation of A. Schönhage's splitting-circle algorithm for the fast computation of the roots of a polynomial to a specified precision. Xavier also assisted with the adaptation of his code for the MAGMA kernel.

Some portions of the **GNU GMP** multiprecision integer library (`http://gmplib.org`) are used for integer multiplication.

Most real arithmetic in MAGMA is based on the **MPFR** package which is developed by **Paul Zimmermann** (Nancy) and associates. (See `www.mpfr.org`).

Representation Theory

The algorithm of John Dixon for constructing the ordinary irreducible representation of a finite group from its character has been implemented by **Derek Holt** (Warwick).

Derek Holt (Warwick) has made a number of important contributions to the design of the module theory algorithms employed in MAGMA.

An algorithm of Sam Conlon for determining the degrees of the ordinary irreducible characters of a soluble group (without determining the full character table) has been implemented by **Derek Holt** (Warwick).

In 2011, **Derek Holt** (Warwick) and **John Cannon** (Magma) developed a package for computing the projective indecomposable KG-modules for a finite group G.

The algorithms used in MAGMA for finding the lattice of submodules and the endomorphism ring of a KG-module (K a finite field) were developed by **Charles Leedham-Green** (QMW, London) and **Allan Steel** (MAGMA).

Topology

A basic module for defining and computing with simplicial complexes was developed by **Mikael Johansson** (Jena).

Nathan Dunfield (Cornell) and **William Thurston** (Cornell) made available their database of the fundamental groups of the 10,986 small-volume closed hyperbolic manifolds in the Hodgson-Weeks census.

Handbook Contributors

Introduction

The Handbook of Magma Functions is the work of many individuals. It was based on a similar Handbook written for Cayley in 1990. Up until 1997 the Handbook was mainly written by Wieb Bosma, John Cannon and Allan Steel but in more recent times, as Magma expanded into new areas of mathematics, additional people became involved. It is not uncommon for some chapters to comprise contributions from 8 to 10 people. Because of the complexity and dynamic nature of chapter authorship, rather than ascribe chapter authors, in the table below we attempt to list those people who have made *significant* contributions to chapters.

We distinguish between:

• **Principal Author**, i.e. one who primarily conceived the core element(s) of a chapter and who was also responsible for the writing of a large part of its current content, and

◦ **Contributing Author**, i.e. one who has written a significant amount of content but who has not had primary responsibility for chapter design and overall content.

It should be noted that attribution of a person as an author of a chapter carries no implications about the authorship of the associated computer code: for some chapters it will be true that the author(s) listed for a chapter are also the authors of the corresponding code, but in many chapters this is either not the case or only partly true. Some information about code authorship may be found in the sections *Magma Development Team* and *External Contributors*.

The attributions given below reflect the authorship of the material comprising the V2.19 edition. Since many of the authors have since moved on to other careers, we have not been able to check that all of the attributions below are completely correct. We would appreciate hearing of any omissions.

In the chapter listing that follows, for each chapter the start of the list of principal authors (if any) is denoted by • while the start of the list of contributing authors is denoted by ◦.

People who have made minor contributions to one or more chapters are listed in a general acknowledgement following the chapter listing.

The Chapters

1 Statements and Expressions • *W. Bosma, A. Steel*
2 Functions, Procedures and Packages • *W. Bosma, A. Steel*
3 Input and Output • *W. Bosma, A. Steel*
4 Environment and Options • *A. Steel* ∘ *W. Bosma*
5 Magma Semantics • *G. Matthews*
6 The Magma Profiler • *D. Fisher*
7 Debugging Magma Code • *D. Fisher*
8 Introduction to Aggregates • *W. Bosma*
9 Sets • *W. Bosma, J. Cannon* ∘ *A. Steel*
10 Sequences • *W. Bosma, J. Cannon*
11 Tuples and Cartesian Products • *W. Bosma*
12 Lists • *W. Bosma*
13 Associative Arrays • *A. Steel*
14 Coproducts • *A. Steel*
15 Records • *W. Bosma*
16 Mappings • *W. Bosma*
17 Introduction to Rings • *W. Bosma*
18 Ring of Integers • *W. Bosma, A. Steel* ∘ *S. Contini, B. Smith*
19 Integer Residue Class Rings • *W. Bosma* ∘ *S. Donnelly, W. Stein*
20 Rational Field • *W. Bosma*
21 Finite Fields • *W. Bosma, A. Steel*
22 Nearfields • *D. Taylor*
23 Univariate Polynomial Rings • *A. Steel*
24 Multivariate Polynomial Rings • *A. Steel*
25 Real and Complex Fields • *W. Bosma*
26 Matrices • *A. Steel*
27 Sparse Matrices • *A. Steel*
28 Vector Spaces • *J. Cannon, A. Steel*
29 Polar Spaces • *D. Taylor*
30 Lattices • *A. Steel, D. Stehlé*
31 Lattices With Group Action • *B. Souvignier* ∘ *M. Kirschmer*
32 Quadratic Forms • *S. Donnelly*
33 Binary Quadratic Forms • *D. Kohel*
34 Number Fields • *C. Fieker* ∘ *W. Bosma, N. Sutherland*
35 Quadratic Fields • *W. Bosma*
36 Cyclotomic Fields • *W. Bosma, C. Fieker*
37 Orders and Algebraic Fields • *C. Fieker* ∘ *W. Bosma, N. Sutherland*
38 Galois Theory of Number Fields • *C. Fieker* ∘ *J. Klüners, K. Geißler*

39 Class Field Theory • *C. Fieker*
40 Algebraically Closed Fields • *A. Steel*
41 Rational Function Fields • *A. Steel* ◦ *A. van der Waall*

General Acknowledgements

In addition to the contributors listed above, we gratefully acknowledge the contributions to the Handbook made by the following people:

J. Brownie (group theory)
K. Geißler (Galois groups)
A. Flynn (algebras and designs)
E. Herrmann (elliptic curves)
E. Howe (Igusa invariants)
B. McKay (graph theory)
S. Pauli (local fields)
C. Playoust (data structures, rings)
C. Roney-Dougal (groups)
T. Womack (elliptic curves)

USING THE HANDBOOK

Most sections within a chapter of this Handbook consist of a brief introduction and explanation of the notation, followed by a list of MAGMA functions, procedures and operators.

Each entry in this list consists of an expression in a box, and an indented explanation of use and effects. The `typewriter` typefont is used for commands that can be used literally; however, one should be aware that most functions operate on variables that must have values assigned to them beforehand, and return values that should be assigned to variables (or the first value should be used in an expression). Thus the entry:

```
Xgcd(a, b)
```

The extended gcd; returns integers d, l and m such that d is the greatest common divisor of the integers a and b, and $d = l * a + m * b$.

indicates that this function could be called in MAGMA as follows:

```
g, a, b := Xgcd(23, 28);
```

If the function has optional named *parameters*, a line like the following will be found in the description:

`Proof` BOOLELT *Default :* `true`

The first word will be the name of the parameter, the second word will be the type which its value should have, and the rest of the line will indicate the default for the parameter, if there is one. Parameters for a function call are specified by appending a colon to the last argument, followed by a comma-separated list of assignments (using `:=`) for each parameter. For example, the function call `IsPrime(n: Proof := false)` calls the function `IsPrime` with argument n but also with the value for the parameter `Proof` set to `false`.

Whenever the symbol `#` precedes a function name in a box, it indicates that the particular function is not yet available but should be in the future.

An index is provided at the end of each volume which contains all the intrinsics in the Handbook.

Running the Examples

All examples presented in this Handbook are available to MAGMA users. If your MAGMA environment has been set up correctly, you can load the source for an example by using the name of the example as printed in boldface at the top (the name has the form HmEn, where m is the Chapter number and n is the Example number). So, to run the first example in the Chapter 28, type:

```
load "H28E1";
```

OVERVIEW

CONTENTS

PART I
THE MAGMA LANGUAGE

1 STATEMENTS AND EXPRESSIONS

Chapter 1
STATEMENTS AND EXPRESSIONS

1.1 Introduction

This chapter contains a very terse overview of the basic elements of the MAGMA language.

1.2 Starting, Interrupting and Terminating

If MAGMA has been installed correctly, it may be activated by typing 'magma'.

`<Ctrl>-C`

Interrupt MAGMA while it is performing some task (that is, while the user does not have a 'prompt') to obtain a new prompt. MAGMA will try to interrupt at a convenient point (this may take some time). If `<Ctrl>-C` is typed twice within half a second, MAGMA will exit completely immediately.

`quit;`

`<Ctrl>-D`

Terminate the current MAGMA-session.

`<Ctrl>-\`

Immediately quit MAGMA (send the signal SIGQUIT to the MAGMA process on Unix machines). This is occasionally useful when `<Ctrl>-C` does not seem to work.

1.3 Identifiers

Identifiers (names for user variables, functions etc.) must begin with a letter, and this letter may be followed by any combination of letters or digits, provided that the name is not a *reserved word* (see the chapter on reserved words a complete list). In this definition the underscore _ is treated as a letter; but note that a single underscore is a reserved word. Identifier names are case-sensitive; that is, they are distinguished from one another by lower and upper case.

Intrinsic MAGMA functions usually have names beginning with capital letters (current exceptions are `pCore, pQuotient` and the like, where the `p` indicates a prime). Note that these identifiers are *not* reserved words; that is, one may use names of intrinsic functions for variables.

1.4 Assignment

In this section the basic forms of assignment of values to identifiers are described.

1.4.1 Simple Assignment

`x := expression;`

Given an identifier `x` and an expression *expression*, assign the value of *expression* to `x`.

Example H1E1

```
> x := 13;
> y := x^2-2;
> x, y;
13 167
```

Intrinsic function names are identifiers just like the x and y above. Therefore it is possible to reassign them to your own variable.

```
> f := PreviousPrime;
> f(y);
163
```

In fact, the same can also be done with the infix operators, except that it is necessary to enclose their names in quotes. Thus it is possible to define your own function `Plus` to be the function taking the arguments of the intrinsic `+` operator.

```
> Plus := '+';
> Plus(1/2, 2);
5/2
```

Note that redefining the infix operator will *not* change the corresponding mutation assignment operator (in this case `+:=`).

$\texttt{x}_1$`, `$\texttt{x}_2$`, ..., `$\texttt{x}_n$` := expression;`

Assignment of $n \geq 1$ values, returned by the expression on the right hand side. Here the $\texttt{x}_i$ are identifiers, and the right hand side expression must return $m \geq n$ values; the first n of these will be assigned to $\texttt{x}_1$`, `$\texttt{x}_2$`, ..., `$\texttt{x}_n$ respectively.

`_ := expression;`

Ignore the value(s) returned by the expression on the right hand side.

`assigned x`

An expression which yields the value `true` if the 'local' identifier x has a value currently assigned to it and `false` otherwise. Note that the `assigned`-expression will return `false` for intrinsic function names, since they are not 'local' variables (the identifiers can be assigned to something else, hiding the intrinsic function).

Example H1E2

The extended greatest common divisor function `Xgcd` returns 3 values: the gcd d of the arguments m and n, as well as multipliers x and y such that $d = xm + yn$. If one is only interested in the gcd of the integers $m = 12$ and $n = 15$, say, one could use:

```
> d := Xgcd(12, 15);
```

To obtain the multipliers as well, type

```
> d, x, y := Xgcd(12, 15);
```

while the following offers ways to retrieve two of the three return values.

```
> d, x := Xgcd(12, 15);
> d, _, y := Xgcd(12, 15);
> _, x, y := Xgcd(12, 15);
```

1.4.2 Indexed Assignment

`x[`*expression*$_1$`][`*expression*$_2$`]...[`*expression*$_n$`] := `*expression*`;`

`x[`*expression*$_1$`,`*expression*$_2$`,...,`*expression*$_n$`] := `*expression*`;`

If the argument on the left hand side allows *indexing* at least n levels deep, and if this indexing can be used to modify the argument, this offers two equivalent ways of accessing and modifying the entry indicated by the expressions `expr`$_i$. The most important case is that of (nested) sequences.

Example H1E3

Left hand side indexing can be used (as is explained in more detail in the chapter on sequences) to modify existing entries.

```
> s := [ [1], [1, 2], [1, 2, 3] ];
> s;
[
       [ 1 ],
       [ 1, 2 ],
       [ 1, 2, 3 ]
]
> s[2, 2] := -1;
> s;
[
       [ 1 ],
       [ 1, -1 ],
       [ 1, 2, 3 ]
]
```

1.4.3 Generator Assignment

Because of the importance of naming the generators in the case of finitely presented magmas, special forms of assignment allow names to be assigned at the time the magma itself is assigned.

`E<`x_1`, `x_2`, ...`x_n`> :=` *expression*`;`

If the right hand side expression returns a structure that allows *naming* of 'generators', such as finitely generated groups or algebras, polynomial rings, this assigns the first n names to the variables x_1, x_2, ..., x_n. Naming of generators usually has two aspects; firstly, the *strings* x_1, x_2, ...x_n are used for printing of the generators, and secondly, to the *identifiers* x_1, x_2, ...x_n are assigned the values of the generators. Thus, except for this side effect regarding printing, the above assignment is equivalent to the $n + 1$ assignments:

`E :=` *expression*`;`
x_1 `:= E.1;` x_2 `:= E.2; ...` x_n `:= E.`n`;`

`E<[x]> :=` *expression*`;`

If the right hand side expression returns a structure S that allows *naming* of 'generators', this assigns the names of S to be those formed by appending the numbers 1, 2, etc. in order enclosed in square brackets to x (considered as a string) and assigns x to the sequence of the names of S.

Example H1E4

We demonstrate the sequence method of generator naming.

```
> P<[X]> := PolynomialRing(RationalField(), 5);
> P;
Polynomial ring of rank 5 over Rational Field
Lexicographical Order
Variables: X[1], X[2], X[3], X[4], X[5]
> X;
[
    X[1],
    X[2],
    X[3],
    X[4],
    X[5]
]
> &+X;
X[1] + X[2] + X[3] + X[4] + X[5]
> (&+X)^2;
X[1]^2 + 2*X[1]*X[2] + 2*X[1]*X[3] + 2*X[1]*X[4] +
    2*X[1]*X[5] + X[2]^2 + 2*X[2]*X[3] + 2*X[2]*X[4] +
    2*X[2]*X[5] + X[3]^2 + 2*X[3]*X[4] + 2*X[3]*X[5] +
    X[4]^2 + 2*X[4]*X[5] + X[5]^2
```

`AssignNames(~S, [s1, ... sn] )`

If S is a structure that allows *naming* of 'generators' (see the Index for a complete list), this procedure assigns the names specified by the strings to these generators. The number of generators has to match the length of the sequence. This will result in the creation of a new structure.

Example H1E5

```
> G<a, b> := Group<a, b | a^2 = b^3 = a^b*b^2>;
> w := a * b;
> w;
a * b
> AssignNames(~G, ["c", "d"]);
> G;
Finitely presented group G on 2 generators
Relations
    c^2 = d^-1 * c * d^3
    d^3 = d^-1 * c * d^3
> w;
a * b
> Parent(w);
Finitely presented group on 2 generators
Relations
    a^2 = b^-1 * a * b^3
    b^3 = b^-1 * a * b^3
> G eq Parent(w);
true
```

1.4.4 Mutation Assignment

`x o:=` *expression*`;`

This is the *mutation assignment*: the expression is evaluated and the operator `o` is applied on the result and the current value of x, and assigned to x again. Thus the result is equivalent to (but an optimized version of): `x := x o` *expression*`;`. The operator may be any of the operations `join`, `meet`, `diff`, `sdiff`, `cat`, `*`, `+`, `-`, `/`, `^`, `div`, `mod`, `and`, `or`, `xor` provided that the operation is legal on its arguments of course.

Example H1E6

The following simple program to produce a set consisting of the first 10 powers of 2 involves the use of two different mutation assignments.

```
> x := 1;
> S := { };
> for i := 1 to 10 do
>    S join:= { x };
>    x *:= 2;
> end for;
> S;
{ 1, 2, 4, 8, 16, 32, 64, 128, 256, 512 }
```

1.4.5 Deletion of Values

`delete x`

(Statement.) Delete the current value of the identifier x. The memory occupied is freed, unless other variables still refer to it. If x is the name of an intrinsic MAGMA function that has been reassigned to, the identifier will after deletion again refer to that intrinsic function. Intrinsic functions cannot be deleted.

1.5 Boolean values

This section deals with logical values ("Booleans").

Booleans are primarily of importance as (return) values for (intrinsic) predicates. It is important to know that the truth-value of the operators `and` and `or` is always evaluated *left to right*, that is, the left-most clause is evaluated first, and if that determines the value of the operator evaluation is aborted; if not, the next clause is evaluated, etc. So, for example, if x is a boolean, it is safe (albeit silly) to type:

```
> if x eq true or x eq false or x/0 eq 1 then
>    "fine";
> else
>    "error";
> end if;
```

even though $x/0$ would cause an error ("Bad arguments", not "Division by zero"!) upon evaluation, because the truth value will have been determined before the evaluation of `x/0` takes place.

1.5.1 Creation of Booleans

`Booleans()`

The Boolean structure.

`#B`

Cardinality of Boolean structure (2).

`true`

`false`

The Boolean elements.

`Random(B)`

Return a random Boolean.

1.5.2 Boolean Operators

`x and y`

Returns `true` if both x and y are `true`, `false` otherwise. If x is `false`, the expression for y is not evaluated.

`x or y`

Returns `true` if x or y is `true` (or both are `true`), `false` otherwise. If x is `true`, the expression for y is not evaluated.

`x xor y`

Returns `true` if either x or y is `true` (but not both), `false` otherwise.

`not x`

Negate the truth value of x.

1.5.3 Equality Operators

MAGMA provides two equality operators: `eq` for strong (comparable) equality testing, and `cmpeq` for weak equality testing. The operators depend on the concept of *comparability*. Objects x and y in MAGMA are said to be *comparable* if both of the following points hold:

(a) x and y are both elements of a structure S or there is a structure S such x and y will be coerced into S by automatic coercion;

(b) There is an equality test for elements of S defined within MAGMA.

The possible automatic coercions are listed in the descriptions of the various MAGMA modules. For instance, the table in the introductory chapter on rings shows that integers can be coerced automatically into the rational field so an integer and a rational are comparable.

`x eq y`

If x and y are comparable, return `true` if x equals y (which will always work by the second rule above). If x and y are not comparable, an error results.

`x ne y`

If x and y are comparable, return `true` if x does not equal y. If x and y are not comparable, an error results.

`x cmpeq y`

If x and y are comparable, return whether x equals y. Otherwise, return `false`. Thus this operator always returns a value and an error never results. It is useful when comparing two objects of completely different types where it is desired that no error can happen. However, it is strongly recommended that `eq` is usually used to allow MAGMA to pick up common unintentional type errors.

`x cmpne y`

If x and y are comparable, return whether x does not equal y. Otherwise, return `true`. Thus this operator always returns a value and an error never results. It is useful when comparing two objects of completely different types where it is desired that no error can happen. However, it is strongly recommended that `ne` is usually used to allow MAGMA to pick up common unintentional type errors.

Example H1E7

We illustrate the different semantics of `eq` and `cmpeq`.

```
> 1 eq 2/2;
true
> 1 cmpeq 2/2;
true
>  1 eq "x";
Runtime error in 'eq': Bad argument types
> 1 cmpeq "x";
false
>  [1] eq ["x"];
Runtime error in 'eq': Incompatible sequences
> [1] cmpeq ["x"];
false
```

1.5.4 Iteration

A Boolean structure B may be used for enumeration: `for x in B do`, and `x in B` in set and sequence constructors.

Example H1E8

The following program checks that the functions `ne` and `xor` coincide.

```
> P := Booleans();
> for x, y in P do
>      (x ne y) eq (x xor y);
> end for;
true
true
true
true
```

Similarly, we can test whether for any pair of Booleans x, y it is true that

$$x = y \quad \Longleftrightarrow \quad (x \wedge y) \vee (\neg x \wedge \neg y).$$

```
> equal := true;
> for x, y in P do
>     if (x eq y) and not ((x and y) or (not x and not y)) then
>         equal := false;
>     end if;
> end for;
> equal;
true
```

1.6 Coercion

Coercion is a fundamental concept in MAGMA. Given a structures A and B, there is often a natural mathematical mapping from A to B (e.g., embedding, projection), which allows one to transfer elements of A to corresponding elements of B. This is known as coercion. Natural and obvious coercions are supported in MAGMA as much as possible; see the relevant chapters for the coercions possible between various structures.

`S ! x`

Given a structure S and an object x, attempt to coerce x into S and return the result if successful. If the attempt fails, an error ensues.

`IsCoercible(S, x)`

Given a structure S and an object x, attempt to coerce x into S; if successful, return `true` and the result of the coercion, otherwise return `false`.

1.7 The `where ... is` Construction

By the use of the `where ... is` construction, one can within an expression temporarily assign an identifier to a sub-expression. This allows for compact code and efficient re-use of common sub-expressions.

expression$_1$ `where` *identifier* `is` *expression*$_2$
expression$_1$ `where` *identifier* `:=` *expression*$_2$

This construction is an expression that temporarily assigns the identifier to the second expression and then yields the value of the first expression. The identifier may be referred to in the first expression and it will equal the value of the second expression. The token `:=` can be used as a synonym for `is`. The scope of the identifier is the `where ... is` construction alone except for when the construction is part of an expression list — see below.

The `where` operator is left-associative. This means that there can be multiple uses of `where ... is` constructions and each expression can refer to variables bound in the enclosing constructions.

Another important feature is found in a set or sequence constructor. If there are `where ... is` constructions in the predicate, then any variables bound in them may be referred to in the expression at the beginning of the constructor. If the whole predicate is placed in parentheses, then any variables bound in the predicate do not extend to the expression at the beginning of the constructor.

The `where` operator also extends left in expression lists. That is, if there is an expression E in a expression list which is a `where` construction (or chain of where constructions), the identifiers bound in that where construction (or chain) will be defined in all expressions in the list which are to the left of E. Expression lists commonly arise as argument lists to functions or procedures, return arguments, print statements (with or without the word 'print') etc. A where construction also overrides (hides) any where construction to the right of it in the same list. Using parentheses around a where expression ensures that the identifiers bound within it are not seen outside it.

Example H1E9

The following examples illustrate simple uses of `where ... is`.

```
> x := 1;
> x where x is 10;
10
> x;
1
> Order(G) + Degree(G) where G is Sym(3);
9
```

Since `where` is left-associative we may have multiple uses of it. The use of parentheses, of course, can override the usual associativity.

```
> x := 1;
```

```
> y := 2;
> x + y where x is 5 where y is 6;
11
> (x + y where x is 5) where y is 6; // the same
11
> x + y where x is (5 where y is 6);
7
> x + y where x is y where y is 6;
12
> (x + y where x is y) where y is 6; // the same
12
> x + y where x is (y where y is 6);
8
```

We now illustrate how the left expression in a set or sequence constructor can reference the identifiers of `where` constructions in the predicate.

```
> { a: i in [1 .. 10] | IsPrime(a) where a is 3*i + 1 };
{  7, 13, 19, 31 }
> [<x, y>: i in [1 .. 10] | IsPrime(x) and IsPrime(y)
>    where x is y + 2 where y is 2 * i + 1];
[ <5, 3>, <7, 5>, <13, 11>, <19, 17> ]
```

We next demonstrate the semantics of `where` constructions inside expression lists.

```
> // A simple use:
> [a, a where a is 1];
[ 1, 1 ]
>  // An error: where does not extend right
>  print [a where a is 1, a];
User error: Identifier 'a' has not been declared
> // Use of parentheses:
> [a, (a where a is 1)] where a is 2;
[ 2, 1 ]
>  // Another use of parentheses:
>  print [a, (a where a is 1)];
User error: Identifier 'a' has not been declared
> // Use of a chain of where expressions:
> [<a, b>, <b, a> where a is 1 where b is 2];
[ <1, 2>, <2, 1> ]
> // One where overriding another to the right of it:
> [a, a where a is 2, a where a is 3];
[ 2, 2, 3 ]
```

1.8 Conditional Statements and Expressions

The conditional statement has the usual form `if ... then ... else ... end if;`. It has several variants. Within the statement, a special prompt will appear, indicating that the statement has yet to be closed. Conditional statements may be nested.

The conditional expression, `select ... else`, is used for in-line conditionals.

1.8.1 The Simple Conditional Statement

```
if Boolean expression then
   statements1
else
   statements2
end if;
```

```
if Boolean expression then
   statements
end if;
```

The standard conditional statement: the value of the Boolean expression is evaluated. If the result is `true`, the first block of statements is executed, if the result is `false` the second block of statements is executed. If no action is desired in the latter case, the construction may be abbreviated to the second form above.

```
if Boolean expression1 then
   statements1
elif Boolean expression2 then
   statements2
else
   statements3
end if;
```

Since nested conditions occur frequently, `elif` provides a convenient abbreviation for `else if`, which also restricts the 'level':

```
if Boolean expression then
   statements1
elif Boolean expression2 then
   statements2
else
   statements3
end if;
```

is equivalent to

```
if Boolean expression1 then
    statements1
else
    if Boolean expression2 then
```

```
        statements2
    else
        statements3
    end if;
end if;
```

Example H1E10

```
> m := Random(2, 10000);
> if IsPrime(m) then
>     m, "is prime";
> else
>     Factorization(m);
> end if;
[ <23, 1>, <37, 1> ]
```

1.8.2 The Simple Conditional Expression

Boolean expression `select` *expression*$_1$ `else` *expression*$_2$

This is an expression, of which the value is that of *expression*$_1$ or *expression*$_2$, depending on whether *Boolean expression* is `true` or `false`.

Example H1E11

Using the `select ... else` construction, we wish to assign the sign of y to the variable s.

```
> y := 11;
> s := (y gt 0) select 1 else -1;
> s;
1
```

This is not quite right (when $y = 0$), but fortunately we can nest `select ... else` constructions:

```
> y := -3;
> s := (y gt 0) select 1 else (y eq 0 select 0 else -1);
> s;
-1
> y := 0;
> s := (y gt 0) select 1 else (y eq 0 select 0 else -1);
> s;
0
```

The `select ... else` construction is particularly important in building sets and sequences, because it enables in-line `if` constructions. Here is a sequence containing the first 100 entries of the Fibonacci sequence:

```
>  f := [ i gt 2 select Self(i-1)+Self(i-2) else 1 : i in [1..100] ];
```

1.8.3 The Case Statement

```
case expression :
   when expression, ..., expression:
      statements
          ⋮
   when expression, ..., expression:
      statements
end case;
```

The expression following `case` is evaluated. The statements following the first expression whose value equals this value are executed, and then the `case` statement has finished. If none of the values of the expressions equal the value of the `case` expression, then the statements following `else` are executed. If no action is desired in the latter case, the construction may be abbreviated to the second form above.

Example H1E12

```
> x := 73;
> case Sign(x):
>    when 1:
>       x, "is positive";
>    when 0:
>       x, "is zero";
>    when -1:
>       x, "is negative";
> end case;
73 is positive
```

1.8.4 The Case Expression

```
case< expression |
      expression_left,1 : expression_right,1 ,
          ⋮
      expression_left,n : expression_right,n ,
      default : expression_def >
```

This is the expression form of `case`. The *expression* is evaluated to the value v. Then each of the left-hand expressions $expression_{\text{left},i}$ is evaluated until one is found whose value equals v; if this happens the value of the corresponding right-hand expression $expression_{\text{right},i}$ is returned. If no left-hand expression with value v is found the value of the default expression $expression_{\text{def}}$ is returned.

The default case cannot be omitted, and must come last.

1.9 Error Handling Statements

MAGMA has facilities for both reporting and handling errors. Errors can arise in a variety of circumstances within MAGMA's internal code (due to, for instance, incorrect usage of a function, or the unexpected failure of an algorithm). MAGMA allows the user to raise errors in their own code, as well as catch many kinds of errors.

1.9.1 The Error Objects

All errors in MAGMA are of type `Err`. Error objects not only include a description of the error, but also information relating to the location at which the error was raised, and whether the error was a user error, or a system error.

`Error(x)`

Constructs an error object with user information given by x, which can be of any type. The object x is stored in the `Object` attributed of the constructed error object, and the `Type` attribute of the object is set to "ErrUser". The remaining attributes are uninitialized until the error is raised by an `error` statement; at that point they are initialized with the appropriate positional information.

`e‘Position`

Stores the position at which the error object e was raised. If the error object has not yet been raised, the attribute is undefined.

`e‘Traceback`

Stores the stack traceback giving the position at which the error object e was raised. If the error object has not yet been raised, the attribute is undefined.

`e‘Object`

Stores the user defined error information for the error. If the error is a system error, then this will be a string giving a textual description of the error.

`e‘Type`

Stores the type of the error. Currently, there are only two types of errors in Magma: "Err" denotes a system error, and "ErrUser" denotes an error raised by the user.

1.9.2 Error Checking and Assertions

`error` *expression*`, ..., `*expression*`;`

Raises an error, with the error information being the printed value of the expressions. This statement is useful, for example, when an illegal value of an argument is passed to a function.

`error if` *Boolean expression*`, `*expression*`, ..., `*expression*`;`

If the given boolean expression evaluates to `true`, then raises an error, with the error information being the printed value of the expressions. This statement is designed for checking that certain conditions must be met, etc.

```
assert Boolean expression;
```

```
assert2 Boolean expression;
```

```
assert3 Boolean expression;
```

These assertion statements are useful to check that certain conditions are satisfied. There is an underlying `Assertions` flag, which is set to 1 by default.

For each statement, if the `Assertions` flag is less than the level specified by the statement (respectively 1, 2, 3 for the above statements), then nothing is done. Otherwise, the given boolean expression is evaluated and if the result is `false`, an error is raised, with the error information being an appropriate message.

It is recommended that when developing package code, `assert` is used for important tests (always to be tested in any mode), while `assert2` is used for more expensive tests, only to be checked in the debug mode, while `assert3` is be used for extremely stringent tests which are very expensive.

Thus the `Assertions` flag can be set to 0 for no checking at all, 1 for normal checks, 2 for debug checks and 3 for extremely stringent checking.

1.9.3 Catching Errors

```
try
   statements1
catch e
   statements2
end try;
```

The `try/catch` statement lets users handle raised errors. The semantics of a `try/catch` statement are as follows: the block of statements $statements_1$ is executed. If no error is raised during its execution, then the block of statements $statements_2$ is not executed; if an error is raised at any point in $statements_1$, execution *immediately* transfers to $statements_2$ (the remainder of $statements_1$ is not executed). When transfer is controlled to the `catch` block, the variable named e is initialized to the error that was raised by $statements_1$; this variable remains in scope until the end of the `catch` block, and can be both read from and written to. The catch block can, if necessary, reraise e, or any other error object, using an `error` statement.

Example H1E13

The following example demonstrates the use of error objects, and `try/catch` statements.

```
> procedure always_fails(x)
>     error Error(x);
> end procedure;
>
> try
>     always_fails(1);
```

```
>     always_fails(2);  // we never get here
> catch e
>     print "In catch handler";
>     error "Error calling procedure with parameter: ", e`Object;
> end try;
In catch handler
Error calling procedure with parameter:  1
```

1.10 Iterative Statements

Three types of iterative statement are provided in MAGMA: the `for`-statement providing definite iteration and the `while`- and `repeat`-statements providing indefinite iteration.

Iteration may be performed over an arithmetic progression of integers or over any finite enumerated structure. Iterative statements may be nested. If nested iterations occur over the same enumerated structure, abbreviations such as `for x, y in X do` may be used; the leftmost identifier will correspond to the outermost loop, etc. (For nested iteration in sequence constructors, see Chapter 10.)

Early termination of the body of loop may be specified through use of the 'jump' commands `break` and `continue`.

1.10.1 Definite Iteration

`for i :=` *expression*$_1$ `to` *expression*$_2$ `by` *expression*$_3$ `do`
statements
`end for;`

The expressions in this `for` loop must return integer values, say b, e and s (for 'begin', 'end' and 'step') respectively. The loop is ignored if either $s > 0$ and $b > e$, or $s < 0$ and $b < e$. If $s = 0$ an error occurs. In the remaining cases, the value $b + k \cdot s$ will be assigned to `i`, and the statements executed, for $k = 0, 1, 2, \ldots$ in succession, as long as $b + k \cdot s \leq e$ (for $e > 0$) or $b + k \cdot s \geq e$ (for $e < 0$).

If the required step size is 1, the above may be abbreviated to:

`for i :=` *expression*$_1$ `to` *expression*$_2$ `do`
statements
`end for;`

`for x in S do`
statements
`end for;`

Each of the elements of the finite enumerated structure S will be assigned to x in succession, and each time the statements will be executed. It is possible to nest several of these `for` loops compactly as follows.

`for` $\mathtt{x}_{11}$`, ...,` $\mathtt{x}_{1n_1}$ `in` $\mathtt{S}_1$`, ...,` $\mathtt{x}_{m1}$`, ...,` $\mathtt{x}_{mn_m}$ `in` $\mathtt{S}_m$ `do`
statements
`end for;`

1.10.2 Indefinite Iteration

```
while Boolean expression do
   statements
end while;
```

Check whether or not the Boolean expression has the value `true`; if it has, execute the statements. Repeat this until the expression assumes the value `false`, in which case statements following the `end while;` will be executed.

Example H1E14

The following short program implements a run of the famous $3x+1$ problem on a random integer between 1 and 100.

```
> x := Random(1, 100);
> while x gt 1 do
> x;
>     if IsEven(x) then
>       x div:= 2;
>     else
>        x := 3*x+1;
>     end if;
> end while;
13
40
20
10
5
16
8
4
2
```

```
repeat
   statements
until Boolean expression;
```

Execute the statements, then check whether or not the Boolean expression has the value `true`. Repeat this until the expression assumes the value `false`, in which case the loop is exited, and statements following it will be executed.

Example H1E15

This example is similar to the previous one, except that it only prints x and the number of steps taken before x becomes 1. We use a `repeat` loop, and show that the use of a `break` statement sometimes makes it unnecessary that the Boolean expression following the `until` ever evaluates to `true`. Similarly, a `while true` statement may be used if the user makes sure the loop will be exited using `break`.

```
> x := Random(1, 1000);
> x;
172
> i := 0;
> repeat
>     while IsEven(x) do
>         i +:= 1;
>         x div:= 2;
>     end while;
>     if x eq 1 then
>         break;
>     end if;
>     x := 3*x+1;
>     i +:= 1;
> until false;
> i;
31
```

1.10.3 Early Exit from Iterative Statements

`continue;`

The `continue` statement can be used to jump to the end of the innermost enclosing loop: the termination condition for the loop is checked immediately.

`continue` *identifier*`;`

As in the case of `break`, this allows jumps out of nested `for` loops: the termination condition of the loop with loop variable *identifier* is checked immediately after `continue` *identifier* is encountered.

`break;`

A `break` inside a loop causes immediate exit from the innermost enclosing loop.

`break` *identifier*`;`

In nested `for` loops, this allows breaking out of several loops at once: this will cause an immediate exit from the loop with loop variable *identifier*.

Example H1E16

```
> p := 10037;
> for x in [1 .. 100] do
>    for y in [1 .. 100] do
>       if x^2 + y^2 eq p then
>          x, y;
>          break x;
>       end if;
>    end for;
> end for;
46 89
```

Note that `break` instead of `break x` would have broken only out of the inner loop; the output in that case would have been:

```
46 89
89 46
```

1.11 Runtime Evaluation: the eval Expression

Sometimes it is convenient to able to evaluate expressions that are dynamically constructed at runtime. For instance, consider the problem of implementing a database of mathematical objects in MAGMA. Suppose that these mathematical objects are very large, but can be constructed in only a few lines of MAGMA code (a good example of this would be MAGMA's database of best known linear codes). It would be very inefficient to store these objects in a file for later retrieval; a better solution would be to instead store a string giving the code necessary to construct each object. MAGMA's `eval` feature can then be used to dynamically parse and execute this code on demand.

`eval` *expression*

The `eval` expression works as follows: first, it evaluates the given *expression*, which must evaluate to a string. This string is then treated as a piece of MAGMA code which yields a result (that is, the code must be an expression, not a statement), and this result becomes the result of the `eval` expression.

The string that is evaluated can be of two forms: it can be a MAGMA expression, e.g., "`1+2`", "`Random(x)`", or it can be a sequence of MAGMA statements. In the first case, the string does not have to be terminated with a semicolon, and the result of the expression given in the string will be the result of the `eval` expression. In the second case, the last statement given in the string should be a `return` statement; it is easiest to think of this case as defining the body of a function.

The string that is used in the `eval` expression can refer to any variable that is in scope during the evaluation of the `eval` expression. However, it is not possible for the expression to *modify* any of these variables.

Example H1E17

In this example we demonstrate the basic usage of the `eval` keyword.

```
> x := eval "1+1";  // OK
> x;
2
> eval "1+1;"; // not OK
2
>> eval "1+1;"; // not OK
   ^
Runtime error: eval must return a value
> eval "return 1+1;"; // OK
2
> eval "x + 1"; // OK
3
> eval "x := x + 1; return x";
>> eval "x := x + 1; return x";
   ^
In eval expression, line 1, column 1:
>> x := x + 1; return x;
   ^
    Located in:
    >> eval "x := x + 1; return x";
       ^
User error: Imported environment value 'x' cannot be used as a local
```

Example H1E18

In this example we demonstrate how `eval` can be used to construct MAGMA objects specified with code only available at runtime.

```
> M := Random(MatrixRing(GF(2), 5));
> M;
[1 1 1 1 1]
[0 0 1 0 1]
[0 0 1 0 1]
[1 0 1 1 1]
[1 1 0 1 1]
> Write("/tmp/test", M, "Magma");
> s := Read("/tmp/test");
> s;
MatrixAlgebra(GF(2), 5) ! [ GF(2) | 1, 1, 1, 1, 1, 0, 0, 1, 0, 1, 0, 0, 1, 0, 1,
1, 0, 1, 1, 1, 1, 1, 0, 1, 1 ]
> M2 := eval s;
> assert M eq M2;
```

1.12 Comments and Continuation

`//`

One-line comment: any text following the double slash on the same line will be ignored by MAGMA.

`/* */`

Multi-line comment: any text between `/*` and `*/` is ignored by MAGMA.

`\`

Line continuation character: this symbol and the `<return>` immediately following is ignored by MAGMA. Evaluation will continue on the next line without interruption. This is useful for long input lines.

Example H1E19

```
>  // The following produces an error:
>  x := 12
>  34;
User error: bad syntax
> /* but this is correct
>       and reads two lines: */
> x := 12\
> 34;
> x;
1234
```

1.13 Timing

`Cputime()`

Return the CPU time (as a real number of default precision) used since the beginning of the MAGMA session. Note that for the MSDOS version, this is the real time used since the beginning of the session (necessarily, since process CPU time is not available).

`Cputime(t)`

Return the CPU time (as a real number of default precision) used since time t. Time starts at 0.0 at the beginning of a MAGMA session.

`Realtime()`

Return the absolute real time (as a real number of default precision), which is the number of seconds since 00:00:00 GMT, January 1, 1970. For the MSDOS version, this is the real time used since the beginning of the session.

`Realtime(t)`

Return the real time (as a real number of default precision) elapsed since time t.

`ClockCycles()`

Return the number of clock cycles of the CPU since Magma's startup. Note that this matches the real time (i.e., not process user/system time). If the operation is not supported on the current processor, zero is returned.

`time` *statement*;

Execute the statement and print the time taken when the statement is completed.

`vtime` *flag*: *statement*;

`vtime` *flag*, *n*: *statement*:

If the verbose flag *flag* (see the function `SetVerbose`) has a level greater than or equal to n, execute the statement and print the time taken when the statement is completed. If the flag has level 0 (i.e., is not turned on), still execute the statement, but do not print the timing. In the first form of this statement, where a specific level is not given, n is taken to be 1. This statement is useful in MAGMA code found in packages where one wants to print the timing of some sub-algorithm if and only if an appropriate verbose flag is turned on.

Example H1E20

The `time` command can be used to time a single statement.

```
> n := 2^109-1;
> time Factorization(n);
[<745988807, 1>, <870035986098720987332873, 1>]
Time: 0.149
```

Alternatively, we can extract the current time t and use `Cputime`. This method can be used to time the execution of several statements.

```
> m := 2^111-1;
> n := 2^113-1;
> t := Cputime();
> Factorization(m);
[<7, 1>, <223, 1>, <321679, 1>, <26295457, 1>, <319020217, 1>, <616318177, 1>]
> Factorization(n);
[<3391, 1>, <23279, 1>, <65993, 1>, <1868569, 1>, <1066818132868207, 1>]
> Cputime(t);
0.121
```

We illustrate a simple use of `vtime` with `vprint` within a function.

```
> function MyFunc(G)
>    vprint User1: "Computing order...";
>    vtime  User1: o := #G;
```

```
>    return o;
> end function;
> SetVerbose("User1", 0);
> MyFunc(Sym(4));
24
> SetVerbose("User1", 1);
> MyFunc(Sym(4));
Computing order...
Time: 0.000
24
```

1.14 Types, Category Names, and Structures

The following functions deal with *types* or *category names* and general structures. MAGMA has two levels of granularity when referring to types. In most cases, the coarser grained types (of type `Cat`) are used. Examples of these kinds of types are "polynomial rings" (`RngUPol`) and "finite fields" (`FldFin`). However, sometimes more specific typing information is sometimes useful. For instance, the algorithm used to factorize polynomials differs significantly, depending on the coefficient ring. Hence, we might wish to implement a specialized factorization algorithm polynomials over some particular ring type. Due to this need, MAGMA also supports *extended types*.

An extended type (of type `ECat`) can be thought of as a type taking a parameter. Using extended types, we can talk about "polynomial rings over the integers" (`RngUPol[RngInt]`), or "maps from the integers to the rationals" (`Map[RngInt, FldRat]`). Extended types can interact with normal types in all ways, and thus generally only need to be used when the extra level of information is required.

`Type(x)`

`Category(x)`

Given any object x, return the type (or category name) of x.

`ExtendedType(x)`

`ExtendedCategory(x)`

Given any object x, return the extended type (or category name) of x.

`ISA(T, U)`

Given types (or extended types) T and U, return whether T ISA U, i.e., whether objects of type T inherit properties of type U. For example, `ISA(RngInt, Rng)` is true, because the ring of integers $\mathbf{Z}$ is a ring.

`MakeType(S)`

Given a string S specifying a type return the actual type corresponding to S. This is useful when some intrinsic name hides the symbol which normally refers to the actual type.

`ElementType(S)`

Given any structure S, return the type of the elements of S. For example, the element type of the ring of integers **Z** is `RngIntElt` since that is the type of the integers which lie in **Z**.

`CoveringStructure(S, T)`

Given structures S and T, return a covering structure C for S and T, so that S and T both embed into C. An error results if no such covering structure exists.

`ExistsCoveringStructure(S, T)`

Given structures S and T, return whether a covering structure C for S and T exists, and if so, return such a C, so that S and T both embed into C.

Example H1E21

We demonstrate the type and structure functions.

```
> Type(3);
RngIntElt
> t := MakeType("RngIntElt");
> t;
RngIntElt
> Type(3) eq t;
true
> Z := IntegerRing();
> Type(Z);
RngInt
> ElementType(Z);
RngIntElt
> ISA(RngIntElt, RngElt);
true
> ISA(RngIntElt, GrpElt);
false
> ISA(FldRat, Fld);
true
```

The following give examples of when covering structures exist or do not exist.

```
> Q := RationalField();
> CoveringStructure(Z, Q);
Rational Field
> ExistsCoveringStructure(Z, DihedralGroup(3));
false
```

```
> ExistsCoveringStructure(Z, CyclotomicField(5));
true Cyclotomic Field of order 5 and degree 4
> ExistsCoveringStructure(CyclotomicField(3), CyclotomicField(5));
true Cyclotomic Field of order 15 and degree 8
> ExistsCoveringStructure(GF(2), GF(3));
false
> ExistsCoveringStructure(GF(2^6), GF(2, 15));
true Finite field of size 2^30
```

Our last example demonstrates the use of extended types:

```
> R<x> := PolynomialRing(Integers());
> ExtendedType(R);
RngUPol[RngInt]
> ISA(RngUPol[RngInt], RngUPol);
true
> f := x + 1;
> ExtendedType(f);
RngUPolElt[RngInt]
> ISA(RngUPolElt[RngInt], RngUPolElt);
true
```

1.15 Random Object Generation

Pseudo-random quantities are used in several MAGMA algorithms, and may also be generated explicitly by some intrinsics. Throughout the Handbook, the word 'random' is used for 'pseudo-random'.

Since V2.7 (June 2000), MAGMA contains an implementation of the *Monster* random number generator of G. Marsaglia [Mar00]. The period of this generator is $2^{29430} - 2^{27382}$ (approximately 10^{8859}), and passes all of the stringent tests in Marsaglia's *Diehard* test suite [Mar95]. Since V2.13 (July 2006), this generator is combined with the MD5 hash function to produce a higher-quality result.

Because the generator uses an internal array of machine integers, one 'seed' variable does not express the whole state, so the method for setting or getting the generator state is by way of a pair of values: (1) the seed for initializing the array, and (2) the number of steps performed since the initialization.

`SetSeed(s, c)`

`SetSeed(s)`

(Procedure.) Reset the random number generator to have initial seed s ($0 \leq s < 2^{32}$), and advance to step c ($0 \leq c < 2^{64}$). If c is not given, it is taken to be 0. Passing `-S`n to MAGMA at startup is equivalent to typing `SetSeed(`n`);` after startup.

`GetSeed()`

Return the initial seed s used to initialize the random-number generator and also the current step c. This is the complement to the `SetSeed` function.

`Random(S)`

Given a finite set or structure S, return a random element of S.

`Random(a, b)`

Return a random integer lying in the interval $[a, b]$, where $a \leq b$.

`Random(b)`

Return a random integer lying in the interval $[0, b]$, where b is a non-negative integer. Because of the good properties of the underlying Monster generator, calling `Random(1)` is a good safe way to produce a sequence of random bits.

Example H1E22

We demonstrate how one can return to a previous random state by the use of `GetSeed` and `SetSeed`. We begin with initial seed 1 at step 0 and create a multi-set of 100,000 random integers in the range [1..4].

```
> SetSeed(1);
> GetSeed();
1 0
> time S := {* Random(1, 4): i in [1..100000] *};
Time: 0.490
> S;
{* 1^^24911, 2^^24893, 3^^25139, 4^^25057 *}
```

We note the current state by `GetSeed`, and then print 10 random integers in the range [1..100].

```
> GetSeed();
1 100000
> [Random(1, 100): i in [1 .. 10]];
[ 85, 41, 43, 69, 66, 61, 63, 31, 84, 11 ]
> GetSeed();
1 100014
```

We now restart with a different initial seed 23 (again at step 0), and do the same as before, noting the different random integers produced.

```
> SetSeed(23);
> GetSeed();
23 0
> time S := {* Random(1, 4): i in [1..100000] *};
Time: 0.500
> S;
{* 1^^24962, 2^^24923, 3^^24948, 4^^25167 *}
> GetSeed();
```

```
23 100000
> [Random(1, 100): i in [1 .. 10]];
[ 3, 93, 11, 62, 6, 73, 46, 52, 100, 30 ]
> GetSeed();
23 100013
```

Finally, we restore the random generator state to what it was after the creation of the multi-set for the first seed. We then print the 10 random integers in the range [1..100], and note that they are the same as before.

```
> SetSeed(1, 100000);
> [Random(1, 100): i in [1 .. 10]];
[ 85, 41, 43, 69, 66, 61, 63, 31, 84, 11 ]
> GetSeed();
1 100014
```

1.16 Miscellaneous

`IsIntrinsic(S)`

Given a string S, return `true` if and only an intrinsic with the name S exists in the current version of MAGMA. If the result is `true`, return also the actual intrinsic.

Example H1E23

We demonstrate the function `IsIntrinsic`.

```
> IsIntrinsic("ABCD");
false
> l, a := IsIntrinsic("Abs");
> l;
true
> a(-3);
3
```

2 FUNCTIONS, PROCEDURES AND PACKAGES

Chapter 2
FUNCTIONS, PROCEDURES AND PACKAGES

2.1 Introduction

Functions are one of the most fundamental elements of the MAGMA language. The first section describes the various ways in which a standard function may be defined while the second section describes the definition of a procedure (i.e. a function which doesn't return a value). The second half of the chapter is concerned with user-defined *intrinsic* functions and procedures.

2.2 Functions and Procedures

There are two slightly different syntactic forms provided for the definition of a user function (as opposed to an intrinsic function). For the case of a function whose definition can be expressed as a single expression, an abbreviated form is provided. The syntax for the definition of user procedures is similar. Names for functions and procedures are ordinary identifiers and so obey the rules as given in Chapter 1 for other variables.

2.2.1 Functions

```
f := function(x1, ..., xn: parameters)
   statements
end function;
```

```
function f(x1, ..., xn: parameters)
   statements
end function;
```

This creates a function taking $n \geq 0$ arguments, and assigns it to f. The statements may comprise any number of valid MAGMA statements, but at least one of them must be of the form `return` *expression*`;`. The value of that expression (possibly dependent on the values of the arguments $x_1, \ldots, x_n$) will be the return value for the function; failure to return a value will lead to a run-time error when the function is invoked. (In fact, a return statement is also required for every additional 'branch' of the function that has been created using an `if ... then ... else ...` construction.)

The function may return multiple values. Usually one uses the form `return` *expression*`, ...,` *expression*`;`. If one wishes to make the last return value(s) undefined (so that the number of return values for the function is the same in all 'branches' of

the function) the underscore symbol (_) may be used. (The undefined symbol may only be used for final values of the list.) This construct allows behaviour similar to the intrinsic function `IsSquare`, say, which returns `true` and the square root of its argument if that exists, and `false` and the undefined value otherwise. See also the example below.

If there are parameters given, they must consist of a comma-separated list of clauses each of the form `identifier := value`. The identifier gives the name of the parameter, which can then be treated as a normal value argument within the statements. The value gives a default value for the parameter, and may depend on any of the arguments or preceding parameters; if, when the function is called, the parameter is not assigned a value, this default value will be assigned to the parameter. Thus parameters are always initialized. If no parameters are desired, the colon following the last argument, together with *parameters*, may be omitted.

The only difference between the two forms of function declaration lies in recursion. Functions may invoke themselves recursively since their name is part of the syntax; if the first of the above declarations is used, the identifier f cannot be used inside the definition of f (and `$$` will have to be used to refer to f itself instead), while the second form makes it possible to refer to f within its definition.

An invocation of the user function f takes the form `f(`$\mathtt{m}_1$`, ..., `$\mathtt{m}_n$`)`, where $m_1, \ldots, m_n$ are the actual arguments.

```
f := function(x1, ..., xn, ...: parameters)
   statements
end function;
```

```
function f(x1, ..., xn, ...: parameters)
   statements
end function;
```

This creates a *variadic* function, which can take n or more arguments. The semantics are identical to the standard function definition described above, with the exception of function invocation. An invocation of a variadic function f takes the form `f(`$\mathtt{y}_1$`, ..., `$\mathtt{y}_m$`)`, where $y_1, \ldots, y_m$ are the arguments to the function, and $m \geq n$. These arguments get bound to the parameters as follows: for $i < n$, the argument y_i is bound to the parameter x_i. For $i \geq n$, the arguments y_i are bound to the last parameter x_n as a list $[*y_n, \ldots, y_m*]$.

```
f := func< x1, ..., xn: parameters | expression>;
```

This is a short form of the function constructor designed for the situation in which the value of the function can be defined by a single expression. A function f is created which returns the value of the expression (possibly involving the function arguments $x_1, \ldots, x_n$). Optional parameters are permitted as in the standard function constructor.

```
f := func< x1, ..., xn, ...: parameters | expression>;
```

This is a short form of the function constructor for *variadic functions*, otherwise identical to the short form describe above.

Example H2E1

This example illustrates recursive functions.

```
> fibonacci := function(n)
>    if n le 2 then
>       return 1;
>    else
>       return $$(n-1) + $$(n-2);
>    end if;
> end function;
>
> fibonacci(10)+fibonacci(12);
199
```

```
> function Lucas(n)
>    if n eq 1 then
>       return 1;
>    elif n eq 2 then
>       return 3;
>    else
>       return Lucas(n-1)+Lucas(n-2);
>    end if;
> end function;
>
> Lucas(11);
199
```

```
> fibo := func< n | n le 2 select 1 else $$(n-1) + $$(n-2) >;
> fibo(10)+fibo(12);
199
```

Example H2E2

This example illustrates the use of parameters.

```
> f := function(x, y: Proof := true, Al := "Simple")
>    return <x, y, Proof, Al>;
> end function;
>
> f(1, 2);
<1, 2, true, Simple>
> f(1, 2: Proof := false);
<1, 2, false, Simple>
> f(1, 2: Al := "abc", Proof := false);
<1, 2, false, abc>
```

Example H2E3

This example illustrates the returning of undefined values.

```
> f := function(x)
>    if IsOdd(x) then
>        return true, x;
>    else
>        return false, _;
>    end if;
> end function;
>
> f(1);
true 1
> f(2);
false
> a, b := f(1);
> a;
true
> b;
1
> a, b := f(2);
> a;
false
>  // The following produces an error:
>  b;
>> b;
   ^
User error: Identifier 'b' has not been assigned
```

Example H2E4

This example illustrates the use of variadic functions.

```
> f := function(x, y, ...)
>     print "x: ", x;
>     print "y: ", y;
>     return [x + z : z in y];
> end function;
>
> f(1, 2);
x:  1
y:  [* 2*]
[ 3 ]
> f(1, 2, 3);
x:  1
y:  [* 2, 3*]
[ 3, 4 ]
> f(1, 2, 3, 4);
```

```
x:  1
y:  [* 2, 3, 4*]
[ 3, 4, 5 ]
```

2.2.2 Procedures

```
p := procedure(x1, ..., xn:  parameters)
   statements
end procedure;
```

```
procedure p(x1, ..., xn:  parameters)
   statements
end procedure;
```

The procedure, taking $n \geq 0$ arguments and defined by the statements is created and assigned to p. Each of the arguments may be either a variable (y_i) or a referenced variable ($\sim y_i$). Inside the procedure only referenced variables (and local variables) may be (re-)assigned to. The procedure p is invoked by typing `p(x1, ..., xn)`, where the same succession of variables and referenced variables is used (see the example below). Procedures cannot return values.

If there are parameters given, they must consist of a comma-separated list of clauses each of the form `identifier := value`. The identifier gives the name of the parameter, which can then be treated as a normal value argument within the statements. The value gives a default value for the parameter, and may depend on any of the arguments or preceding parameters; if, when the function is called, the parameter is not assigned a value, this default value will be assigned to the parameter. Thus parameters are always initialized. If no parameters are desired, the colon following the last argument, together with *parameters*, may be omitted.

As in the case of `function`, the only difference between the two declarations lies in the fact that the second version allows recursive calls to the procedure within itself using the identifier (p in this case).

```
p := procedure(x1, ..., xn, ...:  parameters)
   statements
end procedure;
```

```
procedure p(x1, ..., xn, ...:  parameters)
   statements
end procedure;
```

Creates and assigns a new *variadic* procedure to p. The use of a variadic procedure is identical to that of a variadic function, described previously.

`p := proc< x1, ..., xn: parameters | expression>;`

This is a short form of the procedure constructor designed for the situation in which the action of the procedure may be accomplished by a single statement. A procedure p is defined which calls the procedure given by the expression. This expression must be a simple procedure call (possibly involving the procedure arguments $x_1, \ldots, x_n$). Optional parameters are permitted as in the main procedure constructor.

`p := proc< x1, ..., xn, ...: parameters | expression>;`

This is a short form of the procedure constructor for variadic procedures.

Example H2E5

By way of simple example, the following (rather silly) procedure assigns a Boolean to the variable `holds`, according to whether or not the first three arguments x, y, z satisfy $x^2 + y^2 = z^2$. Note that the fourth argument is referenced, and hence can be assigned to; the first three arguments cannot be changed inside the procedure.

```
> procedure CheckPythagoras(x, y, z, ~h)
>     if x^2+y^2 eq z^2 then
>         h := true;
>     else
>         h := false;
>     end if;
> end procedure;
```

We use this to find some Pythagorean triples (in a particularly inefficient way):

```
> for x, y, z in { 1..15 } do
>     CheckPythagoras(x, y, z, ~h);
>     if h then
>       "Yes, Pythagorean triple!", x, y, z;
>     end if;
> end for;
Yes, Pythagorean triple! 3 4 5
Yes, Pythagorean triple! 4 3 5
Yes, Pythagorean triple! 5 12 13
Yes, Pythagorean triple! 6 8 10
Yes, Pythagorean triple! 8 6 10
Yes, Pythagorean triple! 9 12 15
Yes, Pythagorean triple! 12 5 13
Yes, Pythagorean triple! 12 9 15
```

2.2.3 The forward Declaration

```
forward f;
```

The forward declaration of a function or procedure f; although the assignment of a value to f is deferred, f may be called from within another function or procedure already.

The `forward` statement must occur on the 'main' level, that is, outside other functions or procedures. (See also Chapter 5.)

Example H2E6

We give an example of mutual recursion using the `forward` declaration. In this example we define a primality testing function which uses the factorization of $n-1$, where n is the number to be tested. To obtain the complete factorization we need to test whether or not factors found are prime. Thus the prime divisor function and the primality tester call each other.
First we define a simple function that proves primality of n by finding an integer of multiplicative order $n-1$ modulo n.

```
> function strongTest(primdiv, n)
>     return exists{ x : x in [2..n-1] | \
>       Modexp(x, n-1, n) eq 1 and
>       forall{ p : p in primdiv | Modexp(x, (n-1) div p, n) ne 1 }
>     };
> end function;
```

Next we define a rather crude `isPrime` function: for odd $n > 3$ it first checks for a few (3) random values of a that $a^{n-1} \equiv 1 \bmod n$, and if so, it applies the above primality prover. For that we need the not yet defined function for finding the prime divisors of an integer.

```
> forward primeDivisors;
> function isPrime(n)
>    if n in { 2, 3 } or
>       IsOdd(n) and
>       forall{ a : a in { Random(2, n-2): i in [1..3] } |
>          Modexp(a, n-1, n) eq 1 } and
>          strongTest( primeDivisors(n-1), n )
>    then
>       return true;
>    else
>       return false;
>    end if;
> end function;
```

Finally, we define a function that finds the prime divisors. Note that it calls the `isPrime` function. Note also that this function is recursive, and that it calls a function upon its definition, in the form `func< ..> ( .. )`.

```
> primeDivisors := function(n)
>    if isPrime(n) then
>       return { n };
```

```
>    else
>       return func< d | primeDivisors(d) join primeDivisors(n div d) >
>          ( rep{ d : d in [2..Isqrt(n)] | n mod d eq 0 });
>    end if;
> end function;
> isPrime(1087);
true;
```

2.3 Packages

2.3.1 Introduction

For brevity, in this section we shall use the term *function* to include both functions and procedures.

The term *intrinsic function* or *intrinsic* refers to a function whose signature is stored in the system table of signatures. In terms of their origin, there are two kinds of intrinsics, *system intrinsics* (or *standard functions*) and *user intrinsics*, but they are indistinguishable in their use. A *system intrinsic* is an intrinsic that is part of the definition of the MAGMA system, whereas a user intrinsic is an informal addition to MAGMA, created by a user of the system. While most of the standard functions in MAGMA are implemented in C, a growing number are implemented in the MAGMA language. User intrinsics are defined in the MAGMA language using a *package* mechanism (the same syntax, in fact, as that used by developers to write standard functions in the MAGMA language).

This section explains the construction of user intrinsics by means of packages. From now on, *intrinsic* will be used as an abbreviation for *user intrinsic*.

It is useful to summarize the properties possessed by an intrinsic function that are not possessed by an ordinary user-defined function. Firstly, the signature of every intrinsic function is stored in the system's table of signatures. In particular, such functions will appear when signatures are listed and printing the function's name will produce a summary of the behaviour of the function. Secondly, intrinsic functions are compiled into the MAGMA internal pseudo-code. Thus, once an intrinsic function has been debugged, it does not have to be compiled every time it is needed. If the definition of the function involves a large body of code, this can save a significant amount of time when the function definition has to be loaded.

An intrinsic function is defined in a special type of file known as a *package*. In general terms a package is a MAGMA source file that defines constants, one or more intrinsic functions, and optionally, some ordinary functions. The definition of an intrinsic function may involve MAGMA standard functions, functions imported from other packages and functions whose definition is part of the package. It should be noted that constants and functions (other than intrinsic functions) defined in a package will not be visible outside the package, unless they are explicitly imported.

The syntax for the definition of an intrinsic function is similar to that of an ordinary function except that the function header must define the function's signature together with

text summarizing the semantics of the function. As noted above, an intrinsic function definition must reside in a package file. It is necessary for MAGMA to know the location of all necessary package files. A package may be attached or detached through use of the `Attach` or `Detach` procedures. More generally, a family of packages residing in a directory tree may be specified through provision of a **spec** file which specifies the locations of a collection of packages relative to the position of the spec file. Automatic attaching of the packages in a spec file may be set by means of an environment variable (`MAGMA_SYSTEM_SPEC` for the MAGMA system packages and `MAGMA_USER_SPEC` for a users personal packages).

So that the user does not have to worry about explicitly compiling packages, MAGMA has an auto-compile facility that will automatically recompile and reload any package that has been modified since the last compilation. It does this by comparing the time stamp on the source file (as specified in an `Attach` procedure call or spec file) with the time stamp on the compiled code. To avoid the possible inefficiency caused by MAGMA checking whether the file is up to date every time an intrinsic function is referenced, the user can indicate that the package is stable by including the `freeze;` directive at the top of the package containing the function definition.

A constant value or function defined in the body of a package may be accessed in a context outside of its package through use of the `import` statement. The arguments for an intrinsic function may be checked through use of the `require` statement and its variants. These statements have the effect of generating an error message at the level of the caller rather than in the called intrinsic function.

See also the section on user-defined attributes for the `declare attributes` directive to declare user-defined attributes used by the package and related packages.

2.3.2 Intrinsics

Besides the definition of *constants* at the top, a package file just consists of *intrinsics*. There is only one way a intrinsic can be referred to (whether from within or without the package). When a package is *attached*, its intrinsics are incorporated into MAGMA. Thus intrinsics are 'global' — they affect the global MAGMA state and there is only one set of MAGMA intrinsics at any time. There are no 'local' intrinsics.

A package may contain undefined references to identifiers. These are presumed to be intrinsics from other packages which will be attached subsequent to the loading of this package.

```
intrinsic name(arg-list [, ...])  [ -> ret-list ]
{comment-text}
    statements
end intrinsic;
```

The syntax of a intrinsic declaration is as above, where *name* is the name of the intrinsic (any identifier; use single quotes for non-alphanumeric names like '+'); *arg-list* is the argument list (optionally including parameters preceded by a colon); optionally there is an arrow and return type list *ret-list*; the comment text is any text within the braces (use \} to get a right brace within the text, and use " to repeat the comment from the immediately preceding intrinsic); and *statements* is a list of

statements making up the body. *arg-list* is a list of comma-separated arguments of the form

name::*type*
∼*name*::*type*
∼*name*

where *name* is the name of the argument (any identifier), and *type* designates the type, which can be either a simple category name, an extended type, or one of the following:

`.`	Any type
`[ ]`	Sequence type
`{ }`	Set type
`{[ ]}`	Set or Sequence type
`{@ @}`	Iset type
`{* *}`	Multiset type
`< >`	Tuple type

or a *composite type*:

`[`*type*`]`	Sequences over *type*
{*type*}	Sets over *type*
{`[`*type*`]`}	Sets or sequences over *type*
{@*type*@}	Indexed sets over *type*
{**type***}	Multisets over *type*

where *type* is either a simple or extended type. The reference form *type* ∼*name* requires that the input argument must be initialized to an object of that type. The reference form ∼*name* is a plain reference argument — it need not be initialized. Parameters may also be specified—these are just as in functions and procedures (preceded by a colon). If *arg-list* is followed by "..." then the intrinsic is `variadic`, with semantics similar to that of a variadic function, described previously.

ret-list is a list of comma-separated simple types. If there is an arrow and the return list, the intrinsic is assumed to be functional; otherwise it is assumed to be procedural.

The body of *statements* should return the correct number and types of arguments if the intrinsic is functional, while the body should return nothing if the intrinsic is procedural.

Example H2E7

A functional intrinsic for greatest common divisors taking two integers and returning another:

```
intrinsic myGCD(x::RngIntElt, y::RngIntElt) -> RngIntElt
{ Return the GCD of x and y}
   return ...;
```

```
end intrinsic;
```

A procedural intrinsic for Append taking a reference to a sequence Q and any object then modifying Q:

```
intrinsic Append(~ Q::SeqEnum, . x)
{ Append x to Q }
    ...;
end intrinsic;
```

A functional intrinsic taking a sequence of sets as arguments 2 and 3:

```
intrinsic IsConjugate(G::GrpPerm, R::[ { } ], S::[ { } ]) -> BoolElt
{ True iff partitions R and S of the support of G are conjugate in G }
    return ...;
end intrinsic;
```

2.3.3 Resolving Calls to Intrinsics

It is often the case that many intrinsics share the same name. For instance, the intrinsic `Factorization` has many implementations for various object types. We will call such intrinsics *overloaded intrinsics*, or refer to each of the participating intrinsics as an *overload*. When the user calls such an overloaded intrinsic, MAGMA must choose the "best possible" overload.

MAGMA's overload resolution process is quite simple. Suppose the user is calling an intrinsic of arity r, with a list of parameters $\langle p_1, \ldots, p_r \rangle$. Let the tuple of the types of these parameters be $\langle t_1, \ldots, t_r \rangle$, and let S be the set of all relevant overloads (that is, overloads with the appropriate name and of arity r). We will represent overloads as r-tuples of types.

To pick the "best possible" overload, for each parameter $p \in \{p_1, \ldots, p_r\}$, MAGMA finds the set $S_i \subseteq S$ of participating intrinsics which are the best matches for that parameter. More specifically, an intrinsic $s = \langle u_1, \ldots, u_r \rangle$ is included in S_i if and only if t_i is a u_i, and no participating intrinsic $s' = \langle v_1, \ldots, v_r \rangle$ exists such that t_i is a v_i and v_i is a u_i. Once the sets S_i are computed, MAGMA finds their intersection. If this intersection is empty, then there is no match. If this intersection has cardinality greater than one, then the match is ambiguous. Otherwise, MAGMA calls the overload thus obtained.

An example at this point will make the above process clearer:

Example H2E8

We demonstrate MAGMA's lookup mechanism with the following example. Suppose we have the following overloaded intrinsics:

```
intrinsic overloaded(x::RngUPolElt, y::RngUPolElt) -> RngIntElt
{ Overload 1 }
   return 1;
end intrinsic;

intrinsic overloaded(x::RngUPolElt[RngInt], y::RngUPolElt) -> RngIntElt
```

```
{ Overload 2 }
   return 2;
end intrinsic;

intrinsic overloaded(x::RngUPolElt, y::RngUPolElt[RngInt]) -> RngIntElt
{ Overload 3 }
   return 3;
end intrinsic;

intrinsic overloaded(x::RngUPolElt[RngInt], y::RngUPolElt[RngInt]) -> RngIntElt
{ Overload 4 }
   return 4;
end intrinsic;
```

The following MAGMA session illustrates how the lookup mechanism operates for the intrinsic `overloaded`:

```
> R1<x> := PolynomialRing(Integers());
> R2<y> := PolynomialRing(Rationals());
> f1 := x + 1;
> f2 := y + 1;
> overloaded(f2, f2);
1
> overloaded(f1, f2);
2
> overloaded(f2, f1);
3
> overloaded(f1, f1);
4
```

2.3.4 Attaching and Detaching Package Files

The procedures `Attach` and `Detach` are provided to attach or detach package files. Once a file is attached, all intrinsics within it are included in MAGMA. If the file is modified, it is automatically recompiled just after the user hits return and just before the next statement is executed. So there is no need to re-attach the file (or 're-load' it). If the recompilation of a package file fails (syntax errors, etc.), all of the intrinsics of the package file are removed from the MAGMA session and none of the intrinsics of the package file are included again until the package file is successfully recompiled. When errors occur during compilation of a package, the appropriate messages are printed with the string '[PC]' at the beginning of the line, indicating that the errors are detected by the MAGMA package compiler.

If a package file contains the single directive `freeze;` at the top then the package file becomes `frozen` — it will not be automatically recompiled after each statement is entered into MAGMA. A frozen package is recompiled if need be, however, when it is attached (thus allowing fixes to be updated) — the main point of freezing a package which is 'stable' is to stop MAGMA looking at it between every statement entered into MAGMA interactively.

When a package file is complete and tested, it is usually installed in a spec file so it is automatically attached when the spec file is attached. Thus `Attach` and `Detach` are generally only used when one is developing a single package file containing new intrinsics.

`Attach(F)`

Procedure to attach the package file F.

`Detach(F)`

Procedure to detach the package file F.

`freeze;`

Freeze the package file in which this appears at the top.

2.3.5 Related Files

There are two files related to any package source file `file.m`:

`file.sig`	sig file containing signature information;
`file.lck`	lock file.

The lock file exists while a package file is being compiled. If someone else tries to compile the file, it will just sit there till the lock file disappears. In various circumstances (system down, MAGMA crash) `.lck` files may be left around; this will mean that the next time MAGMA attempts to compile the associated source file it will just sit there indefinitely waiting for the `.lck` file to disappear. In this case the user should search for `.lck` files that should be removed.

2.3.6 Importing Constants

`import "`*filename*`": `*ident_list*`;`

This is the general form of the import statement, where "*filename*" is a string and *ident_list* is a list of identifiers.

The import statement is a normal statement and can in fact be used anywhere in MAGMA, but it is recommended that it only be used to import common constants and functions/procedures shared between a collection of package files. It has the following semantics: for each identifier I in the list *ident_list*, that identifier is declared just like a normal identifier within MAGMA. Within the package file referenced by *filename*, there should be an assignment of the same identifier I to some object O. When the identifier I is then used as an expression after the import statement, the value yielded is the object O.

The file that is named in the import statement must already have been attached by the time the identifiers are needed. The best way to achieve this in practice is to place this file in the spec file, along with the package files, so that all the files can be attached together.

Thus the only way objects (whether they be normal objects, procedures or functions) assigned within packages can be referenced from outside the package is by an explicit import with the 'import' statement.

Example H2E9

Suppose we have a spec file that lists several package files. Included in the spec file is the file `defs.m` containing:

```
MY_LIMIT := 10000;
 function fred(x)
 return 1/x;
end function;
```

Then other package files (in the same directory) listed in the spec file which wish to use these definitions would have the line

```
import "defs.m": MY_LIMIT, fred;
```

at the top. These could then be used inside any intrinsics of such package files. (If the package files are not in the same directory, the pathname of `defs.m` will have to be given appropriately in the import statement.)

2.3.7 Argument Checking

Using 'require' etc. one can do argument checking easily within intrinsics. If a necessary condition on the argument fails to hold, then the relevant error message is printed and the error pointer refers to the caller of the intrinsic. This feature allows user-defined intrinsics to treat errors in actual arguments in exactly the same way as they are treated by the MAGMA standard functions.

`require` *condition*: *print_args*;

The expression *condition* may be any yielding a Boolean value. If the value is false, then *print_args* is printed and execution aborts with the error pointer pointing to the caller. The print arguments *print_args* can consist of any expressions (depending on arguments or variables already defined in the intrinsic).

`requirerange v, L, U;`

The argument variable v must be the name of one of the argument variables (including parameters) and must be of integer type. L and U may be any expressions each yielding an integer value. If v is not in the range $[L, \ldots, U]$, then an appropriate error message is printed and execution aborts with the error pointer pointing to the caller.

`requirege v, L;`

The argument variable v must be the name of one of the argument variables (including parameters) and must be of integer type. L must yield an integer value. If v is not greater than or equal to L, then an appropriate error message is printed and execution aborts with the error pointer pointing to the caller.

Example H2E10

A trivial version of `Binomial(n, k)` which checks that $n \geq 0$ and $0 \leq k \leq n$.

```
intrinsic Binomial(n::RngIntElt, k::RngIntElt) -> RngIntElt
{ Return n choose k }
    requirege n, 0;
    requirerange k, 0, n;
    return Factorial(n) div Factorial(n - k) div Factorial(k);
end intrinsic;
```

A simple function to find a random p-element of a group G.

```
intrinsic pElement(G::Grp, p::RngIntElt) -> GrpElt
{ Return p-element of group G }
   require IsPrime(p): "Argument 2 is not prime";
   x := random{x: x in G | Order(x) mod p eq 0};
   return x^(Order(x) div p);
end intrinsic;
```

2.3.8 Package Specification Files

A *spec file* (short for 'specification file') lists a complete tree of MAGMA package files. This makes it easy to collect many package files together and attach them simultaneously.

The specification file consists of a list of tokens which are just space-separated words. The tokens describe a list of package files and directories containing other packages. The list is described as follows. The files that are to be attached in the directory indicated by S are listed enclosed in { and } characters. A directory may be listed there as well, if it is followed by a list of files from that directory (enclosed in braces again); arbitrary nesting is allowed this way. A filename of the form `+`*spec* is interpreted as another specification file whose contents will be recursively attached when `AttachSpec` (below) is called. The files are taken relative to the directory that contains the specification file. See also the example below.

`AttachSpec(S)`

If S is a string indicating the name of a spec file, this command attaches all the files listed in S. The format of the spec file is given above.

`DetachSpec(S)`

If S is a string indicating the name of a spec file, this command detaches all the files listed in S. The format of the spec file is given above.

Example H2E11

Suppose we have a spec file /home/user/spec consisting of the following lines:

```
{
   Group
   {
      chiefseries.m
      socle.m
   }
   Ring
   {
      funcs.m
      Field
      {
            galois.m
      }
   }
}
```

Then there should be the files

```
/home/user/spec/Group/chiefseries.m
/home/user/spec/Group/socle.m
/home/user/spec/Ring/funcs.m
/home/user/spec/Ring/Field/galois.m
```

and if one typed within MAGMA

```
AttachSpec("/home/user/spec");
```

then each of the above files would be attached. If instead of the filename `galois.m` we have `+galspec`, then the file `/home/user/spec/Ring/Field/galspec` would be a specification file itself whose contents would be recursively attached.

2.3.9 User Startup Specification Files

The user may specify a list of spec files to be attached automatically when MAGMA starts up. This is done by setting the environment variable `MAGMA_USER_SPEC` to a colon separated list of spec files.

Example H2E12

One could have

```
setenv MAGMA_USER_SPEC "$HOME/Magma/spec:/home/friend/Magma/spec"
```

in one's `.cshrc` . Then when MAGMA starts up, it will attach all packages listed in the spec files `$HOME/Magma/spec` and `/home/friend/Magma/spec`.

2.4 Attributes

This section is placed beside the section on packages because the use of attributes is most common within packages.

For any structure within MAGMA, it is possible to have *attributes* associated with it. These are simply values stored within the structure and are referred to by named fields in exactly the same manner as MAGMA records.

There are two kinds of structure attributes: predefined system attributes and user-defined attributes. Both kinds are discussed in the following subsections. A description of how attributes are accessed and assigned then follows.

2.4.1 Predefined System Attributes

The valid fields of predefined system attributes are automatically defined at the startup of Magma. These fields now replace the old method of using the procedure `AssertAttribute` and the function `HasAttribute` (which will still work for some time to preserve backwards compatibility). For each name which is a valid first argument for `AssertAttribute` and `HasAttribute`, that name is a valid attribute field for structures of the appropriate category. Thus the backquote method for accessing attributes described in detail below should now be used instead of the old method. For such attributes, the code:

```
> S`Name := x;
```

is completely equivalent to the code:

```
> AssertAttribute(S, "Name", x);
```

(note that the function `AssertAttribute` takes a string for its second argument so the name must be enclosed in double quotes). Similarly, the code:

```
> if assigned S`Name then
>     x := S`Name;
>     // do something with x...
> end if;
```

is completely equivalent to the code:

```
> l, x := HasAttribute(S, "Name");
> if l then
>     // do something with x...
> end if;
```

(note again that the function `HasAttribute` takes a string for its second argument so the name must be enclosed in double quotes).

Note also that if a system attribute is not set, referring to it in an expression (using the backquote operator) will *not* trigger the calculation of it (while the corresponding intrinsic function will if it exists); rather an error will ensue. Use the `assigned` operator to test whether an attribute is actually set.

2.4.2 User-defined Attributes

For any category C, the user can stipulate valid attribute fields for structures of C. After this is done, any structure of category C may have attributes assigned to it and accessed from it.

There are two ways of adding new valid attributes to a category C: by the procedure `AddAttribute` or by the `declare attributes` package declaration. The former should be used outside of packages (e.g. in interactive usage), while the latter must be used within packages to declare attribute fields used by the package and related packages.

`AddAttribute(C, F)`

(Procedure.) Given a category C, and a string F, append the field name F to the list of valid attribute field names for structures belonging to category C. This procedure should not be used within packages but during interactive use. Previous fields for C are still valid – this just adds another valid one.

`declare attributes` C`:` $F_1, \ldots, F_n$`;`

Given a category C, and a comma-separated list of identifiers $F_1, \ldots, F_n$ append the field names specified by the identifiers to the list of valid attribute field names for structures belonging to category C. This declaration directive must be used within (and only within) packages to declare attribute fields used by the package and packages related to it which use the same fields. It is *not* a statement but a directive which is stored with the other information of the package when it is compiled and subsequently attached – *not* when any code is actually executed.

2.4.3 Accessing Attributes

Attributes of structures are accessed in the same way that records are: using the backquote (‘) operator. The double backquote operator (‘‘) can also be used if the field name is a string.

`S‘`*fieldname*

`S‘‘N`

Given a structure S and a field name, return the current value for the given field in S. If the value is not assigned, an error results. The field name must be valid for the category of S. In the `S‘‘N` form, N is a string giving the field name.

`assigned S‘`*fieldname*

`assigned S‘‘N`

Given a structure S and a field name, return whether the given field in S currently has a value. The field name must be valid for the category of S. In the `S‘‘N` form, N is a string giving the field name.

`S‘`*fieldname* `:=` *expression*`;`

`S‘‘N :=` *expression*`;`

Given a structure S and a field name, assign the given field of S to be the value of the expression (any old value is first discarded). The field name must be valid for the category of S. In the `S‘‘N` form, N is a string giving the field name.

`delete S‘`*fieldname*`;`

`delete S‘‘N;`

Given a structure S and a field name, delete the given field of S. The field then becomes unassigned in S. The field name must be valid for the category of S and the field must be currently assigned in S. This statement is not allowed for predefined system attributes. In the `S‘‘N` form, N is a string giving the field name.

`GetAttributes(C)`

Given a category C, return the valid attribute field names for structures belonging to category C as a sorted sequence of strings.

`ListAttributes(C)`

(Procedure.) Given a category C, list the valid attribute field names for structures belonging to category C.

2.5 User-defined Verbose Flags

Verbose flags may be defined by users within packages.

`declare verbose` F`,` m`;`

Given a verbose flag name F (without quotes), and a literal integer m, create the verbose flag F, with the maximal allowable level for the flag set to m. This directive may only be used within package files.

2.5.1 Examples

In this subsection we give examples which illustrate all of the above features.

Example H2E13

We illustrate how the predefined system attributes may be used. Note that the valid arguments for `AssertAttribute` and `HasAttribute` documented elsewhere now also work as system attributes so see the documentation for these functions for details as to the valid system attribute field names.

```
> // Create group G.
> G := PSL(3, 2);
> // Check whether order known.
> assigned G‘Order;
false
>  // Attempt to access order -- error since not assigned.
>  G‘Order;
```

```
>> G‘Order;
    ^
Runtime error in ‘: Attribute ’Order’ for this structure
is valid but not assigned
> // Force computation of order by intrinsic Order.
> Order(G);
168
> // Check Order field again.
> assigned G‘Order;
true
> G‘Order;
168
> G‘‘"Order"; // String form for field
168
> o := "Order";
> G‘‘o;
168
> // Create code C and set its minimum weight.
> C := QRCode(GF(2), 31);
> C‘MinimumWeight := 7;
> C;
[31, 16, 7] Quadratic Residue code over GF(2)
...
```

Example H2E14

We illustrate how user attributes may be defined and used in an interactive session. This situation would arise rarely – more commonly, attributes would be used within packages.

```
> // Add attribute field MyStuff for matrix groups.
> AddAttribute(GrpMat, "MyStuff");
> // Create group G.
> G := GL(2, 3);
> // Try illegal field.
>  G‘silly;
>> G‘silly;
    ^
Runtime error in ‘: Invalid attribute ’silly’ for this structure
> // Try legal but unassigned field.
>  G‘MyStuff;
>> G‘MyStuff;
    ^
Runtime error in ‘: Attribute ’MyStuff’ for this structure is valid but not
assigned
> // Assign field and notice value.
> G‘MyStuff := [1, 2];
> G‘MyStuff;
```

```
[ 1, 2 ]
```

Example H2E15

We illustrate how user attributes may be used in packages. This is the most common usage of such attributes. We first give some (rather naive) MAGMA code to compute and store a permutation representation of a matrix group. Suppose the following code is stored in the file `permrep.m`.

```
declare attributes GrpMat: PermRep, PermRepMap;
intrinsic PermutationRepresentation(G::GrpMat) -> GrpPerm
{A permutation group representation P of G, with homomorphism f: G -> P};
    // Only compute rep if not already stored.
    if not assigned G`PermRep then
        G`PermRepMap, G`PermRep := CosetAction(G, sub<G|>);
    end if;
    return G`PermRep, G`PermRepMap;
end intrinsic;
```

Note that the information stored will be reused in subsequent calls of the intrinsic. Then the package can be attached within a MAGMA session and the intrinsic `PermutationRepresentation` called like in the following code (assumed to be run in the same directory).

```
>  Attach("permrep.m");
>  G := GL(2, 2);
>  P, f := PermutationRepresentation(G);
>  P;
Permutation group P acting on a set of cardinality 6
    (1, 2)(3, 5)(4, 6)
    (1, 3)(2, 4)(5, 6)
>  f;
Mapping from: GrpMat: G to GrpPerm: P
```

Suppose the following line were also in the package file:

```
declare verbose MyAlgorithm, 3;
```

Then there would be a new verbose flag `MyAlgorithm` for use anywhere within MAGMA, with the maximum 3 for the level.

2.6 User-Defined Types

Since MAGMA V2.19, types may be defined by users within packages. This facility allows the user to declare new type names and create objects with such types and then supply some basic primitives and intrinsic functions for such objects.

The new types are known as *user-defined types*. The way these are typically used is that after declaring such a type T, the user supplies package intrinsics to: (1) create objects of type T and set relevant attributes to define the objects; (2) perform some basic primitives which are common to all objects in MAGMA; (3) perform non-trivial computations on objects of type T.

2.6.1 Declaring User-Defined Types

The following declarations are used to declare user-defined types. They **may only be placed in package files**, i.e., files that are included either by using `Attach` or a spec file (see above). Declarations may appear in any package file and at any place within the file at the top level (not in a function, etc.). In particular, it is not required that the declaration of a type appears before package code which refers to the type (as long as the type is declared before running the code). Examples below will illustrate how the basic declarations are used.

`declare type` T`;`

Declare the given type name T (without quotes) to be a user-defined type.

`declare type` $T : P_1, \ldots, P_n$`;`

Declare the given type name T (without quotes) to be a user-defined type, and also declare T to inherit from the user types $P_1, \ldots, P_n$ (which must be declared separately). As a result, `ISA(`T, P_i`)` will be true for each i and when intrinsic signatures are scanned at a function call, an object of type T will match an argument of a signature with type P_i for any i.

NB: currently one may not inherit from existing MAGMA internal types or virtual types (categories). It is hoped that this restriction will be removed in the future.

`declare type` $T[E]$`;`

Declare the given type names T and E (both without quotes) to be user-defined types. This form also specifies that E is the *element type* corresponding to T; i.e., if an object x has an element of type T for its parent, then x must have type E. This relationship is needed for the construction of sets and sequences which have objects of type T as a universe. The type E may also be declared separately, but this is not necessary.

`declare type` $T[E] : P_1, \ldots, P_n$`;`

This is a combination of the previous kinds two declarations: T and E are declared as user-defined types while E is also declared to be the element type of T, and T is declared to inherit from user-defined types $P_1, \ldots, P_n$.

2.6.2 Creating an Object

`New(T)`

Create an empty object of type T, where T is a user-defined type. Typically, after setting X to the result of this function, the user should set attributes in X to define relevant properties of the object which are characteristic of objects of type T.

2.6.3 Special Intrinsics Provided by the User

Let T be a user-defined type. Besides the declaration of T, the following special intrinsics are mostly required to be defined for type T (the requirements are specified for each kind of intrinsic). These intrinsics allow the internal MAGMA functions to perform some fundamental operations on objects of type T. Note that the special intrinsics need not be in one file or in the same file as the declaration.

```
intrinsic Print(X::T)
{Print X}
    // Code: Print X with no new line, via printf
end intrinsic;

intrinsic Print(X::T, L::MonStgElt)
{Print X at level L}
    // Code: Print X at level L with no new line, via printf
end intrinsic;
```

Exactly one of these intrinsics must be provided by the user for type T. Each is a procedure rather than a function (i.e., nothing is returned), and should contain one or more print statements. The procedure is called automatically by MAGMA whenever the object X of type T is to be printed. A new line should *not* occur at the end of the last (or only) line of printing: one should use `printf` (see examples below).

When the second form of the intrinsic is provided, it allows X to be printed differently depending on the print level L, which is a string equal to one of `"Default", "Minimal", "Maximal", "Magma"`.

```
intrinsic Parent(X::T) -> .
{Parent of X}
    // Code: Return the parent of X
end intrinsic;
```

This intrinsic is only needed when T is an element type, so objects of type T have parents. It should be a user-provided package function, which takes an object X of type T (user-defined), and returns the parent of X, assuming it has one. In such a case, typically the attribute `Parent` will be defined for X and so `X`Parent` should simply be returned.

```
intrinsic 'in'(e::., X::T) -> BoolElt
{Return whether e is in X}
    // Code: Return whether e is in X
end intrinsic;
```

This intrinsic is only needed when objects of type T (user-defined) have elements, and should be a user-provided package function, which takes any object e and an object X of type T (user-defined), and returns whether e is an element of X.

```
intrinsic IsCoercible(X::T, y::.) -> BoolElt, .
{Return whether y is coercible into X and the result if so}
    // Code: do tests on the type of y to see whether coercible
    // On failure, do:
    //    return false, "Illegal coercion"; // Or more particular message
    // Assumed coercible now; set x to result of coercion into X
    return true, x;
end intrinsic;
```

Assuming that objects of type T (user-defined) have elements (and so coercion into such objects makes sense), this must be a user-provided package function, which takes an object X of type T (user-defined) and an object Y of any type. If Y is coercible into X, the function should return `true` and the result of the coercion (whose parent should be X). Otherwise, the function should return `false` and a string giving the reason for failure. If this package intrinsic is provided, then the coercion operation `X!y` will also automatically work for an object X of type T (i.e., the internal coercion code in MAGMA will automatically call this function).

2.6.4 Examples

Some basic examples illustrating the general use of user-defined types are given here. Non-trivial examples can also be found in much of the standard MAGMA package code (one can search for `"declare type"` in the package `.m` files to see several typical uses).

Example H2E16

In this first simple example, we create a user-defined type `MyRat` which is used for a primitive representation of rational numbers. Of course, a serious version would keep the numerators & denominators always reduced, but for simplicity we skip such details. We define the operations `+` and `*` here; one would typically add other operations like `-`, `eq` and `IsZero`, etc.

```
declare type MyRat;
declare attributes MyRat: Numer, Denom;

intrinsic MyRational(n::RngIntElt, d::RngIntElt) -> MyRat
{Create n/d}
```

```
    require d ne 0: "Denominator must be non-zero";
    r := New(MyRat);
    r`Numer := n;
    r`Denom := d;
    return r;
end intrinsic;

intrinsic Print(r::MyRat)
{Print r}
    n := r`Numer;
    d := r`Denom;
    g := GCD(n, d);
    if d lt 0 then g := -g; end if;
    printf "%o/%o", n div g, d div g; // NOTE: no newline!
end intrinsic;

intrinsic '+'(r::MyRat, s::MyRat) -> MyRat
{Return r + s}
    rn := r`Numer;
    rd := r`Denom;
    sn := s`Numer;
    sd := s`Denom;
    return MyRational(rn*sd + sn*rd, rd*sd);
end intrinsic;

intrinsic '*'(r::MyRat, s::MyRat) -> MyRat
{Return r * s}
    rn := r`Numer;
    rd := r`Denom;
    sn := s`Numer;
    sd := s`Denom;
    return MyRational(rn*sn, rd*sd);
end intrinsic;
```

Assuming the above code is placed in a file `MyRat.m`, one could attach it in MAGMA and then do some simple operations, as follows.

```
> Attach("myrat.m");
> r := MyRational(3, -9);
> r;
-1/3
> s := MyRational(4, 7);
> s;
> r+s;
5/21
> r*s;
-4/21
```

Example H2E17

In this example, we define a type `DirProd` for direct products of rings, and a corresponding element type `DirProdElt` for their elements. Objects of type `DirProd` contain a tuple `Rings` with the rings making up the direct product, while objects of type `DirProdElt` contain a tuple `Element` with the elements of the corresponding rings, and also a reference to the parent direct product object.

```
/* Declare types and attributes */

// Note that we declare DirProdElt as element type of DirProd:
declare type DirProd[DirProdElt];
declare attributes DirProd: Rings;
declare attributes DirProdElt: Elements, Parent;

/* Special intrinsics for DirProd */

intrinsic DirectProduct(Rings::Tup) -> DirProd
{Create the direct product of given rings (a tuple)}
    require forall{R: R in Rings | ISA(Type(R), Rng)}:
        "Tuple entries are not all rings";
    D := New(DirProd);
    D`Rings := Rings;
    return D;
end intrinsic;

intrinsic Print(D::DirProd)
{Print D}
    Rings := D`Rings;
    printf "Direct product of %o", Rings; // NOTE: no newline!
end intrinsic;

function CreateElement(D, Elements)
    // Create DirProdElt with parent D and given Elements
    x := New(DirProdElt);
    x`Elements := Elements;
    x`Parent := D;
    return x;
end function;

intrinsic IsCoercible(D::DirProd, x::.) -> BoolElt, .
{Return whether x is coercible into D and the result if so}
    Rings := D`Rings;
    n := #Rings;
    if Type(x) ne Tup then
        return false, "Coercion RHS must be a tuple";
    end if;
    if #x ne n then
        return false, "Wrong length of tuple for coercion";
    end if;
```

```
    Elements := <>;
    for i := 1 to n do
        l, t := IsCoercible(Rings[i], x[i]);
        if not l then
            return false, Sprintf("Tuple entry %o not coercible", i);
        end if;
        Append(~Elements, t);
    end for;
    y := CreateElement(D, Elements);
    return true, y;
end intrinsic;

/* Special intrinsics for DirProdElt */

intrinsic Print(x::DirProdElt)
{Print x}
    printf "%o", x`Elements; // NOTE: no newline!
end intrinsic;

intrinsic Parent(x::DirProdElt) -> DirProd
{Parent of x}
    return x`Parent;
end intrinsic;

intrinsic '+'(x::DirProdElt, y::DirProdElt) -> DirProdElt
{Return x + y}
    D := Parent(x);
    require D cmpeq Parent(y): "Incompatible arguments";
    Ex := x`Elements;
    Ey := y`Elements;
    return CreateElement(D, <Ex[i] + Ey[i]: i in [1 .. #Ex]>);
end intrinsic;

intrinsic '*'(x::DirProdElt, y::DirProdElt) -> DirProdElt
{Return x * y}
    D := Parent(x);
    require D cmpeq Parent(y): "Incompatible arguments";
    Ex := x`Elements;
    Ey := y`Elements;
    return CreateElement(D, <Ex[i] * Ey[i]: i in [1 .. #Ex]>);
end intrinsic;
```

A sample MAGMA session using the above package is as follows. We create elements x, y of a direct product D and do simple operations on x, y. One would of course add other intrinsic functions for basic operations on the elements.

```
> Attach("DirProd.m");
> Z := IntegerRing();
```

```
> Q := RationalField();
> F8<a> := GF(2^3);
> F9<b> := GF(3^2);
> D := DirectProduct(<Z, Q, F8, F9>);
> x := D!<1, 2/3, a, b>;
> y := D!<2, 3/4, a+1, b+1>;
> x;
<1, 2/3, a, b>
> Parent(x);
Direct product of <Integer Ring, Rational Field, Finite field of
size 2^3, Finite field of size 3^2>
> y;
<2, 3/4, a^3, b^2>
> x+y;
<3, 17/12, 1, b^3>
> x*y;
<2, 1/2, a^4, b^3>
> D!x;
<1, 2/3, a, b>
> S := [x, y]; S;
[
    <1, 2/3, a, b>,
    <2, 3/4, a^3, b^2>
]
>
> &+S;
<3, 17/12, 1, b^3>
```

3 INPUT AND OUTPUT

Chapter 3
INPUT AND OUTPUT

3.1 Introduction

This chapter is concerned with the various facilities provided for communication between MAGMA and its environment. The first section describes character strings and their operations. Following this, the various forms of the `print`-statement are presented. Next the file type is introduced and its operations summarized. The chapter concludes with a section listing system calls. These include facilities that allow the user to execute an operating system command from within MAGMA or to run an external process.

3.2 Character Strings

Strings of characters play a central role in input/output so that the operations provided for strings to some extent reflect this. However, if one wishes, a more general set of operations are available if the string is first converted into a sequence. We will give some examples of this below.

MAGMA provides two kinds of strings: normal character strings, and *binary strings*. Character strings are an inappropriate choice for manipulating data that includes non-printable characters. If this is required, a better choice is the binary string type. This type is similar semantically to a sequence of integers, in which each character is represented by its ASCII value between 0 and 255. The difference between a binary string and a sequence of integers is that a binary string is stored internally as an array of bytes, which is a more space-efficient representation.

3.2.1 Representation of Strings

Character strings may consist of all ordinary characters appearing on your keyboard, including the blank (space). Two symbols have a special meaning: the double-quote " and the backslash \. The double-quote is used to delimit a character string, and hence cannot be used inside a string; to be able to use a double-quote in strings the backslash is designed to be an escape character and is used to indicate that the next symbol has to be taken literally; thus, by using \" inside a string one indicates that the symbol " has to be taken literally and is not to be interpreted as the end-of-string delimiter. Thus:

```
> "\"Print this line in quotes\"";
"Print this line in quotes"
```

To obtain a literal backslash, one simply types two backslashes; for characters other than double-quotes and backslash it does not make a difference when a backslash precedes them

inside a string, with the exception of `n`, `r` and `t`. Any occurrence of `\n` or `\r` inside a string is converted into a `<new-line>` while `\t` is converted into a `<tab>`. For example:

```
> "The first line,\nthe second line, and then\ran\tindented line";
The first line,
the second line, and then
an          indented line
```

Note that a backslash followed by a return allows one to conveniently continue the current construction on the next line; so `\<return>` inside a string will be ignored, except that input will continue on a new line on your screen.

Binary strings, on the hand, can consist of any character, whether printable or non-printable. Binary strings cannot be constructed using literals, but must be constructed either from a character string, or during a read operation from a file.

3.2.2 Creation of Strings

`"abc"`

Create a string from a succession of keyboard characters (a, b, c) enclosed in double quotes `" "`.

`BinaryString(s)`

`BString(s)`

Create a binary string from the character string s.

`s cat t`

`s * t`

Concatenate the strings s and t.

`s cat:= t`

`s *:= t`

Modification-concatenation of the string s with t: concatenate s and t and put the result in s.

`&cat s`

`&* s`

Given an enumerated sequence s of strings, return the concatenation of these strings.

`s ^ n`

Form the n-fold concatenation of the string s, for $n \geq 0$. If $n = 0$ this is the empty string, if $n = 1$ it equals s, etc.

`s[i]`

Returns the substring of s consisting of the i-th character.

`s[i]`

Returns the numeric value representing the i-th character of s.

`ElementToSequence(s)`
`Eltseq(s)`

Returns the sequence of characters of s (as length 1 strings).

`ElementToSequence(s)`
`Eltseq(s)`

Returns the sequence of numeric values representing the characters of s.

`Substring(s, n, k)`

Return the substring of s of length k starting at position n.

3.2.3 Integer-Valued Functions

`#s`

The length of the string s.

`Index(s, t)`
`Position(s, t)`

This function returns the position (an integer p with $0 < p \leq \#s$) in the string s where the beginning of a contiguous substring t occurs. It returns 0 if t is not a substring of s. (If t is the empty string, position 1 will always be returned, even if s is empty as well.)

3.2.4 Character Conversion

To perform more sophisticated operations, one may convert the string into a sequence and use the extensive facilities for sequences described in the next part of this manual; see the examples at the end of this chapter for details.

`StringToCode(s)`

Returns the code number of the first character of string s. This code depends on the computer system that is used; it is ASCII on most UNIX machines.

`CodeToString(n)`

Returns a character (string of length 1) corresponding to the code number n, where the code is system dependent (see previous entry).

`StringToInteger(s)`

Returns the integer corresponding to the string of decimal digits s. All non-space characters in the string s must be digits $(0, 1, \ldots, 9)$, except the first character, which is also allowed to be + or −. An error results if any other combination of characters occurs. Leading zeros are omitted.

`StringToInteger(s, b)`

Returns the integer corresponding to the string of digits s, all assumed to be written in base b. All non-space characters in the string s must be digits less than b (if b is greater than 10, 'A' is used for 10, 'B' for 11, etc.), except the first character, which is also allowed to be + or −. An error results if any other combination of characters occurs.

`StringToIntegerSequence(s)`

Returns the sequence of integers corresponding to the string s of space-separated decimal numbers. All non-space characters in the string s must be digits $(0, 1, \ldots, 9)$, except the first character after each space, which is also allowed to be + or −. An error results if any other combination of characters occurs. Leading zeros are omitted. Each number can begin with a sign (+ or −) without a space.

`IntegerToString(n)`

Convert the integer n into a string of decimal digits; if n is negative the first character of the string will be −. (Note that leading zeros and a + sign are ignored when MAGMA builds an integer, so the resulting string will never begin with + or 0 characters.)

`IntegerToString(n, b)`

Convert the integer n into a string of digits with the given base (which must be in the range $[2 \ldots 36]$); if n is negative the first character of the string will be −.

3.2.5 Boolean Functions

`s eq t`

Returns `true` if and only if the strings s and t are identical. Note that blanks are significant.

`s ne t`

Returns `true` if and only if the strings s and t are distinct. Note that blanks are significant.

`s in t`

Returns `true` if and only if s appears as a contiguous substring of t. Note that the empty string is contained in every string.

`s notin t`

Returns `true` if and only if s does not appear as a contiguous substring of t. Note that the empty string is contained in every string.

`s lt t`

Returns `true` if s is lexicographically less than t, `false` otherwise. Here the ordering on characters imposed by their ASCII code number is used.

`s le t`

Returns `true` if s is lexicographically less than or equal to t, `false` otherwise. Here the ordering on characters imposed by their ASCII code number is used.

`s gt t`

Returns `true` if s is lexicographically greater than t, `false` otherwise. Here the ordering on characters imposed by their ASCII code number is used.

`s ge t`

Returns `true` if s is lexicographically greater than or equal to t, false otherwise. Here the ordering on characters imposed by their ASCII code number is used.

Example H3E1

```
> "Mag" cat "ma";
Magma
```

Omitting double-quotes usually has undesired effects:

```
> "Mag cat ma";
Mag cat ma
```

And note that there are two different equalities involved in the following!

```
> "73" * "9" * "42" eq "7" * "3942";
true
> 73 * 9 * 42 eq 7 * 3942;
true
```

The next line shows how strings can be concatenated quickly, and also that strings of blanks can be used for formatting:

```
> s := ("Mag" cat "ma? ")^2;
> s, " "^30, s[4]^12, "!";
Magma? Magma?                              mmmmmmmmmmmm !
```

Here is a way to list (in a sequence) the first occurrence of each of the ten digits in the decimal expansion of π, using `IntegerToString` and `Position`.

```
> pi := Pi(RealField(1001));
> dec1000 := Round(10^1000*(pi-3));
> I := IntegerToString(dec1000);
> [ Position(I, IntegerToString(i)) : i in [0..9] ];
```

```
[ 32, 1, 6, 9, 2, 4, 7, 13, 11, 5 ]
```

Using the length `#` and string indexing `[ ]` it is also easy to count the number of occurrences of each digit in the string containing the first 1000 digits.

```
> [ #[i : i in [1..#I] | I[i] eq IntegerToString(j)] : j in [0..9] ];
[ 93, 116, 103, 102, 93, 97, 94, 95, 101, 106 ]
```

We would like to test if the ASCII-encoding of the string 'Magma' appears. This could be done as follows, using `StringToCode` and `in`, or alternatively, `Position`. To reduce the typing, we first abbreviate `IntegerToString` to `is` and `StringToCode` to `sc`.

```
> sc := StringToCode;
> its := IntegerToString;
> M := its(sc("M")) * its(sc("a")) * its(sc("g")) * its(sc("m")) * its(sc("a"));
> M;
779710310997
> M in I;
false
> Position(I, M);
0
```

So 'Magma' does not appear this way. However, we could be satisfied if the letters appear somewhere in the right order. To do more sophisticated operations (like this) on strings, it is necessary to convert the string into a sequence, because sequences constitute a more versatile data type, allowing many more advanced operations than strings.

```
> Iseq := [ I[i] : i in [1..#I] ];
> Mseq := [ M[i] : i in [1..#M] ];
> IsSubsequence(Mseq, Iseq);
false
> IsSubsequence(Mseq, Iseq: Kind := "Sequential");
true
```

Finally, we find that the string 'magma' lies in between 'Pi' and 'pi':

```
> "Pi" le "magma";
true
> "magma" lt "pi";
true
```

3.2.6 Parsing Strings

`Split(S, D)`

`Split(S)`

Given a string S, together with a string D describing a list of separator characters, return the sequence of strings obtained by splitting S at any of the characters contained in D. That is, S is considered as a sequence of fields, with any character in D taken to be a delimiter separating the fields. If D is omitted, it is taken to be the string consisting of the newline character alone (so S is split into the lines found in it). If S is desired to be split into space-separated words, the argument `" \t\n"` should be given for D.

Example H3E2

We demonstrate elementary uses of `Split`.

```
> Split("a b c d", " ");
[ a, b, c, d ]
> // Note that an empty field is included if the
> // string starts with the separator:
> Split(" a b c d", " ");
[ , a, b, c, d ]
> Split("abxcdyefzab", "xyz");
[ ab, cd, ef, ab ]
> // Note that no splitting happens if the delimiter
> // is empty:
> Split("abcd", "");
[ abcd ]
```

`Regexp(R, S)`

Given a string R specifying a regular expression, together with a string S, return whether S matches R. If so, return also the matched substring of S, together with the sequence of matched substrings of S corresponding to the parenthesized expressions of R. This function is based on the freely distributable reimplementation of the V8 regexp package by Henry Spencer. The syntax and interpretation of the characters `|`, `*`, `+`, `?`, `^`, `$`, `[]`, `\` is the same as in the UNIX command `egrep`. The parenthesized expressions are numbered in left-to-right order of their opening parentheses. Note that the parentheses should not have an initial backslash before them as the UNIX commands `grep` and `ed` require.

Example H3E3

We demonstrate some elementary uses of `Regexp`.

```
> Regexp("b.*d", "abcde");
true bcd []
> Regexp("b(.*)d", "abcde");
true bcd [ c ]
> Regexp("b.*d", "xyz");
false
> date := "Mon Jun 17 10:27:27 EST 1996";
> _, _, f := Regexp("([0-9][0-9]):([0-9][0-9]):([0-9][0-9])", date);
> f;
[ 10, 27, 27 ]
> h, m, s := Explode(f);
> h, m, s;
10 27 27
```

3.3 Printing

3.3.1 The `print`-Statement

`print` *expression*;

`print` *expression*`, ..., ` *expression*;

`print` *expression*`:` *parameters*;

Print the value of the expression. Some limited ways of formatting output are described in the section on strings. Four levels of printing (that may in specific cases coincide) exist, and may be indicated after the colon: `Default` (which is the same as the level obtained if no level is indicated), `Minimal`, `Maximal`, and `Magma`. The last of these produces output representing the value of the identifier as valid MAGMA-input (when possible).

3.3.2 The `printf` and `fprintf` Statements

`printf` *format*`,` *expression*`, ...,` *expression*`;`

Print values of the expressions under control of *format*. The first argument, the *format string*, must be a string which contains two types of objects: plain characters, which are simply printed, and conversion specifications (indicated by the `%` character), each of which causes conversion and printing of zero or more of the expressions. (Use `%%` to get a literal percent character.) Currently, the only conversion specifications allowed are: `%o` and `%O`, which stand for "object", `%m`, which stands for "magma", and `%h`, which stands for "hexadecimal".

The hexadecimal conversion specification will print its argument in hexadecimal; currently, it only supports integer arguments. The object and magma conversion specifications each print the corresponding argument; they differ only in the printing mode used. The `%o` form uses the default printing mode, while the `%O` form uses the printing mode specified by the next argument (as a string). The "magma" conversion specification uses a printing mode of `Magma`. It is thus equivalent to (but shorter than) using `%O` and an extra argument of `"Magma"`.

For each of these conversion specifications, the object can be printed in a field of a particular width by placing extra characters immediately after the `%` character: digits describing a positive integer, specifying a field with width equal to that number and with right-justification; digits describing a negative integer, specifying a field with width equal to the absolute value of the number and with left-justification; or the character `*` specifying a field width given by the next appropriate expression argument (with justification determined by the sign of the number). This statement is thus like the C language function `printf()`, except that `%o` (and `%O` and `%m`) covers all kinds of objects — it is not necessary to have different conversion specifications for the different types of MAGMA objects. Note also that this statement does *not* print a newline character after its arguments while the `print` statement does (a `\n` character should be placed in the format string if this is desired). A newline character will be printed just before the next prompt, though, if there is an incomplete line at that point.

Example H3E4

The following statements demonstrate simple uses of *printf*.

```
> for i := 1 to 150 by 33 do printf "[%3o]\n", i; end for;
[  1]
[ 34]
[ 67]
[100]
[133]
> for i := 1 to 150 by 33 do printf "[%-3o]\n", i; end for;
[1  ]
[34 ]
[67 ]
```

```
[100]
[133]
> for w := 1 to 5 do printf "[%*o]", w, 1; end for;
[1][ 1][  1][   1][    1]
```

Example H3E5

Some further uses of the `printf` statement are illustrated below.

```
> x := 3;
> y := 4;
> printf "x = %o, y = %o\n", x, y;
x = 3, y = 4
> printf "G'"; printf "day";
G'day
> p := 53.211;
> x := 123.2;
> printf "%.3o%% of %.2o is %.3o\n", p, x, p/100.0 * x;
53.211% of 123.20 is 65.556
> Zx<x> := PolynomialRing(Integers());
> printf "%0\n", x, "Magma";
Polynomial(\[0, 1])
```

`fprintf` *file*, *format*, *expression*, ..., *expression*;

Print values of the expressions under control of *format* into the file given by *file*. The first argument *file* must be either a string specifying a file which can be opened for appending (tilde expansion is performed on the filename), or an file object (see the section below on external files) opened for writing. The rest of the arguments are exactly as in the `printf` statement. In the string (filename) case, the file is opened for appending, the string obtained from the formatted printing of the other arguments is appended to the file, and the file is closed. In the file object case, the string obtained from the formatted printing of the other arguments is simply appended to the file. Note that this statement, like `printf`, does *not* print a newline character after its arguments (a `\n` character should be placed in the format string if this is desired).

Example H3E6

The following statements demonstrate a (rather contrived) use of *fprintf* with a file pipe.

```
> p := 10000000000000000000000000000057;
> F := POpen("sort -n", "w");
> for i := 100 to 110 do
>    fprintf F, "%30o (2^%o mod p)\n", 2^i mod p, i;
> end for;
> // Close F and then see output on standard output:
```

```
> delete F;
 37107316853453566312041115519 (2^109 mod p)
 70602400912917605986812821219 (2^102 mod p)
 74214633706907132624082231038 (2^110 mod p)
129638414606681695789005139447 (2^106 mod p)
141204801825835211973625642438 (2^103 mod p)
259276829213363391578010278894 (2^107 mod p)
267650600228229401496703205319 (2^100 mod p)
282409603651670423947251284876 (2^104 mod p)
518553658426726783156020557788 (2^108 mod p)
535301200456458802993406410638 (2^101 mod p)
564819207303340847894502569752 (2^105 mod p)
```

3.3.3 Verbose Printing (`vprint`, `vprintf`)

The following statements allow convenient printing of information conditioned by whether an appropriate verbose flag is turned on.

`vprint` *flag*: *expression*, ..., *expression*;

`vprint` *flag*, *n*: *expression*, ..., *expression*;

If the verbose flag *flag* (see the function `SetVerbose`) has a level greater than or equal to n, print the expressions to the right of the colon exactly as in the `print` statement. If the flag has level 0 (i.e. is not turned on), do nothing. In the first form of this statement, where a specific level is not given, n is taken to be 1. This statement is useful in MAGMA code found in packages where one wants to print verbose information if an appropriate verbose flag is turned on.

`vprintf` *flag*: *format*, *expression*, ..., *expression*;

`vprintf` *flag*, *n*: *format*, *expression*, ..., *expression*;

If the verbose flag *flag* (see the function `SetVerbose`) has a level greater than or equal to n, print using the format and the expressions to the right of the colon exactly as in the `printf` statement. If the flag has level 0 (i.e. is not turned on), do nothing. In the first form of this statement, where a specific level is not given, n is taken to be 1. This statement is useful in MAGMA code found in packages where one wants to print verbose information if an appropriate verbose flag is turned on.

3.3.4 Automatic Printing

MAGMA allows *automatic printing* of expressions: basically, a statement consisting of an expression (or list of expressions) alone is taken as a shorthand for the `print`-statement.

Some subtleties are involved in understanding the precise behaviour of MAGMA in interpreting lone expressions as statements. The rules MAGMA follows are outlined here. In the following, a *call-form* means any expression of the form $f(arguments)$; that is, anything which could be a procedure call *or* a function call.

(a) Any single expression followed by a semicolon which is not a call-form is printed, just as if you had 'print' in front of it.

(b) For a single call-form followed by a semicolon (which could be a function call or procedure call), the first signature which matches the input arguments is taken and if that is procedural, the whole call is taken as a procedure call, otherwise it is taken as function call and the results are printed.

(c) A comma-separated list of any expressions is printed, just as if you had 'print' in front of it. Here any call-form is taken as a function call only so procedure calls are impossible.

(d) A print level modifier is allowed after an expression list (whether the list has length 1 or more). Again any call-form is taken as a function call only so procedure calls are impossible.

(e) Any list of objects printed, whether by any of the above rules or by the 'print' statement, is placed in the previous value buffer. `$1` gives the last printed list, `$2` the one before, etc. Note that multi-return values stay as a list of values in the previous value buffer. The only way to get at the individual values of such a list is by assignment to a list of identifiers, or by `where` (this is of course the only way to get the second result out of `Quotrem`, etc.). In other places, a `$1` expression is evaluated with principal value semantics.

MAGMA also provides procedures to manipulate the previous value buffer in which $1, etc. are stored.

`ShowPrevious()`

Show all the previous values stored. This does *not* change the contents of the previous value buffer.

`ShowPrevious(i)`

Show the i-th previous value stored. This does *not* change the contents of the previous value buffer.

`ClearPrevious()`

Clear all the previous values stored. This is useful for ensuring that no more memory is used than that referred to by the current identifiers.

`SetPreviousSize(n)`

Set the size of the previous value buffer (this is not how many values are defined in it at the moment, but the maximum number that will be stored). The default size is 3.

`GetPreviousSize()`

Return the size of the previous value buffer.

Example H3E7

Examples which illustrate point (a):

```
> 1;
1
> x := 3;
> x;
3
```

Examples which illustrate point (b):

```
> 1 + 1;            // really function call '+'(1, 1)
2
> Q := [ 0 ];
> Append(~Q, 1);    // first (in fact only) match is procedure call
> Append(Q, 1);     // first (in fact only) match is function call
[ 0, 1, 1 ]
>  // Assuming fp is assigned to a procedure or function:
>  fp(x);            // whichever fp is at runtime
> SetVerbose("Meataxe", true);  // simple procedure call
```

Examples which illustrate point (c):

```
> 1, 2;
1 2
> // Assuming f assigned:
>  f(x), 1;                           // f only can be a function
>  SetVerbose("Meataxe", true), 1;    // type error in 'SetVerbose'
>                                     // (since no function form)
```

Examples which illustrate point (d):

```
> 1: Magma;
1
> Sym(3), []: Maximal;
Symmetric group acting on a set of cardinality 3
Order = 6 = 2 * 3
[]
>  SetVerbose("Meataxe", true): Magma; // type error as above
```

Examples which illustrate point (e):

```
> 1;
```

```
1
> $1;
1
> 2, 3;
2 3
> $1;
2 3
> Quotrem(124124, 123);
1009 17
> $1;
1009 17
> a, b := $1;
> a;
1009
```

3.3.5 Indentation

MAGMA has an indentation level which determines how many initial spaces should be printed before each line. The level can be increased or decreased. Each time the top level of Magma is reached (i.e. a prompt is printed), the level is reset to 0. The level is usually changed in verbose output of recursive functions and procedures. The functions `SetIndent` and `GetIndent` are used to control and examine the number of spaces used for each indentation level (default 4).

`IndentPush()`

Increase (push) the indentation level by 1. Thus the beginning of a line will have s more spaces than before, where s is the current number of indentation spaces.

`IndentPop()`

Decrease (pop) the indentation level by 1. Thus the beginning of a line will have s less spaces than before, where s is the current number of indentation spaces. If the current level is already 0, an error occurs.

3.3.6 Printing to a File

`PrintFile(F, x)`

`Write(F, x)`

`Overwrite` BOOLELT *Default :* `false`

Print x to the file specified by the string F. If this file already exists, the output will be appended, unless the optional parameter `Overwrite` is set to true, in which case the file is overwritten.

`WriteBinary(F, s)`

`Overwrite` BoolElt *Default :* `false`

Write the binary string s to the file specified by the string F. If this file already exists, the output will be appended, unless the optional parameter `Overwrite` is set to true, in which case the file is overwritten.

`PrintFile(F, x, L)`

`Write(F, x, L)`

`Overwrite` BoolElt *Default :* `false`

Print x in format defined by the string L to the file specified by the string F. If this file already exists, the output will be appended unless the optional parameter `Overwrite` is set to true, in which case the file is overwritten. The level L can be any of the print levels on the `print` command above (i.e., it must be one of the strings `"Default"`, `"Minimal"`, `"Maximal"`, or `"Magma"`).

`PrintFileMagma(F, x)`

`Overwrite` BoolElt *Default :* `false`

Print x in Magma format to the file specified by the string F. If this file already exists, the output will be appended, unless the optional parameter `Overwrite` is set to true, in which case the file is overwritten.

3.3.7 Printing to a String

Magma allows the user to obtain the string corresponding to the output obtained when printing an object by means of the `Sprint` function. The `Sprintf` function allows formatted printing like the `printf` statement.

`Sprint(x)`

`Sprint(x, L)`

Given any Magma object x, this function returns a string containing the output obtained when x is printed. If a print level L is given also (a string), the printing is done according to that level (see the `print` statement for the possible printing levels).

`Sprintf(F, ...)`

Given a format string F, together with appropriate extra arguments corresponding to F, return the string resulting from the formatted printing of F and the arguments. The format string F and arguments should be exactly as for the `printf` statement – see that statement for details.

Example H3E8

We demonstrate elementary uses of `Sprintf`.

```
> Q := [Sprintf("{%4o<->%-4o}", x, x): x in [1,10,100,1000]];
> Q;
[ {   1<->1   }, {  10<->10  }, { 100<->100 }, {1000<->1000} ]
```

3.3.8 Redirecting Output

`SetOutputFile(F)`

`Overwrite` BoolElt *Default :* `false`

Redirect all Magma output to the file specified by the string F. By using `SetOutputFile(F: Overwrite := true)` the file F is emptied before output is written onto it.

`UnsetOutputFile()`

Close the output file, so that output will be directed to standard output again.

`HasOutputFile()`

If Magma currently has an output or log file F, return `true` and F; otherwise return `false`.

3.4 External Files

Magma provides a special *file* type for the reading and writing of external files. Most of the standard C library functions can be applied to such files to manipulate them.

3.4.1 Opening Files

`Open(S, T)`

Given a filename (string) S, together with a type indicator T, open the file named by S and return a Magma file object associated with it. Tilde expansion is performed on S. The standard C library function `fopen()` is used, so the possible characters allowed in T are the same as those allowed for that function in the current operating system, and have the same interpretation. Thus one should give the value `"r"` for T to open the file for reading, and give the value `"w"` for T to open the file for writing, etc. (Note that in the PC version of Magma, the character `"b"` should also be included in T if the file is desired to be opened in binary mode.) Once a file object is created, various I/O operations can be performed on it — see below. A file is closed by deleting it (i.e. by use of the `delete` statement or by reassigning the variable associated with the file); there is no `Fclose` function. This ensures that the file is not closed while there are still multiple references to it. (The function is called `Open` instead of `Fopen` to follow Perl-style conventions. The following functions also follow such conventions where possible.)

3.4.2 Operations on File Objects

`Flush(F)`

Given a file F, flush the buffer of F.

`Tell(F)`

Given a file F, return the offset in bytes of the file pointer within F.

`Seek(F, o, p)`

Perform `fseek(F, o, p)`; i.e. move the file pointer of F to offset o (relative to p: 0 means beginning, 1 means current, 2 means end).

`Rewind(F)`

Perform `rewind(F)`; i.e. move the file pointer of F to the beginning.

`Put(F, S)`

Put (write) the characters of the string S to the file F.

`Puts(F, S)`

Put (write) the characters of the string S, followed by a newline character, to the file F.

`Getc(F)`

Given a file F, get and return one more character from file F as a string. If F is at end of file, a special EOF marker string is returned; the function `IsEof` should be applied to the character to test for end of file. (Thus the only way to loop over a file character by character is to get each character and test whether it is the EOF marker before processing it.)

`Gets(F)`

Given a file F, get and return one more line from file F as a string. The newline character is removed before the string is returned. If F is at end of file, a special EOF marker string is returned; the function `IsEof` should be applied to the string to test for end of file.

`IsEof(S)`

Given a string S, return whether S is the special EOF marker.

`Ungetc(F, c)`

Given a character (length one string) C, together with a file F, perform `ungetc(C, F)`; i.e. push the character C back into the input buffer of F.

Example H3E9

We write a function to count the number of lines in a file. Note the method of looping over the characters of the file: we must get the line and then test whether it is the special EOF marker.

```
> function LineCount(F)
>     FP := Open(F, "r");
>     c := 0;
>     while true do
>         s := Gets(FP);
>         if IsEof(s) then
>             break;
>         end if;
>         c +:= 1;
>     end while;
>     return c;
> end function;
> LineCount("/etc/passwd");
59
```

3.4.3 Reading a Complete File

`Read(F)`

Function that returns the contents of the text-file with name indicated by the string F. Here F may be an expression returning a string.

`ReadBinary(F)`

Function that returns the contents of the text-file with name indicated by the string F as a binary string.

Example H3E10

In this example we show how `Read` can be used to import the complete output from a separate C program into a MAGMA session. We assume that a file `mystery.c` (of which the contents are shown below) is present in the current directory. We first compile it, from within MAGMA, and then use it to produce output for the MAGMA version of our `mystery` function.

```
> Read("mystery.c");
#include <stdio.h>
main(argc, argv)
int     argc;
char    **argv;
{
    int n, i;
    n = atoi(argv[1]);
    for (i = 1; i <= n; i++)
        printf("%d\n", i * i);
```

```
    return 0;
}
> System("cc mystery.c -o mystery");
> mysteryMagma := function(n)
>    System("./mystery " cat IntegerToString(n) cat " >outfile");
>    output := Read("outfile");
>    return StringToIntegerSequence(output);
> end function;
> mysteryMagma(5);
[ 1, 4, 9, 16, 25 ]
```

3.5 Pipes

Pipes are used to communicate with newly-created processes. Currently pipes are only available on UNIX systems.

The MAGMA I/O module is currently undergoing revision, and the current pipe facilities are a mix of the old and new methods. A more uniform model will be available in future releases.

3.5.1 Pipe Creation

`POpen(C, T)`

Given a shell command line C, together with a type indicator T, open a pipe between the MAGMA process and the command to be executed. The standard C library function `popen()` is used, so the possible characters allowed in T are the same as those allowed for that function in the current operating system, and have the same interpretation. Thus one should give the value `"r"` for T so that MAGMA can read the output from the command, and give the value `"w"` for T so that MAGMA can write into the input of the command. See the `Pipe` intrinsic for a method for sending input to, and receiving output from, a single command.

Important: this function returns a `File` object, and the I/O functions for files described previously must be used rather then those described in the following.

`Pipe(C, S)`

Given a shell command C and an input string S, create a pipe to the command C, send S into the standard input of C, and return the output of C as a string. Note that for many commands, S should finish with a new line character if it consists of only one line.

Example H3E11

We write a function which returns the current time as 3 values: hour, minutes, seconds. The function opens a pipe to the UNIX command "date" and applies regular expression matching to the output to extract the relevant fields.

```
> function GetTime()
>     D := POpen("date", "r");
>     date := Gets(D);
>     _, _, f := Regexp("([0-9][0-9]):([0-9][0-9]):([0-9][0-9])", date);
>     h, m, s := Explode(f);
>     return h, m, s;
> end function;
> h, m, s := GetTime();
> h, m, s;
14 30 01
> h, m, s := GetTime();
> h, m, s;
14 30 04
```

3.5.2 Operations on Pipes

When a read request is made on a pipe, the available data is returned. If no data is currently available, then the process waits until some does becomes available, and returns that. (It will also return if the pipe has been closed and hence no more data can be transmitted.) It does not continue trying to read more data, as it cannot tell whether or not there is some "on the way".

The upshot of all this is that care must be exercised as reads may return less data than is expected.

`Read(P : parameters)`

`Max` RngIntElt *Default :* 0

Waits for data to become available for reading from P and then returns it as a string. If the parameter `Max` is set to a positive value then at most that many characters will be read. Note that less than `Max` characters may be returned, depending on the amount of currently available data.

If the pipe has been closed then the special EOF marker string is returned.

`ReadBytes(P : parameters)`

`Max` RngIntElt *Default :* 0

Waits for data to become available for reading from P and then returns it as a sequence of bytes (integers in the range 0..255). If the parameter `Max` is set to a positive value then at most that many bytes will be read. Note that less than `Max` bytes may be returned, depending on the amount of currently available data.

If the pipe has been closed then the empty sequence is returned.

`Write(P, s)`

Writes the characters of the string s to the pipe P.

`WriteBytes(P, Q)`

Writes the bytes in the byte sequence Q to the pipe P. Each byte must be an integer in the range 0..255.

3.6 Sockets

Sockets may be used to establish communication channels between machines on the same network. Once established, they can be read from or written to in much the same ways as more familiar I/O constructs like files. One major difference is that the data is not instantly available, so the I/O operations take much longer than with files. Currently sockets are only available on UNIX systems.

Strictly speaking, a *socket* is a communication endpoint whose defining information consists of a network address and a port number. (Even more strictly speaking, the communication protocol is also part of the socket. MAGMA only uses TCP sockets, however, so we ignore this point from now on.)

The network address selects on which of the available network interfaces communication will take place; it is a string identifying the machine on that network, in either domain name or dotted-decimal format. For example, both `"localhost"` and `"127.0.0.1"` identify the machine on the loopback interface (which is only accessible from the machine itself), whereas `"foo.bar.com"` or `"10.0.0.3"` might identify the machine in a local network, accessible from other machines on that network.

The port number is just an integer that identifies the socket on a particular network interface. It must be less than 65 536. A value of 0 will indicate that the port number should be chosen by the operating system.

There are two types of sockets, which we will call client sockets and server sockets. The purpose of a client socket is to initiate a connection to a server socket, and the purpose of a server socket is to wait for clients to initiate connections to it. (Thus the server socket needs to be created before the client can connect to it.) Once a server socket accepts a connection from a client socket, a communication channel is established and the distinction between the two becomes irrelevant, as they are merely each side of a communication channel.

In the following descriptions, the network address will often be referred to as the *host*. So a socket is identified by a *(host, port)* pair, and an established communication channel consists of two of these pairs: *(local-host, local-port), (remote-host, remote-port)*.

3.6.1 Socket Creation

`Socket(H, P : parameters)`

`LocalHost`	MONSTGELT	*Default : none*
`LocalPort`	RNGINTELT	*Default :* 0

Attempts to create a (client) socket connected to port P of host H. Note: these are the *remote* values; usually it does not matter which local values are used for client

sockets, but for those rare occasions where it does they may be specified using the parameters `LocalHost` and `LocalPort`. If these parameters are not set then suitable values will be chosen by the operating system. Also note that port numbers below 1 024 are usually reserved for system use, and may require special privileges to be used as the local port number.

`Socket( : parameters)`

`LocalHost`	MonStgElt	*Default : none*
`LocalPort`	RngIntElt	*Default :* 0

Attempts to create a server socket on the current machine, that can be used to accept connections. The parameters `LocalHost` and `LocalPort` may be used to specify which network interface and port the socket will accept connections on; if either of these are not set then their values will be determined by the operating system. Note that port numbers below 1 024 are usually reserved for system use, and may require special privileges to be used as the local port number.

`WaitForConnection(S)`

This may only be used on server sockets. It waits for a connection attempt to be made, and then creates a new socket to handle the resulting communication channel. Thus S may continue to be used to accept connection attempts, while the new socket is used for communication with whatever entity just connected. Note: this new socket is *not* a server socket.

3.6.2 Socket Properties

`SocketInformation(S)`

This routine returns the identifying information for the socket as a pair of tuples. Each tuple is a <*host, port*> pair — the first tuple gives the local information and the second gives the remote information. Note that this second tuple will be undefined for server sockets.

3.6.3 Socket Predicates

`IsServerSocket(S)`

Returns whether S is a server socket or not.

3.6.4 Socket I/O

Due to the nature of the network, it takes significant time to transmit data from one machine to another. Thus when a read request is begun it may take some time to complete, usually because the data to be read has not yet arrived. Also, data written to a socket may be broken up into smaller pieces for transmission, each of which may take different amounts of time to arrive. Thus, unlike files, there is no easy way to tell if there is still more data to be read; the current lack of data is no indicator as to whether more might arrive.

When a read request is made on a socket, the available data is returned. If no data is currently available, then the process waits until some does becomes available, and returns that. (It will also return if the socket has been closed and hence no more data can be transmitted.) It does not continue trying to read more data, as it cannot tell whether or not there is some "on the way".

The upshot of all this is that care must be exercised as reads may return less data than is expected.

`Read(S : parameters)`

`Max` RngIntElt *Default :* 0

Waits for data to become available for reading from S and then returns it as a string. If the parameter `Max` is set to a positive value then at most that many characters will be read. Note that less than `Max` characters may be returned, depending on the amount of currently available data.

If the socket has been closed then the special EOF marker string is returned.

`ReadBytes(S : parameters)`

`Max` RngIntElt *Default :* 0

Waits for data to become available for reading from S and then returns it as a sequence of bytes (integers in the range 0..255). If the parameter `Max` is set to a positive value then at most that many bytes will be read. Note that less than `Max` bytes may be returned, depending on the amount of currently available data.

If the socket has been closed then the empty sequence is returned.

`Write(S, s)`

Writes the characters of the string s to the socket S.

`WriteBytes(S, Q)`

Writes the bytes in the byte sequence Q to the socket S. Each byte must be an integer in the range 0..255.

Example H3E12

Here is a trivial use of sockets to send a message from one MAGMA process to another running on the same machine. The first MAGMA process sets up a server socket and waits for another MAGMA to contact it.

```
> // First Magma process
> server := Socket(: LocalHost := "localhost");
> SocketInformation(server);
<localhost, 32794>
> S1 := WaitForConnection(server);
```

The second MAGMA process establishes a client socket connection to the first, writes a greeting message to it, and closes the socket.

```
> // Second Magma process
> S2 := Socket("localhost", 32794);
> SocketInformation(S2);
<localhost, 32795> <localhost, 32794>
> Write(S2, "Hello, other world!");
> delete S2;
```

The first MAGMA process is now able to continue; it reads and displays all data sent to it until the socket is closed.

```
> // First Magma process
> SocketInformation(S1);
<localhost, 32794> <localhost, 32795>
> repeat
>     msg := Read(S1);
>     msg;
> until IsEof(msg);
Hello, other world!
EOF
```

3.7 Interactive Input

`read` *identifier*;

`read` *identifier*, *prompt*;

This statement will cause MAGMA to assign to the given identifier the string of characters appearing (at run-time) on the following line. This allows the user to provide an input string at run-time. If the optional prompt is given (a string), that is printed first.

`readi` *identifier*;

`readi` *identifier*, *prompt*;

This statement will cause MAGMA to assign to the given identifier the literal integer appearing (at run-time) on the following line. This allows the user to specify integer input at run-time. If the optional prompt is given (a string), that is printed first.

3.8 Loading a Program File

`load "`*filename*`";`

Input the file with the name specified by the string. The file will be read in, and the text will be treated as MAGMA input. Tilde expansion of file names is allowed.

`iload "`*filename*`";`

(Interactive load.) Input the file with the name specified by the string. The file will be read in, and the text will be treated as MAGMA input. Tilde expansion of file names is allowed. In contrast to `load`, the user has the chance to interact as each line is read in:

As the line is read in, it is displayed and the system waits for user response. At this point, the user can skip the line (by moving "down"), edit the line (using the normal editing keys) or execute it (by pressing "enter"). If the line is edited, the new line is executed and the original line is presented again.

3.9 Saving and Restoring Workspaces

`save "`*filename*`";`

Copy all information present in the current MAGMA workspace onto a file specified by the string "*filename*". The workspace is left intact, so executing this command does not interfere with the current computation.

`restore "`*filename*`";`

Copy a previously stored MAGMA workspace from the file specified by the string "*filename*" into central memory. Information present in the current workspace prior to the execution of this command will be lost. The computation can now proceed from the point it was at when the corresponding `save`-command was executed.

3.10 Logging a Session

`SetLogFile(F)`

`Overwrite` BoolElt *Default :* `false`

Set the log file to be the file specified by the string F: all input and output will be sent to this log file as well as to the terminal. If a log file is already in use, it is closed and F is used instead. By using `SetLogFile(F: Overwrite := true)` the file F is emptied before input and output are written onto it. See also `HasOutputFile`.

`UnsetLogFile()`

Stop logging Magma's output.

`SetEchoInput(b)`

Set to true or false according to whether or not input from external files should also be sent to standard output.

3.11 Memory Usage

`GetMemoryUsage()`

Return the current memory usage of Magma (in bytes as an integer). This is the process data size, which does not include the executable code.

`GetMaximumMemoryUsage()`

Return the maximum memory usage of Magma (in bytes as an integer) which has been attained since last reset (see `ResetMaximumMemoryUsage`). This is the maximum process data size, which does not include the executable code.

`ResetMaximumMemoryUsage()`

Reset the value of the maximum memory usage of Magma to be the current memory usage of Magma (see `GetMaximumMemoryUsage`).

3.12 System Calls

`Alarm(s)`

A procedure which when used on UNIX systems, sends the signal SIGALRM to the Magma process after s seconds. This allows the user to specify that a Magma-process should self-destruct after a certain period.

`ChangeDirectory(s)`

Change to the directory specified by the string s. Tilde expansion is allowed.

`GetCurrentDirectory()`

Returns the current directory as a string.

`Getpid()`

Returns Magma's process ID (value of the Unix C system call `getpid()`).

`Getuid()`

Returns the user ID (value of `the Unix C system call getuid()`).

`System(C)`

Execute the system command specified by the string C. This is done by calling the C function `system()`.

This also returns the system command's return value as an integer. On most Unix systems, the lower 8 bits of this value give the process status while the next 8 bits give the value given by the command to the C function `exit()` (see the Unix manual entries for `system(3)` or `wait(2)`, for example). Thus one should normally divide the result by 256 to get the exit value of the program on success.

See also the `Pipe` intrinsic function.

`%!` *shell-command*

Execute the given command in the Unix shell then return to Magma. Note that this type of shell escape (contrary to the one using a `System` call) takes place entirely outside MAGMA and does not show up in MAGMA's history.

3.13 Creating Names

Sometimes it is necessary to create names for files from within MAGMA that will not clash with the names of existing files.

`Tempname(P)`

Given a prefix string P, return a unique temporary name derived from P (by use of the C library function `mktemp()`).

4 ENVIRONMENT AND OPTIONS

Chapter 4
ENVIRONMENT AND OPTIONS

4.1 Introduction

This chapter describes the environmental features of MAGMA, together with options which can be specified at start-up on the command line, or within MAGMA by the `Set-` procedures. The history and line-editor features of MAGMA are also described.

4.2 Command Line Options

When starting up MAGMA, various command-line options can be supplied, and a list of files to be automatically loaded can also be specified. These files may be specified by simply listing their names as normal arguments (i.e., without a `-` option) following the MAGMA command. For each such file name, a search for the specified file is conducted, starting in the current directory, and in directories specified by the environment variable `MAGMA_PATH` after that if necessary. It is also possible to have a *startup file*, in which one would usually store personal settings of parameters and variables. The startup file is specified by the `MAGMA_STARTUP_FILE` environment variable which should be set in the user's `.cshrc` file or similar. This environment variable can be overridden by the `-s` option, or cancelled by the `-n` option. The files specified by the arguments to MAGMA are loaded *after* the startup file. Thus the startup file is not cancelled by giving extra file arguments, which is what is usually desired.

MAGMA also allows one to set variables from the command line — if one of the arguments is of the form *var*`:=`*val*, where *var* is a valid identifier (consisting of letters, underscores, or non-initial digits) and there is no space between *var* and the `:=`, then the variable *var* is assigned within MAGMA to the *string* value *val* at the point where that argument is processed. (Functions like `StringToInteger` should be used to convert the value to an object of another type once inside MAGMA.)

`magma -b`

If the `-b` argument is given to MAGMA, the opening banner and all other introductory messages are suppressed. The final "total time" message is also suppressed. This is useful when sending the whole output of a MAGMA process to a file so that extra removing of unwanted output is not needed.

`magma -c` *filename*

If the `-c` argument is given to MAGMA, followed by a filename, the filename is assumed to refer to a package source file and the package is compiled and MAGMA then exits straight away. This option is rarely needed since packages are automatically compiled when attached.

`magma -d`

If the `-d` option is supplied to MAGMA, the licence for the current `magmapassfile` is dumped. That is, the expiry date and the valid hostids are displayed. MAGMA then exits.

`magma -n`

If the `-n` option is supplied to MAGMA, any startup file specified by the environment variable `MAGMA_STARTUP_FILE` or by the `-s` option is cancelled.

`magma -q name`

If the `-q` option is supplied to MAGMA, then MAGMA operates in a special manner as a slave (with the given name) for the `MPQS` integer factorisation algorithm. Please see that function for more details.

`magma -r workspace`

If the `-r` option is supplied to MAGMA, together with a workspace file, that workspace is automatically restored by MAGMA when it starts up.

`magma -s` *filename*

If the `-s` option is supplied to MAGMA, the given filename is used for the startup file for MAGMA. This overrides the variable of the environment variable `MAGMA_STARTUP_FILE` if it has been set. This option should not be used (as it was before), for automatically loading files since that can be done by just listing them as arguments to the MAGMA process.

`magma -S integer`

When starting up MAGMA, it is possible to specify a seed for the generation of pseudo-random numbers. (Pseudo-random quantities are used in several MAGMA algorithms, and may also be generated explicitly by some intrinsics.) The seed should be in the range 0 to $(2^{32} - 1)$ inclusive. If `-S` is not followed by any number, or if the `-S` option is not used, MAGMA selects the seed itself.

Example H4E1

By typing the command

```
magma file1 x:=abc file2
```

MAGMA would start up, read the user's startup file specified by `MAGMA_STARTUP_FILE` if existent, then read the file `file1`, then assign the variable `x` to the string value `"abc"`, then read the file `file2`, then give the prompt.

4.3 Environment Variables

This section lists some environment variables used by MAGMA. These variables are set by an appropriate operating system command and are used to define various search paths and other run-time options.

`MAGMA_STARTUP_FILE`

The name of the default start-up file. It can be overridden by the `magma -s` command.

`MAGMA_PATH`

Search path for files that are loaded (a colon separated list of directories). It need not include directories for the libraries, just personal directories. This path is searched before the library directories.

`MAGMA_MEMORY_LIMIT`

Limit on the size of the memory that may be used by a MAGMA-session (in bytes).

`MAGMA_LIBRARY_ROOT`

The root directory for the MAGMA libraries (by supplying an absolute path name). From within MAGMA `SetLibraryRoot` and `GetLibraryRoot` can be used to change and view the value.

`MAGMA_LIBRARIES`

Give a list of MAGMA libraries (as a colon separated list of sub-directories of the library root directory). From within MAGMA `SetLibraries` and `GetLibraries` can be used to change and view the value.

`MAGMA_SYSTEM_SPEC`

The MAGMA system spec file containing the system packages automatically attached at start-up.

`MAGMA_USER_SPEC`

The personal user spec file containing the user packages automatically attached at start-up.

`MAGMA_HELP_DIR`

The root directory for the MAGMA help files.

`MAGMA_TEMP_DIR`

Optional variable containing the directory MAGMA is to use for temporary files. If not specified, this defaults to `/tmp` (on Unix-like systems) or the system-wide temporary directory (on Windows systems).

4.4 Set and Get

The `Set-` procedures allow the user to attach values to certain environment variables. The `Get-` functions enable one to obtain the current values of these variables.

`SetAssertions(b)`
`GetAssertions()`

Controls the checking of assertions (see the `assert` statement and related statements in the chapter on the language). Default is `SetAssertions(1)`. The relevant values are 0 for no checking at all, 1 for normal checks, 2 for debug checks and 3 for extremely stringent checking.

`SetAutoColumns(b)`
`GetAutoColumns()`

If enabled, the IO system will try to determine the number of columns in the window by using `ioctl()`; when a window change or a stop/cont occurs, the `Columns` variable (below) will be automatically updated. If disabled, the `Columns` variable will only be changed when explicitly done so by `SetColumns`. Default is `SetAutoColumns(true)`.

`SetAutoCompact(b)`
`GetAutoCompact()`

Control whether automatic compaction is performed. Normally the memory manager of MAGMA will compact all of its memory between each statement at the top level. This removes fragmentation and reduces excessive memory usage. In some very rare situations, the compactions may become very slow (one symptom is that an inordinate pause occurs between prompts when only a trivial operation or nothing is done). In such cases, turning the automatic compaction off may help (at the cost of possibly more use of memory). Default is `SetAutoCompact(true)`.

`SetBeep(b)`
`GetBeep()`

Controls 'beeps'. Default is `SetBeep(true)`.

`SetColumns(n)`
`GetColumns()`

Controls the number of columns used by the IO system. This affects the line editor and the output system. (As explained above, if AutoColumns is on, this variable will be automatically determined.) The number of columns will determine how words are wrapped. If set to 0, word wrap is not performed. The default value is `SetColumns(80)` (unless `SetAutoColumns(true)`).

`GetCurrentDirectory()`

Returns the current directory as a string. (Use `ChangeDirectory(s)` to change the working directory.)

`SetEchoInput(b)`

`GetEchoInput()`

Set to `true` or `false` according to whether or not input from external files should also be sent to standard output.

`GetEnvironmentValue(s)`

`GetEnv(s)`

Returns the value of the external environment variable *s* as a string.

`SetHistorySize(n)`

`GetHistorySize()`

Controls the number of lines saved in the history. If the number is set to 0, no history is preserved.

`SetIgnorePrompt(b)`

`GetIgnorePrompt()`

Controls the option to ignore the prompt to allow the pasting of input lines back in. If enabled, any leading '>' characters (possibly separated by white space) are ignored by the history system when the input file is a terminal, *unless* the line consists of the '>' character alone (without a following space), which could not come from a prompt since in a prompt a space or another character follows a '>'. Default is `SetIgnorePrompt(false)`.

`SetIgnoreSpaces(b)`

`GetIgnoreSpaces()`

Controls the option to ignore spaces when searching in the line editor. If the user moves up or down in the line editor using `<Ctrl>`-P or `<Ctrl>`-N (see the line editor key descriptions) and if the cursor is not at the beginning of the line, a search is made forwards or backwards, respectively, to the first line which starts with the same string as the string consisting of all the characters before the cursor. While doing the search, spaces are ignored if and only if this option is on (value `true`). Default is `SetIgnoreSpaces(true)`.

`SetIndent(n)`

`GetIndent()`

Controls the indentation level for formatting output. The default is `SetIndent(4)`.

`SetLibraries(s)`
`GetLibraries()`

Controls the MAGMA library directories via environment variable `MAGMA_LIBRARIES`. The procedure `SetLibraries` takes a string, which will be taken as the (colon-separated) list of sub-directories in the library root directory for the libraries; the function `GetLibraryRoot` returns the current value as a string. These directories will be searched when you try to `load` a file; note however that first the directories indicated by the current value of your path environment variable `MAGMA_PATH` will be searched. See `SetLibraryRoot` for the root directory.

`SetLibraryRoot(s)`
`GetLibraryRoot()`

Controls the root directory for the MAGMA libraries, via the environment variable `MAGMA_LIBRARY_ROOT`. The procedure `SetLibraryRoot` takes a string, which will be the absolute pathname for the root of the libraries; the function `GetLibraryRoot` returns the current value as a string. See also `SetLibraries`

`SetLineEditor(b)`
`GetLineEditor()`

Controls the line editor. Default is `SetLineEditor(true)`.

`SetLogFile(F)`

`Overwrite` BOOLELT *Default :* `false`

`UnsetLogFile()`

Procedure. Set the log file to be the file specified by the string F: all input and output will be sent to this log file as well as to the terminal. If a log file is already in use, it is closed and F is used instead. The parameter `Overwrite` can be used to indicate that the file should be truncated before writing input and output on it; by default the file is appended.

`SetMemoryLimit(n)`
`GetMemoryLimit()`

Set the limit (in bytes) of the memory which the memory manager will allocate (no limit if 0). Default is `SetMemoryLimit(0)`.

`SetNthreads(n)`
`GetNthreads()`

Set the number of threads to be used in multi-threaded algorithms to be n, if POSIX threads are enabled in this version of Magma. Currently, this affects the coding theory minimum weight algorithm (`MinimumWeight`) and the F_4 Gröbner basis algorithm for medium-sized primes (`Groebner`).

`SetOutputFile(F)`

`Overwrite` BoolElt *Default :* `false`

`UnsetOutputFile()`

Start/stop redirecting all Magma output to a file (specified by the string F). The parameter `Overwrite` can be used to indicate that the file should be truncated before writing output on it.

`SetPath(s)`

`GetPath()`

Controls the path by which the searching of files is done. The path consists of a colon separated list of directories which are searched in order (“.” implicitly assumed at the front). Tilde expansion is done on each directory. (May be overridden by the environment variable MAGMA_PATH.)

`SetPrintLevel(l)`

`GetPrintLevel()`

Controls the global printing level, which is one of `"Minimal"`, `"Magma"`, `"Maximal"`, `"Default"`. Default is `SetPrintLevel("Default")`.

`SetPrompt(s)`

`GetPrompt()`

Controls the terminal prompt (a string). Expansion of the following % escapes occurs:

%% The character %

%h The current history line number.

%S The parser ‘state’: when a new line is about to be read while the parser has only seen incomplete statements, the state consists of a stack of words like “if”, “while”, indicating the incomplete statements.

%s Like %S except that only the topmost word is displayed.

Default is `SetPrompt("%S> ")`.

`SetQuitOnError(b)`

Set whether Magma should quit on any error to b. If b is `true`, Magma will completely quit when any error (syntax, runtime, etc.) occurs. Default is `SetQuitOnError(false)`.

`SetRows(n)`

`GetRows()`

Controls the number of rows in a page used by the IO system. This affects the output system. If set to 0, paging is not performed. Otherwise a prompt is given after the given number of rows for a new page. The default value is `SetRows(0)`.

`GetTempDir()`

Returns the directory MAGMA uses for storing temporary files. May be influenced on startup via the MAGMA_TEMP_DIR environment variable (see Section 4.3).

`SetTraceback(n)`
`GetTraceback()`

Controls whether MAGMA should produce a traceback of user function calls before each error message. The default value is `SetTraceback(true)`.

`SetSeed(s, c)`
`GetSeed()`

Controls the initialization seed and step number for pseudo-random number generation. For details, see the section on random object generation in the chapter on statements and expressions.

`GetVersion()`

Return integers x, y and z such the current version of MAGMA is Vx.y–z.

`SetViMode(b)`
`GetViMode()`

Controls the type of line editor used: Emacs (`false`) or VI style. Default is `SetViMode(false)`.

4.5 Verbose Levels

By turning verbose printing on for certain modules within MAGMA, some information on computations that are performed can be obtained. For each option, the verbosity may have different levels. The default is level 0 for each option.

There are also 5 slots available for user-defined verbose flags. The flags can be set in user programs by `SetVerbose("User`n`", true)` where n should be one of $1, 2, 3, 4, 5$, and the current setting is returned by `GetVerbose("User`n`")`.

`SetVerbose(s, i)`
`SetVerbose(s, b)`

Set verbose level for `s` to be level i or b. Here the argument `s` must be a string. The verbosity may have different levels. An integer i for the second argument selects the appropriate level. A second argument i of 0 or b of `false` means no verbosity. A boolean value for b of `true` for the second argument selects level 1. (See above for the valid values for the string s).

`GetVerbose(s)`

Return the value of verbose flag s as an integer. (See above for the valid values for the string s).

`IsVerbose(s)`

Return the whether the value of verbose flag s is non-zero. (See above for the valid values for the string s).

`IsVerbose(s, l)`

Return the whether the value of verbose flag s is greater than or equal to l. (See above for the valid values for the string s).

`ListVerbose()`

List all verbose flags. That is, print each verbose flag and its maximal level.

`ClearVerbose()`

Clear all verbose flags. That is, set the level for all verbose flags to 0.

4.6 Other Information Procedures

The following procedures print information about the current state of MAGMA.

`ShowMemoryUsage()`

(Procedure.) Show MAGMA's current memory usage.

`ShowIdentifiers()`

(Procedure.) List all identifiers that have been assigned to.

`ShowValues()`

(Procedure.) List all identifiers that have been assigned to with their values.

`Traceback()`

(Procedure.) Display a traceback of the current Magma function invocations.

`ListSignatures(C)`

`Isa`	BOOLELT	*Default :* `true`
`Search`	MONSTGELT	*Default :* "*Both*"
`ShowSrc`	BOOLELT	*Default :* `false`

List all intrinsic functions, procedures and operators having objects from category C among their arguments or return values. The parameter `Isa` may be set to false so that any categories which C inherit from are not considered. The parameter `Search`, with valid string values `Both`, `Arguments`, `ReturnValues`, may be used to specify whether the arguments, the return values, or both, are considered (default both). `ShowSrc` can be used to see where package intrinsics are defined. Use `ListCategories` for the names of the categories.

`ListSignatures(F, C)`

`Isa`	BoolElt	*Default :* `true`
`Search`	MonStgElt	*Default :* "*Both*"
`ShowSrc`	BoolElt	*Default :* `false`

Given an intrinsic F and category C, list all signatures of F which match the category C among their arguments or return values. The parameters are as for the previous procedure.

`ListCategories()`

`ListTypes()`

Procedure to list the (abbreviated) names for all available categories in Magma.

4.7 History

Magma provides a history system which allows the recall and editing of previous lines. The history system is invoked by typing commands which begin with the history character '%'. Currently, the following commands are available.

`%p`

List the contents of the history buffer. Each line is preceded by its history line number.

`%p`n

List the history line n in %p format.

`%p`n_1 n_2

List the history lines in the range n_1 to n_2 in %p format.

`%P`

List the contents of the history buffer. The initial numbers are *not* printed.

`%P`n

List the history line n in %P format.

`%P`n_1 n_2

List the history lines in the range n_1 to n_2 in %P format.

`%s`

List the contents of the history buffer with an initial statement for each line to reset the random number seed to the value it was just before the line was executed. This is useful when one wishes to redo a computation using exactly the same seed as before but does not know what the seed was at the time.

`%s`n

Print the history line n in %s format.

`%s`n_1 n_2

Print the history lines in the range n_1 to n_2 in %s format.

`%S`

As for %s except that the statement to set the seed is only printed if the seed has changed since the previous time it was printed. Also, it is not printed if it would appear in the middle of a statement (i.e., the last line did not end in a semicolon).

`%S`n

Print the history line n in %S format.

`%S`n_1 n_2

Print the history lines in the range n_1 to n_2 in %S format.

`%`

Reenter the last line into the input stream.

`%`n

Reenter the line specified by line number n into the input stream.

`%`n_1 n_2

Reenter the history lines in the range n_1 to n_2 into the input stream.

`%e`

Edit the last line. The editor is taken to be the value of the EDITOR environment variable if is set, otherwise "/bin/ed" is used. If after the editor has exited the file has not been changed then nothing is done. Otherwise the contents of the new file are reentered into the input stream.

`%e`n

Edit the line specified by line number n.

`%e`n_1 n_2

Edit the history lines in the range n_1 to n_2.

`%!` *shell-command*

Execute the given command in the Unix shell then return to Magma.

4.8 The Magma Line Editor

Magma provides a line editor with both Emacs and VI style key bindings. To enable the VI style of key bindings, type

```
SetViMode(true)
```

and type

```
SetViMode(false)
```

to revert to the Emacs style of key bindings. By default ViMode is `false`; that is, the Emacs style is in effect.

Many key bindings are the same in both Emacs and VI style. This is because some VI users like to be able to use some Emacs keys (like `<Ctrl>-P`) as well as the VI command keys. Thus key bindings in Emacs which are not used in VI insert mode can be made common to both.

4.8.1 Key Bindings (Emacs and VI mode)

`<Ctrl>-`*key* means hold down the Control key and press *key*.

`<Return>`

Accept the line and print a new line. This works in any mode.

`<Backspace>`

`<Delete>`

Delete the previous character.

`<Tab>`

Complete the word which the cursor is on or just after. If the word doesn't have a unique completion, it is first expanded up to the common prefix of all the possible completions. An immediately following Tab key will list all of the possible completions. Currently completion occurs for system functions and procedures, parameters, reserved words, and user identifiers.

`<Ctrl>-A`

Move to the beginning of the line ("alpha" = "beginning").

`<Ctrl>-B`

Move back a character ("back").

`<Ctrl>-C`

Abort the current line and start a new line.

`<Ctrl>-D`

On an empty line, send a EOF character (i.e., exit at the top level of the command interpreter). If at end of line, list the completions. Otherwise, delete the character under the cursor ("delete").

`<Ctrl>-E`

Move to the end of the line ("end").

`<Ctrl>-F`

Move forward a character ("forward").

`<Ctrl>-H`

Same as Backspace.

`<Ctrl>-I`

Same as Tab.

`<Ctrl>-J`

Same as Return.

`<Ctrl>-K`

Delete all characters from the cursor to the end of the line ("kill").

`<Ctrl>-L`

Redraw the line on a new line (helpful if the screen gets wrecked by programs like "write", etc.).

`<Ctrl>-M`

Same as `<Return>`.

`<Ctrl>-N`

Go forward a line in the history buffer ("next"). If the cursor is not at the beginning of the line, go forward to the first following line which starts with the same string (ignoring spaces iff the ignore spaces option is on — see `SetIgnoreSpaces`) as the string consisting of all the characters before the cursor. Also, if `<Ctrl>`-N is typed initially at a new line and the last line entered was actually a recall of a preceding line, then the next line after that is entered into the current buffer. Thus to repeat a sequence of lines (with minor modifications perhaps to each), then one only needs to go back to the first line with `<Ctrl>`-P (see below), press `<Return>`, then successively press `<Ctrl>`-N followed by `<Return>` for each line.

`<Ctrl>-P`

Go back a line in the history buffer ("previous"). If the cursor is not at the beginning of the line, go back to the first preceding line which starts with the same string (ignoring spaces iff the ignore spaces option is on — see `SetIgnoreSpaces`) as the string consisting of all the characters before the cursor. For example, typing at a

new line `x:=` and then `<Ctrl>`-P will go back to the last line which assigned `x` (if a line begins with, say, `x :=`, it will also be taken).

`<Ctrl>-U`

Clear the whole of the current line.

`<Ctrl>-V`*char*

Insert the following character literally.

`<Ctrl>-W`

Delete the previous word.

`<Ctrl>-X`

Same as `<Ctrl>`-U.

`<Ctrl>-Y`

Insert the contents of the yank-buffer before the character under the cursor.

`<Ctrl>-Z`

Stop MAGMA.

`<Ctrl>-_`

Undo the last change.

`<Ctrl>-\`

Immediately quit MAGMA.

On most systems the arrow keys also have the obvious meaning.

4.8.2 Key Bindings in Emacs mode only

M*key* means press the Meta key and then *key*. (At the moment, the Meta key is only the Esc key.)

`Mb`
`MB`

Move back a word ("Back").

`Mf`
`MF`

Move forward a word ("Forward").

4.8.3 Key Bindings in VI mode only

In the VI mode, the line editor can also be in two modes: the insert mode and the command mode. When in the insert mode, any non-control character is inserted at the current cursor position. The command mode is then entered by typing the Esc key. In the command mode, various commands are given a *range* giving the extent to which they are performed. The following ranges are available:

`0`

Move to the beginning of the line.

`$`

Move to the end of the line.

`<Ctrl>-`*space*

Move to the first non-space character of the line.

`%`

Move to the matching bracket. (Bracket characters are (,), [,], {, }, <, and >.)

`;`

Move to the next character. (See 'F', 'f', 'T', and 't'.)

`,`

Move to the previous character. (See 'F', 'f', 'T', and 't'.)

`B`

Move back a space-separated word ("Back").

`b`

Move back a word ("back").

`E`

Move forward to the end of the space-separated word ("End").

`e`

Move forward to the end of the word ("end").

`F`*char*

Move back to the first occurrence of *char*.

`f`*char*

Move forward to the first occurrence of *char*.

`h`
`H`

Move back a character (`<Ctrl>-`H = Backspace).

`l`

`L`

Move back a character (`<Ctrl>-L` = forward on some keyboards).

`T`*char*

Move back to just after the first occurrence of *char*.

`t`*char*

Move forward to just before the first occurrence of *char*.

`w`

Move forward a space-separated word ("Word").

`W`

Move forward a word ("word").

Any range may be preceded by a number to multiply to indicate how many times the operation is done. The VI-mode also provides the *yank-buffer*, which contains characters which are deleted or "yanked" – see below.

The following keys are also available in command mode:

`A`

Move to the end of the line and change to insert mode ("Append").

`a`

Move forward a character (if not already at the end of the line) and change to insert mode ("append").

`C`

Delete all the characters to the end of line and change to insert mode ("Change").

`c`*range*

Delete all the characters to the specified range and change to insert mode ("change").

`D`

Delete all the characters to the end of line ("Delete").

`d`*range*

Delete all the characters to the specified range ("delete").

`I`

Move to the first non-space character in the line and change to insert mode ("Insert").

`i`

Change to insert mode ("insert").

`j`

Go forward a line in the history buffer (same as `<Ctrl>`-N).

`k`

Go back a line in the history buffer (same as `<Ctrl>`-P).

`P`

Insert the contents of the yank-buffer before the character under the cursor.

`p`

Insert the contents of the yank-buffer before the character after the cursor.

`R`

Enter over-type mode: typed characters replace the old characters under the cursor without insertion. Pressing Esc returns to the command mode.

`r`*char*

Replace the character the cursor is over with *char*.

`S`

Delete the whole line and change to insert mode ("Substitute").

`s`

Delete the current character and change to insert mode ("substitute").

`U`
`u`

Undo the last change.

`X`

Delete the character to the left of the cursor.

`x`

Delete the character under the cursor.

`Y`

"Yank" the whole line - i.e., copy the whole line into the yank-buffer ("Yank").

`y`*range*

Copy all characters from the cursor to the specified range into the yank-buffer ("yank").

4.9 The Magma Help System

Magma provides extensive online help facilities that can be accessed in different ways. The easiest way to access the documentation is by typing:

```
magmahelp
```

Which should start some browser (usually netscape) on the main page of the MAGMA documentation.

The easiest way to get some information about any MAGMA intrinsic is by typing: (Here we assume you to be interested in `FundamentalUnit`)

```
> FundamentalUnit;
```

Which now will list all signatures for this intrinsic (i.e. all known ways to use this function):

```
> FundamentalUnit;
Intrinsic 'FundamentalUnit'
Signatures:
    (<FldQuad> K) -> FldQuadElt
    (<RngQuad> O) -> RngQuadElt
        The fundamental unit of K or O
    (<RngQuad> R) -> RngQuadElt
        Fundamental unit of the real quadratic order.
```

Next, to get more detailed information, try

```
> ?FundamentalUnit
```

But now several things could happen depending on the installation. Using the default, you get

```
============================================================
PATH: /magma/ring-field-algebra/quadratic/operation/\
      class-group/FundamentalUnit
KIND: Intrinsic
============================================================
FundamentalUnit(K) : FldQuad -> FldQuadElt
FundamentalUnit(O) : RngQuad -> RngQuadElt
    A generator for the unit group of the order O or the
maximal order
    of the quadratic field K.
============================================================
```

Second, a WWW-browser could start on the part of the online help describing your function (or at least the index of the first character). Third, some arbitrary program could be called to provide you with the information.

If `SetVerbose("Help", true);` is set, MAGMA will show the exact command used and the return value obtained.

`SetHelpExternalBrowser(S, T)`

`SetHelpExternalBrowser(S)`

Defines the external browser to be used if `SetHelpUseExternalBrowser(true)` is in effect. The string has to be a valid command taking exactly one argument (`%s`) which will we replaced by a URL. In case two strings are provided, the second defines a fall-back system. Typical use for this is to first try to use an already running browser and if this fails, start a new one.

`SetHelpUseExternalBrowser(b)`

Tells MAGMA to actually use (or stop to use) the external browser. If both `SetHelpUseExternalSystem` and `SetHelpUseExternalBrowser` are set to `true`, the assignment made last will be effective.

`SetHelpExternalSystem(s)`

This will tell MAGMA to use a user defined external program to access the help. The string has to contain exactly one `%s` which will be replaced by the argument to `?`. The resulting string must be a valid command.

`SetHelpUseExternalSystem(b)`

Tells MAGMA to actually use (or stop to use) the external help system. If both `SetHelpUseExternalSystem` and `SetHelpUseExternalBrowser` are set to `true`, the assignment made last will be effective.

`GetHelpExternalBrowser()`

Returns the currently used command strings.

`GetHelpExternalSystem()`

Returns the currently used command string.

`GetHelpUseExternal()`

The first value is the currently used value from `SetHelpUseExternalBrowser`, the second reflects `SetHelpUseExternalSystem`.

4.9.1 Internal Help Browser

MAGMA has a very powerful internal help-browser that can be entered with

```
> ??
```

5 MAGMA SEMANTICS

Chapter 5
MAGMA SEMANTICS

5.1 Introduction

This chapter describes the semantics of MAGMA (how expressions are evaluated, how identifiers are treated, etc.) in a fairly informal way. Although some technical language is used (particularly in the opening few sections) the chapter should be easy and essential reading for the non-specialist. The chapter is descriptive in nature, describing how MAGMA works, with little attempt to justify why it works the way it does. As the chapter proceeds, it becomes more and more precise, so while early sections may gloss over or omit things for the sake of simplicity and learnability, full explanations are provided later.

It is assumed that the reader is familiar with basic notions like a function, an operator, an identifier, a type ...

And now for some buzzwords: MAGMA is an imperative, call by value, statically scoped, dynamically typed programming language, with an essentially functional subset. The remainder of the chapter explains what these terms mean, and why a user might want to know about such things.

5.2 Terminology

Some terminology will be useful. It is perhaps best to read this section only briefly, and to refer back to it when necessary.

The term *expression* will be used to refer to a textual entity. The term *value* will be used to refer to a run-time value denoted by an expression. To understand the difference between an expression and a value consider the expressions `1+2` and `3`. The expressions are textually different but they denote the same value, namely the integer 3.

A *function expression* is any expression of the form `function ... end function` or of the form `func< ... | ... >`. The former type of function expression will be said to be *in the statement form*, the latter *in the expression form*. A *function value* is the run-time value denoted by a function expression. As with integers, two function expressions can be textually different while denoting the same (i.e., extensionally equal) function value. To clearly distinguish function values from function expressions, the notation FUNC(... : ...) will be used to describe function *values*.

The *formal arguments* of a function in the statement form are the identifiers that appear between the brackets just after the `function` keyword, while for a function in the expression form they are the identifiers that appear before the `|`. The *arguments* to a function are the expressions between the brackets when a function is applied.

The *body* of a function in the statement form is the statements after the formal arguments. The body of a function in the expression form is the expression after the `|` symbol.

An identifier is said to occur *inside* a function expression when it is occurs textually anywhere in the body of a function.

5.3 Assignment

An assignment is an association of an identifier to a *value*. The statement,

```
> a := 6;
```

establishes an association between the identifier a and the value 6 (6 is said to be *the value of* a, or to be *assigned to* a). A collection of such assignments is called a *context*.

When a value V is assigned to an identifier I one of two things happens:

(1) if I has not been previously assigned to, it is added to the current context and associated with V. I is said to be *declared* when it is assigned to for the first time.

(2) if I has been previously assigned to, the value associated with I is changed to V. I is said to be *re-assigned*.

The ability to assign and re-assign to identifiers is why MAGMA is called an *imperative* language.

One very important point about assignment is illustrated by the following example. Say we type,

```
> a := 6;
> b := a+7;
```

After executing these two lines the context is `[ (a,6), (b,13) ]`. Now say we type,

```
> a := 0;
```

The context is now `[ (a,0), (b,13) ]`. Note that changing the value of a does *not* change the value of b because b's value is statically determined at the point where it is assigned. Changing a does *not* produce the context `[ (a,0), (b,7) ]`.

5.4 Uninitialized Identifiers

Before executing a piece of code MAGMA attempts to check that it is semantically well formed (i.e., that it will execute without crashing). One of the checks MAGMA makes is to check that an identifier is declared (and thus initialized) before it is used in an expression. So, for example assuming a had not been previously declared, then before executing either of the following lines MAGMA will raise an error:

```
> a;
> b := a;
```

MAGMA can determine that execution of either line will cause an error since a has no assigned value. The user should be aware that the checks made for semantic well-formedness are necessarily not exhaustive!

There is one important rule concerning uninitialized identifiers and assignment. Consider the line,

```
> a := a;
```

Now if a had been previously declared then this is re-assignment of a. If not then it is an error since a on the right hand side of the `:=` has no value. To catch this kind of error MAGMA checks the expression on the right hand side of the `:=` for semantic well formedness *before* it declares the identifiers on the left hand side of the `:=`. Put another way the identifiers on the left hand side are not considered to be declared in the right hand side, *unless* they were declared previously.

5.5 Evaluation in Magma

Evaluation is the process of computing (or constructing) a value from an expression. For example the value 3 can be computed from the expression `1+2`. Computing a value from an expression is also known as *evaluating an expression*.

There are two aspects to evaluation, namely *when* and *how* it is performed. This section discusses these two aspects.

5.5.1 Call by Value Evaluation

MAGMA employs call by value evaluation. This means that the arguments to a function are evaluated before the function is applied to those arguments. Assume f is a function value. Say we type,

```
> r := f( 6+7, true or false );
```

MAGMA evaluates the two arguments to 13 and true respectively, *before* applying f.

While knowing the exact point at which arguments are evaluated is not usually very important, there are cases where such knowledge is crucial. Say we type,

```
> f := function( n, b )
>        if b then return n else return 1;
> end function;
```

and we apply f as follows

```
> r := f( 4/0, false );
```

MAGMA treats this as an error since the $4/0$ is evaluated, and an error produced, *before* the function f is applied.

By contrast some languages evaluate the arguments to a function only if those arguments are encountered when executing the function. This evaluation process is known as call by name evaluation. In the above example r would be set to the value 1 and the expression $4/0$ would never be evaluated because b is false and hence the argument n would never be encountered.

Operators like + and ∗ are treated as infix functions. So

```
> r := 6+7;
```

is treated as the function application,

```
> r := '+'(6,7);
```

Accordingly all arguments to an operator are evaluated before the operator is applied.

There are three operators, 'select', 'and' and 'or' that are exceptions to this rule and are thus not treated as infix functions. These operators use call by name evaluation and only evaluate arguments as need be. For example if we type,

```
> false and (4/0 eq 6);
```

MAGMA will reply with the answer false since MAGMA knows that `false and X` for all X is false.

5.5.2 Magma's Evaluation Process

Let us examine more closely how MAGMA evaluates an expression as it will help later in understanding more complex examples, specifically those using functions and maps. To evaluate an expression MAGMA proceeds by a process of identifier substitution, followed by simplification to a canonical form. Specifically expression evaluation proceeds as follows,

(1) replace each identifier in the expression by its value in the current context.

(2) simplify the resultant *value* to its canonical form.

The key point here is that the replacement step takes an expression and yields an unsimplified *value*! A small technical note: to avoid the problem of having objects that are part expressions, part values, all substitutions in step 1 are assumed to be done simultaneously for all identifiers in the expression. The examples in this chapter will however show the substitutions being done in sequence and will therefore be somewhat vague about what exactly these hybrid objects are!

To clarify this process assume that we type,

```
> a := 6;
> b := 7;
```

producing the context `[ (a,6), (b,7) ]`. Now say we type,

```
> c := a+b;
```

This produces the context `[ (a,6), (b,7), (c,13) ]`. By following the process outlined above we can see how this context is calculated. The steps are,

(1) replace `a` in the expression `a+b` by its value in the current context giving `6+b`.

(2) replace `b` in `6+b` by its value in the current context giving `6+7`.

(3) simplify `6+7` to `13`

The result value of `13` is then assigned to `c` giving the previously stated context.

5.5.3 Function Expressions

MAGMA's evaluation process might appear to be an overly formal way of stating the obvious about calculating expression values. This formality is useful, however when it comes to function (and map) expressions.

Functions in MAGMA are first class values, meaning that MAGMA treats function values just like it treats any other type of value (e.g., integer values). A function value may be passed as an argument to another function, may be returned as the result of a function, and may be assigned to an identifier in the same way that any other type of value is. Most importantly however function expressions are evaluated *exactly* as are all other expressions. The fact that MAGMA treats functions as first class values is why MAGMA is said to have an essentially functional subset.

Take the preceding example. It was,

```
> a := 6;
> b := 7;
> c := a+b;
```

giving the context `[ (a,6),(b,7),(c,13) ]`. Now say I type,

```
> d := func< n | a+b+c+n >;
```

MAGMA uses the same process to evaluate the function expression `func< n | a+b+c+n >` on the right hand side of the assignment `d := ...` as it does to evaluate expression `a+b` on the right hand side of the assignment `c := ...`. So evaluation of this function expression proceeds as follows,

(1) replace `a` in the expression `func< n | a+b+c+n >` by its value in the current context giving `func< n | 6+b+c+n >`.

(2) replace `b` in `func< n | 6+b+c+n >` by its value in the current context giving `func< n | 6+7+c+n >`.

(3) replace c in `func< n | 6+7+c+n >` by its value in the current context giving `FUNC(n : 6+7+13+n)`

(4) simplify the resultant *value* `FUNC(n : 6+7+13+n)` to the *value* `FUNC(n : 26+n)`.

Note again that the process starts with an expression and ends with a value, and that throughout the function expression is evaluated just like any other expression. A small technical point: function simplification may not in fact occur but the user is guaranteed that the simplification process will at least produce a function extensionally equal to the function in its canonical form.

The resultant function value is now assigned to d just like any other type of value would be assigned to an identifier yielding the context `[ (a,6),(b,7), (c,8), (d,FUNC(n : 26+n)) ]`.

As a final point note that changing the value of any of a, b, and c, does *not* change the value of d!

5.5.4 Function Values Assigned to Identifiers

Say we type the following,

```
> a := 1;
> b := func< n | a >;
> c := func< n | b(6) >;
```

The first line leaves a context of the form `[ (a,1) ]`. The second line leaves a context of the form `[ (a,1), (b,FUNC(n : 1)) ]`.

The third line is evaluated as follows,

(1) replace the value of `b` in the expression `func< n | b(6) >` by its value in the current context giving `FUNC(n : (FUNC(n : 1))(6))`.

(2) simplify this value to `FUNC(n : 1)` since applying the function value `FUNC(n : 1)` to the argument 6 always yields 1.

The key point here is that identifiers whose assigned value is a function value (in this case *b*), are treated exactly like identifiers whose assigned value is any other type of value.

Now look back at the example at the end of the previous section. One step in the series of replacements was not mentioned. Remember that `+` is treated as a shorthand for an infix function. So `a+b` is equivalent to `'+'(a,b)`. `+` is an identifier (assigned a function value), and so in the replacement part of the evaluation process there should have been an extra step, namely,

(4) replace `+` in `func< n : 6+7+13+n >` by its value in the current context giving `FUNC(n : A( A( A(6,7), 13 ), n ))`.

(5) simplify the resultant value to `FUNC(n : A( 26, n ))`. where `A` is the (function) value that is the addition function.

5.5.5 Recursion and Mutual Recursion

How do we write recursive functions? Function expressions have no names so how can a function expression apply *itself* to do recursion?

It is tempting to say that the function expression could recurse by using the identifier that the corresponding function value is to be assigned to. But the function value may not be being assigned at all: it may simply be being passed as an actual argument to some other function value. Moreover even if the function value were being assigned to an identifier the function expression cannot use that identifier because the assignment rules say that the identifiers on the left hand side of the `:=` in an assignment statement are not considered declared on the right hand side, unless they were previously declared.

The solution to the problem is to use the `$$` pseudo-identifier. `$$` is a placeholder for the function value denoted by the function expression inside which the `$$` occurs. An example serves to illustrate the use of `$$`. A recursive factorial function can be defined as follows,

```
> factorial := function(n)
>     if n eq 1 then
>         return 1;
```

```
>      else
>          return n * $$(n-1);
>      end if;
>  end function;
```

Here `$$` is a placeholder for the function value that the function expression `function(n) if n eq ... end function` denotes (those worried that the denoted function value appears to be defined in terms of itself are referred to the fixed point semantics of recursive functions in any standard text on denotational semantics).

A similar problem arises with mutual recursion where a function value f applies another function value g, and g likewise applies f. For example,

```
> f := function(...) ... a := g(...); ... end function;
> g := function(...) ... b := f(...); ... end function;
```

Again MAGMA's evaluation process appears to make this impossible, since to construct f MAGMA requires a value for g, but to construct g MAGMA requires a value for f. Again there is a solution. An identifier can be declared 'forward' to inform MAGMA that a function expression for the forward identifier will be supplied later. The functions f and g above can therefore be declared as follows,

```
> forward f, g;
> f := function(...) ... a := g(...); ... end function;
> g := function(...) ... b := f(...); ... end function;
```

(strictly speaking it is only necessary to declare g forward as the value of f will be known by the time the function expression `function(...)  ... b := f(...); ... end function` is evaluated).

5.5.6 Function Application

It was previously stated that MAGMA employs call by value evaluation, meaning that the arguments to a function are evaluated before the function is applied. This subsection discusses how functions are applied once their arguments have been evaluated.

Say we type,

```
> f := func< a, b | a+b >;
```

producing the context `[ (f,FUNC(a,b :  a+b)) ]`.

Now say we apply f by typing,

```
> r := f( 1+2, 6+7 ).
```

How is the value to be assigned to r calculated? If we follow the evaluation process we will reach the final step which will say something like,

> "simplify `(FUNC(a, b :  A(a,b)))(3,13)` to its canonical form"

where as before A is the value that is the addition function. How is this simplification performed? How are function values applied to actual function arguments to yield result

values? Not unsurprisingly the answer is via a process of substitution. The evaluation of a function application proceeds as follows,

(1) replace each formal argument in the function body by the corresponding actual argument.

(2) simplify the function body to its canonical form.

Exactly what it means to "simplify the function body ..." is intentionally left vague as the key point here is the process of replacing formal arguments by values in the body of the function.

5.5.7 The Initial Context

The only thing that remains to consider with the evaluation semantics, is how to get the ball rolling. Where do the initial values for things like the addition function come from? The answer is that when MAGMA starts up it does so with an initial context defined. This initial context has assignments of all the built-in MAGMA function values to the appropriate identifiers. The initial context contains for example the assignment of the addition function to the identifier `+`, the multiplication function to the identifier `*`, etc.

If, for example, we start MAGMA and immediately type,

```
> 1+2;
```

then in evaluating the expression `1+2` MAGMA will replace `+` by its value in the initial context.

Users interact with this initial context by typing statements at the top level (i.e., statements not inside any function or procedure). A user can change the initial context through re-assignment or expand it through new assignments.

5.6 Scope

Say we type the following,

```
> temp := 7;
> f := function(a,b)
>    temp := a * b;
>    return temp^2;
> end function;
```

If the evaluation process is now followed verbatim, the resultant context will look like `[ (temp,7), (f,FUNC(a,b :  7 := a*b; return 7^2;)) ]`, which is quite clearly not what was intended!

5.6.1 Local Declarations

What is needed in the previous example is some way of declaring that an identifier, in this case `temp`, is a 'new' identifier (i.e., distinct from other identifiers with the same name) whose use is confined to the enclosing function. MAGMA provides such a mechanism, called a local declaration. The previous example could be written,

```
> temp := 7;
> f := function(a,b)
>    local temp;
>    temp := a * b;
>    return temp^2;
> end function;
```

The identifier `temp` inside the body of f is said to be '(declared) local' to the enclosing function. Evaluation of these two assignments would result in the context being `[ (temp, 7), (f, FUNC(a,b : local temp := a*b; return local temp^2;)) ]` as intended.

It is very important to remember that `temp` and `local temp` are *distinct*! Hence if we now type,

```
> r := f(3,4);
```

the resultant context would be `[ (temp,7), (f,FUNC(a,b : local temp := a*b; return local temp^2;)), (r,144) ]`. The assignment to `local temp` inside the body of f does *not* change the value of `temp` outside the function. The effect of an assignment to a local identifier is thus localized to the enclosing function.

5.6.2 The 'first use' Rule

It can become tedious to have to declare all the local variables used in a function body. Hence MAGMA adopts a convention whereby an identifier can be implicitly declared according to how it is first used in a function body. The convention is that if the first use of an identifier inside a function body is on the left hand side of a `:=`, then the identifier is considered to be local, and the function body is considered to have an implicit local declaration for this identifier at its beginning. There is in fact no need therefore to declare `temp` as local in the previous example as the first use of `temp` is on the left hand side of a `:=` and hence `temp` is implicitly declared local.

It is very important to note that the term 'first use' refers to the first *textual* use of an identifier. Consider the following example,

```
> temp := 7;
> f := function(a,b)
>    if false then
>       temp := a * b;
>       return temp;
>    else
>       temp;
>       return 1;
```

```
>     end if;
>  end function;
```

The first *textual* use of `temp` in this function body is in the line

```
>  temp := a * b;
```

Hence `temp` is considered as a local inside the function body. It is not relevant that the `if false ...` condition will never be true and so the first time `temp` will be encountered when f is applied to some arguments is in the line

```
>  temp;
```

'First use' means 'first textual use', modulo the rule about examining the right hand side of a `:=` before the left!

5.6.3 Identifier Classes

It is now necessary to be more precise about the treatment of identifiers in MAGMA. Every identifier in a MAGMA program is considered to belong to one of three possible classes, these being:

(a) the class of value identifiers

(b) the class of variable identifiers

(c) the class of reference identifiers

The class an identifier belongs to indicates how the identifier is used in a program.

The class of value identifiers includes all identifiers that stand as placeholders for values, namely:

(a) all loop identifiers;

(b) the $$ pseudo-identifier;

(c) all identifiers whose first use in a function expression is as a value (i.e., not on the left hand side of an `:=`, nor as an actual reference argument to a procedure).

Because value identifiers stand as placeholders for values to be substituted during the evaluation process, they are effectively constants, and hence they cannot be assigned to. Assigning to a value identifier would be akin to writing something like `7 := 8;`!

The class of variable identifiers includes all those identifiers which are declared as local, either implicitly by the first use rule, or explicitly through a local declaration. Identifiers in this class may be assigned to.

The class of reference identifiers will be discussed later.

5.6.4 The Evaluation Process Revisited

The reason it is important to know the class of an identifier is that the class of an identifier effects how it is treated during the evaluation process. Previously it was stated that the evaluation process was,

(1) replace each identifier in the expression by its value in the current context.

(2) simplify the resultant *value* to its canonical form.

Strictly speaking the first step of this process should read,

(1′) replace each *free* identifier in the expression by its value in the current context, where an identifier is said to be free if it is a value identifier which is not a formal argument, a loop identifier, or the $$ identifier.

This definition of the replacement step ensures for example that while computing the value of a function expression F, MAGMA does not attempt to replace F's formal arguments with values from the current context!

5.6.5 The 'single use' Rule

As a final point on identifier classes it should be noted that an identifier may belong to only *one* class within an expression. Specifically therefore an identifier can only be used in one way inside a function body. Consider the following function,

```
> a := 7;
> f := function(n) a := a; return a; end function;
```

It is *not* the case that a is considered as a variable identifier on the left hand side of the `:=`, and as a value identifier on the right hand side of the `:=`. Rather a is considered to be a value identifier as its first use is as a value on the right hand side of the `:=` (remember that MAGMA inspects the right hand side of an assignment, and hence sees a first as a value identifier, *before* it inspects the left hand side where it sees a being used as a variable identifier).

5.7 Procedure Expressions

To date we have only discussed function expressions, these being a mechanism for computing new values from the values of identifiers in the current context. Together with assignment this provides us with a means of changing the current context – to compute a new value for an identifier in the current context, we call a function and then re-assign the identifier with the result of this function. That is we do

```
> X := f(Y);
```

where Y is a list of arguments possibly including the current value of X.

At times however using re-assignment to change the value associated with an identifier can be both un-natural and inefficient. Take the problem of computing some reduced form of a matrix. We could write a function that looked something like this,

```
reduce :=
   function( m )
      local lm;
      ...
      lm := m;
      while not reduced do
```

```
        ...
        lm := some_reduction(m);
        ...
    end while;
...
end function;
```

Note that the local `lm` is necessary since we cannot assign to the function's formal argument `m` since it stands for a value (and values cannot be assigned to). Note also that the function is inefficient in its space usage since at any given point in the program there are at least two different copies of the matrix (if the function was recursive then there would be more than two copies!).

Finally the function is also un-natural. It is perhaps more natural to think of writing a program that takes a given matrix and *changes* that matrix into its reduced form (i.e., the original matrix is lost). To accommodate for this style of programming, Magma includes a mechanism, the *procedure expression* with its *reference arguments*, for changing an association of an identifier and a value *in place*.

Before examining procedure expressions further, it is useful to look at a simple example of a procedure expression. Say we type:

```
> a := 5; b := 6;
```

giving the context `[ (a,5), (b,6) ]`. Say we now type the following:

```
> p := procedure( x, ~y ) y := x; end procedure;
```

This gives us a context that looks like `[ (a,5), (b,6), (p, PROC(x,~y :  y := x;)) ]`, using a notation analogous to the `FUNC` notation.

Say we now type the following *statement*,

```
> p(a, ~b);
```

This is known as a *call of the procedure* p (strictly it should be known as a call to the *procedure value* associated with the identifier p, since like functions, procedures in Magma are first class values!). Its effect is to *change* the current context to `[ (a,5), (b,5), (p, PROC(a,~b :  b := a;)) ]`. a and x are called *actual* and *formal value arguments* respectively since they are not prefixed by a $\sim$, while b and y are called *actual* and *formal reference arguments* respectively because they are prefixed by a $\sim$.

This example illustrates the defining attribute of procedures, namely that rather than returning a value, a procedure changes the context in which it is called. In this case the value of b was changed by the call to p. Observe however that *only* b was changed by the call to p as *only* b in the call, and its corresponding formal argument y in the definition, are reference arguments (i.e., prefixed with a $\sim$). A procedure may therefore only change that part of the context associated with its reference arguments! All other parts of the context are left unchanged. In this case a and p were left unchanged!

Note that apart from reference arguments (and the corresponding fact that that procedures do not return values), procedures are exactly like functions. In particular:

a) procedures are first class values that can be assigned to identifiers, passed as arguments, returned from functions, etc.

b) procedure expressions are evaluated in the same way that function expressions are.

c) procedure value arguments (both formal and actual) behave exactly like function arguments (both formal and actual). Thus procedure value arguments obey the standard substitution semantics.

d) procedures employ the same notion of scope as functions.

e) procedure calling behaves like function application.

f) procedures may be declared 'forward' to allow for (mutual) recursion.

g) a procedure may be assigned to an identifier in the initial context.

The remainder of this section will thus restrict itself to looking at reference arguments, the point of difference between procedures and functions.

5.8 Reference Arguments

If we look at a context it consists of a set of pairs, each pair being a name (an identifier) and a value (that is said to be assigned to that identifier).

When a function is applied actual arguments are substituted for formal arguments, and the body of the function is evaluated. The process of evaluating an actual argument yields a value and any associated names are ignored. Magma's evaluation semantics treats identifiers as 'indexes' into the context – when Magma wants the value of say x it searches through the context looking for a pair whose name component is x. The corresponding value component is then used as the value of x and the name part is simply ignored thereafter.

When we call a procedure with a reference argument, however, the name components of the context become important. When, for example we pass x as an actual reference argument to a formal reference argument y in some procedure, Magma remembers the name x. Then if y is changed (e.g., by assignment) in the called procedure, Magma, knowing the name x, finds the appropriate pair in the calling context and updates it by changing its corresponding value component. To see how this works take the example in the previous section. It was,

```
> a := 5; b := 6;
> p := procedure( x, ~y ) y := x; end procedure;
> p(a, ~b);
```

In the call Magma remembers the name b. Then when y is assigned to in the body of p, Magma knows that y is really b in the calling context, and hence changes b in the calling context appropriately. This example shows that an alternate way of thinking of reference arguments is as synonyms for the same part of (or pair in) the calling context.

5.9 Dynamic Typing

MAGMA is a dynamically typed language. In practice this means that:

(a) there is no need to declare the type of identifiers (this is especially important for identifiers assigned function values!).

(b) type violations are only checked for when the code containing the type violation is actually executed.

To make these ideas clearer consider the following two functions,

```
> f := func< a, b | a+b >;
> g := func< a, b | a+true >;
```

First note that there are no declarations of the types of any of the identifiers.

Second consider the use of + in the definition of function f. Which addition function is meant by the + in a+b? Integer addition? Matrix addition? Group addition? ... Or in other words what is the type of the identifier + in function f? Is it integer addition, matrix addition, etc.? The answer to this question is that + here denotes all possible addition function values (+ is said to denote a *family* of function values), and MAGMA will automatically chose the appropriate function value to apply when it knows the type of a and b.

Say we now type,

```
> f(1,2);
```

MAGMA now knows that a and b in f are both integers and thus + in f should be taken to mean the integer addition function. Hence it will produce the desired answer of 3.

Finally consider the definition of the function g. It is clear X+true for all X is a type error, so it might be expected that MAGMA would raise an error as soon as the definition of g is typed in. MAGMA does not however raise an error at this point. Rather it is only when g is applied and the line `return a + true` is actually executed that an error is raised.

In general the exact point at which type checking is done is not important. Sometimes however it is. Say we had typed the following definition for g,

```
> g := function(a,b)
>    if false then
>       return a+true;
>    else
>       return a+b;
>    end if;
> end function;
```

Now because the `if false` condition will never be true, the line `return a+true` will *never* be executed, and hence the type violation of adding a to true will *never* be raised!

One closing point: it should be clear now that where it was previously stated that the initial context "contains assignments of all the built-in MAGMA function values to the appropriate identifiers", in fact the initial context contains assignments of all the built-in MAGMA function *families* to the appropriate identifiers.

5.10 Traps for Young Players

This section describes the two most common sources of confusion encountered when using MAGMA's evaluation strategy.

5.10.1 Trap 1

We boot MAGMA. It begins with an initial context something like `[ ..., ('+',A), ('-',S), ... ]` where A is the (function) value that is the addition function, and S is the (function) value that is the subtraction function.

Now say we type,

```
> '+' := '-';
> 1 + 2;
```

MAGMA will respond with the answer `-1`.

To see why this is so consider the effect of each line on the current context. After the first line the current context will be `[ ..., ('+',S), ('-',S), ... ]`, where S is as before. The identifier `+` has been re-assigned. Its new value is the value of the identifier '-' in the current context, and the value of '-' is the (function) value that is the subtraction function. Hence in the second line when MAGMA replaces the identifier `+` with its value in the current context, the value that is substituted is therefore S, the subtraction function!

5.10.2 Trap 2

Say we type,

```
> f := func< n | n + 1 >;
> g := func< m | m + f(m) >;
```

After the first line the current context is `[ (f,FUNC( n :  n+1)) ]`. After the second line the current context is `[ (f,FUNC( n :  n+1)), (g,FUNC(m :  m + FUNC(n : n+1)(m))) ]`.

If we now type,

```
> g(6);
```

MAGMA will respond with the answer 13.

Now say we decide that our definition of f is wrong. So we now type in a new definition for f as follows,

```
> f := func< n | n + 2 >;
```

If we again type,

```
> g(6);
```

MAGMA will again reply with the answer 13!

To see why this is so consider how the current context changes. After typing in the initial definitions of f and g the current context is `[ (f, FUNC(n :  n+1)), (g, FUNC(m :  m + FUNC(n :  n+1)(m))) ]`. After typing in the second definition of f the current

context is `[ (f, FUNC(n : n+2)), (g, FUNC(m : m + FUNC(n : n+1)(m)))]`. Remember that changing the *value* of one identifier, in this case f, does *not* change the value of any other identifiers, in this case g! In order to change the value of g to reflect the new value of f, g would have to be re-assigned.

5.11 Appendix A: Precedence

The table below defines the relative precedence of operators in MAGMA, with decreasing strength (so operators higher in the table bind more strongly). The column on the right indicates whether the operator is left-, right-, or non-associative.

‘ ‘‘	*left*
(	*left*
[	*left*

6 THE MAGMA PROFILER

Chapter 6
THE MAGMA PROFILER

6.1 Introduction

One of the most important aspects of the development cycle is optimization. It is often the case that during the implementation of an algorithm, a programmer makes erroneous assumptions about its run-time behavior. These errors can lead to performance which differs in surprising ways from the expected output. The unfortunate tendency of programmers to optimize code before establishing run-time bottlenecks tends to exacerbate the problem.

Experienced programmers will thus often be heard repeating the famous mantra "Premature optimization is the root of all evil", coined by Sir Charles A. R. Hoare, the inventor of the Quick sort algorithm. Instead of optimizing during the initial implementation, it is generally better to perform an analysis of the run-time behaviour of the complete program, to determine what are the actual bottlenecks. In order to assist in this task, MAGMA provides a *profiler*, which gives the programmer a detailed breakdown of the time spent in a program. In this chapter, we provide an overview of how to use the profiler.

6.2 Profiler Basics

The MAGMA profiler records timing information for each function, procedure, map, and intrinsic call made by your program. When the profiler is switched on, upon the entry and exit to each such call the current system clock time is recorded. This information is then stored in a call graph, which can be viewed in various ways.

`SetProfile(b)`

Turns profiling on (if b is `true`) or off (if b is `false`). Profiling information is stored cumulatively, which means that in the middle of a profiling run, the profiler can be switched off during sections for which profiling information is not wanted. At startup, the profiler is off. Turning the profiler on will slow down the execution of your program slightly.

`ProfileReset()`

Clear out all information currently recorded by the profiler. It is generally a good idea to do this after the call graph has been obtained, so that future profiling runs in the same MAGMA session begin with a clean slate.

`ProfileGraph()`

Get the call graph based upon the information recorded up to this point by the profiler. This function will return an error if the profiler has not yet been turned on.

The call graph is a directed graph, with the nodes representing the functions that were called during the program's execution. There is an edge in the call graph from a function x to a function y if y was called during the execution of x. Thus, recursive calls will result in cycles in the call graph.

Each node in the graph has an associated label, which is a record with the following fields:

(i) `Name`: the name of the function

(ii) `Time`: the total time spent in the function

(iii) `Count`: the number of times the function was called

Each edge $\langle x, y \rangle$ in the graph also has an associated label, which is a record with the following fields:

(i) `Time`: the total time spent in function y when it was called from function x

(ii) `Count`: the total number of times function y was called by function x

Example H6E1

We illustrate the basic use of the profiler in the following example. The code we test is a simple implementation of the Fibonacci sequence; this can be replaced by any MAGMA code that needs to be profiled.

```
> function fibonacci(n)
>     if n eq 1 or n eq 2 then
>       return 1;
>     else
>       return fibonacci(n - 1) + fibonacci(n - 2);
>     end if;
> end function;
>
> SetProfile(true);
> time assert fibonacci(27) eq Fibonacci(27);
Time: 10.940
> SetProfile(false);
> G := ProfileGraph();
> G;
Digraph
Vertex  Neighbours
1       2 3 6 7 ;
2       2 3 4 5 ;
3       ;
4       ;
5       ;
```

```
6       ;
7       ;
> V := Vertices(G);
> Label(V!1);
rec<recformat<Name: Strings(), Time: RealField(), Count: IntegerRing()> |
    Name := <main>,
    Time := 10.93999999999999950262,
    Count := 1
    >
> Label(V!2);
rec<recformat<Name: Strings(), Time: RealField(), Count: IntegerRing()> |
    Name := fibonacci,
    Time := 10.93999999999999950262,
    Count := 392835
    >
> E := Edges(G);
> Label(E![1,2]);
rec<recformat<Time: RealField(), Count: IntegerRing()> |
    Time := 10.93999999999999950262,
    Count := 1
    >
```

6.3 Exploring the Call Graph

6.3.1 Internal Reports

The above example demonstrates that while the call graph contains some useful information, it does not afford a particularly usable interface. The MAGMA profiler contains some profile report generators which can be used to study the call graph in a more intuitive way.

The reports are all tabular, and have a similar set of columns:

(i) `Index`: The numeric identifier for the function in the vertex list of the call graph.

(ii) `Name`: The name of the function. The function name will be followed by an asterisk if a recursive call was made through it.

(iii) `Time`: The time spent in the function; depending on the report, the meaning might vary slightly.

(iv) `Count`: The number of times the function was called; depending on the report, the meaning might vary slightly.

`ProfilePrintByTotalCount(G)`

`Percentage`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :* -1

Print the list of functions in the call graph, sorted in descending order by the total number of times they were called. The `Time` and `Count` fields of the report give the total time and total number of times the function was called. If `Percentage` is true, then the `Time` and `Count` fields represent their values as percentages of the total value. If `Max` is non-negative, then the report only displays the first `Max` entries.

`ProfilePrintByTotalTime(G)`

`Percentage`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :* -1

Print the list of functions in the call graph, sorted in descending order by the total time spent in them. Apart from the sort order, this function's behaviour is identical to that of `ProfilePrintByTotalCount`.

`ProfilePrintChildrenByCount(G, n)`

`Percentage`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :* -1

Given a vertex n in the call graph G, print the list of functions called by the function n, sorted in descending order by the number of times they were called by n. The `Time` and `Count` fields of the report give the time spent during calls by the function n and the number of times the function was called by the function n. If `Percentage` is true, then the `Time` and `Count` fields represent their values as percentages of the total value. If `Max` is non-negative, then the report only displays the first `Max` entries.

`ProfilePrintChildrenByTime(G, n)`

`Percentage`	BoolElt	*Default :* `false`
`Max`	RngIntElt	*Default :* -1

Given a vertex n in the call graph G, print the list of functions in the called by the function n, sorted in descending order by the time spent during calls by the function n. Apart from the sort order, this function's behaviour is identical to that of `ProfilePrintChildrenByCount`.

Example H6E2

Continuing with the previous example, we examine the call graph using profile reports.

```
> ProfilePrintByTotalTime(G);
Index Name                                                    Time    Count
1     <main>                                                  10.940  1
2     fibonacci                                               10.940  392835
3     eq(<RngIntElt> x, <RngIntElt> y) -> BoolElt             1.210   710646
```

```
4     -(<RngIntElt> x, <RngIntElt> y) -> RngIntElt            0.630   392834
5     +(<RngIntElt> x, <RngIntElt> y) -> RngIntElt            0.250   196417

```

6.3.2 HTML Reports

While the internal reports are useful for casual inspection of a profile run, for detailed examination a text-based interface has serious limitations. MAGMA's profiler also supports the generation of HTML reports of the profile run. The HTML report can be loaded up in any web browser. If Javascript is enabled, then the tables in the report can be dynamically sorted by any field, by clicking on the column heading you wish to perform a sort with. Clicking the column heading multiple times will alternate between ascending and descending sorts.

`ProfileHTMLOutput(G, prefix)`

Given a call graph G, an HTML report is generated using the file prefix $prefix$. The index file of the report will be "$prefix$.html", and exactly n additional files will be generated with the given filename $prefix$, where n is the number of functions in the call graph.

6.4 Recursion and the Profiler

Recursive calls can cause some difficulty with profiler results. The profiler takes care to ensure that double-counting does not occur, but this can lead to unintuitive results, as the following example shows.

Example H6E3

In the following example, `recursive` is a recursive function which simply stays in a loop for half a second, and then recurses if not in the base case. Thus, the total running time should be approximately $(n+1)/2$ seconds, where n is the parameter to the function.

```
> procedure delay(s)
>     t := Cputime();
>     repeat
>       _ := 1+1;
>     until Cputime(t) gt s;
> end procedure;
>
> procedure recursive(n)
>     if n ne 0 then
>       recursive(n - 1);
>     end if;
>
>     delay(0.5);
> end procedure;
>
> SetProfile(true);
> recursive(1);
> SetProfile(false);
> G := ProfileGraph();
```

Printing the profile results by total time yield no surprises:

```
> ProfilePrintByTotalTime(G);
Index Name                                                    Time    Count
1     <main>                                                  1.020   1
2     recursive                                               1.020   2
5     delay                                                   1.020   2
8     Cputime(<FldReElt> T) -> FldReElt                       0.130   14880
7     +(<RngIntElt> x, <RngIntElt> y) -> RngIntElt            0.020   14880
9     gt(<FldReElt> x, <FldReElt> y) -> BoolElt               0.020   14880
3     ne(<RngIntElt> x, <RngIntElt> y) -> BoolElt             0.000   2
4     -(<RngIntElt> x, <RngIntElt> y) -> RngIntElt            0.000   1
6     Cputime() -> FldReElt                                   0.000   2
10    SetProfile(<BoolElt> v)                                 0.000   1
```

However, printing the children of `recursive`, and displaying the results in percentages, does yield a surprise:

```
> ProfilePrintChildrenByTime(G, 2 : Percentage);
Function: recursive
Function Time: 1.020
Function Count: 2
Index Name                                                    Time    Count
5     delay                                                   100.00  33.33
2     recursive (*)                                           50.00   16.67
```

```
3     ne(<RngIntElt> x, <RngIntElt> y) -> BoolElt              0.00    33.33
4     -(<RngIntElt> x, <RngIntElt> y) -> RngIntElt             0.00    16.67
* A recursive call is made through this child
```

At first glance, this doesn't appear to make sense, as the sum of the time column is 150%! The reason for this behavior is because some time is "double counted": the total time for the first call to `recursive` includes the time for the recursive call, which is also counted separately. In more detail:

```
> V := Vertices(G);
> E := Edges(G);
> Label(V!1)`Name;
<main>
> Label(V!2)`Name;
recursive
> Label(E![1,2])`Time;
1.01999999999999795718
> Label(E![2,2])`Time;
0.51000000000000000888
> Label(V!2)`Time;
1.01999999999999795718
```

As can seen in the above, the total time for `recursive` is approximately one second, as expected. The double-counting of the recursive call can be seen in the values of `Time` for the edges `[1,2]` and `[2,2]`.

7 DEBUGGING MAGMA CODE

Chapter 7
DEBUGGING MAGMA CODE

7.1 Introduction

In ordered to facilitate the debugging of complex pieces of MAGMA code, MAGMA includes a debugger. *This debugger is very much a prototype, and can cause* MAGMA *to crash.*

`SetDebugOnError(f)`

If f is `true`, then upon an error MAGMA will break into the debugger. The usage of the debugger is described in the next section.

7.2 Using the Debugger

When use of the debugger is enabled and an error occurs, MAGMA will break into the command-line debugger. The syntax of the debugger is modelled on the GNU GDB debugger for C programs, and supports the following commands (acceptable abbreviations for the commands are given in parentheses):

`backtrace (bt)` Print out the stack of function and procedure calls, from the top level to the point at which the error occurred. Each line i this trace gives a single *frame*, which consists of the function/procedure that was called, as well as all local variable definitions for that function. Each frame is numbered so that it can be referenced in other debugger commands.

`frame (f)` n Change the current frame to the frame numbered n (the list of frames can be obtained using the `backtrace` command). The current frame is used by other debugger commands, such as `print`, to determine the context within which expressions should be evaluated. The default current frame is the top-most frame.

`list (l)` [n] Print a source code listing for the current context (the context is set by the `frame` command). If n is specified, then the `list` command will print n lines of source code; the default value is 10.

`print (p)` *expr* Evaluate the expression *expr* in the current context (the context is set by the `frame` command). The `print` command has semantics identical to evaluating the expression `eval "expr"` at the current point in the program.

`help (h)` Print brief help on usage.

`quit (q)` Quit the debugger and return to the MAGMA session.

Example H7E1

We now give a sample session in the debugger. In the following, we have written a function to evaluate $f(n) = \Sigma_{i=1}^{n} 1/n$, but have in our implementation we have accidentally included the evaluation of the term at $n = 0$.

```
> function f(n)
>   if n ge 0 then
>      return 1.0 / n + f(n - 1);
>   else
>      return 1.0 / n;
>   end if;
> end function;
>
> SetDebugOnError(true);
> f(3);
f(
    n: 3
)
f(
    n: 2
)
f(
    n: 1
)
f(
    n: 0
)
>>      return 1.0 / n + f(n - 1);
                     ^
Runtime error in '/': Division by zero
debug> p n

```

PART II
SETS, SEQUENCES, AND MAPPINGS

8 INTRODUCTION TO AGGREGATES

Chapter 8
INTRODUCTION TO AGGREGATES

8.1 Introduction

This part of the Handbook comprises four chapters on aggregate objects in MAGMA as well as a chapter on maps.

Sets, sequences, tuples and lists are the four main types of aggregates, and each has its own specific purpose. *Sets* are used to collect objects that are elements of some common structure, and the most important operation is to test element membership. *Sequences* also contain objects of a common structure, but here the emphasis is on the ordering of the objects, and the most important operation is that of accessing (or modifying) elements at given positions. Sets will contain at most one copy of any element, whereas sequences may contain arbitrarily many copies of the same object. *Enumerated* sets and sequences are of arbitrary but finite length and will store all elements explicitly (with the exception of arithmetic progressions), while *formal* sets and sequences may be infinite, and use a Boolean function to test element membership. *Indexed* sets are a hybrid form of sets allowing indexing like sequences. Elements of *Cartesian products* of structures in MAGMA will be called *tuples*; they are of fixed length, and each coefficient must be in the corresponding structure of the defining Cartesian product. *Lists* are arbitrary finite ordered collections of objects of any type, and are mainly provided to the user to store assorted data to which access is not critical.

8.2 Restrictions on Sets and Sequences

Here we will explain the subtleties behind the mechanism dealing with sets and sequences and their universes and parents. Although the same principles apply to their formal counterparts, we will only talk about enumerated sets and sequences here, for two reasons: the enumerated versions are much more useful and common, and the very restricted number of operations on formal sets/sequences make issues of universe and overstructure of less importance for them.

In principle, every object e in MAGMA has some parent structure S such that $e \in S$; this structure can be used for type checking (are we allowed to apply function f to e?), algorithm look-up etc. To avoid storing the structure with every element of a set or sequence and having to look up the structure of every element separately, only elements of a *common structure* are allowed in sets or sequences, and that common parent will only be stored once.

8.2.1 Universe of a Set or Sequence

This common structure is called the *universe* of the set or sequence. In the general constructors it may be specified up front to make clear what the universe for the set or sequence will be; the difference between the sets i and s in

```
> i := { IntegerRing() | 1, 2, 3 };
> s := { RationalField() | 1, 2, 3 };
```

lies entirely in their universes. The specification of the universe may be omitted if there is an obvious common overstructure for the elements. Thus the following provides a shorter way to create the set containing 1, 2, 3 and having the ring of integers as universe:

```
> i := { 1, 2, 3 };
```

Only empty sets and sequences that have been obtained directly from the constructions

```
> S := { };
> T := [ ];
```

do not have their universe defined – we will call them the *null* set or sequence. (There are two other ways in which empty sets and sequences arise: it is possible to create empty sequences with a prescribed universe, using

```
> S := { U |  };
> T := [ U | ];
```

and it may happen that a non-empty set/sequence becomes empty in the course of a computation. In both cases these empty objects have their universe defined and will not be *null*).

Usually (but not always: the exception will be explained below) the universe of a set or sequence is the parent for all its elements; thus the ring of integers is the parent of 2 in the set $i = \{1, 2, 3\}$, rather than that set itself. The universe is not static, and it is not necessarily the same structure as the parent of the elements *before* they were put in the set or sequence. To illustrate this point, suppose that we try to create a set containing integers and rational numbers, say $T = \{1, 2, 1/3\}$; then we run into trouble with the rule that the universe must be common for all elements in T; the way this problem is solved in MAGMA is by automatic coercion: the obvious universe for T is the field of rational numbers of which $1/3$ is already an element and into which any integer can be coerced in an obvious way. Hence the assignment

```
> T := { 1, 2, 1/3 }
```

will result in a set with universe the field of rationals (which is also present when MAGMA is started up). Consequently, when we take the element 1 of the set T, it will have the rational field as its parent rather than the integer ring! It will now be clear that

```
> s := { 1/1, 2, 3 };
```

is a shorter way to specify the set of rational numbers 1,2, 3 than the way we saw before, but in general it is preferable to declare the universe beforehand using the `{ U | }` notation.

Of course

```
> T := { Integers() | 1, 2, 1/3 }
```

would result in an error because $1/3$ cannot be coerced into the ring of integers.

So, usually not every element of a given structure can be coerced into another structure, and even if it can, it will not always be done automatically. The possible (automatic) coercions are listed in the descriptions of the various MAGMA modules. For instance, the table in the introductory chapter on rings shows that integers can be coerced automatically into the rational field.

In general, every MAGMA structure is valid as a universe. This includes enumerated sets and sequences themselves, that is, it is possible to define a set or sequence whose elements are confined to be elements of a given set or sequence. So, for example,

```
> S := [ [ 1..10 ] | x^2+x+1 : x in { -3 .. 2 by 1 } ];
```

produces the sequence $[7, 3, 1, 1, 3, 7]$ of values of the polynomial $x^2 + x + 1$ for $x \in \mathbf{Z}$ with $-3 \leq x \leq 2$. However, an entry of S will in fact have the ring of integers as its parent (and *not* the sequence [1..10]), because the effect of the above assignment is that the values after the | are calculated and coerced into the universe, which is [1..10]; but coercing an element into a sequence or set means that it will in fact be coerced into the *universe* of that sequence/set, in this case the integers. So the main difference between the above assignment and

```
> T := [ Integers() | x^2+x+1 : x in { -3 .. 2 by 1} ];
```

is that in the first case it is checked that the resulting values y satisfy $1 \leq y \leq 10$, and an error would occur if this is violated:

```
> S := [ [ 1..10 ] | x^2+x+1 : x in { -3 .. 3 by 1} ];
```

leads to a run-time error.

In general then, the parent of an element of a set or sequence will be the universe of the set or sequence, unless that universe is itself a set or sequence, in which case the parent will be the universe of this universe, and so on, until a non-set or sequence is encountered.

8.2.2 Modifying the Universe of a Set or Sequence

Once a (non-null) set or sequence S has been created, the universe has been defined. If one attempts to *modify* S (that is, to add elements, change entries etc. using a procedure that will not reassign the result to a new set or sequence), the universe will not be changed, and the modification will only be successful if the new element can be coerced into the current universe. Thus,

```
> Z := Integers();
> T := [ Z | 1, 2, 3/3 ];
> T[2] := 3/4;
```

will result in an error, because $3/4$ cannot be coerced into Z.

The universe of a set or sequence S can be explicitly modified by creating a *parent* for S with the desired universe and using the `!` operator for the coercion; as we will see in the next subsection, such a parent can be created using the `PowerSet` and `PowerSequence` commands. Thus, for example, the set $\{1, 2\}$ can be made into a sequence of rationals as follows:

```
> I := { 1, 2 };
> P := PowerSet( RationalField() );
> J := P ! I;
```

The coercion will be successful if every element of the sequence can be coerced into the new universe, and it is *not* necessary that the old universe could be coerced completely into the new one: the set $\{3/3\}$ of rationals can be coerced into `PowerSet(Integers())`. As a consequence, the empty set (or sequence) with any universe can be coerced into the power set (power sequence) of any other universe.

Binary functions on sets or sequences (like `join` or `cat`) can only applied to sets and sequences that are *compatible*: the operation on S with universe A and T with universe B can only be performed if a common universe C can be found such that the elements of S and T are all elements of C. The compatibility conditions are dependent on the particular MAGMA module to which A and B belong (we refer to the corresponding chapters of this manual for further information) and do also apply to elements of $a \in A$ and $b \in B$ — that is, the compatibility conditions for S and T are the same as the ones that determine whether binary operations on $a \in A$ and $b \in B$ are allowed. For example, we are able to join a set of integers and a set of rationals:

```
> T := { 1, 2 } join { 1/3 };
```

for the same reason that we can do

```
> c := 1 + 1/3;
```

(automatic coercion for rings). The resulting set T will have the rationals as universe.
The basic rules for compatibility of two sets or sequences are then:

(1) every set/sequence is compatible with the null set/sequence (which has no universe defined (see above));

(2) two sets/sequences with the same universe are compatible;

(3) a set/sequence S with universe A is compatible with set/sequence T with universe B if the elements of A can be automatically coerced into B, or vice versa;

(4) more generally, a set/sequence S with universe A is also compatible with set/sequence T with universe B if MAGMA can automatically find an *over-structure* for the parents A and B (see below);

(5) nested sets and sequences are compatible only when they are of the same 'depth' and 'type' (that is, sets and sequences appear in exactly the same recursive order in both) and the universes are compatible.

The possibility of finding an overstructure C for the universe A and B of sets or sequences S and T (such that $A \subset C \supset B$), is again module-dependent. We refer the reader for

details to the Introductions of Parts III–VI, and we give some examples here; the next subsection contains the rules for parents of sets and sequences.

8.2.3 Parents of Sets and Sequences

The universe of a set or sequence S is the common parent for all its elements; but S itself is a MAGMA object as well, so it should have a parent too.

The parent of a set is a *power set*: the set of all subsets of the universe of S. It can be created using the `PowerSet` function. Similarly, `PowerSequence(A)` creates the parent structure for a sequence of elements from the structure A – that is, the elements of `PowerSequence(A)` are all sequences of elements of A.

The rules for finding a common overstructure for structures A and B, where either A or B is a set/sequence or the parent of a set/sequence, are as follows. (If neither A nor B is a set, sequence, or its parent we refer to the Part of this manual describing the operations on A and B.)

(1) The overstructure of A and B is the same as that of B and A.

(2) If A is the null set or sequence (empty, and no universe specified) the overstructure of A and B is B.

(3) If A is a set or sequence with universe U, the overstructure of A and B is the overstructure of U and B; in particular, the overstructure of A and A will be the universe U of A.

(4) If A is the parent of a set (a power set), then A and B can only have a common overstructure if B is also the parent of a set, in which case the overstructure is the power set of the overstructure of the universes U and V of A and B respectively. Likewise for sequences instead of sets.

We give two examples to illustrate rules (3) and (4). It is possible to create a set with a set as its universe:

```
> S := { { 1..100 } | x^3 : x in [ 0..3 ] };
```

If we wish to intersect this set with some set of integers, say the formal set of odd integers

```
> T := {! x : x in Integers() | IsOdd(x) !};
> W := S meet T;
```

then we can only do that if we can find a universe for W, which must be the common overstructure of the universe $U = \{1, 2, \ldots, 100\}$ of S and the universe 'ring of integers' of T. By rule (3) above, this overstructure of $U = \{1, 2, \ldots, 100\}$ will be the overstructure of the universe of U and the ring of integers; but the universe of U is the ring of integers (because it is the default for the set $\{1, 2, \ldots, 100\}$), and hence the overstructure we are looking for (and the universe for W) will be the ring of integers.

For the second example we look at sequences of sequences:

```
> a := [ [ 1 ], [ 1, 2, 3 ] ];
```

```
> b := [ [ 2/3 ] ];
```

so a is a sequence of sequences of integers, and b is a sequence of sequences of rationals. If we wish to concatenate a and b,

```
> c := a cat b;
```

we will only succeed if we find a universe for c. This universe must be the common overstructure of the universes of a and b, which are the 'power sequence of the integers' and the 'power sequence of the rationals' respectively. By rule (4), the overstructure of these two power sequences is the power sequence of the common overstructure of the rationals and the integers, which is the rationals themselves. Hence c will be a sequence of sequences of rationals, and the elements of a will have to be coerced.

8.3 Nested Aggregates

Enumerated sets and sequences can be arbitrarily nested (that is, one may create sets of sets, as well as sequences of sets etc.); tuples can also be nested and may be freely mixed with sets and sequences (as long as the proper Cartesian product parent can be created). Lists can be nested, and one may create lists of sets or sequences or tuples.

8.3.1 Multi-indexing

Since sequences (and lists) can be nested, assignment functions and mutation operators allow you to use *multi-indexing*, that is, one can use a multi-index $i_1, i_2, \ldots, i_r$ rather than a single i to reach r levels deep. Thus, for example, if $S = [\ [1,2],\ [2,3]\ ]$, instead of

```
> S[2][2] := 4;
```

one may use the multi-index $2, 2$ to obtain the same effect of changing the 3 into a 4:

```
> S[2,2] := 4;
```

All i_j in the multi-index $i_1, i_2, \ldots, i_r$ have to be greater than 0, and an error will also be flagged if any i_j indexes beyond the length at level j, that is, if $i_j > \#S[i_1, \ldots, i_{j-1}]$, (which means $i_1 > \#S$ for $j = 1$). There is one exception: the last index i_r is allowed to index beyond the current length of the sequence at level r if the multi-index is used on the left-hand side of an assignment, in which case any intermediate terms will be undefined. This generalizes the possibility to assign beyond the length of a 'flat' sequence. In the above example the following assignments are allowed:

```
> S[2,5] := 7;
```

(and the result will be $S = [\ [1,2],\ [2,3,\text{undef},\text{undef},7]\ ]$)

```
> S[4] := [7];
```

(and the result will be $S = [\ [1,2],\ [2,3],\ \text{undef},\ [7]\ ]$). But the following results in an error:

```
> S[4,1] := 7;
```

Finally we point out that multi-indexing should not be confused with the use of sequences as

indexes to create subsequences. For example, to create a subsequence of $S = [5, 13, 17, 29]$ consisting of the second and third terms, one may use

```
> S := [ 5, 13, 17, 29 ];
> T := S[ [2, 3] ];
```

To obtain the second term of this subsequence one could have done:

```
> x := S[ [2, 3] ][2];
```

(so x now has the value $S[3] = 17$), but it would have been more efficient to index the indexing sequence, since it is rather expensive to build the subsequence [$S[2], S[3]$] first, so:

```
> x :=  S[ [2, 3][2] ];
```

has the same effect but is better (of course `x := S[3]` would be even better in this simple example.) To add to the confusion, it is possible to mix the above constructions for indexing, since one can use lists of sequences and indices for indexing; continuing our example, there is now a third way to do the same as above, using an indexing list that first takes out the subsequence consisting of the second and third terms and then extracts the second term of that:

```
> x :=  S[ [2, 3], 2 ];
```

Similarly, the construction

```
> X :=  S[ [2, 3], [2] ];
```

pulls out the subsequence consisting of the second term of the subsequence of terms two and three of S, in other words, this assigns the *sequence* consisting of the element 17, not just the element itself!

9 SETS

Chapter 9
SETS

9.1 Introduction

A *set* in MAGMA is a (usually unordered) collection of objects belonging to some common structure (called the *universe* of the set). There are four basic types of sets: *enumerated sets*, whose elements are all stored explicitly (with one exception, see below); *formal sets*, whose elements are stored implicitly by means of a predicate that allows for testing membership; *indexed sets*, which are restricted enumerated sets having a numbering on elements; and *multisets*, which are enumerated sets with possible repetition of elements. In particular, enumerated and indexed sets and multisets are always finite, and formal sets are allowed to be infinite.

9.1.1 Enumerated Sets

Enumerated sets are finite, and can be specified in three basic ways (see also section 2 below): by listing all elements; by an expression involving elements of some finite structure; and by an arithmetic progression. If an arithmetic progression is specified, the elements are not calculated explicitly until a modification of the set necessitates it; in all other cases all elements of the enumerated set are stored explicitly.

9.1.2 Formal Sets

A formal set consists of the subset of elements of some carrier set (structure) on which a certain predicate assumes the value 'true'.

The only set-theoretic operations that can be performed on formal sets are union, intersection, difference and symmetric difference, and element membership testing.

9.1.3 Indexed Sets

For some purposes it is useful to be able to access elements of a set through an index map, which numbers the elements of the set. For that purpose MAGMA has indexed sets, on which a very few basic set operations are allowed (element membership testing) as well as some sequence-like operations (such as accessing the i-th term, getting the index of an element, appending and pruning).

9.1.4 Multisets

For some purposes it is useful to construct a set with some of its members repeated. For that purpose MAGMA has multisets, which take into account the repetition of members. The number of times an object x occurs in a multiset S is called the *multiplicity* of x in S. MAGMA has the `^^` operator to specify a multiplicity: the expression `x^^n` means the object x with multiplicity n. In the following, whenever any multiset constructor or function expects an element y, the expression x`^^`n may usually be used.

9.1.5 Compatibility

The binary operators for sets do not allow mixing of the four types of sets (so one cannot take the intersection of an enumerated set and a formal set, for example), but it is easy to convert an enumerated set into a formal set – see the section on binary operators below – and there are functions provided for making an enumerated set out of an indexed set or a multiset (and vice versa).

By the limitation on their construction formal sets can only contain elements from one structure in MAGMA. The elements of enumerated sets are also restricted, in the sense that either some universe must be specified upon creation, or MAGMA must be able to find such universe automatically. The rules for compatibility of elements and the way MAGMA deals with these universes are the same for sequences and sets, and are described in the previous chapter. The restrictions on indexed sets are the same as those for enumerated sets.

9.1.6 Notation

Certain expressions appearing in the sections below (possibly with subscripts) have a standard interpretation:

U the universe: any MAGMA structure;

E the carrier set for enumerated sets: any enumerated structure (it must be possible to loop over its elements – see the Introduction to this Part (Chapter 8));

F the carrier set for formal sets: any structure for which membership testing using `in` is defined – see the Introduction to this Part (Chapter 8));

x a free variable which successively takes the elements of E (or F in the formal case) as its values;

P a Boolean expression that usually involves the variable(s) x, $x_1, \ldots, x_k$;

e an expression that also usually involves the variable(s) x, $x_1, \ldots, x_k$.

9.2 Creating Sets

The customary braces { and } are used to define enumerated sets. Formal sets are delimited by the composite braces {`!` and `!`}. For indexed sets {`@` and `@`} are used. For multisets {`*` and `*`} are used.

9.2.1 The Formal Set Constructor

The formal set constructor has the following fixed format (the expressions appearing in the construct are defined above):

```
{!  x in F | P(x) !}
```

Form the formal set consisting of the subset of elements x of F for which $P(x)$ is true. If $P(x)$ is true for every element of F, the set constructor may be abbreviated to {`!  x in F !`}. Note that the universe of a formal set will always be equal to the carrier set F.

9.2.2 The Enumerated Set Constructor

Enumerated sets can be constructed by expressions enclosed in braces, provided that the values of all expressions can be automatically coerced into some common structure, as outlined in the Introduction, (Chapter 8). All general constructors have an optional universe (U in the list below) up front, that allows the user to specify into which structure all terms of the sets should be coerced.

`{ }`

The null set: an empty set that does not have its universe defined.

`{ U | }`

The empty set with universe U.

`{ e1, e2, ..., en }`

Given a list of expressions $e_1, \ldots, e_n$, defining elements $a_1, a_2, \ldots, a_n$ all belonging to (or automatically coercible into) a single algebraic structure U, create the set $\{ a_1, a_2, ..., a_n \}$ of elements of U.

Example H9E1

We create a set by listing its elements explicitly.

```
> S := { (7^2+1)/5, (8^2+1)/5, (9^2-1)/5 };
> S;
{ 10, 13, 16 }
> Parent(S);
Set of subsets of Rational Field
```

Thus S was created as a set of rationals, because `/` on integers has a rational result. If one wishes to obtain a set of integers, one could specify the universe (or one could use `div`, or one could use `!` on every element to coerce it into the ring of integers):

```
> T := { Integers() | (7^2+1)/5, (8^2+1)/5, (9^2-1)/5 };
> T;
{ 10, 13, 16 }
> Parent(T);
Set of subsets of Integer Ring
```

`{ U | e1, e2, ..., en }`

Given a list of expressions $e_1, \ldots, e_n$, which define elements $a_1, a_2, \ldots, a_n$ that are all coercible into U, create the set $\{a_1, a_2, ..., a_n \}$ of elements of U.

```
{ e(x) :  x in E | P(x) }
```

Form the set of elements $e(x)$, all belonging to some common structure, for those $x \in E$ with the property that the predicate $P(x)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8) (in particular, E must be a finite structure that can be enumerated).

If $P(x)$ is true for every value of x in E, then the set constructor may be abbreviated to { e(x) : x in E }.

```
{ U | e(x) :  x in E | P(x) }
```

Form the set of elements of U consisting of the values $e(x)$ for those $x \in E$ for which the predicate $P(x)$ is true (an error results if not all $e(x)$ are coercible into U). The expressions appearing in this construct have the same interpretation as before.

If P is always true, it may be omitted (including the |).

```
{ e(x1,...,xk) :  x1 in E1, ..., xk in Ek | P(x1, ..., xk) }
```

The set consisting of those elements $e(x_1, \ldots, x_k)$, in some common structure, for which $x_1, \ldots, x_k$ in $E_1, \ldots, E_k$ have the property that $P(x_1, \ldots, x_k)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8).

Note that if two successive allowable structures E_i and E_{i+1} are identical, then the specification of the carrier sets for x_i and x_{i+1} may be abbreviated to `xi, xi+1 in Ei`.

Also, if $P(x_1, ..., x_k)$ is always true, it may be omitted (including the |).

```
{ U | e(x1,...,xk) :  x1 in E1, ..., xk in Ek | P(x1, ..., xk) }
```

As in the previous entry, the set consisting of those elements $e(x_1, \ldots, x_k)$ for which $P(x_1, \ldots, x_k)$ is true, is formed, as a set of elements of U (an error occurs if not all $e(x_1, \ldots, x_k)$ are elements of or coercible into U).

Again, identical successive structures may be abbreviated, and a predicate that is always true may be omitted.

Example H9E2

Now that Fermat's last theorem may have been proven, it may be of interest to find integers that almost satisfy $x^n + y^n = z^n$. In this example we find all $2 < x, y, z < 1000$ such that $x^3 + y^3 = z^3 + 1$. First we build a set of cubes, then two sets of pairs for which the sum of cubes differs from a cube by 1. Note that we build a *set* rather than a sequence of cubes because we only need fast membership testing. Also note that the resulting sets of pairs do not have their elements in the order in which they were found.

```
> cubes := { Integers() | x^3 : x in [1..1000] };
> plus := { <a, b> : a in [2..1000], b in [2..1000] | \
>    b ge a and (a^3+b^3-1) in cubes };
> plus;
{
```

```
        < 9, 10 >,
        < 135, 235 >
        < 334, 438 >,
        < 73, 144 >,
        < 64, 94 >,
        < 244, 729 >
}
```

Note that we spend a lot of time cubing integers this way. For a more efficient approach, see a subsequent example.

9.2.3 The Indexed Set Constructor

The creation of indexed sets is similar to that of enumerated sets.

`{@ @}`

The null set: an empty indexed set that does not have its universe defined.

`{@ U | @}`

The empty indexed set with universe U.

`{@` e_1`,` e_2`, ...,` e_n `@}`

Given a list of expressions $e_1, \ldots, e_n$, defining elements $a_1, a_2, \ldots, a_n$ all belonging to (or automatically coercible into) a single algebraic structure U, create the indexed set $Q = \{\ a_1, a_2, ..., a_n\ \}$ of elements of U.

`{@ U |` e_1`,` e_2`, ...,` e_m `@}`

Given a list of expressions $e_1, \ldots, e_m$, which define elements $a_1, a_2, \ldots, a_n$ that are all coercible into U, create the indexed set $Q = \{a_1, a_2, ..., a_n\ \}$ of elements of U.

`{@ e(x) : x in E | P(x) @}`

Form the indexed set of elements $e(x)$, all belonging to some common structure, for those $x \in E$ with the property that the predicate $P(x)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8) (in particular, E must be a finite structure that can be enumerated).

If P is always true, it may be omitted (including the |).

`{@ U | e(x) : x in E | P(x) @}`

Form the indexed set of elements of U consisting of the values $e(x)$ for those $x \in E$ for which the predicate $P(x)$ is true (an error results if not all $e(x)$ are coercible into U). The expressions appearing in this construct have the same interpretation as before.

If P is always true, it may be omitted (including the |).

{@ e(x$_1$,...,x$_k$) : x$_1$ in E$_1$, ..., x$_k$ in E$_k$ | P(x$_1$, ..., x$_k$) @}

The indexed set consisting of those elements $e(x_1, \ldots, x_k)$ (in some common structure), for which $x_1, \ldots, x_k$ in $E_1 \times \ldots \times E_k$ have the property that $P(x_1, \ldots, x_k)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8).

Note that if two successive allowable structures E_i and E_{i+1} are identical, then the specification of the carrier sets for x_i and x_{i+1} may be abbreviated to x$_i$, x$_{i+1}$ in E$_i$.

Also, if $P(x_1, ..., x_k)$ is always true, it may be omitted.

{@ U | e(x$_1$,...,x$_k$) : x$_1$ in E$_1$, ..., x$_k$ in E$_k$ | P(x$_1$, ..., x$_k$)@}

As in the previous entry, the indexed set consisting of those elements $e(x_1, \ldots, x_k)$ for which $P(x_1, \ldots, x_k)$ is true is formed, as an indexed set of elements of U (an error occurs if not all $e(x_1, \ldots, x_k)$ are elements of or coercible into U).

Again, identical successive structures may be abbreviated, and a predicate that is always true may be omitted.

Example H9E3

In the previous example we found pairs x, y such that $x^3 + y^3$ differs by one from some cube z^3. Using indexed sets it is somewhat easier to retrieve the integer z as well. We give a small example. Note also that it is beneficial to know here that evaluation of expressions proceeds left to right.

```
> cubes := { @ Integers() | z^3 : z in [1..25] @};
> plus := { <x, y, z> : x in [-10..10], y in [-10..10], z in [1..25] |
>    y ge x and Abs(x) gt 1 and Abs(y) gt 1 and (x^3+y^3-1) in cubes
>    and (x^3+y^3-1) eq cubes[z] };
> plus;
{ <-6, 9, 8>, <9, 10, 12>, <-8, 9, 6> }
```

9.2.4 The Multiset Constructor

The creation of multisets is similar to that of enumerated sets. An important difference is that repetitions are significant and the operator ^^ (mentioned above) may be used to specify the multiplicity of an element.

{* *}

The null set: an empty multiset that does not have its universe defined.

{* U | *}

The empty multiset with universe U.

`{* e1, e2, ..., en *}`

Given a list of expressions $e_1, \ldots, e_n$, defining elements $a_1, a_2, \ldots, a_n$ all belonging to (or automatically coercible into) a single algebraic structure U, create the multiset $Q = \{* \ a_1, a_2, ..., a_n \ *\}$ of elements of U.

`{* U | e1, e2, ..., em *}`

Given a list of expressions $e_1, \ldots, e_m$, which define elements $a_1, a_2, \ldots, a_n$ that are all coercible into U, create the multiset $Q = \{* \ a_1, a_2, ..., a_n \ *\}$ of elements of U.

`{* e(x) : x in E | P(x) *}`

Form the multiset of elements $e(x)$, all belonging to some common structure, for those $x \in E$ with the property that the predicate $P(x)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8) (in particular, E must be a finite structure that can be enumerated).

If P is always true, it may be omitted (including the |).

`{* U | e(x) : x in E | P(x) *}`

Form the multiset of elements of U consisting of the values $e(x)$ for those $x \in E$ for which the predicate $P(x)$ is true (an error results if not all $e(x)$ are coercible into U). The expressions appearing in this construct have the same interpretation as before.

If P is always true, it may be omitted (including the |).

`{* e(x1,...,xk) : x1 in E1, ..., xk in Ek | P(x1, ..., xk) *}`

The multiset consisting of those elements $e(x_1, \ldots, x_k)$ (in some common structure), for which $x_1, \ldots, x_k$ in $E_1 \times \ldots \times E_k$ have the property that $P(x_1, \ldots, x_k)$ is true. The expressions appearing in this construct have the interpretation given in the Introduction (Chapter 8).

Note that if two successive allowable structures E_i and E_{i+1} are identical, then the specification of the carrier sets for x_i and x_{i+1} may be abbreviated to `xi, xi+1 in Ei`.

Also, if $P(x_1, ..., x_k)$ is always true, it may be omitted.

`{* U | e(x1,...,xk) : x1 in E1, ..., xk in Ek | P(x1, ..., xk)*}`

As in the previous entry, the multiset consisting of those elements $e(x_1, \ldots, x_k)$ for which $P(x_1, \ldots, x_k)$ is true is formed, as an multiset of elements of U (an error occurs if not all $e(x_1, \ldots, x_k)$ are elements of or coercible into U).

Again, identical successive structures may be abbreviated, and a predicate that is always true may be omitted.

Example H9E4

Here we demonstrate the use of the multiset constructors.

```
> M := {* 1, 1, 1, 3, 5 *};
> M;
{* 1^^3, 3, 5 *}
> M := {* 1^^4, 2^^5, 1/2^^3 *};
> M;
> // Count frequency of digits in first 1000 digits of pi:
> pi := Pi(RealField(1001));
> dec1000 := Round(10^1000*(pi-3));
> I := IntegerToString(dec1000);
> F := {* I[i]: i in [1 .. #I] *};
> F;
{* 7^^95, 3^^102, 6^^94, 2^^103, 9^^106, 5^^97,
1^^116, 8^^101, 4^^93, 0^^93 *}
> for i := 0 to 9 do i, Multiplicity(F, IntegerToString(i)); end for;
0 93
1 116
2 103
3 102
4 93
5 97
6 94
7 95
8 101
9 106
```

9.2.5 The Arithmetic Progression Constructors

Some special constructors exist to create and store enumerated sets of integers in arithmetic progression efficiently. This only works for arithmetic progressions of elements of the ring of integers.

`{ i..j }`

`{ U | i..j }`

The enumerated set whose elements form the arithmetic progression $i, i+1, i+2, \ldots, j$, where i and j are (expressions defining) integers. If j is less than i then the empty set will be created.

The only universe U that is legal here is the ring of integers.

`{ i .. j by k }`

`{ U | i .. j by k }`

The enumerated set consisting of the integers forming the arithmetic progression $i, i+k, i+2*k, \ldots, j$, where i, j and k are (expressions defining) integers (but $k \neq 0$).

If k is positive then the last element in the progression will be the greatest integer of the form $i + n * k$ that is less than or equal to j. If j is less than i, the empty set will be constructed.

If k is negative then the last element in the progression will be the least integer of the form $i + n * k$ that is greater than or equal to j. If j is greater than i, the empty set will be constructed.

As for the previous constructor, only the ring of integers is allowed as a legal universe U.

Example H9E5

It is possible to use the arithmetic progression constructors to save typing in the creation of 'arithmetic progressions' of elements of other structures than the ring of integers, but it should be kept in mind that the result will not be treated especially efficiently like the integer case. Here is the 'wrong' way, as well as two correct ways to create a set of 10 finite field elements.

```
>  S := { FiniteField(13) | 1..10 };
Runtime error in { .. }: Invalid set universe
> S := { FiniteField(13) | x : x in { 1..10 } };
> S;
{ 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 }
> G := PowerSet(FiniteField(13));
> S := G ! { 1..10 };
> S;
{ 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 }
```

9.3 Power Sets

The `PowerSet` constructor returns a structure comprising the subsets of a given structure R; it is mainly useful as a parent for other set and sequence constructors. The only operations that are allowed on power sets are printing, testing element membership, and coercion into the power set (see the examples below).

`PowerSet(R)`

The structure comprising all enumerated subsets of structure R.

`PowerIndexedSet(R)`

The structure comprising all indexed subsets of structure R.

`PowerMultiset(R)`

The structure consisting of all submultisets of the structure R.

`S in P`

Returns `true` if enumerated set S is in the power set P, that is, if all elements of the set S are contained in or coercible into R, where P is the power set of R; `false` otherwise.

`PowerFormalSet(R)`

The structure comprising all formal subsets of structure R.

`S in P`

Returns `true` if indexed set S is in the power set P, that is, if all elements of the set S are contained in or coercible into R, where P is the power set of R; `false` otherwise.

`S in P`

Returns `true` if multiset S is in the power set P, that is, if all elements of the set S are contained in or coercible into R, where P is the power set of R; `false` otherwise.

`P ! S`

Return a set with universe R consisting of the elements of the set S, where P is the power set of R. An error results if not all elements of S can be coerced into R.

`P ! S`

Return an indexed set with universe R consisting of the elements of the set S, where P is the power set of R. An error results if not all elements of S can be coerced into R.

`P ! S`

Return an multiset with universe R consisting of the elements of the set S, where P is the power set of R. An error results if not all elements of S can be coerced into R.

Example H9E6

```
> S := { 1 .. 10 };
> P := PowerSet(S);
> P;
Set of subsets of { 1 .. 10 }
> F := { 6/3, 12/4 };
> F in P;
true
> G := P ! F;
> Parent(F);
Set of subsets of Rational Field
> Parent(G);
Set of subsets of { 1 .. 10 }
```

9.3.1 The Cartesian Product Constructors

Using `car< >` and `CartesianProduct( )`, it is possible to create the Cartesian product of sets (or, in fact, of any combination of structures), but the result will be of type 'Cartesian product' rather than set, and the elements are tuples – we refer the reader to Chapter 11 for details.

9.4 Sets from Structures

`Set(M)`

Given a finite structure that allows explicit enumeration of its elements, return the set containing its elements (having M as its universe).

`FormalSet(M)`

Given a structure M, return the formal set consisting of its elements.

9.5 Accessing and Modifying Sets

Enumerated sets can be modified by inserting or removing elements. Indexed sets allow some sequence-like operators for modification and access.

9.5.1 Accessing Sets and their Associated Structures

`#R`

Cardinality of the enumerated, indexed, or multi- set R. Note that for a multiset, repetitions are significant, so the result may be greater than the underlying set.

`Category(S)`

`Type(S)`

The category of the object S. For a set this will be one of `SetEnum`, `SetIndx`, `SetMulti`, or `SetFormal`. For a power set the type is one of `PowSetEnum`, `PowSetIndx`, `PowSetMulti`.

`Parent(R)`

Returns the parent structure of R, that is, the structure consisting of all (enumerated) sequences over the universe of R.

`Universe(R)`

Returns the 'universe' of the (enumerated or indexed or multi- or formal) set R, that is, the common structure to which all elements of the set belong. An error is signalled when R is the null set.

`Index(S, x)`

`Position(S, x)`

Given an indexed set S, and an element x, returns the index i such that $S[i] = x$ if such index exists, or return 0 if x is not in S. If x is not in the universe of S, an attempt will be made to coerce it; an error occurs if this fails.

`S[i]`

Return the i-th entry of indexed set S. If $i < 1$ or $i > \#S$ an error occurs. Note that indexing is *not* allowed on the left hand side.

`S[I]`

The indexed set $\{S[i_1], \ldots, S[i_r]\}$ consisting of terms selected from the indexed set S, according to the terms of the integer sequence I. If any term of I lies outside the range 1 to $\#S$, then an error results. If I is the empty sequence, then the empty set with universe the same as that of S is returned.

Example H9E7

We build an indexed set of sets to illustrate the use of the above functions.

```
> B := { @ { i : i in [1..k] } :  k in [1..5] @};
> B;
{ @
   { 1 },
   { 1, 2 },
   { 1, 2, 3 },
   { 1, 2, 3, 4 },
   { 1, 2, 3, 4, 5 },
@}
> #B;
5
> Universe(B);
Set of subsets of Integer Ring
> Parent(B);
Set of indexed subsets of Set of subsets of Integer Ring
> Category(B);
SetIndx
> Index(B, { 2, 1});
2
> #B[2];
2
> Universe(B[2]);
Integer Ring
```

9.5.2 Selecting Elements of Sets

Most finite structures in MAGMA, including enumerated sets, allow one to obtain a random element using `Random`. There is an alternative (and often preferable) option for enumerated sets in the `random{ }` constructor. This makes it possible to choose a random element of the set without generating the whole set first.

Likewise, `rep{ }` is an alternative to the general `Rep` function returning a representative element of a structure, having the advantage of aborting the construction of the set as soon as one element has been found.

Here, E will again be an enumerable structure, that is, a structure that allows enumeration of its elements (see the Appendix for an exhaustive list).

Note that `random{ e(x) :  x in E | P(x)}` does *not* return a random element of the set of values $e(x)$, but rather a value of $e(x)$ for a random x in E which satisfies P (and mutatis mutandis for `rep`).

See the subsection on Notation in the Introduction (Chapter 8) for conventions regarding e, x, E, P.

`Random(R)`

A random element chosen from the enumerated, indexed or multi- set R. Every element has an equal probability of being chosen for enumerated or indexed sets, and a weighted probability in proportion to its multiplicity for multisets. Successive invocations of the function will result in independently chosen elements being returned as the value of the function. If R is empty an error occurs.

`random{ e(x) : x in E | P(x) }`

Given an enumerated structure E and a Boolean expression P, return the value of the expression $e(y)$ for a randomly chosen element y of E for which $P(y)$ is true.

P may be omitted if it is always true.

`random{e(`x_1`, ..., `x_k`) : `x_1` in E`$_1$`, ..., `x_k` in E`$_k$` | P(`x_1`, ..., `x_k`)}`

Given enumerated structures $E_1, \ldots, E_k$, and a Boolean expression $P(x_1, \ldots, x_k)$, return the value of the expression $e(y_1, \cdots, y_k)$ for a randomly chosen element $< y_1, \ldots, y_k >$ of $E_1 \times \cdots \times E_k$, for which $P(y_1, \ldots, y_k)$ is true.

P may be omitted if it is always true.

If successive structures E_i and E_{i+1} are identical, then the abbreviation `x`$_i$`, x`$_{i+1}$ `in E`$_i$ may be used.

Example H9E8

Here are two ways to find a 'random' primitive element for a finite field.

```
> p := 10007;
> F := FiniteField(p);
> proots := {  z : z in F | IsPrimitive(z) };
> #proots;
5002
> Random(proots);
5279
```

This way, a set of 5002 elements is built (and primitivity is checked for all elements of F), and a random choice is made. Alternatively, we use `random`.

```
> random{ x : x in F | IsPrimitive(x) };
4263
```

In this case random elements in F are chosen until one is found that is primitive. Since almost half of F's elements are primitive, only very few primitivity tests will be done before success occurs.

`Representative(R)`

`Rep(R)`

An arbitrary element chosen from the enumerated, indexed, or multi- set R.

`ExtractRep(~R, ~r)`

Assigns an arbitrary element chosen from the enumerated set R to r, and removes it from R. Thus the set R is modified, as well as the element r. An error occurs if R is empty.

`rep{ e(x) : x in E | P(x) }`

Given an enumerated structure E and a Boolean expression P, return the value of the expression `e(y)` for the first element y of E for which $P(y)$ is true. If $P(x)$ is false for every element of E, an error will occur.

`rep{ e(x1, ..., xk) : x1 in E1, ..., xk in Ek | P(x1, ..., xk) }`

Given enumerated structures $E_1, \ldots, E_k$, and a Boolean expression $P(x_1, \ldots, x_k)$, return the value of the expression $e(y_1, \cdots, y_k)$ for the first element $< y_1, \ldots, y_k >$ of $E_1 \times \cdots \times E_k$, for which $P(y_1, \ldots, y_k)$ is true. An error occurs if no element of $E_1 \times \cdots \times E_k$ satisfies P.

P may be omitted if it is always true.

If successive structures E_i and E_{i+1} are identical, then the abbreviation `xi, xi+1 in Ei` may be used.

Example H9E9

As an illustration of the use of `ExtractRep`, we modify an earlier example, and find cubes satisfying $x^3 + y^3 = z^3 - 1$ (with $x, y, z \leq 1000$).

```
> cubes := { Integers() | x^3 : x in [1..1000] };
> cc := cubes;
> min := { };
> while not IsEmpty(cc) do
>    ExtractRep(~cc, ~a);
>    for b in cc do
>       if a+b+1 in cubes then
>          min join:= { <a, b> };
>       end if;
>    end for;
> end while;
> { < Iroot(x[1], 3), Iroot(x[2], 3) > : x in min };
{ <138, 135>, <823, 566>, <426, 372>, <242, 720>,
      <138, 71>, <426, 486>, <6, 8> }
```

Note that instead of taking cubes over again, we only have to take cube roots in the last line (on the small resulting set) once.

`Minimum(S)`
`Min(S)`

Given a non-empty enumerated, indexed, or multi- set S, such that `lt` and `eq` are defined on the universe of S, this function returns the minimum of the elements of S. If S is an indexed set, the position of the minimum is also returned.

`Maximum(S)`
`Max(S)`

Given a non-empty enumerated, indexed, or multi- set S, such that `lt` and `eq` are defined on the universe of S, this function returns the maximum of the elements of S. If S is an indexed set, the position of the maximum is also returned.

`Hash(x)`

Given a Magma object x which can be placed in a set, return the hash value of x used by the set machinery. This is a fixed but arbitrary non-negative integer (whose maximum value is the maximum value of a C unsigned long on the particular machine). The crucial property is that if x and y are objects and x equals y then the hash values of x and y are equal (even if x and y have different internal structures). Thus one could implement sets manually if desired by the use of this function.

9.5.3 Modifying Sets

`Include(~S, x)`
`Include(S, x)`

Create the enumerated, indexed, or multi- set obtained by putting the element x in S (S is unchanged if S is not a multiset and x is already in S). If S is an indexed set, the element will be appended at the end. If S is a multiset, the multiplicity of x will be increased accordingly. If x is not in the universe of S, an attempt will be made to coerce it; an error occurs if this fails.

There are two versions of this: a procedure, where S is replaced by the new set, and a function, which returns the new set. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the set S will not be copied.

`Exclude(~S, x)`
`Exclude(S, x)`

Create a new set by removing the element x from S. If S is an enumerated set, nothing happens if x is not in S. If S is a multiset, the multiplicity of x will be decreased accordingly. If x is not in the universe of S, an attempt will be made to coerce it; an error occurs if this fails.

There are two versions of this: a procedure, where S is replaced by the new set, and a function, which returns the new set. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the set S will not be copied.

`ChangeUniverse(~S, V)`

`ChangeUniverse(S, V)`

Given an enumerated, indexed, or multi- set S with universe U and a structure V which contains U, construct a new set of the same type which consists of the elements of S coerced into V.

There are two versions of this: a procedure, where S is replaced by the new set, and a function, which returns the new set. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the set S will not be copied.

`CanChangeUniverse(S, V)`

Given an enumerated, indexed, or multi- set S with universe U and a structure V which contains U, attempt to construct a new set T of the same type which consists of the elements of S coerced into V; if successful, return `true` and T, otherwise return `false`.

Example H9E10

This example uses `Include` and `Exclude` to find a set (if it exists) of cubes of integers such that the elements of a given set R can be expressed as the sum of two of those.

```
> R := { 218, 271, 511 };
> x := 0;
> cubes := { 0 };
> while not IsEmpty(R) do
>    x +:= 1;
>    c := x^3;
>    Include(~cubes, c);
>    Include(~cubes, -c);
>    for z in cubes do
>        Exclude(~R, z+c);
>        Exclude(~R, z-c);
>    end for;
> end while;
```

We did not record how the elements of R were obtained as sums of a pair of cubes. For that, the following suffices.

```
> R := { 218, 271, 511 }; // it has been emptied !
> { { x, y } : x, y in cubes | x+y in R };
```

```
{
    { -729, 1000 },
    { -125, 343 },
    { -1, 512 },
}
```

`SetToIndexedSet(E)`

Given an enumerated set E, this function returns an indexed set with the same elements (and universe) as E.

`IndexedSetToSet(S)`

`Isetset(S)`

Given an indexed set S, this function returns an enumerated set with the same elements (and universe) as E.

`IndexedSetToSequence(S)`

`Isetseq(S)`

Given an indexed set S, this function returns a sequence with the same elements (and universe) as E.

`MultisetToSet(S)`

Given a multiset S, this function returns an enumerated set with the same elements (and universe) as S.

`SetToMultiset(E)`

Given an enumerated set E, this function returns a multiset with the same elements (and universe) as E.

`SequenceToMultiset(Q)`

Given an enumerated sequence E, this function returns a multiset with the same elements (and universe) as E.

9.6 Operations on Sets

9.6.1 Boolean Functions and Operators

As explained in the Introduction (Chapter 8), when elements are taken out of a set their parent will be the universe of the set (or, if the universe is itself a set, the universe of the universe, etc.); in particular, the set itself is not the parent. Hence equality testing on set elements is in fact equality testing between two elements of certain algebraic structures, and the sets are irrelevant. We only list the (in)equality operator for convenience here.

Element membership testing is of critical importance for all types of sets.

Testing whether or not R is a subset of S can be done if R is an enumerated or indexed set and S is any set; hence (in)equality testing is only possible between sets that are not formal sets.

`IsNull(R)`

Returns `true` if and only if the enumerated, indexed, or multi- set R is empty and does not have its universe defined.

`IsEmpty(R)`

Returns `true` if and only if the enumerated, indexed or multi- set R is empty.

`x eq y`

Given an element x of a set R with universe U and an element y of a set S with universe V, where a common overstructure W can be found with $U \subset W \supset V$ (see the Introduction (Chapter 8) for details on overstructures), return `true` if and only if x and y are equal as elements of W.

`x ne y`

Given an element x of a set R with universe U and an element y of a set S with universe V, where a common overstructure W can be found with $U \subset W \supset V$ (see the Introduction (Chapter 8) for details on overstructures), return `true` if and only if x and y are distinct as elements of W.

`x in R`

Returns `true` if and only if the element x is a member of the set R. If x is not an element of the universe U of R, it is attempted to coerce x into U; if this fails, an error occurs.

`x notin R`

Returns `true` if and only if the element x is not a member of the set R. If x is not an element of the parent structure U of R, it is attempted to coerce x into U; if this fails, an error occurs.

`R subset S`

Returns `true` if the enumerated, indexed or multi- set R is a subset of the set S, `false` otherwise. For multisets, if an element x of R has multiplicity n in R, the multiplicity of x in S must be at least n. Coercion of the elements of R into S is attempted if necessary, and an error occurs if this fails.

`R notsubset S`

Returns `true` if the enumerated, indexed, or multi- set R is a not a subset of the set S, `false` otherwise. Coercion of the elements of R into S is attempted if necessary, and an error occurs if this fails.

`R eq S`

Returns `true` if and only if R and S are identical sets, where R and S are enumerated, indexed or multi- sets For indexed sets, the index function is irrelevant for deciding equality. For multisets, matching multiplicities must also be equal. Coercion of the elements of R into S is attempted if necessary, and an error occurs if this fails.

`R ne S`

Returns `true` if and only if R and S are distinct sets, where R and S are enumerated indexed, or multi- sets. For indexed sets, the index function is irrelevant for deciding equality. For multisets, matching multiplicities must also be equal. Coercion of the elements of R into S is attempted if necessary, and an error occurs if this fails.

`IsDisjoint(R, S)`

Returns `true` iff the enumerated, indexed or multi- sets R and S are disjoint. Coercion of the elements of R into S is attempted if necessary, and an error occurs if this fails.

9.6.2 Binary Set Operators

For each of the following operators, R and S are sets of the same type. If R and S are both formal sets, then an error will occur unless both have been constructed with the same carrier structure F in the definition. If R and S are both enumerated, indexed, or multi-sets, then an error occurs unless the universes of R and S are compatible, as defined in the Introduction to this Part (Chapter 8).
Note that

`Q := { ! x in R !}`

converts an enumerated set R into a formal set Q.

`R join S`

Union of the sets R and S (see above for the restrictions on R and S). For multisets, matching multiplicities are added in the union.

`R meet S`

Intersection of the sets R and S (see above for the restrictions on R and S). For multisets, the minimum of matching multiplicities is stored in the intersection.

`R diff S`

Difference of the sets R and S. i.e., the set consisting of those elements of R which are not members of S (see above for the restrictions on R and S). For multisets, the difference contains any elements of R remaining after removing the corresponding elements of S the appropriate number of times.

`R sdiff S`

Symmetric difference of the sets R and S. i.e., the set consisting of those elements which are members of either R or S but not both (see above for the restrictions on R and S). Alternatively, it is the union of the difference of R with S and the difference of S with R.

Example H9E11

```
> R := { 1, 2, 3 };
> S := { 1, 1/2, 1/3 };
> R join S;
{ 1/3, 1/2, 1, 2, 3 }
> R meet S;
{ 1 }
> R diff S;
{ 2, 3 }
> S diff R;
{ 1/3, 1/2 }
> R sdiff S;
{ 1/3, 1/2, 2, 3 }
```

9.6.3 Other Set Operations

`Multiplicity(S, x)`

Return the multiplicity in multiset S of element x. If x is not in S, zero is returned.

`Multiplicities(S)`

Returns the sequence of multiplicities of distinct elements in the multiset S. The order is the same as the internal enumeration order of the elements.

`Subsets(S)`

The set of all subsets of S.

`Subsets(S, k)`

The set of subsets of S of size k. If k is larger than the cardinality of S then the result will be empty.

`RandomSubset(S, k)`

A random subset of S of size k. It is an error if k is larger than the size of S.

`Multisets(S, k)`

The set of multisets consisting of k not necessarily distinct elements of S.

`Subsequences(S, k)`

The set of sequences of length k with elements from S.

`Permutations(S)`

The set of permutations (stored as sequences) of the elements of S.

`Permutations(S, k)`

The set of permutations (stored as sequences) of each of the subsets of S of cardinality k.

9.7 Quantifiers

To test whether some enumerated set is empty or not, one may use the `IsEmpty` function. However, to use `IsEmpty`, the set has to be created in full first. The existential quantifier `exists` enables one to do the test and abort the construction of the set as soon as an element is found; moreover, the element found will be assigned to a variable.

Likewise, `forall` enables one to abort the construction of the set as soon as an element not satisfying a certain property is encountered.

Note that `exists(t){ e(x) : x in E | P(x) }` is *not* designed to return true if an element of the set of values $e(x)$ satisfies P, but rather if there is an $x \in E$ satisfying $P(x)$ (in which case $e(x)$ is assigned to t).

For the notation used here, see the beginning of this chapter.

`exists(t){ e(x): x in E | P(x) }`

`exists(t1, ..., tr){ e(x) : x in E | P(x) }`

Given an enumerated structure E and a Boolean expression $P(x)$, the Boolean value true is returned if E contains at least one element x for which $P(x)$ is true. If $P(x)$ is not true for any element x of E, then the Boolean value false is returned.

Moreover, if $P(x)$ is found to be true for the element y, say, of E, then in the first form of the exists expression, variable t will be assigned the value of the expression $e(y)$. If $P(x)$ is never true for an element of E, t will be left unassigned. In the second form, where r variables $t_1, \ldots, t_r$ are given, the result $e(y)$ should be a tuple of length r; each variable will then be assigned to the corresponding component of

the tuple. Similarly, all the variables will be left unassigned if $P(x)$ is never true. The clause `(t)` may be omitted entirely.

P may be omitted if it is always true.

`exists(t){e(`x_1`, ..., `x_k`): `x_1` in `E_1`, ..., `x_k` in `E_k` | P(`x_1`, ..., `x_k`)}`

`exists(`t_1`, ..., `t_r`){ e(`x_1`, ..., `x_k`) : `x_1` in `E_1`, ..., `x_k` in `E_k` | P }`

Given enumerated structures $E_1, \ldots, E_k$, and a Boolean expression $P(x_1, \ldots, x_k)$, the Boolean value true is returned if there is an element $< y_1, \ldots, y_k >$ in the Cartesian product $E_1 \times \cdots \times E_k$, such that $P(y_1, \ldots, y_k)$ is true. If $P(x_1, \ldots, x_k)$ is not true for any element $(y_1, \ldots, y_k)$ of $E_1 \times \cdots \times E_k$, then the Boolean value false is returned.

Moreover, if $P(x_1, \ldots, x_k)$ is found to be true for the element $< y_1, \ldots, y_k >$ of $E_1 \times \cdots \times E_k$, then in the first form of the exists expression, the variable t will be assigned the value of the expression $e(y_1, \cdots, y_k)$. If $P(x_1, \ldots, x_k)$ is never true for an element of $E_1 \times \cdots \times E_k$, then the variable t will be left unassigned. In the second form, where r variables $t_1, \ldots, t_r$ are given, the result $e(y_1, \cdots, y_k)$ should be a tuple of length r; each variable will then be assigned to the corresponding component of the tuple. Similarly, all the variables will be left unassigned if $P(x_1, \ldots, x_k)$ is never true. The clause `(t)` may be omitted entirely.

P may be omitted if it is always true.

If successive structures E_i and E_{i+1} are identical, then the abbreviation `x`$_i$`, x`$_{i+1}$ `in E`$_i$ may be used.

Example H9E12

As a variation on an earlier example, we check whether or not some integers can be written as sums of cubes (less than 10^3 in absolute value):

```
> exists(t){ <x, y> : x, y in [ t^3 : t in [-10..10] ] | x + y eq 218 };
true
> t;
<-125, 343>
> exists(t){ <x, y> : x, y in [ t^3 : t in [1..10] ] | x + y eq 218 };
false
>  t;
>> t;
          ^
User error: Identifier 't' has not been declared
```

`forall(t){ e(x) : x in E | P(x) }`

`forall(t1, ..., tr){ e(x) : x in E | P(x) }`

Given an enumerated structure E and a Boolean expression $P(x)$, the Boolean value true is returned if $P(x)$ is true for every element x of E.

If $P(x)$ is not true for at least one element x of E, then the Boolean value false is returned.

Moreover, if $P(x)$ is found to be false for the element y, say, of E, then in the first form of the exists expression, variable t will be assigned the value of the expression $e(y)$. If $P(x)$ is true for every element of E, t will be left unassigned. In the second form, where r variables $t_1, \ldots, t_r$ are given, the result $e(y)$ should be a tuple of length r; each variable will then be assigned to the corresponding component of the tuple. Similarly, all the variables will be left unassigned if $P(x)$ is always true. The clause `(t)` may be omitted entirely.

P may be omitted if it is always true.

`forall(t){e(x1, ..., xk): x1 in E1, ..., xk in Ek | P(x1, ..., xk)}`

`forall(t1, ..., tr){ e(x1, ..., xk) : x1 in E1, ..., xk in Ek | P }`

Given sets $E_1, \ldots, E_k$, and a Boolean expression $P(x_1, \ldots, x_k)$, the Boolean value true is returned if $P(x_1, \ldots, x_k)$ is true for every element $(x_1, \ldots, x_k)$ in the Cartesian product $E_1 \times \cdots \times E_k$.

If $P(x_1, \ldots, x_k)$ fails to be true for some element $(y_1, \ldots, y_k)$ of $E_1 \times \cdots \times E_k$, then the Boolean value false is returned.

Moreover, if $P(x_1, \ldots, x_k)$ is false for the element $< y_1, \ldots, y_k >$ of $E_1 \times \cdots \times E_k$, then in the first form of the exists expression, the variable t will be assigned the value of the expression $e(y_1, \cdots, y_k)$. If $P(x_1, \ldots, x_k)$ is true for every element of $E_1 \times \cdots \times E_k$, then the variable t will be left unassigned. In the second form, where r variables $t_1, \ldots, t_r$ are given, the result $e(y_1, \cdots, y_k)$ should be a tuple of length r; each variable will then be assigned to the corresponding component of the tuple. Similarly, all the variables will be left unassigned if $P(x_1, \ldots, x_k)$ is never true. The clause `(t)` may be omitted entirely.

P may be omitted if it is always true.

If successive structures E_i and E_{i+1} are identical, then the abbreviation `xi, xi+1 in Ei` may be used.

Example H9E13

This example shows that `forall` and `exists` may be nested.
It is well known that every prime that is 1 modulo 4 can be written as the sum of two squares, but not every integer m congruent to 1 modulo 4 can. In this example we explore for small m whether perhaps $m \pm \epsilon$ (with $|\epsilon| \leq 1$) is always a sum of squares.

```
> forall(u){ m : m in [5..1000 by 4] |
>       exists{ <x, y, z> : x, y in [0..30], z in [-1, 0, 1] |
>          x^2+y^2+z eq m } };
```

```
false
> u;
77
```

9.8 Reduction and Iteration over Sets

Both enumerated and indexed sets allow enumeration of their elements; formal sets do not. For indexed sets the enumeration will occur according to the order given by the indexing.

Instead of using a loop to apply the same binary associative operator to all elements of an enumerated or indexed set, it is in certain cases possible to use the *reduction operator* `&`.

`x in S`

Enumerate the elements of an enumerated or indexed set S. This can be used in *loops*, as well as in the set and sequence *constructors*.

`&o S`

Given an enumerated or indexed set $S = \{ a_1, a_2, \ldots, a_n\}$ of elements belonging to an algebraic structure U, and an (associative) operator $\circ : U \times U \rightarrow U$, form the element $a_{i_1} \circ a_{i_2} \circ a_{i_3} \circ \ldots \circ a_{i_n}$, for some permutation $i_1, \ldots, i_n$ of $1, \ldots, n$.

Currently, the following operators may be used to reduce enumerated sets: `+, *, and, or, join, meet` and `+, *, and, or` to reduce indexed sets. An error will occur if the operator is not defined on U.

If S contains a single element a, then the value returned is a. If S is the null set (empty and no universe specified) or S is empty with universe U (and the operation is defined in U), then the result (or error) depends on the operation and upon U. The following table defines the return value:

	empty	*null*
&+	U ! 0	error
&∗	U ! 1	error
&and	`true`	`true`
&or	`false`	`false`
&join	*empty*	*null*
&meet	error	error

Warning: since the reduction may take place in an arbitrary order on the arguments $a_1, \ldots, a_n$, the result is not unambiguously defined if the operation is not commutative on the arguments!

Example H9E14

The function `choose` defined below takes a set S and an integer k as input, and produces a set of all subsets of S with cardinality k.

```
> function choose(S, k)
>    if k eq 0 then
>       return { { } };
>    else
>       return &join{{  s join { x} : s in choose(S diff { x}, k-1) } : x in S};
>    end if;
> end function;
```

So, for example:

```
>  S := { 1, 2, 3, 4 };
> choose(S, 2);
{
       { 1, 3 },
       { 1, 4 },
       { 2, 4 },
       { 2, 3 },
       { 1, 2 },
       { 3, 4 }
}
```

Try to guess what happens if $k < 0$.

10 SEQUENCES

Chapter 10
SEQUENCES

10.1 Introduction

A *sequence* in MAGMA is a linearly ordered collection of objects belonging to some common structure (called the *universe* of the sequence).

There are two types of sequence: *enumerated sequences*, of which the elements are all stored explicitly (with one exception, see below); and *formal sequences*, of which elements are stored implicitly by means of a predicate that allows for testing membership. In particular, enumerated sequences are always finite, and formal sequences are allowed to be infinite. In this chapter a *sequence* will be either a formal or an enumerated sequence.

10.1.1 Enumerated Sequences

An *enumerated sequence of length* l is an array of indefinite length of which only finitely many terms – including the l-th term, but no term of bigger index — have been defined to be elements of some common structure. Such sequence is called *complete* if all of the terms (from index 1 up to the length l) are defined.

In practice the length of an enumerated sequence must be less than 2^{30}.

Incomplete enumerated sequences are allowed as a convenience for the programmer in building complete enumerated sequences. Some sequence functions require their arguments to be complete; if that is the case, it is mentioned explicitly in the description below. However, all functions using sequences in *other* MAGMA modules always assume that a sequence that is passed in as an argument is complete. Note that the following line converts a possibly incomplete sequence S into a complete sequence T:

```
T := [ s :  s in S ];
```

because the enumeration using the `in` operator simply ignores undefined terms.

Enumerated sequences of *Booleans* are highly optimized (stored as bit-vectors).

10.1.2 Formal Sequences

A formal sequence consists of elements of some range set on which a certain predicate assumes the value 'true'.

There is only a very limited number of operations that can be performed on them.

10.1.3 Compatibility

The binary operators for sequences do not allow mixing of the formal and enumerated sequence types (so one cannot take the concatenation of an enumerated sequence and a formal sequence, for example); but it is easy to convert an enumerated sequence into a formal sequence – see the section on binary operators below.

By the limitation on their construction formal sequences can only contain elements from one structure in MAGMA. The elements of enumerated sequences are also restricted, in the sense that either some common structure must be specified upon creation, or MAGMA must be able to find such universe automatically. The rules for compatibility of elements and the way MAGMA deals with these parents is the same for sequences and sets, and is outlined in Chapter 8.

10.2 Creating Sequences

Square brackets are used for the definition of enumerated sequences; formal sequences are delimited by the composite brackets `[!` and `!]`.

Certain expressions appearing below (possibly with subscripts) have the standard interpretation:

U the universe: any MAGMA structure;

E the range set for enumerated sequences: any enumerated structure (it must be possible to loop over its elements – see the Introduction to this Part);

F the range set for formal sequences: any structure for which membership testing using `in` is defined – see the Introduction to this Part);

x a free variable which successively takes the elements of E (or F in the formal case) as its values;

P a Boolean expression that usually involves the variable(s) x, $x_1, \ldots, x_k$;

e an expression that also usually involves the variable(s) x, $x_1, \ldots, x_k$.

10.2.1 The Formal Sequence Constructor

The formal sequence constructor has the following fixed format (the expressions appearing in the construct are defined above):

```
[!  x in F | P(x) !]
```

Create the formal sequence consisting of the subsequence of elements x of F for which $P(x)$ is true. If $P(x)$ is true for every element of F, the sequence constructor may be abbreviated to `[!  x in F !]`

10.2.2 The Enumerated Sequence Constructor

Sequences can be constructed by expressions enclosed in square brackets, provided that the values of all expressions can be automatically coerced into some common structure, as outlined in the Introduction. All general constructors have the universe U optionally up front, which allows the user to specify into which structure all terms of the sequences should be coerced.

`[ ]`

The null sequence (empty, and no universe specified).

`[ U | ]`

The empty sequence with universe U.

`[ e`$_1$`, e`$_2$`, ..., e`$_n$ `]`

Given a list of expressions $e_1, \ldots, e_n$, defining elements $a_1, a_2, \ldots, a_n$ all belonging to (or automatically coercible into) a single algebraic structure U, create the sequence $Q = [a_1, a_2, ..., a_n\ ]$ of elements of U.

As for multisets, one may use the expression `x^^n` to specify the object x with multiplicity n: this is simply interpreted to mean x repeated n times (i.e., no internal compaction of the repetition is done).

`[ U | e`$_1$`, e`$_2$`, ..., e`$_m$ `]`

Given a list of expressions $e_1, \ldots, e_m$, which define elements $a_1, a_2, \ldots, a_n$ that are all coercible into U, create the sequence $Q = [a_1, a_2, ..., a_n\ ]$ of elements of U.

`[ e(x) :  x in E | P(x) ]`

Form the sequence of elements $e(x)$, all belonging to some common structure, for those $x \in E$ with the property that the predicate $P(x)$ is true. The expressions appearing in this construct have the interpretation given at the beginning of this section.

If $P(x)$ is true for every element of E, the sequence constructor may be abbreviated to `[ e(x) :  x in E ]` .

`[ U | e(x) :  x in E | P(x) ]`

Form the sequence of elements of U consisting of the values $e(x)$ for those $x \in E$ for which the predicate $P(x)$ is true (an error results if not all $e(x)$ are coercible into U). The expressions appearing in this construct have the same interpretation as above.

`[ e(x`$_1$`,...,x`$_k$`) :  x`$_1$ `in E`$_1$`, ..., x`$_k$ `in E`$_k$ `| P(x`$_1$`, ..., x`$_k$`) ]`

The sequence consisting of those elements $e(x_1, \ldots, x_k)$, in some common structure, for which $x_1, \ldots, x_k$ in $E_1, \ldots, E_k$ have the property that $P(x_1, \ldots, x_k)$ is true.

The expressions appearing in this construct have the interpretation given at the beginning of this section.

Note that if two successive ranges E_i and E_{i+1} are identical, then the specification of the ranges for x_i and x_{i+1} may be abbreviated to `x`$_i$`, x`$_{i+1}$ `in E`$_i$.

Also, if $P(x_1, ..., x_k)$ is always true, it may be omitted.

```
[ U | e(x1,...,xk) :  x1 in E1, ..., xk in Ek | P(x1, ..., xk) ]
```

As in the previous entry, the sequence consisting of those elements $e(x_1, \ldots, x_k)$ for which $P(x_1, \ldots, x_k)$ is true is formed, as a sequence of elements of U (an error occurs if not all $e(x_1, \ldots, x_k)$ are coercible into U).

10.2.3 The Arithmetic Progression Constructors

Since enumerated sequences of integers arise so often, there are a few special constructors to create and handle them efficiently in case the entries are in arithmetic progression. The universe must be the ring of integers. Some effort is made to preserve the special way of storing arithmetic progressions under sequence operations.

```
[ i..j ]
```

```
[ U | i..j ]
```

The enumerated sequence of integers whose elements form the arithmetic progression $i, i+1, i+2, \ldots, j$, where i and j are (expressions defining) arbitrary integers. If j is less than i then the empty sequence of integers will be created.

The universe U, if it is specified, has to be the ring of integers; any other universe will lead to an error.

```
[ i ..  j by k ]
```

```
[ U | i ..  j by k ]
```

The enumerated sequence consisting of the integers forming the arithmetic progression $i, i+k, i+2*k, \ldots, j$, where i, j and k are (expressions defining) arbitrary integers (but $k \neq 0$).

If k is positive then the last element in the progression will be the greatest integer of the form $i + n * k$ that is less than or equal to j; if j is less than i, the empty sequence of integers will be constructed.

If k is negative then the last element in the progression will be the least integer of the form $i + n * k$ that is greater than or equal to j; if j is greater than i, the empty sequence of integers will be constructed.

The universe U, if it is specified, has to be the ring of integers; any other universe will lead to an error.

Example H10E1

As in the case of sets, it is possible to use the arithmetic progression constructors to save some typing in the creation of sequences of elements of rings other than the ring of integers, but the result will not be treated especially efficiently.

```
> s := [ IntegerRing(200) | x : x in [ 25..125 ] ];
```

10.2.4 Literal Sequences

A literal sequence is an enumerated sequence all of whose terms are from the same structure and all of these are 'typed in' literally. The sole purpose of literal sequences is to load certain enumerated sequences very fast and very space-efficiently; this is only useful when reading in very large sequences (all of whose elements must have been specified literally, that is, not as some expression other than a literal), but then it may save a lot of time. The result will be an enumerated sequence, that is, not distinguished in any way from other such sequences.

At present, only literal sequences of integers are supported.

`\[ m1, ..., mn ]`

Given a succession of literal integers $m_1, \ldots, m_n$, build the enumerated sequence $[m_1, \ldots, m_n]$, in a time and space efficient way.

10.3 Power Sequences

The `PowerSequence` constructor returns a structure comprising the enumerated sequences of a given structure R; it is mainly useful as a parent for other set and sequence constructors. The only operations that are allowed on power sequences are printing, testing element membership, and coercion into the power sequence (see the examples below).

`PowerSequence(R)`

The structure comprising all enumerated sequences of elements of structure R. If R itself is a sequence (or set) then the power structure of its universe is returned.

`S in P`

Returns `true` if enumerated sequence S is in the power sequence P, that is, if all elements of the sequence S are contained in or coercible into R, where P is the power sequence of R; `false` otherwise.

`P ! S`

Return a sequence with universe R consisting of the entries of the enumerated sequence S, where P is the power sequence of R. An error results if not all elements of S can be coerced into R.

Example H10E2

```
> S := [ 1 .. 10 ];
> P := PowerSequence(S);
> P;
Set of sequences over [ 1 .. 10 ]
> F := [ 6/3, 12/4 ];
> F in P;
true
> G := P ! F;
```

```
> Parent(F);
Set of sequences over Rational Field
> Parent(G);
Set of sequences over [ 1 .. 10 ]
```

10.4 Operators on Sequences

This section lists functions for obtaining information about existing sequences, for modifying sequences and for creating sequences from others. Most of these operators only apply to enumerated sequences.

10.4.1 Access Functions

`#S`

Returns the length of the enumerated sequence S, which is the index of the last term of S whose value is defined. The length of the empty sequence is zero.

`Parent(S)`

Returns the parent structure for a sequence S, that is, the structure consisting of all (enumerated) sequences over the universe of S.

`Universe(S)`

Returns the 'universe' of the sequence S, that is, the common structure to which all elements of the sequence belong. This universe may itself be a set or sequence. An error is signalled when S is the null sequence.

`S[i]`

The i-th term s_i of the sequence S. If $i \leq 0$, or $i > \#S + 1$, or $S[i]$ is not defined, then an error results. Here i is allowed to be a multi-index (see Introduction for the interpretation). This can be used as the left hand side of an assignment: `S[i] := x` redefines the i-th term of the sequence S to be x. If $i \leq 0$, then an error results. If $i > n$, then the sequence $[s_1, \ldots, s_n, s_{n+1}, \ldots, s_{i-1}, x]$ replaces S, where $s_{n+1}, \ldots, s_{i-1}$ are all undefined. Here i is allowed to be a multi-index.

An error occurs if x cannot be coerced into the universe of S.

10.4.2 Selection Operators on Enumerated Sequences

Here, S denotes an enumerated sequence $[s_1, \ldots, s_n]$. Further, i and j are integers or multi-indices (see Introduction).

`S[I]`

The sequence $[s_{i_1}, \ldots, s_{i_r}]$ consisting of terms selected from the sequence S, according to the terms of the integer sequence I. If any term of I lies outside the range 1 to $\#S$, then an error results. If I is the empty sequence, then the empty set with universe the same as that of S is returned.

The effect of `T := S[I]` differs from that of `T := [ S[i] : i in I ]`: if in the first case an undefined entry occurs for $i \in I$ between 1 and $\#S$ it will be copied over; in the second such undefined entries will lead to an error.

`Minimum(S)`
`Min(S)`

Given a non-empty, complete enumerated sequence S such that `lt` and `eq` are defined on the universe of S, this function returns two values: a minimal element s in S, as well as the first position i such that $s = S[i]$.

`Maximum(S)`
`Max(S)`

Given a non-empty, complete enumerated sequence S such that `gt` and `eq` are defined on the universe of S, this function returns two values: a maximal element s in S, as well as the first position i such that $s = S[i]$.

`Index(S, x)`
`Index(S, x, f)`
`Position(S, x)`
`Position(S, x, f)`

Returns either the position of the first occurrence of x in the sequence S, or zero if S does not contain x. The second variants of each function starts the search at position f. This can save time in second (and subsequent) searches for the same entry further on. If no occurrence of x in S from position f onwards is found, then zero is returned.

`Representative(R)`
`Rep(R)`

An (arbitrary) element chosen from the enumerated sequence R

`Random(R)`

A random element chosen from the enumerated sequence R. Every element has an equal probability of being chosen. Successive invocations of the function will result in independently chosen elements being returned as the value of the function. If R is empty an error occurs.

`Explode(R)`

Given an enumerated sequence R of length r this function returns the r entries of the sequence (in order).

`Eltseq(R)`

The enumerated sequence R itself. This function is just included for completeness.

10.4.3 Modifying Enumerated Sequences

The operations given here are available as both procedures and functions. In the procedure version, the given sequence is destructively modified 'in place'. This is very efficient, since it is not necessary to make a copy of the sequence. In the function version, the given sequence is not changed, but a modified version of it is returned. This is more suitable if the old sequence is still required. Some of the functions also return useful but non-obvious values.

Here, S denotes an enumerated sequence, and x an element of some structure V. The modifications involving S and x will only be successful if x can be coerced into the universe of S; an error occurs if this fails. (See the Introduction to this Part).

`Append(~S, x)`

`Append(S, x)`

Create an enumerated sequence by adding the object x to the end of S, i.e., the enumerated sequence $[s_1, \ldots s_n, x]$.

There are two versions of this: a procedure, where S is replaced by the appended sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Exclude(~S, x)`

`Exclude(S, x)`

Create an enumerated sequence obtained by removing the first occurrence of the object x from S, i.e., the sequence $[s_1, \ldots s_{i-1}, s_{i+1}, \ldots, s_n]$, where s_i is the first term of S that is equal to x. If x is not in S then this is just S.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Include(~S, x)`

`Include(S, x)`

Create a sequence by adding the object x to the end of S, provided that no term of S is equal to x. Thus, if x does not occur in S, the enumerated sequence $[s_1, \ldots, s_n, x]$ is created.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Insert(~S, i, x)`

`Insert(S, i, x)`

Create the sequence formed by inserting the object x at position i in S and moving the terms $S[i], \ldots, S[n]$ down one place, i.e., the enumerated sequence [s_1,... s_{i-1}, x, s_i, ..., s_n]. Note that i may be bigger than the length n of S, in which case the new length of S will be i, and the entries $S[n+1], \ldots, S[i-1]$ will be undefined.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Insert(~S, k, m, T)`

`Insert(S, k, m, T)`

Create the sequence [s_1, ..., s_{k-1}, t_1, ..., t_l, s_{m+1}, ..., s_n]. If $k \leq 0$ or $k > m+1$, then an error results. If $k = m+1$ then the terms of T will be inserted into S immediately before the term s_k. If $k > n$, then the sequence $[s_1, \ldots, s_n, s_{n+1}, \ldots, s_{k-1}, t_1, \ldots, t_l]$ is created, where $s_{n+1}, \ldots, s_{k-1}$ are all undefined. In the case where T is the empty sequence, terms $s_k, \ldots, s_m$ are deleted from S.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Prune(~S)`

`Prune(S)`

Create the enumerated sequence formed by removing the last term of the sequence S, i.e., the sequence $[s_1, \ldots, s_{n-1}]$. An error occurs if S is empty.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Remove(~S, i)`

`Remove(S, i)`

Create the enumerated sequence formed by removing the i-th term from S, i.e., the sequence $[s_1, \ldots s_{i-1}, s_{i+1}, \ldots, s_n]$. An error occurs if $i < 1$ or $i > n$.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Reverse(~S)`

`Reverse(S)`

Create the enumerated sequence formed by reversing the order of the terms in the complete enumerated sequence S, i.e., the sequence $[s_n, \ldots, s_1]$.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Rotate(~S, p)`

`Rotate(S, p)`

Given a complete sequence S and an integer p, create the enumerated sequence formed by cyclically rotating the terms of the sequence p terms: if p is positive, rotation will be to the right; if p is negative, S is cyclically rotated $-p$ terms to the left; if p is zero nothing happens.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Sort(~S)`

`Sort(S)`

Given a complete enumerated sequence S whose terms belong to a structure on which `lt` and `eq` are defined, create the enumerated sequence formed by (quick-)sorting the terms of S into increasing order.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`Sort(~S, C)`

`Sort(~S, C, ~p)`

`Sort(S, C)`

Given a complete enumerated sequence S and a comparison function C which compares elements of S, create the enumerated sequence formed by sorting the terms of S into increasing order with respect to C. The comparison function C must take two arguments and return an integer less than, equal to, or greater than 0 according to whether the first argument is less than, equal to, or greater than the second argument (e.g.: `func<x, y | x - y>`).

There are three versions of this: a procedure, where S is replaced by the new sequence, a procedure, where S is replaced by the new sequence and the corresponding permutation p is set, and a function, which returns the new sequence and the corresponding permutation. The procedural version takes a reference $\sim S$ to S as an argument. Note that the procedural version is much more efficient since the sequence S will not be copied.

`ParallelSort(~S, ~T)`

Given a complete enumerated sequence S, sorts it in place and simultaneously sorts T in the same order. That is, whenever the sorting process would swap the two elements `S[i]` and `S[j]` then the two elements `T[i]` and `T[j]` are also swapped.

`Undefine(~S, i)`

`Undefine(S, i)`

Create the sequence which is the same as the enumerated sequence S but with the i-th term of S undefined; i may be bigger than $\#S$, but $i \leq 0$ produces an error.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`ChangeUniverse(S, V)`

`ChangeUniverse(S, V)`

Given a sequence S with universe U and a structure V which contains U, construct a sequence which consists of the elements of S coerced into V.

There are two versions of this: a procedure, where S is replaced by the new sequence, and a function, which returns the new sequence. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the sequence S will not be copied.

`CanChangeUniverse(S, V)`

Given a sequence S with universe U and a structure V which contains U, attempt to construct a sequence T which consists of the elements of S coerced into V; if successful, return `true` and T, otherwise return `false`.

Example H10E3

We present three ways to obtain the Farey series F_n of degree n.
The Farey series F_n of degree n consists of all rational numbers with denominator less than or equal to n, in order of magnitude. Since we will need numerator and denominator often, we first abbreviate those functions.

```
> D := Denominator;
> N := Numerator;
```

The first method calculates the entries in order. It uses the fact that for any three consecutive Farey fractions $\frac{p}{q}$, $\frac{p'}{q'}$, $\frac{p''}{q''}$ of degree n:

$$p'' = \lfloor \frac{q+n}{q'} \rfloor p' - p, \quad q'' = \lfloor \frac{q+n}{q'} \rfloor q' - q.$$

```
> farey := function(n)
>    f := [ RationalField() | 0, 1/n ];
>    p := 0;
>    q := 1;
>    while p/q lt 1 do
>       p := ( D(f[#f-1]) + n) div D(f[#f]) * N(f[#f])  - N(f[#f-1]);
>       q := ( D(f[#f-1]) + n) div D(f[#f]) * D(f[#f])  - D(f[#f-1]);
>       Append(~f, p/q);
>    end while;
>    return f;
> end function;
```

The second method calculates the Farey series recursively. It uses the property that F_n may be obtained from F_{n-1} by inserting a new fraction (namely $\frac{p+p'}{q+q'}$) between any two consecutive rationals $\frac{p}{q}$ and $\frac{p'}{q'}$ in F_{n-1} for which $q + q'$ equals n.

```
> function farey(n)
```

```
>    if n eq 1 then
>       return [RationalField() | 0, 1 ];
>    else
>       f := farey(n-1);
>       i := 0;
>       while i lt #f-1 do
>          i +:= 1;
>          if D(f[i]) + D(f[i+1]) eq n then
>             Insert( ~f, i+1, (N(f[i]) + N(f[i+1]))/(D(f[i]) + D(f[i+1])));
>          end if;
>       end while;
>       return f;
>    end if;
> end function;
```

The third method is very straightforward, and uses `Sort` and `Setseq` (defined above).

```
> farey := func< n |
>               Sort(Setseq({ a/b : a in { 0..n}, b in { 1..n} | a le b }))>;
> farey(6);
[ 0, 1/6, 1/5, 1/4, 1/3, 2/5, 1/2, 3/5, 2/3, 3/4, 4/5, 5/6, 1 ]
```

10.4.4 Creating New Enumerated Sequences from Existing Ones

`S cat T`

The enumerated sequence formed by concatenating the terms of S with the terms of T, i.e. the sequence $[s_1, \ldots, s_n, t_1, \ldots, t_m]$.

If the universes of S and T are different, an attempt to find a common overstructure is made; if this fails an error results (see the Introduction).

`S cat:= T`

Mutation assignment: change S to be the concatenation of S and T. Functionally equivalent to `S := S cat T`.

If the universes of S and T are different, an attempt to find a common overstructure is made; if this fails an error results (see the Introduction).

`Partition(S, p)`

Given a complete non-empty sequence S as well as an integer p that divides the length n of S, construct the sequence whose terms are the sequences formed by taking p terms of S at a time.

`Partition(S, P)`

Given a complete non-empty sequence S as well as a complete sequence of positive integers P, such that the sum of the entries of P equals the length of S, construct the sequence whose terms are the sequences formed by taking $P[i]$ terms of S, for $i = 1, \ldots, \#P$.

`Setseq(S)`

`SetToSequence(S)`

Given a set S, construct a sequence whose terms are the elements of S taken in some arbitrary order.

`Seqset(S)`

`SequenceToSet(S)`

Given a sequence S, create a set whose elements are the distinct terms of S.

Example H10E4

The following example illustrates several of the access, creation and modification operations on sequences.
Given a rational number r, this function returns a sequence of different integers d_i such that $r = \sum 1/d_i$ [Bee93].

```
> egyptian := function(r)
>       n := Numerator(r);
>       d := Denominator(r);
>       s := [d : i in [1..n]];
>       t := { d};
>       i := 2;
>       while i le #s do
>              c := s[i];
>              if c in t then
>                     Remove(~s, i);
>                     s cat:= [c+1, c*(c+1)];
>              else
>                     t join:= { c};
>                     i := i+1;
>              end if;
>       end while;
>       return s;
> end function;
```

Note that the result may be rather larger than necessary:

```
> e := egyptian(11/13);
> // Check the result!
> &+[1/d : d in e];
11/13
```

```
> #e;
2047
> #IntegerToString(Maximum(e));
1158
```

while instead of this sequence of 2047 integers, the biggest of the entries having 1158 decimal digits, the following equation also holds:

$$\frac{1}{3}+\frac{1}{4}+\frac{1}{6}+\frac{1}{12}+\frac{1}{78}=\frac{11}{13}.$$

10.4.4.1 Operations on Sequences of Booleans

The following operation work pointwise on sequences of booleans of equal length.

`And(S, T)`
`And(~S, T)`

The sequence whose ith entry is the logical and of the ith entries of S and T. The result is placed in S if it is given by reference (~).

`Or(S, T)`
`Or(~S, T)`

The sequence whose ith entry is the logical or of the ith entries of S and T. The result is placed in S if it is given by reference.

`Xor(S, T)`
`Xor(~S, T)`

The sequence whose ith entry is the logical xor of the ith entries of S and T. The result is placed in S if it is given by reference.

`Not(S)`
`Not(~S)`

The sequence whose ith entry is the logical not of the ith entry of S. The result is placed in S if it is given by reference.

10.5 Predicates on Sequences

Boolean valued operators and functions on enumerated sequences exist to test whether entries are defined (see previous section), to test for membership and containment, and to compare sequences with respect to an ordering on its entries. On formal sequences, only element membership can be tested.

`IsComplete(S)`

Boolean valued function, returning `true` if and only if each of the terms $S[i]$ for $1 \leq i \leq \#S$ is defined, for an enumerated sequence S.

`IsDefined(S, i)`

Given an enumerated sequence S and an index i, this returns `true` if and only if $S[i]$ is defined. (Hence the result is `false` if $i > \#S$, but an error results if $i < 1$.) Note that the index i is allowed to be a multi-index; if $i = [i_1, \ldots, i_r]$ is a multi-index and $i_j > \#S[i_1, \ldots, i_{j-1}]$ the function returns false, but if S is s levels deep and $r > s$ while $i_j \leq \#S[i_1, \ldots, i_{j-1}]$ for $1 \leq j \leq s$, then an error occurs.

`IsEmpty(S)`

Boolean valued function, returning `true` if and only if the enumerated sequence S is empty.

`IsNull(S)`

Boolean valued function, returning `true` if and only if the enumerated sequence S is empty and its universe is undefined, `false` otherwise.

10.5.1 Membership Testing

Here, S and T denote sequences. The element x is always assumed to be compatible with S.

`x in S`

Returns `true` if the object x occurs as a term of the enumerated or formal sequence S, `false` otherwise. If x is not in the universe of S, coercion is attempted. If that fails, an error results.

`x notin S`

Returns `true` if the object x does not occur as a term of the enumerated or formal sequence S, `false` otherwise. If x is not in the universe of S, coercion is attempted. If that fails, an error results.

`IsSubsequence(S, T)`

`IsSubsequence(S, T: Kind := option)`

`Kind` MonStgElt *Default : "Consecutive"*

Returns `true` if the enumerated sequence S appears as a subsequence of consecutive elements of the enumerated sequence T, `false` otherwise.

By changing the default value `"Consecutive"` of the parameter `Kind` to `"Sequential"` or to `"Setwise"`, this returns `true` if and only if the elements of S appear in order (but not necessarily consecutively) in T, or if and only if all elements of S appear as elements of T; so in the latter case the test is merely whether the set of elements of S is contained in the set of elements of T.

If the universes of S and T are not the same, coercion is attempted.

`S eq T`

Returns `true` if the enumerated sequences S and T are equal, `false` otherwise. If the universes of S and T are not the same, coercion is attempted.

`S ne T`

Returns `true` if the enumerated sequences S and T are not equal, `false` otherwise. If the universes of S and T are not the same, coercion is attempted.

10.5.2 Testing Order Relations

Here, S and T denote complete enumerated sequences with universe U and V respectively, such that a common overstructure W for U and V can be found (as outlined in the Introduction), and such that on W an ordering on the elements is defined allowing the Magma operators `eq` ($=$), `le` ($\leq$), `lt` ($<$), `gt` ($>$), and `ge` ($\geq$) to be invoked on its elements.

With these comparison operators the *lexicographical* ordering is used to order complete enumerated sequences. Sequences S and T are equal (`S eq T`) if and only if they have the same length and all terms are the same. A sequence S precedes T (`S lt T`) in the ordering imposed by that of the terms if at the first index i where S and T differ then $S[i] < T[i]$. If the length of T exceeds that of S and S and T agree in all places where S until after the length of S, then `S lt T` is true also. In all other cases where $S \neq T$ one has `S gt T`.

`S lt T`

Returns `true` if the sequence S precedes the sequence T under the ordering induced from S, `false` otherwise. Thus, `true` is returned if and only if either $S[k] < T[k]$ and $S[i] = T[i]$ (for $1 \leq i < k$) for some k, or $S[i] = T[i]$ for $1 \leq i \leq \#S$ and $\#S < \#T$.

`S le T`

Returns `true` if the sequence S either precedes the sequence T, under the ordering induced from S, or is equal to T, `false` otherwise. Thus, `true` is returned if and only if either $S[k] < T[k]$ and $S[i] = T[i]$ (for $1 \leq i < k$) for some k, or $S[i] = T[i]$ for $1 \leq i \leq \#S$ and $\#S \leq \#T$.

`S ge T`

Returns `true` if the sequence S either comes after the sequence T, under the ordering induced from S, or is equal to T, `false` otherwise. Thus, `true` is returned if and only if either $S[k] > T[k]$ and $S[i] = T[i]$ (for $1 \leq i < k$) for some k, or $S[i] = T[i]$ for $1 \leq i \leq \#T$ and $\#S \geq \#T$.

`S gt T`

Returns `true` if the sequence S comes after the sequence T under the ordering induced from S, `false` otherwise. Thus, `true` is returned if and only if either $S[k] > T[k]$ and $S[i] = T[i]$ (for $1 \leq i < k$) for some k, or $S[i] = T[i]$ for $1 \leq i \leq \#T$ and $\#S > \#T$.

10.6 Recursion, Reduction, and Iteration

10.6.1 Recursion

It is often very useful to be able to refer to a sequence currently under construction, for example to define the sequence recursively. For this purpose the `Self` operator is available.

`Self(n)`
`Self()`

This operator enables the user to refer to an already defined previous entry $s[n]$ of the enumerated sequence s inside the sequence constructor, or the sequence s itself.

Example H10E5

The example below shows how the sequence of the first 100 Fibonacci numbers can be created recursively, using `Self`. Next it is shown how to use reduction on these 100 integers.

```
> s := [ i gt 2 select Self(i-2)+Self(i-1) else 1 : i in [1..100] ];
> &+s;
927372692193078999175
```

10.6.2 Reduction

Instead of using a loop to apply the same binary associative operator to all elements of a complete enumerated sequence, it is possible to use the *reduction operator* `&`.

`&○ S`

Given a complete enumerated sequence $S = [a_1, a_2, \ldots, a_n]$ of elements belonging to an algebraic structure U, and an (associative) operator $\circ : U \times U \to U$, form the element $a_1 \circ a_2 \circ a_3 \circ \ldots \circ a_n$.

Currently, the following operators may be used to reduce sequences: `+, *, and, or, join, meet, cat`. An error will occur if the operator is not defined on U.

If S contains a single element a, then the value returned is a. If S is the null sequence (empty and no universe specified), then reduction over S leads to an error; if S is empty with universe U in which the operation is defined, then the result (or error) depends on the operation and upon U. The following table defines the return value:

	empty	*null*
&+	U ! 0	error
&∗	U ! 1	error
&and	`true`	`true`
&or	`false`	`false`
&join	*empty*	*null*
&meet	error	error
&cat	*empty*	*null*

10.7 Iteration

Enumerated sequences allow iteration over their elements. In particular, they can be used as the range set in the sequence and set constructors, and as domains in `for` loops.

When multiple range sequences are used, it is important to know in which order the range are iterated over; the rule is that the repeated iteration takes place as nested loops where the first range forms the innermost loop, etc. See the examples below.

`for x in S do` *statements*`; end for;`

An enumerated sequence S may be the range for the `for`-statement. The iteration only enumerates the defined terms of the sequence.

Example H10E6

The first example shows how repeated iteration inside a sequence constructor corresponds to nesting of loops.

```
> [<number, letter> : number in [1..5], letter in ["a", "b", "c"]];
```

```
[ <1, a>, <2, a>, <3, a>, <4, a>, <5, a>, <1, b>, <2, b>, <3, b>, <4, b>, <5,
b>, <1, c>, <2, c>, <3, c>, <4, c>, <5, c> ]
> r := [];
> for letter in ["a", "b", "c"] do
>     for number in [1..5] do
>         Append(~r, <number, letter>);
>     end for;
> end for;
> r;
[ <1, a>, <2, a>, <3, a>, <4, a>, <5, a>, <1, b>, <2, b>, <3, b>, <4, b>, <5,
b>, <1, c>, <2, c>, <3, c>, <4, c>, <5, c> ]
```

This explains why the first construction below leads to an error, whereas the second leads to the desired sequence.

```
>  // The following produces an error:
>  [ <x, y> : x in [0..5], y in [0..x] | x^2+y^2 lt 16 ];
                                          ^
User error: Identifier 'x' has not been declared

> [ <x, y> : x in [0..y], y in [0..5] | x^2+y^2 lt 16 ];
[ <0, 0>, <0, 1>, <1, 1>, <0, 2>, <1, 2>, <2, 2>, <0, 3>, <1, 3>, <2, 3> ]
```

Note the following! In the last line below there are two different things with the name x. One is the (inner) loop variable, the other just an identifier with value 1000 that is used in the bound for the other (outer) loop variable y: the limited scope of the inner loop variable x makes it invisible to y, whence the error in the first case.

```
>  // The following produces an error:
>  #[ <x, y> : x in [0..5], y in [0..x] | x^2+y^2 lt 100 ];
                                           ^
User error: Identifier 'x' has not been declared

> x := 1000;
> #[ <x, y> : x in [0..5], y in [0..x] | x^2+y^2 lt 100 ];
59
```

11 TUPLES AND CARTESIAN PRODUCTS

Chapter 11
TUPLES AND CARTESIAN PRODUCTS

11.1 Introduction

A cartesian product may be constructed from a finite number of factors, each of which may be a set or algebraic structure. The term *tuple* will refer to an element of a cartesian product.

Note that the rules for tuples are quite different to those for sequences. Sequences are elements of a cartesian product of n copies of a fixed set (or algebraic structure) while tuples are elements of cartesian products where the factors may be different sets (structures). The semantics for tuples are quite different to those for sequences. In particular, the parent cartesian product of a tuple is fixed once and for all. This is in contrast to a sequence, which may grow and shrink during its life (thus implying a varying parent cartesian product).

11.2 Cartesian Product Constructor and Functions

The special constructor `car< ... >` is used for the creation of cartesian products of structures.

`car< R1, ..., Rk >`

Given a list of sets or algebraic structures $R_1, \ldots, R_k$, construct the cartesian product set $R_1 \times \cdots \times R_k$.

`CartesianProduct(R, S)`

Given structures R and S, construct the cartesian product set $R \times S$. This is the same as calling the `car` constructor with the two arguments R and S.

`CartesianProduct(L)`

Given a sequence or tuple L of structures, construct the cartesian product of the elements of L.

`CartesianPower(R, k)`

Given a structure R and an integer k, construct the cartesian power set R^k.

`Flat(C)`

Given a cartesian product C of structures which may themselves be cartesian products, return the cartesian product of the base structures, considered in depth-first order (see `Flat` for the element version).

`NumberOfComponents(C)`

Given a cartesian product C, return the number of components of C.

`Component(C, i)`

`C[i]`

The i-th component of C.

`#C`

Given a cartesian product C, return the cardinality of C.

`Rep(C)`

Given a cartesian product C, return a representative of C.

`Random(C)`

Given a cartesian product C, return a random element of C.

Example H11E1

We create the product of **Q** and **Z**.

```
> C := car< RationalField(), Integers() >;
> C;
Cartesian Product<Rational Field, Ring of Integers>
```

11.3 Creating and Modifying Tuples

`elt< C | a1, a2, ..., ak >`

`C ! < a1, a2, ..., ak >`

Given a cartesian product $C = R_1 \times \cdots \times R_k$ and a sequence of elements $a_1, a_2, \ldots, a_k$, such that a_i belongs to the set R_i $(i = 1, \ldots, k)$, create the tuple $T =< a_1, a_2, ..., a_k >$ of C.

`< a1, a2, ..., ak >`

Given a cartesian product $C = R_1 \times \cdots \times R_k$ and a list of elements $a_1, a_2, \ldots, a_k$, such that a_i belongs to the set R_i, $(i = 1, \ldots, k)$, create the tuple $T =< a_1, a_2, ..., a_k >$ of C. Note that if C does not already exist, it will be created at the time this expression is evaluated.

`Append(T, x)`

Return the tuple formed by adding the object x to the end of the tuple T. Note that the result lies in a new cartesian product of course.

`Append(~T, x)`

(Procedure.) Destructively add the object x to the end of the tuple T. Note that the new T lies in a new cartesian product of course.

`Prune(T)`

Return the tuple formed by removing the last term of the tuple T. The length of T must be greater than 1. Note that the result lies in a new cartesian product of course.

`Prune(~T)`

(Procedure.) Destructively remove the last term of the tuple T. The length of T must be greater than 1. Note that the new T lies in a new cartesian product of course.

`Flat(T)`

Construct the flattened version of the tuple T. The flattening is done in the same way as `Flat`, namely depth-first.

Example H11E2

We build a set of pairs consisting of primes and their reciprocals.

```
> C := car< Integers(), RationalField() >;
> C ! < 26/13, 13/26 >;
<2, 1/2>
> S := { C | <p, 1/p> : p in [1..25] | IsPrime(p) };
> S;
{ <5, 1/5>, <7, 1/7>, <2, 1/2>, <19, 1/19>, <17, 1/17>, <23, 1/23>, <11, 1/11>,
<13, 1/13>, <3, 1/3> }
```

11.4 Tuple Access Functions

`Parent(T)`

The cartesian product to which the tuple T belongs.

`#T`

Number of components of the tuple T.

`T[i]`

Return the i-th component of tuple T. Note that this indexing can also be used on the left hand side for modification of T.

`Explode(T)`

Given a tuple T of length n, this function returns the n entries of T (in order).

`TupleToList(T)`

`Tuplist(T)`

Given a tuple T return a list containing the entries of T.

Example H11E3

```
>  f := < 11/2, 13/3, RootOfUnity(3, CyclotomicField(3)) >;
> f;
<11/2, 13/3, (zeta_3)>
> #f;
3
> Parent(f);
Cartesian Product<Rational Field, Rational Field, Cyclotomic field Q(zeta_3)>
> f[1]+f[2]+f[3];
(1/6) * (59 + 6*zeta_3)
> f[3] := 7;
> f;
<11/2, 13/3, 7>
```

11.5 Equality

`T eq U`

Return `true` if and only if the tuples T and U are equal.

`T ne U`

Return `true` if and only if the tuples T and U are distinct.

11.6 Other operations

`&*T`

For a tuple T where each component lies in a structure that supports multiplication and such there exists a common over structure, return the product of the entries.

12 LISTS

Chapter 12
LISTS

12.1 Introduction

A *list* in MAGMA is an ordered finite collection of objects. Unlike sequences, lists are not required to consist of objects that have some common parent. Lists are not stored compactly and the operations provided for them are not extensive. They are mainly provided to enable the user to gather assorted objects temporarily together.

12.2 Construction of Lists

Lists can be constructed by expressions enclosed in special brackets `[*` and `*]`.

`[* *]`

The empty list.

`[* e1, e2, ..., en *]`

Given a list of expressions $e_1, \ldots, e_n$, defining elements $a_1, a_2, \ldots, a_n$, create the list containing $a_1, a_2, \ldots, a_n$.

12.3 Creation of New Lists

Here, S denotes the list $[* s_1, \ldots, s_n *]$, while T denotes the list $[* t_1, \ldots, t_m *]$.

`S cat T`

The list formed by concatenating the terms of the list S with the terms of the list T, i.e. the list $[* s_1, \ldots, s_n, t_1, \ldots, t_m *]$.

`S cat:= T`

(Procedure.) Destructively concatenate the terms of the list T to S; i.e. so S becomes the list $[* s_1, \ldots, s_n, t_1, \ldots, t_m *]$.

`Append(S, x)`

The list formed by adding the object x to the end of the list S, i.e. the list $[* s_1, \ldots s_n, x *]$.

`Append(~S, x)`

(Procedure.) Destructively add the object x to the end of the list S; i.e. so S becomes the list $[* s_1, \ldots s_n, x *]$.

`Insert(~S, i, x)`

`Insert(S, i, x)`

Create the list formed by inserting the object x at position i in S and moving the terms $S[i], \ldots, S[n]$ down one place, i.e., the list $[* s_1, \ldots, s_{i-1}, x, s_i, \ldots, s_n *]$. Note that i must not be bigger than $n+1$ where n is the length of S.

There are two versions of this: a procedure, where S is replaced by the new list, and a function, which returns the new list. The procedural version takes a reference $\sim S$ to S as an argument.

Note that the procedural version is much more efficient since the list S will not be copied.

`Prune(S)`

The list formed by removing the last term of the list S, i.e. the list $[* s_1, \ldots, s_{n-1} *]$.

`Prune(~S)`

(Procedure.) Destructively remove the last term of the list S; i.e. so S becomes the list $[* s_1, \ldots, s_{n-1} *]$.

`SequenceToList(Q)`

`Seqlist(Q)`

Given a sequence Q, construct a list whose terms are the elements of Q taken in the same order.

`TupleToList(T)`

`Tuplist(T)`

Given a tuple T, construct a list whose terms are the elements of T taken in the same order.

`Reverse(L)`

Given a list L return the same list, but in reverse order.

12.4 Access Functions

`#S`

The length of the list S.

`IsEmpty(S)`

Return whether S is empty (has zero length).

`S[i]`

Return the i-th term of the list S. If either $i \leq 0$ or $i > \#S+1$, then an error results. Here i is allowed to be a multi-index (see Section 8.3.1 for the interpretation).

`S[I]`

Return the sublist of S given by the indices in the sequence I. Each index in I must be in the range $[1..l]$, where l is the length of S.

`IsDefined(L, i)`

Checks whether the ith item in L is defined or not, that is it returns `true` if i is at most the length of L and `false` otherwise.

12.5 Assignment Operator

`S[i] := x`

Redefine the i-th term of the list S to be x. If $i \leq 0$, then an error results. If $i = \#S + 1$, then x is appended to S. Otherwise, if $i > \#S + 1$, an error results. Here i is allowed to be a multi-index.

13 ASSOCIATIVE ARRAYS

Chapter 13
ASSOCIATIVE ARRAYS

13.1 Introduction

An *associative array* in MAGMA is an array which may be indexed by arbitrary elements of an index structure I. The indexing may thus be by objects which are not integers. These objects are known as the *keys*. For each current key there is an associated value. The *values* associated with the keys need not lie in a fixed universe but may be of any type.

13.2 Operations

`AssociativeArray()`

Create the null associative array with no index universe. The first assignment to the array will determine its index universe.

`AssociativeArray(I)`

Create the empty associative array with index universe I.

`A[x] := y`

Set the value in A associated with index x to be y. If x is not coercible into the current index universe I of A, then an attempt is first made to lift the index universe of A to contain both I and x.

`A[x]`

Given an index x coercible into the index universe I of A, return the value associated with x. If x is not in the keys of A, then an error is raised.

`IsDefined(A, x)`

Given an index x coercible into the index universe I of A, return whether x is currently in the keys of A and if so, return also the value $A[x]$.

`Remove(~ A, x)`

(Procedure.) Destructively remove the value indexed by x from the array A. If x is not present as an index, then nothing happens (i.e., an error is not raised).

`Universe(A)`

Given an associative array A, return the index universe I of A, in which the keys of A currently lie.

Keys(A)

Given an associative array A, return the current keys of A as a set. Warning: this constructs a new copy of the set of keys, so should only be called when that is needed. It is not meant to be used as a quick access function.

Example H13E1

This example shows simple use of associative arrays. First we create an array indexed by rationals.

```
> A := AssociativeArray();
> A[1/2] := 7;
> A[3/8] := "abc";
> A[3] := 3/8;
> A[1/2];
7
> IsDefined(A, 3);
true 3/8
> IsDefined(A, 4);
false
> IsDefined(A, 3/8);
true abc
> Keys(A);
{ 3/8, 1/2, 3 }
> for x in Keys(A) do x, A[x]; end for;
1/2 7
3/8 abc
3 3/8
> Remove(~A, 3/8);
> IsDefined(A, 3/8);
false
> Keys(A);
{ 1/2, 3 }
> Universe(A);
Rational Field
```

We repeat that an associative array can be indexed by elements of any structure. We now index an array by elements of the symmetric group S_3.

```
> G := Sym(3);
> A := AssociativeArray(G);
> v := 1; for x in G do A[x] := v; v +:= 1; end for;
> A;
Associative Array with index universe GrpPerm: G, Degree 3, Order 2 * 3
> Keys(A);
{
    (1, 3, 2),
    (2, 3),
    (1, 3),
    (1, 2, 3),
```

```
    (1, 2),
    Id(G)
}
> A[G!(1,3,2)];
3
```

14 COPRODUCTS

Chapter 14
COPRODUCTS

14.1 Introduction

Coproducts can be useful in various situations, as they may contain objects of entirely different types. Although the coproduct structure will serve as a single parent for such diverse objects, the proper parents of the elements are recorded internally and restored whenever the element is retrieved from the coproduct.

14.2 Creation Functions

There are two versions of the coproduct constructor. Ordinarily, coproducts will be constructed from a list of structures. These structures are called the `constituents` of the coproduct. A single sequence argument is allowed as well to be able to create coproducts of parameterized families of structures conveniently.

14.2.1 Creation of Coproducts

`cop< S1, S2, ..., Sk >`

`cop< [ S1, S2, ..., Sk ] >`

Given a list or a sequence of two or more structures S_1, S_2, ..., S_k, this function creates and returns their coproduct C as well as a sequence of maps [m_1, m_2, ..., m_k] that provide the injections $m_i : S_i \to C$.

14.2.2 Creation of Coproduct Elements

Coproduct elements are usually created by the injections returned as the second return value from the `cop<>` constructor. The bang (!) operator may also be used but only if the type of the relevant constituent is unique for the particular coproduct.

`m(e)`

Given a coproduct injection map m and an element of one of the constituents of the coproduct C, create the coproduct element version of e.

`C ! e`

Given a coproduct C and an element e of one of the constituents of C such that the type of that constituent is unique within that coproduct, create the coproduct element version of e.

14.3 Accessing Functions

`Injections(C)`

Given a coproduct C, return the sequence of injection maps returned as the second argument from the `cop<>` constructor.

`#C`

Given a coproduct C, return the length (number of constituents) of C.

`Constituent(C, i)`

Given a coproduct C and an integer i between 1 and the length of C, return the i-th constituent of C.

`Index(x)`

Given an element x from a coproduct C, return the constituent number of C to which x belongs.

14.4 Retrieve

The function described here restores an element of a coproduct to its original state.

`Retrieve(x)`

Given an element x of some coproduct C, return the element as an element of the structure that formed its parent before it was mapped into C.

Example H14E1

We illustrate basic uses of the coproduct constructors and functions.

```
> C := cop<IntegerRing(), Strings()>;
> x := C ! 5;
> y := C ! "abc";
> x;
5
> y;
abc
> Parent(x);
Coproduct<Integer Ring, String structure>
> x eq 5;
true
> x eq y;
false
> Retrieve(x);
5
> Parent(Retrieve(x));
Integer Ring
```

14.5 Flattening

The function described here enables the 'concatenation' of coproducts into a single one.

`Flat(C)`

Given a coproduct C of structures which may themselves be coproducts, return the coproduct of the base structures, considered in depth-first order.

14.6 Universal Map

`UniversalMap(C, S, [ n`$_1$`, ..., n`$_m$` ])`

Given maps n_1, ..., n_m from structures S_1, ..., S_m that compose the coproduct C, to some structure S, this function returns the universal map $C \to S$.

15 RECORDS

Chapter 15
RECORDS

15.1 Introduction

In a *record* several objects can be collected. The objects in a record are stored in *record fields*, and are accessed by using *fieldnames*. Records are like tuples (and unlike sets or sequences) in that the objects need not all be of the same kind. Though records and tuples are somewhat similar, there are several differences too. The components of tuples are indexed by integers, and every component must be defined. The fields of records are indexed by fieldnames, and it is possible for some (or all) of the fields of a record not to be assigned; in fact, a field of a record may be assigned or deleted at any time. A record must be constructed according to a pre-defined *record format*, whereas a tuple may be constructed without first giving the Cartesian product that is its parent, since MAGMA can deduce the parent from the tuple.

In the definition of a record format, each field is given a fieldname. If the field is also given a parent magma or a category, then in any record created according to this format, that field must conform to this requirement. However, if the field is not given a parent magma or category, there is no restriction on the kinds of values stored in that field; different records in the format may contain disparate values in that field. By contrast, every component of a Cartesian product is a magma, and the components of all tuples in this product must be elements of the corresponding magma.

Because of the flexibility of records, with respect to whether a field is assigned and what kind of value is stored in it, Boolean operators are not available for comparing records.

15.2 The Record Format Constructor

The special constructor `recformat< ... >` is used for the creation of record formats. A record format must be created before records in that format are created.

`recformat< L >`

Construct the record format corresponding to the non-empty fieldname list L. Each term of L must be one of the following:

(a) *fieldname* in which case there is no restriction on values that may be stored in this field of records having this format;

(b) *fieldname*:*expression* where the expression evaluates to a magma which will be the parent of values stored in this field of records having this format; or

(c) *fieldname*:*expression* where the expression evaluates to a category which will be the category of values stored in this field of records having this format;

where *fieldname* consists of characters that would form a valid identifier name. Note that it is not a string.

Example H15E1

We create a record format with these fields: `n`, an integer; `misc`, which has no restrictions; and `seq`, a sequence (with any universe possible).

```
> RF := recformat< n : Integers(), misc, seq : SeqEnum >;
> RF;
recformat<n: IntegerRing(), misc, seq: SeqEnum>
> Names(RF);
[ n, misc, seq ]
```

15.3 Creating a Record

Before a record is created, its record format must be defined. A record may be created by assigning as few or as many of the record fields as desired.

`rec< F | L >`

Given a record format F, construct the record format corresponding to the field assignment list L. Each term of L must be of the form *fieldname* := *expression* where *fieldname* is in F and the value of the expression conforms (directly or by coercion) to any restriction on it. The list L may be empty, and there is no fixed order for the fieldnames.

Example H15E2

We build some records having the record format `RF`.

```
> RF := recformat< n : Integers(), misc, seq : SeqEnum >;
> r := rec< RF | >;
> r;
rec<RF | >
> s := rec< RF | misc := "adsifaj", n := 42, seq := [ GF(13) | 4, 8, 1 ]>;
> s;
rec<RF | n := 42, misc := adsifaj, seq := [ 4, 8, 1 ]>
> t := rec< RF | seq := [ 4.7, 1.9 ], n := 51/3 >;
> t;
rec<RF | n := 17, seq := [ 4.7, 1.9 ]>
> u := rec< RF | misc := RModule(PolynomialRing(Integers(7)), 4) >;
> u;
rec<RF | misc := RModule of dimension 4 with base ring Univariate Polynomial
Algebra over Integers(7)>
```

15.4 Access and Modification Functions

Fields of records may be inspected, assigned and deleted at any time.

`Format(r)`

The format of record r.

`Names(F)`

The fieldnames of the record format F returned as a sequence of strings.

`Names(r)`

The fieldnames of record r returned as a sequence of strings.

`r‘`*fieldname*

Return the field of record r with this fieldname. The format of r must include this fieldname, and the field must be assigned in r.

`r‘`*fieldname*`:=` *expression*`;`

Reassign the given field of r to be the value of the expression. The format of r must include this fieldname, and the expression's value must satisfy (directly or by coercion) any restriction on the field.

`delete r‘`*fieldname*

(Statement.) Delete the current value of the given field of record r.

`assigned r‘`*fieldname*

Returns true if and only if the given field of record r currently contains a value.

`r‘‘s`

Given an expression s that evaluates to a string, return the field of record r with the fieldname corresponding to this string. The format of r must include this fieldname, and the field must be assigned in r.

This syntax may be used anywhere that r‘*fieldname* may be used, including in left hand side assignment, `assigned` and `delete`.

Example H15E3

```
> RF := recformat< n : Integers(), misc, seq : SeqEnum >;
> r := rec< RF | >;
> s := rec< RF | misc := "adsifaj", n := 42, seq := [ GF(13) | 4, 8, 1 ]>;
> t := rec< RF | seq := [ 4.7, 1.9 ], n := 51/3 >;
> u := rec< RF | misc := RModule(PolynomialRing(Integers(7)), 4) >;
> V4 := u`misc;
> assigned r`seq;
false
> r`seq := Append(t`seq, t`n); assigned r`seq;
true
> r;
rec<RF | seq := [ 4.7, 1.9, 17 ]>
>  // The following produces an error:
>  t``(s`misc);
>> t``(s`misc);
          ^
Runtime error in `: Field 'adsifaj' does not exist in this record
> delete u``("m" cat "isc"); u;
rec<RF | >
```

16 MAPPINGS

Chapter 16
MAPPINGS

16.1 Introduction

Mappings play a fundamental role in algebra and, indeed, throughout mathematics. Reflecting this importance, mappings are one of the fundamental datatypes in our language. The most general way to define a mapping $f : A \to B$ in a programming language is to write a *function* which, given any element of A, will return its image under f in B. While this approach to the definition of mappings is completely general, it is desirable to have mappings as an independent datatype. It is then possible to provide a very compact notation for specifying important classes of mappings such as homomorphisms. Further, a range of operations peculiar to the mapping type can be provided.

Mappings are created either through use of *mapping constructors* as described in this Chapter, or through use of certain standard functions that return mappings as either primary or secondary values.

All mappings are objects in the MAGMA category `Map`.

16.1.1 The Map Constructors

There are three main mapping constructors: the general map constructor `map< >`, the homomorphism constructor `hom< >`, and the partial map constructor `pmap< >`. The general form of all constructors is the same: inside the angle brackets there are two components separated by a pipe `|`. To the left the user specifies a *domain* A and a *codomain* B, separated by `->`; to the right of the pipe the user specifies how images are obtained for elements of the domain. The latter can be done in one of several ways: one specifies either the *graph* of the map, or a *rule* describing how images are to be formed, or for homomorphisms, one specifies generator images. We will describe each in the next subsections. The result is something like `map< A -> B |` *expression*`>`.

The domain and codomain of the map can be arbitrary magmas. When a full map (as opposed to a partial map) is constructed by use of a graph, the domain is necessarily finite.

The main difference between maps and partial maps is that a partial map need not be defined for every element of the domain. The main difference between these two types of map and homomorphisms is that the latter are supposed to provide *structure-preserving* maps between algebraic structures. On the one hand this makes it possible to allow the specification of images for homomorphisms in a different fashion: homomorphism can be given via *images* for *generators* of the domain. On the other hand homomorphisms are restricted to cases where domain and (image in the) codomain have a similar structure. The generator image form only makes sense for domains that are *finitely presented*. Homomorphisms are described in more detail below.

16.1.2 The Graph of a Map

Let A and B be structures. A *subgraph* of the cartesian product $C = A \times B$ is a subset G of C such that each element of A appears at most once among the first components of the pairs $< a, b >$ of G. A subgraph having the additional property that every element of A appears as the first component of some pair $< a, b >$ of G is called a *graph* of $A \times B$.

A mapping between A and B can be identified with a graph G of $A \times B$, a partial map can be identified with a subgraph. We now describe how a graph may be represented in the context of the map constructor. An element of the graph of $A \times B$ can be given either as a *tuple* `<a, b>`, or as an *arrow pair* `a -> b`. The specification of a (sub)graph in a map constructor should then consist of either a (comma separated) list, a sequence, or a set of such tuples or arrow pairs (a mixture is permitted).

16.1.3 Rules for Maps

The specification of a rule in the map constructor involves a free variable and an expression, usually involving the free variable, separated by `:->`, for example `x :-> 3*x - 1`. The scope of the free variable is restricted to the map constructor (so the use of x does not interfere with values of x outside the constructor). A general expression is allowed in the rule, which may involve intrinsic or user functions, and even in-line definitions of such functions.

16.1.4 Homomorphisms

Probably the most useful form of the map-constructor is the version for homomorphisms. Most interesting mappings in algebra are homomorphisms, and if an algebraic structure A belongs to a family of algebraic structures which form a variety we have the fundamental result that a homomorphism is uniquely determined by the images of any generating set. This provides us with a particularly compact way of defining and representing homomorphisms. While the syntax of the homomorphism constructor is similar to that of the general mapping constructor, the semantics are sometimes different.

The kind of homomorphism built by the hom-constructor is determined entirely by the domain: thus, a *group* homomorphism results from applying `hom` to a domain A that is one of the types of group in Magma, a *ring* homomorphism results when A is a ring, etc. As a consequence, the requirements on the specification of homomorphisms are dependent on the category to which A belongs. Often, the codomain of a homomorphism is required to belong to the same variety. But even within a category the specification may depend on the type of structure; for details we refer the reader to the specific chapters.

A homomorphism can be specified using either a rule map or by generator images. In the latter case the processor will seek to express an element as a word in the generators of A when asked to compute its image. Thus A needs to be finitely presented.

16.1.5 Checking of Maps

It should be pointed out that checking the 'correctness' of mappings can be done to a limited extent only. If the mapping is given by means of a graph, Magma will check that no multiple images are specified, and that an image is given for every element of the

domain (unless a partial map is defined). If a rule is given, it cannot be checked that it is defined on all of the domain. Also, it is in general the responsibility of the user to ensure that the images provided for a `hom` constructor do indeed define a homomorphism.

16.2 Creation Functions

In this section we describe the creation of maps, partial maps, and homomorphisms via the various forms of the constructors, as well as maps that define coercions between algebraic structures.

16.2.1 Creation of Maps

Maps between structures A and B may be specified either by providing the full graph (as defined in the previous section) or by supplying an expression rule for finding images.

```
map<  A -> B | G  >
```

Given a finite structure A, a structure B and a graph G of $A \times B$, construct the mapping $f : A \to B$, as defined by G. The graph G may be given by either a set, sequence, or list of tuples or arrow-pairs as described in the Introduction to this Chapter. Note that G must be a full graph, i.e., every element of A must occur exactly once as a first component.

```
map<  A -> B | x :-> e(x)  >
```

Given a set or structure A, a set or structure B, a variable x and an expression $e(x)$, usually involving x, construct the mapping $f : A \to B$, as defined by $e(x)$. It is the user's responsibility to ensure that a value is defined for every $x \in A$. The scope of the variable x is restricted to the map-constructor.

```
map<  A -> B | x :-> e(x), y :-> i(y)  >
```

Given a set or structure A, a set or structure B, a variable x, an expression $e(x)$, usually involving x, a variable y, and an expression $i(y)$, usually involving y, construct the mapping $f : A \to B$, as defined by $x \mapsto e(x)$, with corresponding inverse $f^{-1} : B \to A$, as defined by $y \mapsto i(y)$. It is the user's responsibility to ensure that a value $e(x)$ is defined for every $x \in A$, a value $i(y)$ is defined for every $y \in B$, and that $i(y)$ is the true inverse of $e(x)$. The scope of the variables x and y is restricted to the map-constructor.

16.2.2 Creation of Partial Maps

Partial mappings are quite different to both general mappings and homomorphisms, in that images need not be defined for every element of the domain.

`pmap< A -> B | G >`

Given a finite structure A of cardinality n, a structure B and a subgraph G of $A \times B$, construct the partial map $f : A \to B$, as defined by G. The subgraph G may be given by either a set, sequence, or list of tuples or arrow-pairs as described in the Introduction to this Chapter.

`pmap< A -> B | x :-> e(x) >`

Given a set A, a set B, a variable x and an expression $e(x)$, construct the partial map $f : A \to B$, as defined by $e(x)$. This form of the map constructor is a special case of the previous one whereby the image of x can be defined using a single expression. Again the scope of x is restricted to the map-constructor.

`pmap< A -> B | x :-> e(x), y :-> i(y) >`

This constructor is the same as the map constructor above which allows the inverse map $i(y)$ to be specified, except that the result is marked to be a partial map.

16.2.3 Creation of Homomorphisms

The principal construction for homomorphisms consists of the generator image form, where the images of the generators of the domain are listed. Note that the kind of homomorphism and the kind and number of generators for which images are expected, depend entirely on the type of the domain. Moreover, some features of the created homomorphism, e.g. whether checking of the homomorphism is done during creation or whether computing preimages is possible, depend on the types of the domain and the codomain. We refer to the appropriate handbook chapters for further information.

`hom< A -> B | G >`

Given a finitely generated algebraic structure A and a structure B, as well as a graph G of $A \times B$, construct the homomorphism $f : A \to B$ defined by extending the map of the generators of A to all of A. The graph G may be given by either a set, sequence, or list of tuples or arrow-pairs as described in the Introduction to this Chapter.

The detailed requirements on the specification are module-dependent, and can be found in the chapter describing the domain A.

`hom< A -> B | y`$_1$`, ..., y`$_n$ `>`

`hom< A -> B | x`$_1$ `-> y`$_1$`, ..., x`$_n$ `-> y`$_n$ `>`

This is a module-dependent constructor for homomorphisms between structures A and B; see the chapter describing the functions for A. In general after the bar the images for all generators of the structure A must be specified.

```
hom<  A -> B | x :-> e(x)  >
```

Given a structure A, a structure B, a variable x and an expression $e(x)$, construct the homomorphism $f : A \to B$, as defined by $e(x)$. This form of the map constructor is a special case of the previous one whereby the image of x can be defined using a single expression. Again the scope of x is restricted to the map-constructor.

```
hom<  A -> B | x :-> e(x), y :-> i(y)  >
```

This constructor is the same as the map constructor above which allows the inverse map $i(y)$ to be specified, except that the result is marked to be a homomorphism.

16.2.4 Coercion Maps

MAGMA has a sophisticated machinery for coercion of elements into structures other than the parent. Non-automatic coercion is usually performed via the `!` operator. To obtain the coercion map corresponding to `!` in a particular instance the `Coercion` function can be used.

```
Coercion(D, C)
```

```
Bang(D, C)
```

Given structures D and C such that elements from D can be coerced into C, return the map m that performs this coercion. Thus the domain of m will be D and the codomain will be C.

16.3 Operations on Mappings

16.3.1 Composition

Although compatible maps can be composed by repeated application, say $g(f(x))$, it is also possible to create a composite map.

```
f * g
```

Given a mapping $f : A \to B$, and a mapping $g : B \to C$, construct the composition h of the mappings f and g as the mapping $h = g \circ f : A \to C$.

```
Components(f)
```

Returns the maps which were composed to form f.

16.3.2 (Co)Domain and (Co)Kernel

The domain and codomain of any map can simply be accessed. Only for some intrinsic maps and for maps with certain domains and codomains, also the formation of image, kernel and cokernel is available.

`Domain(f)`

The domain of the mapping f.

`Codomain(f)`

The codomain of the mapping f.

`Image(f)`

Given a mapping f with domain A and codomain B, return the image of A in B as a substructure of B. This function is currently supported only for some intrinsic maps and for maps with certain domains and codomains.

`Kernel(f)`

Given the homomorphism f with domain A and codomain B, return the kernel of f as a substructure of A. This function is currently supported only for some intrinsic maps and for maps with certain domains and codomains.

16.3.3 Inverse

`Inverse(m)`

The inverse map of the map m.

16.3.4 Function

For a map given by a rule, it is possible to get access to the rule as a user defined function.

`Function(f)`

The function underlying the mapping f. Only available if f has been defined by the user by means of a rule map (i. e., an expression for the image under f of an arbitrary element of the domain).

16.4 Images and Preimages

The standard mathematical notation is used to denote the calculation of a map image. Some mappings defined by certain system intrinsics and constructors permit the taking of preimages. However, preimages are not available for any mapping defined by means of the mapping constructor.

`a @ f`
`f(a)`

Given a mapping f with domain A and codomain B, and an element a belonging to A, return the image of a under f as an element of B.

`S @ f`
`f(S)`

Given a mapping f with domain A and codomain B, and a finite enumerated set, indexed set, or sequence S of elements belonging to A, return the image of S under f as an enumerated set, indexed set, or sequence of elements of B.

`C @ f`
`f(C)`

Given a homomorphism f with domain A and codomain B, and a substructure C of A, return the image of C under f as a substructure of B.

`y @@ f`

Given a mapping f with domain A and codomain B, where f supports preimages, and an element y belonging to B, return the preimage of y under f as an element of A.

If the mapping f is a homomorphism, then a single element is returned as the preimage of y. In order to obtain the full preimage of y, it is necessary to form the coset $K * y@@f$, where K is the kernel of f.

`R @@ f`

Given a mapping f with domain A and codomain B, where f supports preimages, and a finite enumerated set, indexed set, or sequence of elements R belonging to B, return the preimage of R under f as an enumerated set, indexed set, or sequence of elements of A.

`D @@ f`

Given a mapping f with domain A and codomain B, where f supports preimages and the kernel of f is known or can be computed, and a substructure D of B, return the preimage of D under f as a substructure of A.

`HasPreimage(x, f)`

Return whether the preimage of x under f can be taken and the preimage as a second argument if it can.

16.5 Parents of Maps

Parents of maps are structures knowing a domain and a codomain. They are often used in automorphism group calculations where a map is returned from an automorphism group into the set of all automorphisms of some structure. Parents of maps all inherit from the type `PowMap`. The type `PowMapAut` which inherits from `PowMap` is type which the parents of automorphisms inherit from.

There is also a power structure of maps (of type `PowStr`, similar to that of other structures) which is used as a common overstructure of the different parents.

`Parent(m)`

The parent of m.

`Domain(P)`

`Codomain(P)`

The domain and codomain of the maps for which P is the parent.

`Maps(D, C)`

`Iso(D, C)`

The parent of maps (or isomorphisms) from D to C. `Iso` will only return a different structure to `Maps` if it has been specifically implemented for such maps.

`Aut(S)`

The parent of automorphisms of S.

PART III
BASIC RINGS

17 INTRODUCTION TO RINGS

Chapter 17
INTRODUCTION TO RINGS

17.1 Overview

Rings of various kinds form the richest source of algebraic structures in MAGMA. Tables 1 and 2 list the most important types.

symbol	*description*	`Category`	*Ch*
$\mathbf{Z}$	ring of integers	`RngInt`	18
$\mathbf{Z}/m\mathbf{Z}$	ring of residue classes	`RngIntRes`	18
$R[x]$	univariate polynomial ring	`RngUPol`	23
$F[x]/f(x)$	polynomial factor ring	`RngUPolRes`	23
$R[x_1, \cdots, x_m]$	multivariate polynomial ring	`RngMPol`	24
$R[x_1, \cdots, x_m]^G$	invariant ring	`RngInvar`	110
$R[[x]]$	power series ring	`RngSer`	49
O	order in a number field	`RngOrd`	37
O	order in a function field	`RngFunOrd`	42
$\mathbf{Z}_p$	p-adic ring	`RngPad`	47
R_m	local ring	`RngLoc`	47
V	valuation ring	`RngVal`	45

Table 1: The main types of Ring in MAGMA.

symbol	*description*	`Category`	*Ch*
$\mathbf{Q}$	rational field	`FldRat`	20
$\mathbf{F}_q$	finite field	`FldFin`	21
$F(x_1, \cdots, x_m)$	rational function field	`FldFunRat`	41
$F((x))$	field of Laurent series	`RngSerLaur`	49
$\mathbf{Q}(\sqrt{D})$	quadratic number field	`FldQuad`	35
$\mathbf{Q}(\zeta_n)$	cyclotomic number field	`FldCyc`	36
$\mathbf{Q}(\alpha)$	number field	`FldNum`	34
$F(x)(\alpha)$	function field	`FldFun`	42
$\mathbf{Q}_p$	p-adic field	`FldPad`	47
$\mathbf{Q}_p(\alpha)$	local field	`FldLoc`	47
$\mathbf{R}$	real field	`FldRe`	25
$\mathbf{C}$	complex field	`FldCom`	25

Table 2: The main types of Field in MAGMA.

The list of rings in Table 1 is not exhaustive, for two reasons. In the first place, some rings have been categorized differently, because their module structure or algebra structure seems pre-eminent; thus matrix rings and finitely presented algebras appear (more or less arbitrarily) in the Part on Algebras, and vector spaces and their generalizations appear in the Module Part. (Also, rings of class functions appear in the Part on Groups.) Furthermore, certain general constructions (such as `sub`) allow the user to define rings that do not appear in the above list, most notably subrings of **Z**.

Looking at the table it may seem that all rings in MAGMA are commutative and unital. This is not the case (even though it would have made life much easier); since polynomial rings and the like can be defined over any coefficient ring, the matrix rings and finitely presented algebras not listed here that are not generally commutative, allow the construction of non-commutative rings. Furthermore, the `sub` constructor allows the creation of rings without 1; certain functions for the construction of new rings from old ones do not allow such non-unital coefficient rings.

In this Chapter we give an overview of the various types and the relations between them. Moreover, we describe the important principles underlying the rules for coercion of elements of one ring into another. This Chapter also describes the common functions for all types of rings (and their elements), and subsequent Chapters deal with particular categories of rings, as indicated by the table.

17.2 The World of Rings

There are various ways in which to order the families of rings appearing in Table 1. We look at some in this section.

17.2.1 New Rings from Existing Ones

It is important to realize at the outset that to work comfortably with a ring, it should be finitely generated (over some subring); indeed, the only violations of this rule occur for real and complex fields, and p-adic and power series type structures, in which we necessarily have to cope with approximations. All other rings we will label as *exact*.

All rings in Table 1 can be obtained from the ring of rational integers **Z** by repeated application of a handful of fundamental mathematical constructions. The first such construction is *forming fractions*: the rational field **Q** can be obtained as the field of fractions of **Z**. The second construction is that of forming quotients: in this way the rings $\mathbf{Z}/m\mathbf{Z}$ are obtained from **Z**. The third important construction is that of *transcendental extension*: by adjoining an element that satisfies no relation over the coefficient ring, a polynomial ring is obtained. An *algebraic extension* can be obtained by a combination of a transcendental extension and a quotient. Finally, *completion* of a ring at a prime leads in general to the rings that were labelled above as not exact. Some other constructions are: tensoring, taking direct products (leading to tuple modules), and taking valuation rings (an operation inverse to taking fields of fractions).

Most of these constructions are supported by MAGMA. In many situations the `quo` and `ext` constructors will perform the quotient and algebraic extension operations, just like

`sub` creates sub-structures. Note an important distinction: usually `sub` creates structures of exactly the same type as the original structure—this is precisely why the construction of sub-object does not appear as an important construction for creating new objects in the previous paragraph.

Care should be taken not to confuse the mathematical properties of rings (or objects in MAGMA in general) and the properties of the object that MAGMA is aware of. For example, if one creates the ring of residue classes $\mathbf{Z}/p\mathbf{Z}$ for a prime number p, using the command `IntegerRing(p)`, the MAGMA object created is a residue class ring (whose modulus happens to be prime) and *not* a finite field; the functions applicable are the residue class ring functions, and it is, for instance, not possible to create a field extension over this object. If the intention was to create a finite field, the `FiniteField(p)` command should have been used, and for that object it is possible to create a field extension.

Similarly, a convenient way of thinking about a number field $K = \mathbf{Q}(\alpha)$ is to regard it as a quotient of the polynomial ring $\mathbf{Q}[X]$ and the ideal generated by the minimal polynomial f of the primitive element α:

$$K = \mathbf{Q}(\alpha) \cong \mathbf{Q}[X]/(f).$$

This is, however, not the way to create number fields in MAGMA. The quotient ring of a polynomial ring will be an object to which only the generic ring functions apply, whereas to obtain the number field with all the machinery to manipulate it one has to use a command like `NumberField(f)`.

17.2.2 Attributes

17.3 Coercion

A ring element can often be coerced into a ring other than its parent. The need for this occurs for example when one wants to perform a binary ring operation on elements of different structures, or when an intrinsic function is invoked on elements for which it has not been defined.

The basic principle is that such an operation may be performed whenever it makes sense mathematically. Before the operation can be performed however, an element may need to be coerced into some structure in which the operation can legally be performed. There are two types of coercion: *automatic* and *forced* coercion. Automatic coercion occurs when MAGMA can figure out for itself what the target structure should be, and how elements of the originating structure can be coerced into that structure. In other cases MAGMA may still be able to perform the coercion, provided the target structure has been specified; for this type of coercion `R ! x` instructs MAGMA to execute the coercion of element x into ring R.

The precise rules for automatic and forced coercion between rings are explained in the next two subsections. It is good to keep an important general distinction between automatic and forced coercion in mind: whether or not automatic coercion will succeed depends on the originating and the target structure alone, while for forced coercion success

may depend on the particular element as well. Thus, integers can be lifted automatically to the rationals if necessary, but conversely, only the integer elements of **Q** can be coerced into **Z** by using `!`.

The subsections below will describe for specific rings R and S in MAGMA whether or not an element r of R can be lifted automatically or by force into S. Suppose that the unary MAGMA function `Function` takes elements of the type of S as argument and one is interested in the result of that function when applied to r. If R can be coerced automatically into a unique structure S of the desired type, then `Function(r)` will produce the required result. If R cannot be coerced automatically into such S, but forced coercion on r is possible, then `Function(S ! r)` will yield the desired effect. If, finally, neither automatic nor forced coercion is possible, it may be possible to define a map m from R to S, and then `Function( m(r) )` will give the answer.

For example, the function `Order` is defined for elements of residue class rings (among others). But `Order(3)` has no obvious interpretation (and an error will arise) because there is not a unique residue class ring in which this should be evaluated.

If a binary operation $\circ : C \times C \to C$ on members C of a category of rings $\mathcal{C}$ is applied to elements r and s of members R and S from $\mathcal{C}$, the same rules for coercion will be used to determine the legality of $r \circ s$. If s can be coerced automatically into R, then this will take place and $r \circ s$ will be evaluated in R; otherwise, if r can be coerced automatically into S, then $r \circ s$ will be evaluated in S. If neither succeeds, then, in certain cases, MAGMA will try to find an existing *common overstructure* T for R and S, that is, an object T from $\mathcal{C}$ such that $\subset T \supset S$; then both r and s will be coerced into T and the result $t = r \circ s$ will be returned as an element of T. If none of these cases apply, an error results. It may still be possible to evaluate by forced coercion of r into S or s into R, using `(S ! r) o s` or using `r o (R ! s)`.

17.3.1 Automatic Coercion

We will first deal with the easier of the two cases: automatic coercion. A simple demonstration of the desirability of automatic coercion is given by the following example:

```
print 1 + (1/2);
```

It is obvious that one wants the result to be 3/2: we want to identify the integer 1 with the rational number 1 and perform the addition in **Q**, that is, we clearly wish to have automatic coercion from **Z** to **Q**.

The basic rule for automatic coercion is:

> *automatic coercion will only take place when there exists a unique target structure and an obvious homomorphism from the parent structure to the target structure*

In particular, if one structure is naturally contained in the other (and MAGMA knows about it!), automatic coercion will take place. (The provision that MAGMA must know about the embedding is in particular relevant for finite fields and number fields; in these cases it is possible to create subrings, or even isomorphic rings/fields, for which the embedding is not known.)

Also, for any ring R there is a natural ring homomorphism $\mathbf{Z} \to R$, hence any integer can be coerced automatically into any ring.

Table 3 gives a summary for all cases in which MAGMA will apply automatic coercion: if a ring operation is attempted on an element from one of the structures in the first row, and the specifications for the operation require that the argument is an element from a structure in the first column, the element will be coerced into the structure indicated by the table.

Automatic Coercion (Ring Elements)										
	$\mathbf{F}_{p^s}$	$\mathbf{Z}/n\mathbf{Z}$	$\mathbf{Z}$	$\mathbf{Q}$	$\mathbf{Q}(\sqrt{\Delta_2})$	$\mathbf{Q}(\zeta_n)$	L	O_L	$\mathbf{R}_n$	$\mathbf{C}_n$

Table 3.

The symbols in the table have the following meaning:

– indicates that automatic coercion will *not* take place; as the table shows for instance, automatic coercion will not take place when we try to add a finite field element and an element of $\mathbf{Z}/n\mathbf{Z}$ (not even when n is prime and of the same characteristic as the field).

$\subset$ indicates that automatic coercion will *only* take place if one structure is contained in the other, or MAGMA can find a common overstructure to both structures. Thus the top-left entry in the table indicates that two finite field elements can be added if they are members of finite fields F_1 and F_2 such that $F_1 \subset F_2$ or $F_2 \subset F_1$, or both fields have been created inside a field F, so $F_1 \subset F \supset F_2$.

= The = is used to denote that automatic coercion only takes place if both structures are the same. The entry $K = L$ is used to indicate that an element of an order O_K will only be coerced into the number field L if $K = L$.

In addition to these rules, general rules apply to polynomial and matrix algebras. The rules for polynomial rings are as follows. An element s from a ring S can be automatically coerced into $R[X_1, \ldots, X_n]$ if either S equals $R[X_1, \ldots, X_i]$ for some $1 \leq i \leq n$, or $S = R$. Note that in the latter case the element s must be an element of the coefficient ring R, and that it is not sufficient for it to be coercible into R.

So, for example, we can add an integer and a polynomial over the integers, we can add an element f of $\mathbf{Z}[X]$ and g of $\mathbf{Z}[X,Y]$, but *not* an integer and a polynomial over the rationals.

An element s can be coerced automatically in the matrix ring $M_{n,n}(R)$ if it is coercible automatically into the coefficient ring R, in which case s will be identified with the diagonal matrix that has each diagonal entry equal to s.

So we can add an integer and a matrix ring element over the rationals, but we cannot automatically add elements of $M_{n,n}(\mathbf{Z})$ and $M_{n,n}(\mathbf{Q})$, nor elements from $M_{2,2}(\mathbf{Z})$ and $M_{3,3}(\mathbf{Z})$.

17.3.2 Forced Coercion

In certain cases where automatic coercion will not take place, one can cast an element into the ring in which the operation should take place.

If, for example, one is working in a ring $\mathbf{Z}/p\mathbf{Z}$, and p happens to be prime, it may occur that one wishes to perform some finite field operations on an element in the ring; if F is a finite field of characteristic p an element x of $\mathbf{Z}/p\mathbf{Z}$ can be cast into an element of F using

```
F ! x;
```

Table 4 describes the possibilities for using `!` for coercion in rings. It shows when it is possible to coerce an element from a structure in the first row into a structure in the first column.

! Non-Automatic Coercion (Ring Elements)										
↙	$\mathbf{F}_{p^s}$	$\mathbf{Z}/n\mathbf{Z}$	$\mathbf{Z}$	$\mathbf{Q}$	$\mathbf{Q}(\sqrt{\Delta_2})$	$\mathbf{Q}(\zeta_n)$	L	O_L	$\mathbf{R}_n$	$\mathbf{C}_n$
$\mathbf{F}_{p^r}$	$s\|r$ or $\ni$	$n=p$	+	−	−	−	−	−	−	−
$\mathbf{Z}/m\mathbf{Z}$	$m=p, s=1$	$m\|n$	+	−	−	−	−	−	−	−
$\mathbf{Z}$	$s=1$ or $\ni$	+	+	$\ni$	$\ni$	$\ni$	$\ni$	$\ni$	−	−
$\mathbf{Q}$	−	−	+	+	$\ni$	$\ni$	$\ni$	$\ni$	−	−
$\mathbf{Q}(\sqrt{\Delta_1})$	−	−	+	+	$\Delta_1=\Delta_2$ or $\ni$	$\ni$	−	−	−	−
$\mathbf{Q}(\zeta_m)$	−	−	+	+	$\supset$ or $\ni$	$n\|m$ or $\ni$	−	−	−	−
K	−	−	+	+	−	−	$K=L$	$K=L$	−	−
O_K	−	−	+	$\ni$	−	−	$K=L, \ni$	$K=L$	−	−
$\mathbf{Q}_p$	$s=1$	$n=p$	+	$\ni$	−	−	−	−	−	−
$\mathbf{Z}_p$	$s=1$	$n=p$	+	−	−	−	−	−	−	−
$\mathbf{R}_m$	−	−	+	+	$\Delta_2>0$ or $\ni$	$\ni$	−	−	+	$\ni$
$\mathbf{C}_m$	−	−	+	+	+	+	−	−	+	+

Table 4.

The symbols are the same as those in Table 3 except:

+ indicates that coercion can take place without restrictions (sometimes it will be done automatically if necessary);

|, = (In)equalities on parameters of the structures indicate the restrictions for `!` to work; thus, an element from $\mathbf{F}_{p^s}$ can only be coerced into $\mathbf{Z}/m\mathbf{Z}$ if $s=1$ and $m=p$;

$\ni$ The $\ni$ symbols in this table indicates that coercion only applies to certain elements of the domain; thus only those elements of **Q** can be coerced into **Z** that are in fact integers.

or In some cases coercion may either take place if some condition on parameters is satisfied *or* on a subset of the domain; thus the entry $s|r$ or $\ni$ for coercion of $\mathbf{F}_{p^s}$ into $\mathbf{F}_{p^r}$ indicates that such coercion is always possible if s divides r, and only on a subset of $\mathbf{F}_{p^s}$ (like $\mathbf{F}_p$) in general (note that the characteristics have to be the same).

The rules for coercion from and to polynomial rings and matrix rings are as follows.

If an attempt is made to forcibly coerce s into $P = R[X_1, \ldots, X_n]$, the following steps are executed successively:

(a) if s is an element of P it remains unchanged;

(b) if s is a sequence, then the zero element of P is returned if s is empty, and if it is non-empty but the elements of the sequence can be coerced into $P[X_1, \ldots, X_{n-1}]$ then the polynomial $\sum_j s[j]X_n^{j-1}$ is returned;

(c) if s can be coerced into the coefficient ring R, then the constant polynomial s is returned;

(d) if s is a polynomial in $R[X_1, \ldots, X_k]$ for some $1 \leq k \leq n$, then it is lifted in the obvious way into P;

(e) if s is a polynomial in $R[X_1, \ldots, X_k]$ for some $k > n$, but constant in the indeterminates $X_{n+1}, \ldots, X_k$, then s is projected down in the obvious way to P.

If none of these steps successfully coerces s into P, an error occurs.

The ring element s can be coerced into $M_{n,n}(R)$ if either it can be coerced into R (in which case s will be identified with the diagonal matrix with s on the diagonal), or $s \in S = M_{n,n}(R')$, where R' can be coerced into R. Also a sequence of n^2 elements coercible into R can be coerced into the matrix ring $M_{n,n}(R)$.

Elements from a matrix ring $M_{n,n}(R)$ can only be coerced into rings other than a matrix ring if $n = 1$; in that case the usual rules for the coefficient ring R apply.

Note that in some cases it is possible to go from (a subset of) some structure to another in two steps, but not directly: it is possible to go

```
> y := L ! (Q ! x)
```

to coerce a rational element of one number field into another via the rationals.

Finally we note that the binary Boolean operator `in` returns true if and only if forced coercion will be successful.

17.4 Generic Ring Functions

The generic functions described in this Chapter apply in principle to every type of ring. For certain rings these are the only applicable functions. The qualification 'in principle' in the first sentence is made because for some classes of rings an algorithm to compute certain of these functions does not exist, or has not been implemented. In that case an error will result.

This general list is provided primarily to avoid duplication of common descriptions. In the following Chapters the generic functions will be listed merely without further description, and the emphasis can be on the functions specific to a particular type of ring.

17.4.1 Related Structures

`Parent(R)`

The parent of ring R. Currently this returns the *power structure* of the ring.

`Category(R)`

`Type(R)`

The 'type' of R, that is, the MAGMA category to which the ring R belongs. The procedure call `ListCategories()` gives a list of all the categories, as does the Appendix.

`PrimeField(F)`

For a field F, this returns either $\mathbf{F}_p$, if the characteristic p of F is positive, or $\mathbf{Q}$, if the characteristic of F is 0. If F is an extension field then it will return the field at the bottom of the extension tower.

`PrimeRing(R)`

For a unitary ring R, this returns either $\mathbf{Z}/n\mathbf{Z}$, if the characteristic n of R is positive, or $\mathbf{Z}$, if the characteristic of R is 0. If R is an extension ring then it will return the ring at the bottom of the extension tower.

`Centre(R)`

`Center(R)`

Given a ring R, return its centre, consisting of the subring of elements commuting with all other elements of R.

17.4.2 Numerical Invariants

`Characteristic(R)`

The characteristic of the ring R, which is the smallest positive integer m such that $m \cdot r = 0$ for every $r \in R$, or zero if such m does not exist.

`#R`

The cardinality of the ring R; here R must be finite.

17.4.3 Predicates and Boolean Operations

`IsCommutative(R)`

Returns `true` if it is known that the ring R is commutative, `false` if it is known that R is not commutative. An error results if the answer is not known.

`IsUnitary(R)`

Returns `true` if the ring R is known to be unitary (that is, if R has a multiplicative identity), `false` if R has no 1.

`IsFinite(R)`

Returns `true` if the ring R is known to be a finite ring, `false` if it is known to be infinite. An error results if the answer is not known.

`IsOrdered(R)`

Returns `true` if the ring R has a total ordering defined on the set of its elements, `false` otherwise.

`IsField(R)`

Returns `true` if the ring R is known to be a field, `false` if it is known to not be a field. An error results if the answer is not known.

`IsDivisionRing(R)`

Returns `true` if the ring R is known to be a division ring (that is, every non-zero element is invertible), `false` if it is known that R is not a division ring. An error results if the answer is not known.

`IsEuclideanDomain(R)`

Returns `true` if the ring R is known to be a euclidean domain, `false` if it is known that R is not a euclidean domain. An error results if the answer is not known.

`IsEuclideanRing(R)`

Returns `true` if the ring R is known to be euclidean, `false` if it is known that R is not euclidean. An error results if the answer is not known.

`IsMagmaEuclideanRing(R)`

Returns `true` iff the ring R is a computable euclidean ring within Magma (i.e., iff the necessary euclidean operations are defined for R so algorithms requiring a euclidean ring will work).

`IsPID(R)`

`IsPrincipalIdealDomain(R)`

Returns `true` if the ring R is known to be a principal ideal domain, `false` if it is known that R is not a principal ideal domain. An error results if the answer is not known.

`IsPIR(R)`

`IsPrincipalIdealRing(R)`

Returns `true` if the ring R is known to be a principal ideal ring, `false` if it is known that R has non-principal ideals. An error results if the answer is not known.

`IsUFD(R)`

`IsUniqueFactorizationDomain(R)`

Returns `true` if the ring R is known to be a unique factorization domain, `false` if it is known that R is not a unique factorization domain. An error results if the answer is not known.

`IsDomain(R)`

`IsIntegralDomain(R)`

Returns `true` if it is known that R is an integral domain (i. e., R has no zero divisors), `false` if R is known to have zero divisors. An error results if the answer is not known.

`HasGCD(R)`

Returns `true` iff there is a GCD algorithm for elements of ring R in MAGMA.

`R eq S`

For certain pairs R, S of rings, this returns `true` if R and S refer to the same ring, and `false` otherwise. However, if R and S belong to different categories an error may result.

`R ne S`

For certain pairs R, S of rings, this returns `true` if R and S refer to different rings, and `false` otherwise. However, if R and S belong to different categories an error may result.

17.5 Generic Element Functions

17.5.1 Parent and Category

`Parent(r)`

The (default) parent ring of ring element r. Usually the parent of r has been created explicitly before, but in certain cases, such as literal integers, rationals, reals, and values returned by certain functions a default parent is created in the background.

`Category(r)`

`Type(r)`

The 'type' of r, that is, the MAGMA category to which the ring element r belongs. The procedure call `ListCategories()` gives a list of all the categories, as does the Appendix.

17.5.2 Creation of Elements

`Zero(R)`

The zero element of ring R; this is equivalent to `R ! 0`.

`One(R)`

`Id(R)`

The multiplicative identity 1 of ring R; this is equivalent to `R ! 1`.

`R ! a`

Coerce the element a of some ring into the ring R. (The rules on coercion are explained earlier in this Chapter.) If a is an integer, the coercion will always succeed: the element $a \cdot 1_R$ will be returned, where 1_R is the unit element of R.

`Random(R)`

A random element of the finite ring R (every element of R has the same probability of being returned).

`Representative(R)`

`Rep(R)`

A representative element of the finite ring R.

17.5.3 Arithmetic Operations

`+a`

Element a.

`-a`

The negation (additive inverse) of element a.

`a + b`

The sum of the ring elements a and b; if a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the sum can be taken.

`a - b`

The difference of the ring elements a and b; if a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the difference can be taken.

`a * b`

The product of the ring elements a and b; if a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the product can be taken.

`a ^ k`

Form the k-th power of the ring element a, for small, non-negative, k. If $a = 0$ then we must have $k > 0$.

`a ^ -k`

Form the k-th power of the multiplicative inverse of the unit a.

`a / b`

Given an element a of R and a unit b of R, form the quotient of the elements a and b. If b is not invertible in R, an error results, unless both a and b are integers, in which case `a / b` returns the rational number a/b. If a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the quotient can be taken.

`a +:= b`

Mutation assignment: change a into the sum of a and b.

`a -:= b`

Mutation assignment: change a into the difference of a and b.

`a *:= b`

Mutation assignment: change a into the product of a and b.

`a /:= b`

Mutation assignment: change a into the quotient of a and b.

`a ^:= k`

Mutation assignment: change a into the power a^k.

17.5.4 Equality and Membership

`a eq b`

Returns `true` if the elements a and b of R are the same, otherwise `false`.

`a ne b`

Returns `true` if the elements a and b of R are distinct, otherwise `false`.

`R eq S`

Returns `true` if the rings R and S are the same, otherwise `false`.

`R ne S`

Returns `true` if the rings R and S are distinct, otherwise `false`.

`a in R`

Returns `true` if and only if a is an element of R.

`a notin R`

Returns `true` if and only if a is not an element of R.

17.5.5 Predicates on Ring Elements

`IsZero(a)`

Returns `true` if and only if the element a of R equals 0_R.

`IsOne(a)`

Returns `true` if and only if the element a of R equals 1_R.

`IsMinusOne(a)`

Returns `true` if and only if the element a of R equals the element -1 of R.

`IsUnit(a)`

Returns `true` if a is a unit in its parent R, `false` otherwise.

`IsIdempotent(x)`

Returns `true` if and only if x^2 equals x.

`IsNilpotent(x)`

Returns `true` if and only if some integer power x^i of x is zero.

`IsZeroDivisor(x)`

Returns `true` if and only if x is a zero-divisor, that is, there exists an element y in the parent R of x such that $xy = 0$.

`IsIrreducible(x)`

Returns `true` if and only if the parent R of the element x is a domain and x is irreducible in R, that is, x is a non-unit of R and whenever a product ab of elements of R divides x then a or b is a unit of R.

`IsPrime(x)`

Returns `true` if and only if the parent R of the element x is a domain and x is a prime element of R, that is, x is neither 0 nor a unit and whenever x divides the product ab of two elements of R it divides a or b.

17.5.6 Comparison of Ring Elements

The comparison operations are only defined on types of ring that are ordered.

`a gt b`

Returns `true` if the ring element a is greater than the ring element b, otherwise `false`.

`a ge b`

Returns `true` if the ring element a is greater than or equal to the ring element b, otherwise `false`.

`a lt b`

Returns `true` if the ring element a is less than the ring element b, otherwise `false`.

`a le b`

Returns `true` if the ring element a is less than or equal to the ring element b, otherwise `false`.

`Maximum(a, b)`

The maximum of the ring elements a and b; if a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the maximum can be taken.

`Maximum(Q)`

The maximum of the sequence Q of ring elements.

`Minimum(a, b)`

The minimum of the ring elements a and b; if a and b do not belong to the same ring R, an attempt will be made to find a common overstructure in which the minimum can be taken.

`Minimum(Q)`

The minimum of the sequence Q of ring elements.

17.6 Ideals and Quotient Rings

The following entries describe the operations on ideals in a *commutative ring* R. Certain operations on left and right ideals in non-commutative rings will be described in the Chapters for the corresponding rings.

17.6.1 Defining Ideals and Quotient Rings

`ideal< R | a1, ..., ar >`

Given a ring R and elements $a_1, \ldots, a_r$ of R, create the ideal I of R generated by $a_1, \ldots, a_r$.

`quo< R | ar, ..., ar >`

Given a ring R and elements $a_1, \ldots, a_r$ of R, construct the quotient ring $Q = R/I$, where I is the ideal of R generated by $a_1, \ldots, a_r$.

`R / I`

Given a ring R and an ideal I of R, construct the quotient ring $Q = R/I$, as well as the canonical map $R \to R/I$.

`PowerIdeal(R)`

The set of ideals of R. This is the parent of all ideals of R.

17.6.2 Arithmetic Operations on Ideals

`I + J`

The sum of the ideals I and J of the ring R. This ideal consists of elements $a + b$, with $a \in I$ and $b \in J$. If I is generated by $\{a_1, \ldots, a_k\}$ and J is generated by $\{b_1, \ldots, b_m\}$, then $I + J$ is generated by $\{a_1, \ldots, a_k, b_1, \ldots, b_m\}$.

`I * J`

The product of the ideals I and J of the ring R. This is the ideal generated by elements $a \cdot b$, with $a \in I$ and $b \in J$, and it consists of elements $a_1 b_1 + \cdots + a_n b_n$, with $a_i \in I$ and $b_j \in J$.

`I meet J`

The intersection of the ideals I and J of the ring R.

17.6.3 Boolean Operators on Ideals

Throughout this subsection I and J are ideals belonging to the same integer ring R, while a is an element of R.

`a in I`

Returns `true` if and only if the element a is a member of the ideal I.

`a notin I`

Returns `true` if and only if the element a is not a member of the ideal I.

`I eq J`

Returns `true` if and only if the ideals I and J are equal.

`I ne J`

Returns `true` if and only if the ideals I and J are distinct.

`I subset J`

Returns `true` if and only if the ideal I is contained in the ideal J.

`I notsubset J`

Returns `true` if and only if the ideal I is not contained in the ideal J.

17.7 Other Ring Constructions

MAGMA allows the construction of residue fields, localization of rings, and completion of rings. These constructions really just create appropriate rings of different categories within MAGMA.

17.7.1 Residue Class Fields

`ResidueClassField(I)`

Given a maximal ideal I of a ring R, create the residue class field K of the quotient ring R/I, together with a map sending an element of R to the corresponding element of K.

17.7.2 Localization

`loc< R | a`$_1$`, ..., a`$_r$ `>`

Given a ring R and elements $a_1, \ldots, a_r$ of R, which generate a prime ideal P of R, create the localization L of R at P, together with a map sending an element of R to the corresponding element of L.

`Localization(R, P)`

Given a ring R and a prime ideal P of R, create the localization L of R at P, together with a map sending an element of R to the corresponding element of L.

17.7.3 Completion

`comp< R | a1, ..., ar >`

Given a ring R and elements $a_1, \ldots, a_r$ of R, which generate a prime ideal or zero ideal P of R, create the completion C of R at P, together with a map sending an element of R to the corresponding element of C.

`Completion(R, P)`

Given a ring R and a prime ideal or zero ideal P of R, create the completion C of R at P, together with a map sending an element of R to the corresponding element of C.

17.7.4 Transcendental Extension

`ext< R | >`

Given a ring R create the univariate transcendental extension $R[x]$ of R. This is equivalent to `PolynomialRing(R)`.

`ext< R, n | >`

Given a ring R and an integer $n \geq 1$, create the multivariate transcendental extension $R[x_1, \ldots, x_n]$ of R. This is equivalent to `PolynomialRing(R, n)`.

18 RING OF INTEGERS

Chapter 18
RING OF INTEGERS

18.1 Introduction

This Chapter describes the operators and functions for working with the ring of rational integers **Z**.

Integers are the most commonly used objects in MAGMA. They can be created by just typing in the literal (decimal) digits. Integers thus created are elements of the ring of integers which is automatically created when MAGMA is started up. There is just one single object 'integer ring' around, but references to it (new 'names' for it) can be created using the `IntegerRing` function.

18.1.1 Representation

Since large integers occur so frequently, the first requirement for a computer algebra system is to support fast arithmetic for integers of arbitrary size. Indeed, within the bounds set by the available memory, it is possible to operate reasonably efficiently with integers of any number of decimal digits.

Although it is well possible to use the integer facilities without being aware of the internal representation of (large) integers, it is sometimes useful to know how integers are stored. The most important fact is that integers smaller than $2^{30} = 1073741824$ in absolute value are 'single precision', and in many circumstances such 'small integers' allow considerably faster arithmetic (they are treated slightly differently internally and escape the overhead of memory management used to deal with multi-precision integers).

18.1.2 Coercion

Integers will be automatically coerced into almost every unitary ring R using the identification of 1 and 1_R. This means that integer arguments are allowed for almost any ring element function, and that it is not necessary to convert an integer before applying binary operators (such as +) on a combination of arguments consisting of an integer and another ring element.

For more on coercion we refer to Chapter 17.

18.1.3 Homomorphisms

Ring homomorphisms are required to be unitary. Therefore, to specify a homomorphism with the integers as its domain requires merely the specification of the codomain.

```
hom<  Z -> R |  >
```

The natural homomorphism from **Z** to the ring R.

Example H18E1

```
> h := hom< Integers() -> MatrixRing(RealField(12), 3) | >;
> h(2)^-1;
[0.5   0   0]
[  0 0.5   0]
[  0   0 0.5]
```

18.2 Creation Functions

18.2.1 Creation of Structures

The ring of integers is automatically created when Magma is first loaded. The ring may be formally created (and, if desired, assigned to a variable) using the function `IntegerRing()`. Subrings of **Z** are always ideals; see the section on ideals for details.

`IntegerRing()`

`Integers()`

`IntegerRing(Q)`

`RingOfIntegers(Q)`

Create the ring of integers **Z**. Analogous to the creation of the ring of integers of any number field, there is a version of `IntegerRing` that creates **Z** as the ring of integers of **Q**.

18.2.2 Creation of Elements

Since the ring of integers is present when Magma is started up, integers typed into Magma without any explicit context will be regarded as elements of the ring of integers. Integers can be specified using both decimal and hexadecimal notation.

`a`$_1$`a`$_2$`...a`$_r$

Given a succession of decimal digits $a_1, \ldots, a_r$, create the corresponding integer. Leading zeros will be ignored.

`0xa`$_1$`a`$_2$`...a`$_r$

Given a succession of hexadecimal digits $a_1, \ldots, a_r$, create the corresponding integer. Leading zeros will be ignored.

`elt< Z | a`$_1$`a`$_2$`...a`$_r$ `>`

Given a succession of decimal digits $a_1, \ldots, a_r$, create the corresponding integer as an element of Z.

`elt< Z | 0xa1a2...ar >`

Given a succession of hexadecimal digits $a_1, \ldots, a_r$, create the corresponding integer as an element of Z.

`Z ! a`
`Z ! [a]`

Coerce the ring element a into the ring of integers Z. The element a is allowed to be an element of the ring of integers modulo m (in which case the result r satisfies $0 \leq r < m$), or an element of a finite field (in which case the result r satisfies $0 \leq r < p$ if a is in the prime field, of characteristic p, and an error otherwise), or an element of the integers, rationals, a quadratic field, a cyclotomic field or a number field (in which cases the result is the obvious integer if a is integral and an error otherwise).

Example H18E2

```
> Z := IntegerRing();
> n := 1234567890;
> n in Z;
true
> m := elt< Z | 1234567890 >;
> m eq n;
true
> l := Z ! elt< QuadraticField(3) | 1234567890, 0>;
> l;
1234567890
> k := elt< Z | 0x499602D2 >;
1234567890
```

`One(Z)` `Identity(Z)`
`Zero(Z)` `Representative(Z)`

These generic functions (cf. Chapter 17) create 1, 1, 0, and 0 respectively, in the integer ring **Z**.

18.2.3 Printing of Elements

Magma supports the printing of integers in both decimal and hexadecimal form. The default print method is to print integers in base 10; base 16 printing is performed using the `Hex` print level.

Example H18E3

```
> n := 1234567890;
> n;
1234567890
> n:Hex;
0x499602D2
```

18.2.4 Element Conversions

`FactorizationToInteger(s)`

`FactorisationToInteger(s)`

`Facint(s)`

Given a sequence of two-element tuples $s = [< p_1, k_1 >, ..., < p_r, k_r >]$ containing pairs of integers $< p_i, k_i >$, $1 \leq i \leq r$, with k_i non-negative, this function returns the integer $p_1^{k_1} \cdots p_r^{k_r}$. It is normally used for converting a factorization sequence to the corresponding integer.

`IntegerToSequence(n, b)`

`Intseq(n, b)`

Given a non-negative integer n and a positive integer $b \geq 2$, return the unique base b representation of n in the form of a sequence Q. That is, if $n = a_0 b^0 + a_1 b^1 + \ldots + a_{k-1} b^{k-1}$ with $0 \leq a_i < b$ and $a_{k-1} > 0$, then $Q = [a_0, a_1, \ldots, a_{k-1}]$. (If $n = 0$, then $Q = [\,]$.)

`SequenceToInteger(s, b)`

`Seqint(s, b)`

Given a positive integer $b \geq 2$ and a sequence $Q = [a_0, \ldots, a_{k-1}]$ of non-negative integers such that $0 \leq a_i < b$, return the integer $n = a_0 b^0 + a_1 b^1 + \ldots + a_{k-1} b^{k-1}$. If Q is the empty sequence, the integer zero is returned. This function performs the inverse operation of the base b representation.

`IntegerToString(n)`

Create the string consisting of the decimal digits of the integer n. In the case in which n is negative the first character will be the minus sign.

`IntegerToString(n, b)`

Create the string consisting of the digits of the integer n in base b. In the case in which n is negative the first character will be the minus sign. The base b can be between 2 and 36. For $b \leq 10$, the digits are represented numerically. For $b > 10$, the digits are represented both numerically and alphabetically, so that, 10 is 'A', 11 is 'B', et cetera.

`Eltseq(n)`

The sequence $[n]$ which can be coerced back into $\mathbf{Z}$.

`Denominator(n)`

The denominator of n, ie. 1.

18.3 Structure Operations

The following generic ring functions are applicable to the ring of integers and its elements.

18.3.1 Related Structures

`Category(Z)` `Parent(Z)` `PrimeRing(Z)` `Center(Z)`

`AdditiveGroup(Z)`

Create the abelian group of integers under addition. This returns an infinite (additive) abelian group A of rank 1 together with a map from A to the ring of integers Z, sending $A.1$ to 1.

`MultiplicativeGroup(Z)`
`UnitGroup(Z)`

Create the abelian group of invertible integers, that is, an abelian group isomorphic to the multiplicative subgroup $\langle -1 \rangle$. This returns an (additive) abelian group A of order 2 together with a map from A to the ring of integers Z, sending $A.1$ to -1.

`ClassGroup(Z)`

The class group of the ring of $\mathbf{Z}$ (which is trivial).

`FieldOfFractions(Z)`

Create the field of fractions $\mathbf{Q}$ of the ring of rational integers.

`sub< Z | n >`

Given Z, the ring of integers or an ideal of it, and an element n of Z, create the ideal $aZ \cap Z$ of the ring of integers. Note that this creates an ideal, not just a subring.

18.3.2 Numerical Invariants

```
Characteristic(Z)
```

```
Signature(Z)
```

The signature of **Z** as an order of **Q**, i.e. `1, 0`.

18.3.3 Ring Predicates and Booleans

```
IsCommutative(Z)   IsUnitary(Z)
IsFinite(Z)   IsOrdered(Z)
IsField(Z)   IsEuclideanDomain(Z)
IsPID(Z)   IsUFD(Z)
IsDivisionRing(Z)   IsEuclideanRing(Z)
IsPrincipalIdealRing(Z)   IsDomain(Z)
Z eq R   Z ne R
```

18.4 Element Operations

18.4.1 Arithmetic Operations

Magma includes both the Karatsuba algorithm and the Schönhage-Strassen FFT-based algorithm for the multiplication of integers ([AHU74, Chap. 7], [vzGG99, Sec. 8.3]). The crossover point (where the FFT method beats the Karatsuba method) is currently 2^{15} bits (approx. 10000 decimal digits) on Sun SPARC workstations and 2^{17} bits (approx. 40000 decimal digits) on Digital Alpha workstations. Assembler macros are used for critical operations and 64-bit operations are used on DEC-Alpha machines.

Magma also contains an asymptotically-fast integer (and polynomial) division algorithm which reduces division to multiplication with a constant scale factor that is in the practical range. Thus division of integers and polynomials are based on the Karatsuba and Schönhage-Strassen (FFT) methods when applicable. The crossover point for integer division (when the new method outperforms the classical method) is currently at the point of dividing a 2^{12} bit (approx. 1200 decimal digit) integer by a 2^{11} (approx. 600 decimal digit) integer on Sun SPARC workstations.

`+ n` `- n`

`m + n` `m - n` `m * n` `n ^ k` `m / n`

`m +:= n` `m -:= n` `m *:= n` `m /:= n` `m ^:= k`

`n div m`

The quotient q of the division with remainder $n = qm + r$, where $0 \leq r < m$ or $m < r \leq 0$ (depending on the sign of m), for integers n and $m \neq 0$.

`n mod m`

The remainder r of the division with remainder $n = qm + r$, where $0 \leq r < m$ or $m < r \leq 0$ (depending on the sign of m), for integers n and $m \neq 0$.

`ExactQuotient(n, d)`

Assuming that the integer n is exactly divisible by the integer d, return the exact quotient of n by d (as an integer). An error results if d does not divide n exactly.

`n div:= m` `n mod:= m`

18.4.2 Bit Operations

The following functions use bit operations on the internal representation, so are in general quicker than using the usual arithmetic operators.

`ShiftLeft(n, b)`

Given integers n and b, with $b \geq 0$, return $n \times 2^b$.

`ShiftRight(n, b)`

Given integers n and b, with $b \geq 0$, return n `div` 2^b.

`ModByPowerOf2(n, b)`

Given integers n and b, with $b \geq 0$, return $n \bmod 2^b$ (so the result is always non-negative).

18.4.3 Equality and Membership

`m eq n` `m ne n`

`n in R` `n notin R`

18.4.4 Parent and Category

`Parent(n)` `Category(n)`

18.4.5 Predicates on Ring Elements

`IsEven(n)`

Returns `true` if the integer n is even, otherwise `false`.

`IsOdd(n)`

Returns `true` if the integer n is odd, otherwise `false`.

`IsDivisibleBy(n, d)`

Returns `true` if and only if the integer n is divisible by the integer d; if `true`, the quotient of n by d is also returned.

`IsSquare(n)`

Returns `true` if the non-negative integer n is the square of an integer, `false` otherwise. If n is a square, its positive square root is also returned.

`IsSquarefree(n)`

Returns `true` if the non-zero integer n is not divisible by the square of any prime, `false` otherwise.

`IsPower(n)`

If the integer $n > 1$ is a power $n = b^k$ of an integer b, with $k > 1$, this function returns true, the minimal positive b and its associated k; if it is not such integer power the function returns false.

`IsPower(n, k)`

If the integer $n > 1$ is k-th power, with $k > 1$, of some integer b, so that $n = b^k$, this function returns true, and b; if it is not a k-th integer power the function returns false.

`IsPrime(n)`

`Proof` BoolElt *Default :* `true`

Returns `true` if and only if the integer n is a prime. A rigorous primality test which returns a proven result will be used unless the parameter `Proof` is `false`. The reader is referred to the section 18.9 for a complete description of this function.

Example H18E4

In this example we find some 10-digit primes that are congruent to 3 modulo 4 such that $(p-1)/2$ is also prime.

```
> { p : p in [10^10+3..10^10+1000 by 4] |
>       IsPrime(p) and IsPrime((p-1) div 2)};
{ 10000000259, 10000000643 }
```

`IsIntegral(n)`

Returns `true` if and only if a is integral, which is of course true for every integer n.

`IsSinglePrecision(n)`

Returns `true` if n fits in a single word in the internal representation of integers in MAGMA, that is, if $|n| < 2^{30}$, `false` otherwise.

`IsZero(n)` `IsOne(n)` `IsMinusOne(n)`
`IsNilpotent(n)` `IsIdempotent(n)`
`IsUnit(n)` `IsZeroDivisor(n)` `IsRegular(n)`
`IsIrreducible(n)` `IsPrime(n)`

18.4.6 Comparison of Ring Elements

`m gt n` `m ge n` `m lt n` `m le n`
`Maximum(m, n)` `Maximum(Q)`
`Minimum(m, n)` `Minimum(Q)`

18.4.7 Conjugates, Norm and Trace

`ComplexConjugate(n)`

The complex conjugate of n, which will be the integer n itself.

`Conjugate(n)`

The conjugate of n, which will be the integer n itself.

`Norm(n)`

The norm in $\mathbf{Q}$ of n, which will be the integer n itself.

`EuclideanNorm(n)`

The Euclidean norm (length) of n, which will equal the absolute value of n.

`Trace(n)`

The trace (in $\mathbf{Q}$) of n, which will be the integer n itself.

`MinimalPolynomial(n)`

Returns the minimal polynomial of the integer n, which is the monic linear polynomial with constant coefficient n in a univariate polynomial ring R over the integers.

18.4.8 Other Elementary Functions

`AbsoluteValue(n)`
`Abs(n)`

Absolute value of the integer n.

`Ilog2(n)`

The integral part of the logarithm to the base two of the positive integer n.

`Ilog(b, n)`

The integral part of the logarithm to the base b of the positive integer n i.e., the largest integer k such that $b^k \leq n$. The integer b must be greater than or equal to two.

`Quotrem(m, n)`

Returns both the quotient q and remainder r obtained upon dividing the integer m by the integer n, that is, $m = q \cdot n + r$, where $0 \leq r < n$ if $n > 0$ and $n < r \leq 0$ if $n < 0$.

`Valuation(x, p)`

The valuation of the integer x at the prime p. This is the largest integer v for which p^v divides x. If $x = 0$ then $v = \infty$. The optional second return value is the integer u such that $x = p^v u$.

`Iroot(a, n)`

Given a positive integer a, return the integer $b = \lfloor \sqrt[n]{a} \rfloor$, i.e. the integral part of the n-th root of a. To obtain the actual root (as a real number), a must e coerced into a real field and the function `Root` applied.

`Sign(n)`

Returns -1, 0 or 1 depending upon whether the integer n is negative, zero or positive, respectively.

`Ceiling(n)`

The ceiling of the integer n, that is, n itself.

`Floor(n)`

The floor of the integer n, that is, n itself.

`Round(n)`

This function rounds the integer n to itself.

`Truncate(n)`

This function returns the integer truncation of the integer n, that is, n itself.

`SquarefreeFactorization(n)`

Given a non-negative integer n, return a squarefree integer x as well as a positive integer y, such that $n = xy^2$.

`Isqrt(n)`

Given a positive integer n, return the integer $\lfloor\sqrt{n}\rfloor$, i.e., the integral part of the square root of the integer n.

18.5 Random Numbers

Pseudo-random integers in MAGMA are generated using the *Monster* random number generator of G. Marsaglia [Mar00]. The period of this generator is $2^{29430} - 2^{27382}$ (approximately 10^{8859}), and the generator passes all of the stringent tests in Marsaglia's *Diehard* test suite [Mar95]. Throughout the following text, the word 'random' is used to mean 'pseudo-random'.

`Random(a, b)`

A random integer lying in the interval $[a, b]$, where $a \leq b$.

`Random(b)`

A random integer lying in the interval $[0, b]$, where b is a non-negative integer. Because of the good properties of the underlying Monster generator, calling `Random(1)` is a good safe way of producing a sequence of random bits.

`RandomBits(n)`

A random integer m such that $0 \leq m < 2^n$, where n is a small non-negative integer. Thus, m has n random bits with a probability of $1/2$ for each bit. The function always returns 0 when $n = 0$.

`RandomPrime(n:` *parameter*`)`

`Proof` BOOLELT *Default :* `true`

A random prime integer m such that $0 < m < 2^n$, where n is a small non-negative integer. The function always returns 0 for $n = 0$ or $n = 1$. A rigorous method will be used to check primality, unless $m > 34 \cdot 10^{13}$ and the optional parameter `Proof` is set to `Proof := false`, in which case the result indicates that m is a probable prime (of order 20).

`RandomPrime(n, a, b, x:` *parameter*`)`

`Proof` BOOLELT *Default :* `true`

Tries up to x iterations to find a random prime integer m congruent to a modulo b such that $0 < m < 2^n$. If successful, the function returns true and the integer m, otherwise false. The integer n must be larger than 0, a must lie between 0 and $b-1$ and b must be larger than 0. A rigorous method will be used to establish primality, unless $m > 34 \cdot 10^{13}$ and the optional parameter `Proof` is set to `Proof := false`, in which case the result indicates that m is a probable prime (of order 20).

`RandomConsecutiveBits(n, a, b)`

A integer m such that $0 \leq m < 2^n$, and the binary expansion of n consists of consecutive strings of zeros or ones each of random length in the range $[a \dots b]$.

18.6 Common Divisors and Common Multiples

This section deals with computing greatest common divisors and related computations.

Within the classical range, MAGMA uses the fast classical Accelerated GCD algorithm of Kenneth Weber [Web95] to compute the GCD of two integers, and the fast classical Lehmer extended GCD ('XGCD') algorithm [Knu97, pp. 345–348] (which is about 5 times faster than the Euclidean XGCD algorithm) to compute the extended GCD of two integers.

For larger integers, MAGMA uses the asymptotically fast Schönhage recursive ("half-GCD") algorithm ([Sch71]; see also [Mon92, Sec. 3.8] for the basic idea, applied to polynomials). On a Sun SPARC workstation, the crossover point for the Schönhage GCD algorithm (where it beats the classical Accelerated GCD algorithm) is 32768 bits (about 10000 decimal digits), while the crossover point for the Schönhage XGCD algorithm (when it beats the Lehmer XGCD algorithm) is 6000 bits (about 2000 decimal digits).

`GreatestCommonDivisor(m, n)`
`Gcd(m, n)`
`GCD(m, n)`

The greatest common divisor of m and n, normalized to be non-negative. If either of the inputs is zero, then the result is the absolute value of the other input, while if m and n are both zero the result is zero.

`GreatestCommonDivisor(s)`
`Gcd(s)`
`GCD(s)`

The GCD of the entries of the sequence s. If all entries of the sequence are zero, the result is zero. An error results if the sequence is the null sequence.

`ExtendedGreatestCommonDivisor(m, n)`
`Xgcd(m, n)`
`XGCD(m, n)`

The extended GCD of m and n; returns integers g, x and y such that g is the greatest common divisor of the integers m and n, and $g = x \cdot m + y \cdot n$. If m and n are both zero, g is zero; otherwise g is always positive. If m and m are both non-zero, the multipliers x and y are unique.

`ExtendedGreatestCommonDivisor(s)`

`Xgcd(s)`

`XGCD(s)`

Given a sequence of integers $s = [s_1, \ldots, s_r]$, return the non-negative integer g and a sequence $X = (x_1, \ldots, x_r)$ such that g is the greatest common divisor of the integers s_i and $g = \sum_{i=1}^{r} x_i \cdot s_i$.

`LeastCommonMultiple(m, n)`

`Lcm(m, n)`

`LCM(m, n)`

The smallest non-negative integer divisible by both m and n. If m or n equals zero, the result is zero; this ensures that $\text{lcm}(m, n)\text{gcd}(m, n) = m \cdot n$.

`LeastCommonMultiple(s)`

`Lcm(s)`

`LCM(s)`

Least common multiple of the sequence of integers s.

18.7 Arithmetic Functions

Each of the functions in this section may take an integer or the factorization of that integer.

`CarmichaelLambda(n)`

`CarmichaelLambda(Q)`

`CarmichaelLambda(Q)`

The Carmichael function $\lambda(n)$; its value equals the exponent of $(\mathbf{Z}/n\mathbf{Z})^*$.

`DickmanRho(u)`

Computes $\rho(u)$ where ρ is Dickman's rho function.

`FactoredCarmichaelLambda(n)`

`FactoredCarmichaelLambda(Q)`

`FactoredCarmichaelLambda(Q)`

The Carmichael function $\lambda(n)$, returned as a factorization sequence.

`DivisorSigma(i, n)`

`DivisorSigma(i, Q)`

The divisor function $\sigma_i(n) = \sum_{d|n} d^i$ for integer n and small non-negative integer i.

`NumberOfDivisors(n)`
`NumberOfDivisors(Q)`

The number of divisors of the positive integer n. This is a special case of `DivisorSigma`.

`SumOfDivisors(n)`
`SumOfDivisors(Q)`

The sum of the divisors of the positive integer n. This is a special case of `DivisorSigma`.

`EulerPhi(n)`
`EulerPhi(Q)`
`EulerPhi(Q)`

The Euler totient function $\phi(n)$; its value equals the order of $(\mathbf{Z}/n\mathbf{Z})^*$.

`FactoredEulerPhi(n)`
`FactoredEulerPhi(Q)`
`FactoredEulerPhi(Q)`

The Euler totient function $\phi(n)$, returned as a factorization sequence.

`EulerPhiInverse(m)`
`EulerPhiInverse(Q)`

The inverse of the Euler totient function $\phi(n)$; that is, the sorted sequence of all integers n such that $\phi(n) = m$.

`FactoredEulerPhiInverse(n)`
`FactoredEulerPhiInverse(Q)`

The factored inverse of the Euler totient function $\phi(n)$; that is, the sorted sequence of the factorizations of all integers n such that $\phi(n) = m$.

`LegendreSymbol(n, m)`

The Legendre symbol $\left(\frac{n}{m}\right)$: for prime m this checks whether or not n is a quadratic residue modulo m. The function returns 0 if m divides n, -1 if n is not a quadratic residue, and 1 if n is a quadratic residue modulo m. A fast probabilistic primality test is performed on m. If m fails the test (and is therefore composite), an error results; if it passes the test the Jacobi symbol is computed.

`JacobiSymbol(n, m)`

The Jacobi symbol $\left(\frac{n}{m}\right)$. For odd $m > 1$ this is defined (but not calculated!) as the product of the Legendre symbols $\left(\frac{n}{p_i}\right)$, where the product is taken over all primes p_i dividing m including multiplicities. Quadratic reciprocity is used to calculate this symbol, which has the values -1, 0 or 1.

`KroneckerSymbol(n, m)`

The Kronecker symbol $\left(\frac{n}{m}\right)$. This is the extension of the Jacobi symbol to all integers m, by multiplicativity, and by defining $\left(\frac{n}{2}\right) = (-1)^{(n^2-1)/8}$ for odd n (and 0 for even n) and $\left(\frac{n}{-1}\right) = \pm 1$ according to the sign of n for $n \neq 0$ (and 1 for $n = 0$).

`MoebiusMu(n)`

`MoebiusMu(Q)`

The Möbius function $\mu(n)$. This is a multiplicative function characterized by $\mu(1) = 1$, $\mu(p) = -1$, and $\mu(p^k) = 0$ for $k \geq 2$, where p is a prime number.

Example H18E5

A pair of positive integers (m, n) is called *amicable* if the sum of the proper divisors (that is: excluding m itself) of m equals n, and vice versa. The following function finds such pairs. Note that it also finds perfect numbers: amicable pairs of the form (m, m).

```
> d := func< m | DivisorSigma(1, m)-m >;
> z := func< m | d(d(m)) eq m >;
> for m := 2 to 10000 do
>     if z(m) then
>         m, d(m);
>     end if;
> end for;
6 6
28 28
220 284
284 220
496 496
1184 1210
1210 1184
2620 2924
2924 2620
5020 5564
5564 5020
6232 6368
6368 6232
8128 8128
```

18.8 Combinatorial Functions

`Binomial(n, r)`

The binomial coefficient $\binom{n}{r}$.

`Multinomial(n, [a1, ... an])`

Given a sequence $Q = [r_1, \ldots, r_k]$ of positive integers such that $n = r_1 + ... + r_k$, return the multinomial coefficient $\binom{n}{r_1,\ldots,r_k}$.

`Factorial(n)`

The factorial $n!$ for positive small integer n.

`IsFactorial(n)`

Tests if $n = k!$ for some k. If so, return `true` and k, `false` otherwise.

`Partitions(n)`

The unrestricted partitions of the positive integer n. This function returns a sequence of integer sequences, each of which is a different sequence of positive integers (in descending order) adding up to n. The integer n must be small.

`NumberOfPartitions(n)`

The number of unrestricted partitions of the non-negative integer n. The integer n must be small.

`RestrictedPartitions(n, Q)`

The partitions of the positive integer n, restricted to elements of the positive integer sequence Q.

`RestrictedPartitions(n, k, M)`

The partitions of the positive integer n into k parts, restricted to elements of the positive integer sequence Q.

`StirlingFirst(n, k)`

The Stirling number of the first type, $\left[{n \atop k}\right]$, where n and k are non-negative integers.

`StirlingSecond(n, k)`

The Stirling number of the second type, $\left\{{n \atop k}\right\}$, where n and k are non-negative integers.

`Bell(n)`

The nth Bell number, giving the number of partitions of a set of size n. (Not to be confused with `NumberOfPartitions(n)`, which gives the number of partitions of the *integer* n.) This is equal to the sum of `StirlingSecond(n,k)` for k between 0 and n (inclusive).

`Fibonacci(n)`

Given an integer n, this function returns the n-th Fibonacci number F_n, which can be defined via the recursion $F_0 = 0$, $F_1 = 1$ and $F_n = F_{n-1} + F_{n-2}$ for all integers n. Note that n is allowed to be negative, and that $F_{-n} = (-1)^{n+1}F_n$.

`Lucas(n)`

Given an integer n, this function returns the n-th Lucas number L_n, which can be defined via the recursion $L_0 = 2$, $L_1 = 1$ and $L_n = L_{n-1} + L_{n-2}$ for all integers n. Note that n is allowed to be negative, and that $L_{-n} = (-1)^n L_n$.

`GeneralizedFibonacciNumber(g0, g1, n)`

The nth member of the generalized Fibonacci sequence defined by $G_0 = g_0$, $G_1 = g_1$ and $G_n = G_{n-1} + G_{n-2}$ for all integers n. Note that n is allowed to be negative. The Fibonacci and Lucas numbers are special cases where $(g_0, g_1) = (0, 1)$ or $(2, 1)$ respectively.

18.9 Primes and Primality Testing

Primality testing algorithms enable the user to certify the primality of prime integers. Proving the primality of very big integers can be time consuming and therefore in some of the algorithms using primes and factorization of integers the user can speed up the algorithm by explicitly allowing MAGMA to use probable primes rather than certified primes.

A *probable prime* is an integer that has failed some compositeness test; if an integer passes a compositeness test it will be composite, but there is a (small) probability that a composite number will fail the test and is hence called a probable prime. Each Miller-Rabin test for instance, has a probability of less than 1/4 of declaring a composite number probably prime; in practice that means that numbers that fail several such cheap independent Miller-Rabin compositeness tests will be prime.

Unless specifically asked otherwise, MAGMA will use rigorous primality proofs.

18.9.1 Primality

If a positive integer n is composite, this can be shown quickly by exhibiting a *witness* to this fact. A witness for the compositeness of n is an integer $1 < a < n$ with the property that

$$a^r \not\equiv 1 \bmod n \quad \text{and} \quad a^{r2^i} \not\equiv -1 \bmod n \text{ for } i = 0, 1, \ldots, k-1$$

where r odd, and k are such that $n - 1 = r \cdot 2^k$. A witness never falsely claims that n is composite, because for prime n it must hold that $a^{n-1} \equiv 1 \bmod n$ and only ± 1 are square roots of 1 modulo prime n. Moreover, it has been shown that a fraction of at least 3/4 of all a in the range $2 \ldots n-1$ will witness the compositeness of n. Thus randomly choosing a will usually quickly expose compositeness. Unless more than 3/4 of all possibilities for a are checked though (which in practice will be impossible for reasonable n) the procedure of checking k bases a at random for being a witness (often referred to as 'Miller-Rabin') will not suffice to prove the primality of n; it does however lend credibility to the claim that n

is most likely prime if among k (say 20) random choices for a no witness for compositeness has been found. In such cases n is called *probably prime of order* k, and in some sense the probability that n is composite is less than 4^{-k}.

A slight adaptation of this compositeness test can be used for primality proofs in a bounded range. There are no composites smaller than $34 \cdot 10^{13}$ for which a witness does not exist among $a = 2, 3, 5, 7, 11, 13, 17$ ([Jae93]). Using these values of a for candidate witnesses it is certain that for any number n less than $34 \cdot 10^{13}$ the test will either find a witness or correctly declare n prime.

But even for large integers it is thus usually easy to identify composites without finding a factor; to be certain that a large probable prime is truly prime, a primality proving algorithm is invoked. MAGMA uses the ECPP (Elliptic Curve Primality Proving) method, as implemented by François Morain (Ecole Polytechnique and INRIA). The ECPP program in turn uses the BigNum package developed jointly by INRIA and Digital PRL. This ECPP method is both fast and rigorous, but for large integers (of say more than 100 decimal digits) it will be still be much slower than the Miller-Rabin compositeness test. The method is too involved to be explained here; we refer the reader to the literature ([AM93]).

The `IsPrime` function invokes ECPP, unless a Boolean flag is used to indicate that only 'probable primality' is required. The latter is equivalent to a call to `IsProbablePrime`.

`IsPrime(n)`

`IsPrime(n: parameter)`

`Proof`	BOOLELT	*Default :* `true`

Returns `true` iff the integer n is prime. A rigorous method will be used, unless $n > 34 \cdot 10^{13}$ and the optional parameter `Proof` is set to `Proof := false`, in which case the result indicates that n is a probable prime (a strong pseudoprime to 20 bases).

`SetVerbose("ECPP", v)`

Sets the verbose level for output when the ECPP algorithm is used in the above primality tests. The legal values are `true`, `false`, 0, 1 and 2 (`false` and `true` are the same as 0 and 1 respectively). Level 1 outputs only basic information about the times for the top-level stages (downrun and uprun). Level 2 outputs full information about every step : this level is very verbose!

`PrimalityCertificate(n)`

`IsPrimeCertificate(cert)`

`ShowCertificate`	BOOLELT	*Default :* `true`
`Trust`	RNGINTELT	*Default :* 0

`PrimalityCertificate` is a variant on `IsPrime` which uses ECPP and outputs a certificate of primality at the conclusion. If the number n is actually proven to be composite or the test fails, then a runtime error occurs. The certificate is a `Magma` list with data in the format described in [AM93].

To verify that a given number is prime from its primality certificate, the function `IsPrimeCertificate` is used. By default, this outputs only the result of the verification : `true` or `false`. If the user wishes to see the stages of the verification, the parameter `ShowCertificate` should be set to `true`. This is rather verbose as it shows the verification of primality of all small factors that need to be shown to be prime at each substage of the algorithm. It is usually more convenient to set the parameter `Trust` to a positive integer N which means that asserted primes less than N are not checked. This slightly reduces the time for the verification, but more importantly, it greatly reduces the output of `ShowCertificate`.

`IsProbablePrime(n:` *parameter*`)`

`IsProbablyPrime(n:` *parameter*`)`

`Bases` RngIntElt *Default :* 20

Returns `true` if and only if the integer n is a probable prime. More precisely, the function returns `true` if and only if either n is prime for $n < 34 \cdot 10^{13}$, or n is a strong pseudoprime for 20 random bases b with $1 < b < n$. By setting the optional parameter `Bases` to some value B, the number of random bases used is B instead of 20.

`IsPrimePower(n)`

Returns `true` if and only if the integer n is a prime power; that is, if n equals p^k for some prime p and exponent $k \geq 1$. If this is the case, the prime p and the exponent k are also returned, Note that the primality of p is rigorously proven.

Example H18E6

This piece of code uses 5 Miller-Rabin tests to find the next probable *repunit*-prime (consisting of all 1's as decimal digits), using the fact that primes of this form consist of a prime number of digits:

```
> NextPPRepunit := function(nn)
>    n := nn;
>    repeat
>       n := NextPrime(n);
>    until IsProbablePrime( (10^n-1) div 9 : Bases := 5);
>    return n;
> end function;
```

The first few cases are easy:

```
> NextPPRepunit(1);
2
> NextPPRepunit(2);
19
> NextPPRepunit(19);
23
> NextPPRepunit(23);
```

```
317
```

So we found a 317 digit prime (although we should check genuine primality, using `IsPrime`)! We leave it to the reader to find the next (it has more than 1000 decimal digits).

18.9.2 Other Functions Relating to Primes

The functions `NextPrime` and `PreviousPrime` can be used to find primes in the neighbourhood of a given integer. After sieving out only multiples of very small primes, the remaining integers are tested for primality in order. Again, a rigorous method is used unless the user flags that probable primes suffice.

The `PrimeDivisors` function is different from all other functions in this section since it requires the factorization of its argument.

`NextPrime(n)`

`NextPrime(n:` *parameter*`)`

`Proof` BoolElt *Default :* `true`

The least prime number greater than n, where n is a non-negative integer. The primality is proved. The optional boolean parameter 'Proof' (`Proof := true` by default) can be set to `Proof := false`, to indicate that the next probable prime (of order 20) may be returned.

`PreviousPrime(n)`

`PreviousPrime(n:` *parameter*`)`

`Proof` BoolElt *Default :* `true`

The greatest prime number less than n, where $n \geq 3$ is an integer. The primality is proved. The optional boolean parameter 'Proof' (`Proof := true` by default) can be set to `Proof := false`, to indicate that the previous probable prime (of order 20) may be returned.

`PrimesUpTo(B)`

This function lists the primes up to (and including) the (positive) bound B. The algorithm is not super-optimised, but is reasonable.

`PrimesInInterval(b, e)`

This function lists the primes in the interval from b to e, including the endpoints. The algorithm is not very optimised.

`NthPrime(n)`

Given a number n, this function returns the nth prime. This is implemented for primes up to 10^{10}.

`RandomPrime(n: parameter)`

`Proof` BoolElt *Default :* `true`

A random prime integer m such that $0 < m < 2^n$, where n is a small non-negative integer. The function always returns 0 for $n = 0$ or $n = 1$. A rigorous method will be used to check primality, unless $m > 34 \cdot 10^{13}$ and the optional parameter 'Proof' is set to `Proof := false`, in which case the result indicates that m is a probable prime (of order 20).

`RandomPrime(n, a, b, x: parameter)`

`Proof` BoolElt *Default :* `true`

Tries up to x iterations to find a random prime integer m congruent to a modulo b such that $0 < m < 2^n$. Returns true, m if found, or false if not found. n must be larger than 0. a must be between 0 and $b - 1$ and b must be larger than 0. A rigorous method will be used to check primality, unless $m > 34 \cdot 10^{13}$ and the optional parameter 'Proof' is set to `Proof := false`, in which case the result indicates that m is a probable prime (of order 20).

`PrimeBasis(n)`

`PrimeDivisors(n)`

A sequence containing the distinct prime divisors of the positive integer $|n|$.

18.10 Factorization

This section contains a description of most of the machinery provided in Magma for the factorization of integers. An account of the Number Field Sieve is deferred until later in the chapter.

In the first subsection the general-purpose `Factorization` function is described. It employs a combination of methods in an attempt to find the complete prime factorization of a given integer. Some control is possible over each of the methods, but in general default choices for the parameters would give good results for a wide range of arguments.

In the second subsection we describe functions that enable access to each of the factorization methods available in Magma. The user has control over parameters for these methods.

Factorization functions in Magma return a *factorization sequence*. This is a sequence of two-element tuples $[< p_1, k_1 >, \ldots, < p_r, k_r >]$, with $p_1 < p_2 < \cdots < p_r$ distinct prime numbers and k_i positive, which is used to represent integers in factored form: $n = \prod_{i=1}^{r} p_i^{k_i}$. Although such sequences are printed like ordinary sequences, they form a separate category `RngIntEltFact`. Operations on such factorization sequences are described in the next section.

18.10.1 General Factorization

The general `Factorization` function is designed to give close to optimal performance for the factorization of integers that may be encountered in the course of daily computations. The strategy employed is as follows (the next subsection gives a more detailed description of the individual methods). First of all a compositeness test is used to ensure that the argument is composite; if not the primality proving algorithm is invoked (unless a flag is set to avoid this — see below). See the previous section for compositeness testing and primality proving. This operation is repeated for any non-trivial factor (and cofactor) found along the way. Before any of the general factorization techniques is employed, it is checked whether $|n|$ is of the special form $b^k \pm 1$, in which case an intelligent database look-up is used which is likely to be successful if b and k are not too large. This is equivalent to the `Cunningham` function on $b, k, \pm 1$, described in the next subsection. In the first true stage of factorization *trial division* is used to find powers of 2 and other small primes (by default up to 10000). After this it is checked whether the remaining composite number is the power of a positive integer; if so the appropriate root is used henceforth. After this *Pollard's ρ method* is applied (using 8191 iterations by default). The bound on trial division factors and the number of iterations for ρ can be set by the optional parameters `TrialDivisionLimit` and `PollardRhoLimit`. It is possible, from this point on, that several composite factors still need factorization. The description below applies to each of these.

The final two algorithms deployed are usually indicated by ECM (for Elliptic Curve Method) and MPQS (for Multiple Polynomial Quadratic Sieve). By default, ECM (which is likely to find 'smaller' factors if they exist) is used with parameters that depend on the size of the remaining (composite) factors. After that, if a composite factor of at least 25 digits remains, MPQS is used; it is the best method available for factoring integers of more than about 40 decimal digits especially for products of two primes of roughly equal size. If the remaining composite is smaller than 25 digits, ECM is again invoked, now in an indefinite loop until a factor is found. The latter will also occur if the user, via a flag `MPQSLimit` indicates that MPQS should not be applied to numbers of the given size, and provided the user has not limited the number of ECM trials by setting the `ECMLimit`. Thus, unless both `MPQSLimit` and `ECMLimit` are set as optional parameters by the users, the algorithm will continue until the complete factorization has been completed.

Besides the limiting parameters just mentioned it also possible to avoid the use of primality proofs and receive probable primes, with a flag similar to that used on `IsPrime`; see the previous section.

A verbose flag can be set to obtain informative printing on progress in the various stages of factorization. Specific flags for ECM and MPQS may be used as well; they are described in the next subsection.

```
SetVerbose("Factorization", v)
```

(Procedure.) Set the verbose printing level for all of the factorization algorithms to be v. Currently the legal values for v are `true`, `false`, 0 or 1 (`false` is the same as 0, and `true` is the same as 1). If the level is 1, information is printed at each stage of the algorithm as a number is factored.

`Factorization(n)`
`Factorisation(n)`
`Factorization(n:` *parameters*`)`
`Factorisation(n:` *parameters*`)`

A combination of algorithms (Cunningham, trial division, SQUFOF, Pollard ρ, ECM and MPQS) is used to attempt to find the complete factorization of $|n|$, where n is a non-zero integer. A factorization sequence is returned, representing the completely factored part of $|n|$ (which is usually all of $|n|$). The second return value is 1 or -1, reflecting the sign of n. If the factorization could not be completed, a third sequence is returned, containing composite factors that could not be decomposed with the given values of the parameters; this can only happen if both `ECMLimit` and `MPQSLimit` have been set. (Note that the third variable will remain unassigned if the full factorization is found.)

When a very large prime (more than 200 decimal digits say), appears in the factorization, proving its primality may dominate the running time.

There are 6 optional parameters.

`Proof`	BoolElt	*Default :* `true`
`Bases`	RngIntElt	*Default :* 20

The parameter `Proof` (`Proof := true` by default) can be set to false to indicate that the first sequence may contain probable primes (see also the previous section), in which case the parameter `Bases` indicates the number of tests used by Miller-Rabin (`Bases := 20` by default).

`TrialDivisionLimit`	RngIntElt	*Default :* 10000

The parameter `TrialDivisionLimit` can be used to specify an upper bound for the primes used in the trial division stage (default `TrialDivisionLimit := 10000`).

`SQUFOFLimit`	RngIntElt	*Default :* 24

The parameter `SQUFOFLimit` can be used specify the maximum number of decimal digits for an integer to which SQUFOF should be applied; this is Shank's square form factorization method (default `SQUFOFLimit := 24`).

`PollardRhoLimit`	RngIntElt	*Default :* 8191

The parameter `PollardRhoLimit` can be used to specify an upper bound on the number of iterations in the ρ method (default `PollardRhoLimit := 8191`).

`ECMLimit`	RngIntElt	*Default :*

This optional parameter can be used to limit the number of curves used by the ECM part of the factorization attempt. Setting `ECMLimit := 0` prevents the use of ECM. The default value depends on the size of the input, and ranges from 2 for n with less than 37 digits to around 500 for n with 80 digits. The smoothness is incremented in each step to grow by default from 500 to 600 (for 37 digits and less), and from 500 to about 10000 for n having 80 digits. For the indefinite case of ECM (which applies

when MPQS is disallowed) the initial smoothness is 500, the number of curves is infinite and the smoothness is incremented by 100 in each step.

`MPQSLimit` RngIntElt *Default :* ∞

The parameter `MPQSLimit` can be used specify the maximum number of decimal digits for an integer to which MPQS should still be applied; MPQS will not be invoked on integers having less than (or sometimes equal) 25 decimal digits. Setting the parameter to anything less than 25 will therefore prevent MPQS from being used. Unless `ECMLimit` has been set, this will imply that ECM will be applied until the full factorization has been obtained.

Note that progress can be monitored by use of `Verbose("Factorization", true)`.

18.10.2 Storing Potential Factors

As of V2.14 (October 2007), Magma now internally stores a list of factors found by the ECM and MPQS algorithms. Subsequently, when either of those algorithms are to be invoked by the `Factorization` function, the integers in the list are first tried to see whether factors can be easily found. One may also give prime factors to Magma to store in this list via the following procedure.

`StoreFactor(n)`
`StoreFactor(S)`

(Procedure.) Store the single integer n or the integers in the set/sequence S in the list of factors to be tried by the `Factorization` function. Each integer must be a positive *prime*.

`GetStoredFactors()`

Return a sequence containing the currently stored integers.

18.10.3 Specific Factorization Algorithms

In this subsection we discuss how various factorization algorithms can be accessed individually. Generally these function should not be used for ordinary factorization (for that use `Factorization` discussed in the previous subsection), but they can be used for experimentation, or to build a personal factorization function with control over each of the methods used.

On some functions a little preprocessing is done to ensure that the argument is composite, that powers of 2 (and sometimes 3) are taken out and that the integer to be factored is not the power of an integer.

For each of these functions the `Proof` (default true) and `Bases` parameters can be used to indicate that primality of prime factors need not be rigorously proved, and how many bases should be used in the compositeness test, as discussed in the subsection on `IsPrime`.

```
SetVerbose("Cunningham", b)
```

```
SetVerbose("ECM", b)
```

```
SetVerbose("MPQS", b)
```

Using this procedure to set either of the verbose flags `"Cunningham"`, `"ECM"` or `"MPQS"`, (which are false by default) enables the user to obtain progress information on attempts to factor integers using the 'Cunningham' method, ECM or MPQS.

```
Cunningham(b, k, c)
```

This function attempts to factor $n = b^k + c$, where $c \in \{\pm 1\}$ and b and k are not too big. This function uses R. Brent's factor algorithm [BtR92], which employs a combination of table-lookups and attempts at 'algebraic' factorization (Aurifeuillian techniques). An error results if the tables, containing most of the known factors for numbers of this form (including the 'Cunningham tables'), cannot be located by the system. The function will always return the complete prime factorization (in the form of a factorization sequence) of the number n (but it may take very long before it completes); it should be pointed out, however, that the primes appearing in the factorization are only *probable primes* and a rigorous primality prover has not been applied.

```
AssertAttribute(RngInt, "CunninghamStorageLimit", l)
```

This attribute is used to change the number of Cunningham factorizations which are stored in MAGMA. Normally, MAGMA stores a certain number of factorizations computed by the `Cunningham` intrinsic function so that commonly needed factorizations can be recalled quickly. When the stored list fills up, the factorization least recently accessed is removed from the list. Setting this attribute to zero ensures that no storage is done. The default value is 20.

```
TrialDivision(n)
```

```
TrialDivision(n, B)
```

`Proof`	BOOLELT	*Default :* `true`
`Bases`	RNGINTELT	*Default :* 20

The integer $n \neq 0$ is subjected to trial division by primes up to a certain bound B (the sign of n is ignored). If only the argument n is given, B is taken to be 10000. The function returns a factorization sequence and a sequence containing an unfactored composite that remains.

`PollardRho(n)`

`PollardRho(n, c, s, k)`

`Proof`	BoolElt	*Default :* `true`
`Bases`	RngIntElt	*Default :* 20

The ρ-method of Pollard is invoked by this function to find the factorization of an integer $n > 1$. For this method a quadratic function $x^2 + c$ is iterated k times, with starting value $x = s$. If only n is used as argument to the function, the default values $c = 1$, $s = 1$, and $k = 8191$ are selected. A speed-up to the original algorithm, due to R. P. Brent [Bre80], is implemented. The function returns two values: a factorization sequence and a sequence containing unfactored composite factors.

`pMinus1(n, B1)`

`x0`	RngIntElt	*Default :*
`B2`	RngIntElt	*Default :*
`k`	RngIntElt	*Default :*

Given an integer $n > 1$, an attempt to find a factor is made using Paul Zimmermann's GMP-ECM implementation of Pollard's $p - 1$ method. If a factor f with $1 < f < n$ is found, then f is returned; otherwise 0 is returned.

The Step 1 bound B_1 is given as the second argument `B1`. By default, the Step 2 bound B_2 is optimally chosen, but may be given with the parameter `B2` instead. By default, an optimal number of blocks is chosen for Step 2, but this may be overridden via the parameter `k` (see the function `ECM`). The base x_0 is chosen randomly by default, but may instead be supplied via the parameter `x0`.

This method will return a prime factor p of n if $p - 1$ has all its prime factors less than or equal to the Step 1 bound B_1, except for one factor which may be less than or equal to the Step 2 bound B_2.

`pPlus1(n, B1)`

`x0`	RngIntElt	*Default :*
`B2`	RngIntElt	*Default :*
`k`	RngIntElt	*Default :*

Given an integer $n > 1$, an attempt to find a factor is made using Paul Zimmermann's GMP-ECM implementation of Williams' $p + 1$ method. If a factor f with $1 < f < n$ is found, then f is returned; otherwise 0 is returned.

The Step 1 bound B_1 is given as the second argument `B1`. By default, the Step 2 bound B_2 is optimally chosen, but may be given with the parameter `B2` instead. By default, an optimal number of blocks is chosen for Step 2, but this may be overridden via the parameter `k` (see the function `ECM`). The base x_0 is chosen randomly by default, but may instead be supplied via the parameter `x0`.

This method may return a prime factor p of n if $p + 1$ has all its prime factors less than or equal to the Step 1 bound B_1, except for one factor which may be

less than or equal to the Step 2 bound B_2. A base x_0 is used, and not all bases will succeed: only half of the bases work (namely those where the Jacobi symbol of $x_0^2 - 4$ and p is -1.) Unfortunately, since p is usually not known in advance, there is no way to ensure that this holds. However, if the base is chosen randomly, there is a probability of about 1/2 that it will give a Jacobi symbol of -1 (so that the factor p would be found assuming that $p+1$ is smooth enough). A rule of thumb is to run `pPlus1` three times with different random bases.

`SQUFOF(n)`

`SQUFOF(n, k)`

`Proof`	BoolElt	*Default :* `true`
`Bases`	RngIntElt	*Default :* 20

This is a fast implementation of Shanks's square form factorization method that will only work for integers $n > 1$ less than 2^{2b-2}, where b is the number of bits in a long (which is either 32 or 64). The argument k may be used to specify the maximum number of iterations used to find the square; by default it is 200000. The expected number of iterations is $O(N^{1/4})$.

`ECM(n, B1)`

`Sigma`	RngIntElt	*Default :*
`x0`	RngIntElt	*Default :*
`B2`	RngIntElt	*Default :*
`k`	RngIntElt	*Default :* 2

Given an integer $n > 1$, an attempt is made to find a factor using the GMP-ECM implementation of the Elliptic Curve Method (ECM). If a factor f with $1 < f < n$ is found, then f is returned together with the corresponding successful σ seed; otherwise 0 is returned.

The Step 1 bound B_1 is given as the second argument `B1`. By default, the Step 2 bound B_2 is optimally chosen, but may be given with the parameter `B2` instead.

The elliptic curve used is defined by Suyama's parametrization and is determined by a parameter σ. By default, σ is chosen randomly with $0 < \sigma < 2^{32}$, but an alternative positive integer may be supplied instead via the parameter `Sigma`. Let $u = \sigma^2 - 5$, $v = 4\sigma$ and $a = (v-u)^3(3u+v)/(4u^3v) - 2$. The starting point used is $(x_0 : 1)$, where by default $x_0 = u^3/v^3$, but x_0 may instead be supplied via the parameter `x0`. Finally, the curve used is $by^2 = x^3 + ax^2 + x$, where $b = x_0^3 + ax_0^2 + x_0$.

Step 1 uses very little memory, but Step 2 may use a large amount of memory, especially for large B_2, since its efficient algorithms use some large tables. To reduce the memory usage of Step 2, one may increase the parameter `k`, which controls the number of "blocks" used. Multiplying the default value of k by 4 will decrease the memory usage by a factor of 2. For example, with $B_2 = 10^{10}$ and a 155-digit number n, Step 2 requires about 96MB with the default $k = 2$, but only 42MB with $k = 8$. Increasing k does, however, slightly increase the time required for Step 2.

`ECMSteps(n, L, U)`

Given an integer $n > 1$, an attempt to find a factor of n is made by repeated calls to ECM. The initial B_1 bound is taken to be L, and subsequently B_1 is replaced with $B_1 + \lfloor \sqrt{B_1} \rfloor$ at each step. If a factor is found at any point, then this is returned with the corresponding successful σ seed; otherwise, if B_1 becomes greater than the upper bound U, then 0 is returned.

`MPQS(n)`

`MPQS(n, D)`

`Proof`	BoolElt	*Default :* `true`
`Bases`	RngIntElt	*Default :* 20

This function can be used to drive Arjen Lenstra's implementation of the multiple polynomial quadratic sieve MPQS. Given an integer $n > 5 \cdot 10^{24}$ an attempt is made to find the prime factorization of n using MPQS. The name of a directory (which should not yet exist) may be specified as a string D where files used by MPQS will be stored. By default, the directory indicated by the environment variable `MAGMA_QS_DIR` will be used, and if that has not been set, the directory `/tmp`. It is possible to assist the master running the main Magma job by generating relations on other machines (slaves), starting an auxiliary process on such machine, in the directory D, by typing `magma -q D machine` where `machine` is the name of the machine. The function returns two values: a factorization sequence and a sequence containing unfactored composite factors.

18.10.4 Factorization Related Functions

`ECMOrder(p, s)`

`ECMFactoredOrder(p, s)`

Suppose p is a prime factor found by the ECM algorithm and such that the σ value determining the successful curve was s. These functions compute the order of the corresponding elliptic curve. The first function returns the order as an integer, while the second function returns the factorization of the order. In general, this order will have been smooth with respect to the relevant bounds for the ECM algorithm to have worked, and these functions allow one to examine how small the prime divisors of the curve order really are.

`PrimeBasis(n)`

`PrimeDivisors(n)`

A sequence containing the distinct prime divisors of the positive integer $|n|$, given in increasing order.

`Divisors(n)`
`Divisors(f)`

Returns a sequence containing all divisors of the positive integer, including 1 and the integer itself, given in increasing order. The argument given must be either the integer n itself, or a factorization sequence f representing it.

`CoprimeBasis(S)`

Given a set or sequence S of integers, return a coprime basis of S in the form of a factorization sequence Q whose integer value is the same as the product of the elements of S but Q has coprime bases (i.e., the first components of tuples from Q are coprime).

Example H18E7

In this example we use the `Divisors` function together with the `&+` reduction of sequences to find the first few perfect numbers, that is, numbers n such that the sum of the divisors less than n equals n.

```
> {  x : x in [2..1000] | &+Divisors(x) eq 2*x };
{ 6, 28, 496 }
> f := Factorization(496);
> f;
[ <2, 4>, <31, 1> ]
> Divisors(f);
[ 1, 2, 4, 8, 16, 31, 62, 124, 248, 496 ]
```

`PartialFactorization(S)`

Given a sequence of non-zero integers S, return, for each integer $S[i]$, two factorization lists F_i and G_i, such that $S[i] =$ `Facint`$(F_i)*$`Facint`(G_i). All the divisors in F_i are square factors, and, for any i and j, the divisors in G_i and G_j are either equal or are pairwise coprime. In other terms, `PartialFactorization(S)` provides a partial decomposition of the integers in S in square and coprime factors. The interesting fact is that this factorization uses only gcd and exact integer division. This algorithm is due to J.E. Cremona.

Example H18E8

A partial factorization is shown.

```
> PartialFactorization([1380, 675, 3408, 654]);
[
  [
    [ <2, 2> ],
    [ <115, 1>, <3, 1> ]
  ],
  [
```

```
    [ <5, 2>, <3, 2> ],
    [ <3, 1> ]
  ],
  [
    [ <2, 4> ],
    [ <71, 1>, <3, 1> ]
  ],
  [
    [],
    [ <218, 1>, <3, 1> ]
  ]
]
```

18.11 Factorization Sequences

The factorization of integers results in a factorization sequence, consisting of a sequence of pairs of prime and exponent. It is sometimes convenient to perform operations on such sequences without converting back to the integers they represent — it would, for example, be very inefficient to factor the product of two integers that have both been factored already. In this section we briefly list the operations that are allowed on such factorization sequences — note that these factorization sequences now have their own special type: `RngIntEltFact`. Conversion functions are supplied as well.

18.11.1 Creation and Conversion

Factorization sequence usually arise as the result of the `Factorization` of an integer, possibly via functions like `FactoredOrder`. The functions below allow conversion from and to ordinary sequences, and the inverse operation to factorization, creating an integer from a factorization.

`Facint(f)`

`FactorizationToInteger(f)`

Create the integer corresponding to the factorization sequence f.

`SeqFact(s)`

`SequenceToFactorization(s)`

Given a sequence of tuples, each consisting of pairs of prime integers and positive integer exponents, create the corresponding factorization sequence. The pairs must be ordered with strictly increasing primes as first components.

`Eltseq(f)`

`ElementToSequence(f)`

Given a factorization sequence f, create the enumerated sequence containing the same pairs of primes and exponents.

18.11.2 Arithmetic

The difference of two factorization sequences is only permitted when the first integer represented is greater than the second integer represented. An error results from division when the quotient does not correspond to an integer.

`s + t` `s - t` `s * t` `s / t` `s ^ k`

18.11.3 Divisors

The functions listed below can be applied to factorization sequences; their behaviour will be clear, and all of them are documented elsewhere when the argument is the corresponding positive integer.

`Lcm(s, t)` `Gcd(s, t)` `SquarefreeFactorization(f)`

`MoebiusMu(f)` `Divisors(f)` `PrimeDivisors(f)`

`NumberOfDivisors(f)` `SumOfDivisors(f)`

18.11.4 Predicates

All predicates listed below are applicable both to factorization sequences and to the positive integers these represent, and have been documented for integer arguments elsewhere.

`IsOne(s)` `IsOdd(s)` `IsEven(s)` `IsUnit(s)`

`IsPrime(s)` `IsPrimePower(s)` `IsSquare(s)` `IsSquarefree(s)`

18.12 Modular Arithmetic

In this section we describe some functions that make it possible to perform modular arithmetic without conversions to residue class rings.

18.12.1 Arithmetic Operations

`Modexp(n, k, m)`

The modular power $n^k \bmod m$, where n is an integer, k is an integer and m is an integer greater than one. If k is negative, n must have an inverse i modulo m, and the result is then $i^{-k} \bmod m$. The result is always an integer r with $0 \leq r < m$.

`n mod m`

Remainder upon dividing the integer n by the integer m. The result always has the same sign as m. An error results if m is zero.

`Modinv(n, m)`

`InverseMod(n, m)`

Given an integer n and a positive integer m, such that n and m are coprime, return an inverse u of n modulo m, that is, return an integer $1 \leq u < m$ such that $u \cdot n \equiv 1 \bmod m$.

`Modsqrt(n, m)`

Given an integer n and an integer $m \geq 2$, this function returns an integer b such that $0 \leq b < m$ and $b^2 \equiv n \bmod m$ if such b exists; an error results if no such root exists.

`Modorder(n, m)`

For integers n and m, $m > 1$, the function returns the least integer $k \geq 1$ such that $n^k \equiv 1 \bmod m$, or zero if $\gcd(n, m) \neq 1$.

`IsPrimitive(n, m)`

Returns `true` if n is a primitive root for m, `false` otherwise $(0 < n < m)$.

`PrimitiveRoot(m)`

Given an integer $m > 1$, this function returns an integer value defined as follows: If $\mathbf{Z}/m\mathbf{Z}$ has a primitive root and the function is successful in finding it, the root a is returned. If $\mathbf{Z}/m\mathbf{Z}$ has a primitive root but the algorithm does not succeed in finding it, or $\mathbf{Z}/m\mathbf{Z}$ does not possess a primitive root, then zero is returned.

18.12.2 The Solution of Modular Equations

The functions described here can be used if an occasional modular operation is required; the results are integers again. For more extensive modular arithmetic it is preferable to convert to residue class ring arithmetic. See section 19.4 for details.

`Solution(a, b, m)`

If a solution exists to the linear congruence $ax \equiv b \bmod m$, then returns $x0, k$ such that $x = x0 + i * k$ represents the complete set of solutions, where i can be any integer. Otherwise, returns -1.

`ChineseRemainderTheorem(X, N)`

`CRT(X, N)`

Apply the Chinese Remainder Theorem to the integer sequences X and N. The sequences must have the same length, k say. The function returns the unique integer x in the range $0 \leq x < LCM(N[1] \cdot \ldots \cdot N[k])$ such that $x \equiv X[i] \bmod N[i]$. The elements of N must all be positive integers greater than one. If there is no solution, then -1 is returned.

`Solution(A, B, N)`

Return a solution x to the system of simultaneous linear congruences defined by the integer sequences A, B and N. Each of these sequences must have the same number of terms, k say. The elements of N must all be positive integers greater than one. The i-th congruence is $A[i] \cdot x \equiv B[i] \bmod N[i]$. The solution x will satisfy $0 \leq x < LCM(N[1] \cdot \ldots \cdot N[k])$. If no solution exists, -1 is returned.

`NormEquation(d, m)`

`NormEquation(d, m:` *parameters*`)`

`Factorization` [<RngIntElt, RngIntElt>]

Given a positive integer d and a non-negative integer m, return true and two non-negative integers x and y, such that $x^2 + y^2 d = m$, if such a solution exists. If such a solution does not exists only the value false is returned. If the factorization of m is known, it may be supplied as the value of the parameter `Factorization` to speed up the computation.

Example H18E9

```
> d := 95744000009574400000227774976O;
> m := 5102197760510219776012138128480644;
> time NormEquation(d, m);
true 98 73
Time: 2.990
> time f := Factorization(m);
Time: 4.670
> f;
[ <2, 2>, <19, 1>, <671341810593449970527912911642l9, 1> ]
> time NormEquation(d, m: Factorization := f);
true 98 73
Time: 0.420
```

18.13 Infinities

Occasionally it is convenient to work with infinite quantities (for example, when working with valuations or cardinalities). Magma provides two such objects, the positive and negative infinities. This section describes the Magma facilities for dealing with such objects.

The infinities are compatible with certain finite quantities: integers, rationals and real numbers. In contexts where a common universe is needed to contain both finite and infinite quantities (for example, if creating a sequence of valuations) the extended reals (type `ExtRe`) are used. The extended reals are a coproduct-like object that can contain both infinities and compatible finite objects. When viewed as members of the extended reals, the elements are of type `ExtReElt`.

18.13.1 Creation

Certain system intrinsics such as `Valuation` which normally return an integer may return an infinite object for appropriate exceptional cases. Two special intrinsics are also provided to create infinite objects.

`Infinity()`

The positive infinity object.

`MinusInfinity()`

The negative infinity object.

18.13.2 Arithmetic

Only basic arithmetic operations are provided for infinite objects. The operations described below may freely mix infinite and finite quantities, but note that certain forms (such as $\infty - \infty$ or $\infty * 0$) are not well defined and will cause an error.

`- x`

`x + y` `x - y` `x * y` `x / y` `x ^ n`

18.13.3 Comparison

Infinite objects may be compared with themselves and finite quantities.

`x eq y` `x ne y` `x lt y` `x le y` `x gt y` `x ge y`

`Maximum(x, y)` `Minimum(x, y)`

18.13.4 Miscellaneous

`Sign(x)`

Returns 1 if x is the positive infinite object, -1 if x is the negative infinite object.

`Abs(x)`

`AbsoluteValue(x)`

Returns the positive infinite object.

`Round(x)`

`Floor(x)`

`Ceiling(x)`

Returns the infinite object x again; these functions are for convenience when dealing with objects which could be either finite numeric types or infinite objects.

`IsFinite(x)`

Returns `true` if x is finite, otherwise `false`. This is more convenient than checking the type of x.

18.14 Advanced Factorization Techniques: The Number Field Sieve

MAGMA provides an experimental implementation of the fastest general purpose factoring algorithm known: the Number Field Sieve (NFS). The implementation may be used both as a General Number Field Sieve and a Special Number Field Sieve – the only difference is in the selection of a suitable polynomial.

18.14.1 The MAGMA Number Field Sieve Implementation

In order to make use of the MAGMA NFS, the user should have some knowledge of the algorithm. The MAGMA NFS implementation also requires a significant amount of memory and disk space to be available for the duration of the factorization. For example, factorization of an 80-digit number may require at least 64 megabytes of RAM and half a gigabyte of disk space.

MAGMA's NFS implementation uses one linear polynomial (the "rational side") and one polynomial of higher degree (the "algebraic side"). At the time of writing this is not a major restriction, since the best methods for selecting polynomials for factorization of numbers of more than 100 digits involve one linear and one non-linear polynomial. MAGMA provides a number of functions to assist in choosing a good algebraic-side polynomial for the factorization of a particular number, following the ideas of Montgomery and Murphy in [Mur99].

MAGMA provides two methods for using the NFS implementation. The first is the one-step function `NFS`, which provides a naive NFS factorization attempt using default algorithm parameters.

The second, more powerful method is to work with an NFS process object, splitting the algorithm into four stages: Sieving, Auxiliary data, Linear algebra and Final factorization. This approach allows greater control over the algorithm, as the user may supply their own algorithm parameter values. It also allows the user to distribute the computationally intensive sieving and final factorization stages over several machines or processors.

Some functions are included to allow MAGMA users to co-operate in factorization attempts using CWI tools.

A verbose flag may be set to obtain informative printing on progress in the various stages of the NFS algorithm.

```
SetVerbose("NFS", v)
```

Set the verbose printing level for the NFS algorithms to the integer v. Currently the legal values for v are 0, 1, 2 and 3.

If the level is 0, no verbose output is produced.

If the level is 1, NFS will produce basic information about its progress, and will also print information on NFS algorithm parameters.

If the level is 2, NFS will provide more detailed information about progress and parameters.

If the level is 3, NFS will print out extremely detailed information about progress and data. This level will only be useful for experts and developers.

18.14.2 Naive NFS

MAGMA's Number Field Sieve implementation provides a one-step black-box function NFS. Here, the user provides the integer n to be factored, a homogeneous bivariate integer polynomial F and integers $m1$ and $m2$ such that $F(m1, m2) \equiv 0 \bmod n$. MAGMA will attempt to factor n using F, $m1$ and $m2$, automatically selecting the other parameters (see below) for the algorithm.

The automatically chosen parameters are NOT optimal in general, and therefore no conclusions should be drawn about the speed of the implementation or the algorithm itself based on the use of this function.

For example, note that the default algebraic factor base size of NFS is chosen to be rather large to decrease the likelihood of running out of useful relations. This slows the algorithm considerably, since it increases the size of the matrix to be reduced – but it also means that the algorithm should succeed in finding a factor unless one chooses a really bad polynomial.

```
NumberFieldSieve(n, F, m1, m2)
```

```
NFS(n, F, m1, m2)
```

Performs the factorization of an integer n using the Number Field Sieve with algebraic polynomial F, where the integers $m1$ and $m2$ satisfy $F(m1, m2) \equiv 0 \bmod n$. Returns a nontrivial factor of n if one is found, or 0 otherwise.

18.14.3 Factoring with NFS Processes

An NFS Process (an object of category NFSProc) encapsulates the data of a MAGMA NFS factorization. It contains the number n to be factored, the algebraic polynomial F and the integers m_1 and m_2. It also provides access to a number of NFS algorithm parameters (such as approximate factor base sizes). These parameters are attributes of the NFS process. If any of the parameters are not set, sensible (but not necessarily optimal) defaults will be provided by MAGMA.

The NFS algorithm is divided into four stages:

1. Sieving
2. Auxiliary data gathering
3. Linear algebra
4. Factorization

The stages are described in detail below.

After creating an NFS process for the factorization attempt, the user should proceed through each of the four stages in the above order.

```
NFSProcess(n, F, m1, m2)
```

Given a (composite) integer n, a bivariate homogeneous integer polynomial F, and nonzero integers $m1$ and $m2$ such that $F(m1, m2) \equiv 0 \bmod n$, this function creates an NFS process object for an NFS factorization of n.

Example H18E10

The attributes associated with an NFS process are:

```
> ListAttributes(NFSProc);
AlgebraicError              OutputFilename
AlgebraicFBBound            RationalError
AlgebraicLargePrimeBound    RationalFBBound
CacheSize                   RationalLargePrimeBound
F                           m1
Firstb                      m2
Lastb                       n
Maximuma
```

`OutputFilename` is the base name for NFS-generated data files. These files (and their actual names) are discussed below.
`AlgebraicFBBound` is the upper bound for smooth primes in the algebraic-side factor base, and `RationalFBBound`, the upper bound for smooth primes in rational-side factor base.
`Maximuma` bounds the sieve interval for a: NFS will sieve for relations with $|a| \leq$ `Maximuma`.
`Firstb` is the first value of b to sieve on, and `Lastb` is the last.
`AlgebraicLargePrimeBound` gives the upper bound for "large" (non-smooth) primes in the algebraic-side factor base. Similarly, `RationalLargePrimeBound` is the upper bound for the rational side.
`AlgebraicError` defines an "error" tolerance for logarithm arithmetic on algebraic side. Similarly, `RationalError` defines an "error" tolerance for the rational side.
`CacheSize` is a flag reflecting the computer cache memory size, for optimisation.

18.14.3.1 Attribute Selection

As a guideline for the selection of attributes, we include here a few examples of attributes that we have determined to be good for the MAGMA NFS implementation.

Example H18E11

Sample attributes for a 70-digit number:

```
> n := 52358696802333662953669045107254580530431112410356788979338022350609 27;
> R<X,Y> := PolynomialRing(Integers( ), 2);
> F := 2379600*X^4 - 12052850016*X^3*Y - 13804671642407*X^2*Y^2 +
>      11449640164912254*X*Y^3 + 7965530070546332840*Y^4 ;
> m1 := 6848906180202117;
> m2 := 1;
> P := NFSProcess(n,F,m1,m2);
> P`AlgebraicFBBound := 8*10^5;
> P`RationalFBBound := 6*10^5;
> P`OutputFilename := "/tmp/nfs_70_digit";
> P`Maximuma := 4194280;
> P`AlgebraicError := 16;
> P`RationalError := 14;
```

Example H18E12

Sample attributes for an 80-digit number:

```
> n := 187183186635768649345112272295104022206327935038373865025390693348907\
> 2483083589;
> P<X,Y> := PolynomialRing(Integers(),2);
> F := 15901200*X^4 + 9933631795*X^3*Y - 112425819157429*X^2*Y^2 -
>     231659214929438137*X*Y^3 - 73799500175565303965*Y^4;
> m1 := 1041619817688573426;
> m2 := 1;
> P := NFSProcess(n, F, m1, m2);
> P`AlgebraicFBBound := 8*10^5;
> P`RationalFBBound := 6*10^5;
> P`OutputFilename := "/tmp/nfs_80_dgit";
> P`Maximuma := 10485760;
> P`AlgebraicError := 16;
> P`RationalError := 14;
```

Example H18E13

Sample attributes for an 87-digit number:

```
> n := 12118618732463427472219179104631767765107839384219612469780841876821498\
> 2402918637227743;
> P<X,Y> := PolynomialRing(Integers(),2);
> F := 190512000*X^4 - 450872401242*X^3*Y +
>     1869594915648551*X^2*Y^2 + 2568544235742498*X*Y^3 -
>     93229655834198010101044*Y^4;
> m1 := 282411707411952732l1;
> m2 := 1;
> P := NFSProcess(n, F, m1, m2);
> P`AlgebraicFBBound := 16*10^5;
> P`RationalFBBound := 10^6;
> P`OutputFilename := "/tmp/nfs_87_digit";
> P`Maximuma := 2^24;
> P`AlgebraicError := 24;
> P`RationalError := 18;
```

The best choice for the factor base size depends on many variables, including the average log size and the Murphy α parameter (defined in [Mur99]) for the polynomial F. Our polynomials above are quite good: if the user does not know much about determining the quality of polynomials, then he or she should use much larger factor bases.

18.14.3.2 The Sieving stage

MAGMA's NFS uses a "line-by-line" (or "classical") sieving algorithm. Future versions may include lattice sieving.

The line-by-line siever sieves values of $F(a, b)$ on the algebraic side and corresponding values $a \cdot m2 - b \cdot m1$ on the rational side. This is done by fixing a value of b (beginning with the parameter `Firstb`, if supplied), then sieving all values of a between $-a_0$ and a_0, where a_0 is approximately equal to the parameter `Maximuma` (some rounding off is done to make sure that the sieve interval length is divisible by a high power of 2). When this is completed b is incremented, and the next value of b is processed.

The sieving continues until either the maximum value of b (specified by the parameter `Lastb`) has been reached, or until enough relations are obtained to complete the factorization. If `Lastb` is not defined, the sieve simply continues until enough relations are found. The number of relations required may be determined by the function `NumberOfRelationsRequired`.

"Cycles" among partial relations are counted after every 256 iterations.

The sieve implementation uses (rounded natural) logarithms of primes to mark the sieve interval. Moreover, the implementation does not sieve with prime powers. Therefore, we must allow for some error in scanning the sieve arrays for useful relations; the acceptable sieve threshold errors for each side are defined by the `AlgebraicError` and `RationalError` parameters. If, in addition, the user wants to take advantage of large prime relations (recommended), then larger error terms should be used. The implementation will keep relations having up to 2 large primes on each side, but will only find such relations if the user selects large enough sieve threshold error bounds. The user should be cautious when sieving for (and subsequently using) relations with large primes, as they greatly increase overall disk space requirements. Some experimentation may be required in order to determine the best error bounds for speed or disk space optimization purposes.

The `CacheSize` parameter may be used to take advantage of the cache memory size of the computer: a value of 1 indicates a small cache size, 2 a medium cache size, and 3 a for large cache size.

`NumberOfRelationsRequired(P)`

The minimum number of relations required for an NFS factor attempt with NFS process P.

`FindRelations(P)`

Given an NFS process P for factoring an integer n, generates relations to factor n with the Number Field Sieve algorithm. Returns the number of full relations plus the number of cycles found.

18.14.3.3 The Auxiliary data stage

In this stage of the algorithm, "cycles"[LD95] are detected in the partial relations from the sieving stage, and quadratic characters are calculated for the relations. This greatly improves the efficiency of the NFS.

In a typical factorization, the user should call the procedures `CreateCycleFile` and `CreateCharacterFile` in succession.

`CreateCycleFile(P)`

Creates a file with all the cycle information that the NFS algorithm requires to complete the matrix reduction and final factorization stages for the NFS process P.

`CycleCount(P)`

Returns the number of cycles in the partial relations of the NFS process P. This function is mainly intended for factoring with multiple processors.

`CycleCount(fn)`

Returns the number of cycles in the partial data file corresponding to the base file name fn. This function is mainly intended for factoring with multiple processors.

`CreateCharacterFile(P)`

Creates a file with the quadratic character data for the full relations and cycles in the NFS process P.

`CreateCharacterFile(P, cc)`

Creates a file with the quadratic character data for the full relations and cycles in the NFS process P. There are cc sets of 32 quadratic character columns created.

18.14.3.4 Finding dependencies: the Linear algebra stage

In this stage, the relations are collected together to form a matrix, and then block Lanczos reduction is applied to find linear dependencies among the relations. These dependencies become candidates for factorization.

`FindDependencies(P)`

Finds dependencies between relations in the NFS process P.

18.14.3.5 The Factorization stage

In this stage, number field square roots are extracted and we attempt to factor the dependencies found in the linear algebra stage.

`Factor(P)`

Try to factor with each dependency in the NFS process P until a proper factor is found. Returns the factor, or 0 if no factor is found.

`Factor(P,k)`

Attempt to factor with the k-th dependency in the NFS process P. Returns a proper factor if found, 0 otherwise.

18.14.4 Data files

Many data files are ued for an NFS factorization. The user can control the names and location of the files by specifying the `OutputFilename` parameter; then all output files will have names beginning with the `OutputFilename` string, with a range of suffixes depending on their purpose.

In general, all files are appended to rather than overwritten; so to avoid inconsistencies (and to save disk space) the user should call `RemoveFiles` after a successful factorization.

When distributing factorizations, or collecting results from sieving stages that have been broken up into several runs for some reason (for example, if a process has been interrupted), MAGMA provides the function `MergeFiles`. This takes a sequence of base filenames (which are treated as if they were the value for `OutputFilename`), and reads in the corresponding relation and partial relation files; it then combines the contents of these files, removing duplicates and corrupted lines of data, and places the results into new relation and partial relation files.

`RemoveFiles(P)`

Deletes any data files created by the NFS process P.

`MergeFiles(S, fn)`

Merges the NFS relation files named in the sequence S (and their associated partial relation files) into a pair of new relation and partial relation files, while removing duplicate and corrupted lines of data; returns the number of relations and the number of partial relations in the new output files. The combined full relations are stored in a file named fn, and the partial relations in a file named fn_partials.

18.14.4.1 MAGMA native NFS data files

Here we describe the files used in a typical MAGMA NFS factorization. These files all use formats peculiar to `Magma`'s NFS.

The first kind of file created by NFS stores the relations generated in the sieving stage by the `FindRelations` procedure. The name of the file is precisely the `OutputFilename` string.

NFS also stores partial relations generated in the sieving stage; these are stored in a file named `OutputFilename`_partials.

Whenever cycles [LD95] are counted (for example, in `CycleCount`, a file named `OutputFilename`_cycles is created to store them in. Some other files are also created and then deleted during the cycle counting process.

The quadratic characters calculated in `CreateCharacterFile` are stored in a file named `OutputFilename`_cc.

The linear algebra stage creates a file named `OutputFilename`_null_space, which lists relations making up null space vectors for the NFS matrix.

18.14.5 Distributing NFS Factorizations

MAGMA provides a number of tools for distributing the sieving and final factoring stages over a number of computers.

To distribute the sieving stage, each processor should get a unique range of b-values to sieve and unique data file names. During the sieving, the user must manually check when the combined data has enough relations to factor the number. To do this, the data files must first be merged using `MergeFiles`, and then the cycles can be counted with `CycleCount`. If the combined number of full relations plus the number of cycles exceeds the size of both factor bases combined, then the user can proceed to the other stages of the factorization attempt using the merged data file name.

To distribute the factorization stage, the user may choose a dependency for each process to factor, then call `Factor(P,k)` where P is the NFS process and k the number specifying the dependency to factor, with a different value of k for each process.

Example H18E14

Here we demonstrate a distributed NFS factorization (of a very small n) over two processes, A and B – which may be on different machines, or different magma processes on the same machine, or even in the same magma process.
We begin with process A:

```
> R<X,Y> := PolynomialRing(Integers( ),2);
> n := 704787824974797479087234958341;
> F := 814*X^4 + 3172*X^3*Y - 49218*X^2*Y^2 - 142775*X*Y^3
>      - 65862*Y^4;
> m1 := 3050411;
> m2 := 1;
> A := NFSProcess(n,F,m1,m2);
> A`Firstb := 0;
> A`Lastb := 99;
> A`OutputFilename := "/tmp/nfs-distrib-A";
> FindRelations(A);
3852
```

Now, process B, with n, F, $m1$ and $m2$ as above:

```
> B := NFSProcess(n,F,m1,m2);
> B`Firstb := 99;
> B`Lastb := 199;
> B`OutputFilename := "/tmp/nfs-distrib-B";
> FindRelations(B);
2455
```

Then later, on a single machine,

```
> input_files := ["/tmp/nfs-distrib-A","/tmp/nfs-distrib-B"];
> P := NFSProcess(n,F,m1,m2);
> P`OutputFilename := "/tmp/nfs-distrib-all";
> MergeFiles(input_files, P`OutputFilename);
```

```
4162 25925
> CycleCount(P);
4368
> CreateCycleFile(P);
> CreateCharacterFile(P);
> FindDependencies(P);
```

Now, the final factorization stage may be distributed over more than one processor also. We attempt to factor a relation on A:

```
> A‘OutputFilename := "/tmp/nfs-distrib-all";
> Factor(A,9);  // factor dependency 9
0
```

No factor was found on machine A, but meantime on B:

```
> B‘OutputFilename := "/tmp/nfs-distrib-all";
> Factor(P,1);  // factor dependency 1
94899629
> n mod $1, n div $1;
0 74266575624650207929
```

We have a successful factorisation.

18.14.6 MAGMA and CWI NFS Interoperability

At the time of writing, the record NFS factorizations were lead by the CWI group and by people using CWI's or Arjen Lenstra's code. The CWI tools use a different data file format to MAGMA's native format, but MAGMA supplies some tools to allow users to assist in CWI factorization attempts.

The user may generate relations in CWI relation format, rather than MAGMA native format, by using `FindRelationsInCWIFormat`. The user should note that relations in CWI format cannot at present be used in the Auxiliary data, Linear algebra or Factorization stages of the MAGMA NFS.

Alternatively, assuming some MAGMA NFS relations have already been computed for a process, then the user may use the procedure `ConvertToCWIFormat` to convert the relation data files from MAGMA native format to CWI format. The resulting data file is named `OutputFilename`_CWI_format, and will contain both the full and partial relations of the process.

`FindRelationsInCWIFormat(P)`

Given an NFS process P for factoring an integer n, generates relations to factor n with the Number Field Sieve algorithm, in a file format suitable for use with CWI's NFS tools. Returns the number of relations found.

`ConvertToCWIFormat(P, pb)`

Converts the relation files of the NFS process P to CWI format, storing primes only greater than or equal to the prime printing bound pb. The resulting data file name will be named `P‘OutputFilename`_CWI_format.

18.14.7 Tools for Finding a Suitable Polynomial

MAGMA does not provide a function to select an optimal polynomial for the factorization of a given number. However, MAGMA does provide some functions that are useful for the implementation of the polynomial selection algorithms developed by Peter Montgomery and Brian Murphy in [Mur99].

The functions `BaseMPolynomial`, `MurphyAlphaApproximation`, `OptimalSkewness`, `BestTranslation`, `PolynomialSieve`, and `DickmanRho`, will be useful for those wanting to implement polynomial selection routines within the MAGMA interpreter language.

`BaseMPolynomial(n, m, d)`

Given integers n, m and d, returns a homogeneous bivariate polynomial $F = \sum_{i=0}^{d} c_i X^i Y^{d-i}$ such that the coefficients c_i give a base m representation of n: that is, $\sum_{i=0}^{d} c_i m^i = n$. The coefficients also satisfy $|c_i| \leq m/2$.

This polynomial F may be used to factorize n using the number field sieve (with $m_1 := m$ and $m_2 := 1$).

This function requires that $d \geq 2$ and $n \geq m^d$.

`MurphyAlphaApproximation(F, b)`

Given a univariate or homogeneous bivariate polynomial F, return an approximation of the α value of F, using primes less than the positive integer bound b.

The α value of a polynomial is defined in [Mur99].

Since random sampling is used for primes dividing the discriminant, successive calls to this function will give slightly different results.

`OptimalSkewness(F)`

Given a univariate or homogeneous bivariate polynomial F, return its optimal skewness and corresponding average log size.

The optimal skewness and average log size values are defined in [Mur99].

Example H18E15

This example illustrates an effective (though not optimal) method for finding a "good" polynomial for use in NFS factorizations.
Here we search for a degree $d = 4$ polynomial to use in factoring a 52-digit integer n.
We define the rating of a polynomial to be the sum of the α value and corresponding "average log size" (see [Mur99]).
We then proceed by iterating over base m polynomials with successive leading coefficients (with the values of m near $(m^{1/d} m^{1/d+1})^{1/2}$, and chosen to minimize the second-to-leading coefficient), and choosing as a result the polynomial with the smallest rating.

```
> n := RandomPrime(90)*RandomPrime(90);
> n;
359635470725625320407673937416777014871521894980388 9
> d := 4;
> approx_m := Iroot( Iroot( n, d+1 ) * Iroot( n, d ) , 2 );
> leading_coeff := n div approx_m^d;
```

```
> leading_coeff;
143082
> m := Iroot( n div leading_coeff, d );
> P<X,Y> := PolynomialRing( Integers(), 2 );
> F<X,Y> := BaseMPolynomial(n,m,d);
> F;

```

`BestTranslation(F, m, a)`

Given a univariate or homogeneous bivariate polynomial F, an integer m, and real value a (which should be the average log size of F for some optimal skewness), returns a polynomial G and an integer m' such that $G(m') = F(m)$, together with the average log size and optimal skewness of G. The translation G is selected such that the average log size is a local minimum.

`PolynomialSieve(F, m, J0, J1,MaxAlpha)`

`PrimeBound` RngIntElt *Default :* 1000

Given a homogeneous bivariate integer polynomial F of degree d, together with integers m, J_0 and J_1 and a real value `MaxAlpha`, returns a list of tuples, each of which contains a polynomial $G = F + j_1 x^2 y^{d-2} - (|j_0| + j_1 m)xy^{d-1} + (j_0 m)y^d$, where $|j_0| \leq J_0$ and $|j_1| \leq J_1$ such that the α value (see [Mur99]) of G is "better" (that is, lower) than `MaxAlpha`.

Each tuple contains the data <average log size + α, skewness, α, G, m, j_0, j_1 >.

If the optional parameter `PrimeBound` is set, it is used as an upper bound for primes used to calculate α.

19 INTEGER RESIDUE CLASS RINGS

Chapter 19
INTEGER RESIDUE CLASS RINGS

19.1 Introduction

This chapter presents the machinery provided in MAGMA for computing in quotient rings of the ring of integers **Z**, that is, integer residue class rings. The first half of the chapter describes operations with ideals of **Z** and their quotient rings while the second half provides an introduction to computing with Dirichlet characters.

19.2 Ideals of Z

The theory of ideals of **Z** is very elementary but for completeness the general machinery for ring ideals applies. Such ideals will have type `RngInt`, that is, the same type as the ring of integers itself (`ideal<Integers() | 1>`).

In the case of **Z** any subring is an ideal so that the `sub`-constructor creates the same object as does the `ideal`-constructor.

`ideal< R | a >`

Given the ring of integers **Z** and an integer a, return the ideal of **Z** generated by a.

Example H19E1

We construct some ideals of **Z**.

```
> Z := IntegerRing();
> I13 := ideal< Z | 13 >;
> I13;
Ideal of Integer Ring generated by 13
> 1 in I13;
false
> 0 in I13;
true
> -13 in I13;
true
> I0 := ideal< Z | 0 >;
> 0 in I0;
true
> 1 in I0;
false
```

We check that that **Z** is regarded as an ideal.

```
> I1 := ideal< Z | 1 >;
```

```
> I1 eq Z;
true
```

19.3 Z as a Number Field Order

A collection of functions are provided that make **Z** behave like an order of a number field. Note however, that **Z** is not of type `RngOrd`. If complete compatibility is necessary, the user should create the maximal order of a degree 1 extension of **Q**.

`Decomposition(R, p)`

Returns the ideal decomposition of the prime p, i.e. a list `[ < ideal<Z|p>, 1> ]` as in the number field case.

`Generator(I)`

A generator for the given ideal.

`RamificationIndex(I, p)`

`RamificationIndex(I)`

The ramification index of I over **Z** which is always 1.

`Degree(I)`

The inertia degree of the ideal I, which is always 1.

`TwoElementNormal(I)`

Two integers that generate the ideal I. In this case the generator is returned twice.

`ChineseRemainderTheorem(I, J, a, b)`

The Chinese remainder theorem for ideals. Given ideals I and J of **Z** together with integers a and b, an integer x such that $x - a \in I$ and $x - b \in J$ is returned.

`Valuation(x, I)`

The valuation of the integer x at the prime ideal I.

`ClassRepresentative(I)`

The representative of the ideal I of **Z** in the basis of the class group.

19.4 Residue Class Rings

The ring $\mathbf{Z}/m\mathbf{Z}$ consists of representatives for the residue classes of integers modulo $m > 1$. This Section describes the operations in MAGMA for such rings and their elements.

At any stage during a session, MAGMA will have at most one copy of $\mathbf{Z}/m\mathbf{Z}$ present, for any $m > 1$. In other words, different names for the same residue class ring will in fact be different references to the same structure. This saves memory and avoids confusion about different but isomorphic structures.

If m is a prime number, the ring $\mathbf{Z}/m\mathbf{Z}$ forms a field; however, MAGMA has special functions for dealing with finite fields. The operations described here should *not* be used for finite field calculations: the implementation of finite field arithmetic in MAGMA as described in Chapter 21 takes full advantage of the special structure of finite fields and leads to superior performance.

19.4.1 Creation

In addition to the general quotient constructor, a number of abbreviations are provided for computing residue class rings.

```
quo< Z | I >
```

Given the ring of integers Z, and an ideal I, create the residue class ring modulo the ideal.

```
quo< Z | m >
```

Given the ring of integers Z, and an integer $m \neq 0$, create the residue class ring $\mathbf{Z}/m\mathbf{Z}$.

```
ResidueClassRing(m)
IntegerRing(m)
Integers(m)
RingOfIntegers(m)
```

Given an integer greater than zero, create the residue class ring $\mathbf{Z}/m\mathbf{Z}$.

```
ResidueClassRing(Q)
IntegerRing(Q)
Integers(Q)
```

Create the residue class ring $\mathbf{Z}/m\mathbf{Z}$, where m is the integer corresponding to the factorization sequence Q. This is more efficient than creating the ring by m alone, since the factorization Q will be stored so it can be reused later.

Example H19E2

We construct a residue ring having modulus the largest prime not exceeding 2^{16}.

```
> p := PreviousPrime(2^16);
> p;
65521
> R := ResidueClassRing(p);
Residue class ring of integers modulo 65521
```

Now we try to find an element x in R such that $x^3 = 23$.

```
> exists(t){x : x in R | x^3 eq 23};
true
> t;
12697
```

19.4.2 Coercion

As can be seen from the tables in Chapter 17, automatic coercion takes place between $\mathbf{Z}/m\mathbf{Z}$ and $\mathbf{Z}$ so that a binary operation like + applied to an element of $\mathbf{Z}/m\mathbf{Z}$ and an integer will result in a residue class from $\mathbf{Z}/m\mathbf{Z}$.

Using `!`, elements from a prime field $\mathbf{F}_p$ can be coerced into $\mathbf{Z}/p\mathbf{Z}$, and elements from $\mathbf{Z}/p\mathbf{Z}$ can be coerced into $\mathbf{F}_{p^r}$. Also, transitions between $\mathbf{Z}/m\mathbf{Z}$ and $\mathbf{Z}/n\mathbf{Z}$ can be made using `!` provided that m divides n or n divides m. In cases where there is a choice – such as when an element r from $\mathbf{Z}/m\mathbf{Z}$ is coerced into $\mathbf{Z}/n\mathbf{Z}$ with m dividing n – the result will be the residue class containing the representative for r.

Example H19E3

```
> r := ResidueClassRing(3) ! 5;
> r;
2
> ResidueClassRing(6) ! r;
2
```

So the representative 2 of 5 mod 3 is mapped to the residue class 2 mod 6, and not to 5 mod 6.

19.4.3 Elementary Invariants

`Characteristic(R)` `# R`

`Modulus(R)`

Given a residue class ring $R = \mathbf{Z}/m\mathbf{Z}$, this function returns the common modulus m for the elements of R.

`FactoredModulus(R)`

Given a residue class ring $R = \mathbf{Z}/m\mathbf{Z}$, this function returns the factorization of the common modulus m for the elements of R.

19.4.4 Structure Operations

`AdditiveGroup(R)`

Given $R = \mathbf{Z}/m\mathbf{Z}$, create the abelian group of integers modulo m under addition. This returns the finite additive abelian group A (of order m) together with a map from A to the ring $\mathbf{Z}/m\mathbf{Z}$, sending $A.1$ to 1.

`MultiplicativeGroup(R)`
`UnitGroup(R)`

Given $R = \mathbf{Z}/m\mathbf{Z}$, create the multiplicative group of R as an abelian group. This returns an (additive) abelian group A of order $\phi(m)$, together with a map from A to R.

`sub< R | n >`

Given R, the ring of integers modulo m or an ideal of it, and an element n of R create the ideal of R generated by n.

`Set(R)`

Create the enumerated set consisting of the elements of the residue class ring R.

`Category(R)` `Parent(R)` `PrimeRing(R)`
`Center(R)`

19.4.5 Ring Predicates and Booleans

IsCommutative(R) IsUnitary(R)
IsFinite(R) IsOrdered(R)
IsField(R) IsEuclideanDomain(R)
IsPID(R) IsUFD(R)
IsDivisionRing(R) IsEuclideanRing(R)
IsPrincipalIdealRing(R) IsDomain(R)
R eq R R ne R

19.4.6 Homomorphisms

Ring homomorphisms with domain $\mathbf{Z}/m\mathbf{Z}$ are completely determined by the image of 1. As usual (see Chapter 18), we require our homomorphisms to map 1 to 1. Therefore, the general homomorphism constructor with domain $\mathbf{Z}/m\mathbf{Z}$ needs no arguments.

hom< R -> S | >

Given a residue class ring R, and a ring S, create a homomorphism from R to S, determined by $f(1_R) = 1_S$. Note that it is the responsibility of the user that the map defines a homomorphism!

19.5 Elements of Residue Class Rings

19.5.1 Creation

elt< R | k >

Create the residue class containing the integer k in residue class ring R.

R ! k

Create the residue class containing k in the residue class ring R. Here k is allowed to be either an integer, or an element of the finite field $\mathbf{F}_p$ in the case $R = \mathbf{Z}/p\mathbf{Z}$, or an element of $S = \mathbf{Z}/n\mathbf{Z}$ for a multiple or divisor n of m (with $R = \mathbf{Z}/m\mathbf{Z}$).

One(R) Identity(R)
Zero(R) Representative(R)

These generic functions (cf. Chapter 17) create 1, 1, 0, and 0 respectively, in any $\mathbf{Z}/m\mathbf{Z}$.

Random(R)

Create a "random" residue class in R.

19.5.2 Arithmetic Operators

`+ n` `- n`

`m + n` `m - n` `m * n` `n ^ k` `m / n` `m div n`

`m +:= n` `m -:= n` `m *:= n` `m /:= n` `m ^:= k`

19.5.3 Equality and Membership

`m eq n` `m ne n`

`n in R` `n notin R`

19.5.4 Parent and Category

`Parent(n)` `Category(n)`

19.5.5 Predicates on Ring Elements

`IsZero(n)` `IsOne(n)` `IsMinusOne(n)`

`IsNilpotent(n)` `IsIdempotent(n)`

`IsUnit(n)` `IsZeroDivisor(n)` `IsRegular(n)`

`IsIrreducible(n)` `IsPrime(n)`

19.5.6 Solving Equations over $\mathbf{Z}/m\mathbf{Z}$

`Solution(a, b)`

Given elements a and b of $\mathbf{Z}/m\mathbf{Z}$, return a solution x to the linear congruence $a \cdot x = b \in \mathbf{Z}/m\mathbf{Z}$. An error is signalled if no solution exists.

`IsSquare(n)`

`Factorization` [<RngIntElt, RngIntElt>]

Given an element $n \in \mathbf{Z}/m\mathbf{Z}$ this function returns `true` if there exists $a \in \mathbf{Z}/m\mathbf{Z}$ such that $a^2 = n \in \mathbf{Z}/m\mathbf{Z}$, `false` otherwise. If n is a square, a square root a is also returned. If m is large and its prime factorization is known, the computation may be speeded up by assigning the factorization sequence for m to the optional argument `Factorization`.

`Sqrt(a)`

`SquareRoot(a)`

`Factorization` [<RngIntElt, RngIntElt>]

Given an element a of the ring $\mathbf{Z}/m\mathbf{Z}$, this function returns an element b of $\mathbf{Z}/m\mathbf{Z}$ such that $b^2 = a \in \mathbf{Z}/m\mathbf{Z}$, if such an element exists, and an error otherwise. If m is large and its prime factorization is known, the computation may be speeded up by assigning the factorization sequence for m to the optional argument `Factorization`.

`AllSquareRoots(a)`

`AllSqrts(a)`

`Factorization` [<RngIntElt, RngIntElt>]

Return a sequence containing all square roots of the element a in a residue class ring $\mathbf{Z}/m\mathbf{Z}$. If the modulus m is large and its prime factorization is known, the computation may be speeded up by assigning the factorization sequence for m to the optional argument `Factorization`.

Example H19E4

We construct the residue class ring having modulus 2340 and find all the square roots of 1404.

```
> R := ResidueClassRing(2340);
Residue class ring of integers modulo 2340
> x := R!1404;
> sqrts := AllSquareRoots(x);
> sqrts;
[ 78, 312, 468, 702, 858, 1092, 1248, 1482, 1638,
  1872, 2028, 2262 ]
> [ y^2 : y in sqrts ];
[ 1404, 1404, 1404, 1404, 1404, 1404, 1404, 1404,
  1404, 1404, 1404, 1404 ]
```

So 1404 has 12 square roots!

19.6 Ideal Operations

`ideal< R | a1, ..., ar >`

The ideal of the residue ring R generated by the greatest common divisor of the elements a_i and the modulus of R.

`GreatestCommonDivisor(a, b)`
`Gcd(a, b)`
`GCD(a, b)`

Greatest common divisor of the elements a and b of R, that is, a generator for the R-ideal $(a) + (b)$.

`GreatestCommonDivisor(Q)`
`Gcd(Q)`
`GCD(Q)`

Greatest common divisor of the sequence of elements Q, that is, a generator for the R-ideal generated by the elements in Q.

`LeastCommonMultiple(a, b)`
`Lcm(a, b)`
`LCM(a, b)`

Least common multiple of the elements a and b of R, that is, a generator for the R-ideal $(a) \cap (b)$.

`LeastCommonMultiple(Q)`
`Lcm(Q)`
`LCM(Q)`

Least common multiple of the sequence of elements Q, that is, a generator for the R-ideal formed by the intersection of the principal ideals generated by elements of Q.

`I + J` `I * J` `I meet J`
`a in I` `a notin I`
`I eq J` `I ne J`
`I subset J` `I notsubset J`

19.7 The Unit Group

`UnitGroup(R)`

Given $R = \mathbf{Z}/m\mathbf{Z}$, construct the unit group of R as an abelian group. This returns an (additive) abelian group A of order $\phi(m)$, together with a map from A to R.

`IsPrimitive(n)`

Returns `true` if the element $n \in \mathbf{Z}/m\mathbf{Z}$ is primitive, that is, if it generates the multiplicative group of $\mathbf{Z}/m\mathbf{Z}$, `false` otherwise.

`PrimitiveElement(R)`

`PrimitiveRoot(R)`

Given $R = \mathbf{Z}/m\mathbf{Z}$, this function returns a generator for the group of units of R if this group is cyclic, and returns 0 otherwise. Thus a valid generator is only returned if $m = 2, 4, p^t$ or $2p^t$, with p an odd prime and $t \geq 1$.

`Order(a)`

Given an element a belonging to $\mathbf{Z}/m\mathbf{Z}$, return the multiplicative order $k \geq 1$ of a if a is in the unit group $(\mathbf{Z}/m\mathbf{Z})^*$, and zero if a is not a unit.

`Normalize(x)`

`Normalise(x)`

Given an element $x \in R = \mathbf{Z}/m\mathbf{Z}$, this function returns the unique canonical associate $y \in R$ of x and a unit $u \in R$ such that $u \cdot x = y$. The canonical associate of x is the GCD of x and m, considered as natural integers (unless x is 0, in which case it is 0).

Example H19E5

We determine the unit group of the ring with modulus 735 and then verify its order by comparing it with $\phi(m)$.

```
> m := 735;
> R := ResidueClassRing(m);
Residue class ring of integers modulo 735
> U, psi := UnitGroup(R);
> U;
Abelian Group isomorphic to Z/2 + Z/2 + Z/84
Defined on 3 generators
Relations:
    2*U.1 = 0
    4*U.2 = 0
    42*U.3 = 0
> #U;
336
> EulerPhi(735);
```

```
336
```

So the order of U is equal to $\phi(m)$ as it should be. Finally, we look for three elements of R that generate the unit group.

```
> gens := [ psi(U.i) : i in [1..3] ]; gens;
> [ Order(x) : x in gens ];
[ 2, 4, 42 ]
```

Example H19E6

We construct a residue class ring $R = \mathbf{Z}/m\mathbf{Z}$ having cyclic unit group. By a theorem of Gauss, the ring R has cyclic unit group precisely when $n = 4, n = p^e$, or $n = 2p^e$, and p is an odd prime.

```
> R := IntegerRing(50);
> U, psi := UnitGroup(R);
Abelian Group isomorphic to Z/20
Defined on 1 generator
Relations:
    20*U.1 = 0
> w := PrimitiveElement(R);
> w;
3
> Order(w);
20
```

We verify that the powers of w are precisely the elements of the unit group U.

```
> powers := { w^i : i in [0..19] };
> powers;
{ 29, 1, 31, 3, 33, 7, 37, 9, 39, 11, 41, 13, 43, 17, 47, 19, 49, 21, 23, 27 }
> powers eq { psi(u) : u in U };
true
```

19.8 Dirichlet Characters

Let R be a ring. Then a *Dirichlet character over R of modulus N* is a homomorphism

$$\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to R^*,$$

where R^* is the group of invertible elements of R. We extend ε to a set theoretic map on the whole of $\mathbf{Z}$ by defining $\varepsilon(x) = 0$ if $\gcd(x, N) \neq 1$. The *conductor* of ε is the smallest positive integer M such that the homomorphism $(\mathbf{Z}/N\mathbf{Z})^* \to R^*$ factors through $(\mathbf{Z}/M\mathbf{Z})^*$ via the natural map $(\mathbf{Z}/N\mathbf{Z})^* \to (\mathbf{Z}/M\mathbf{Z})^*$.

19.8.1 Creation

`DirichletGroup(N)`

The group of Dirichlet characters modulo N with image in `RationalField()`. Note that this is a group of exponent at most 2.

`DirichletGroup(N,R)`

The group of Dirichlet characters modulo N with image in the ring R. Here R can be the integers, rationals, a number field or a finite field.

`DirichletGroup(N,R,z,r)`

The group of Dirichlet characters mod N with image in the order-r cyclic subgroup of the ring R generated by the root of unity z. Here z must be an element of R of exact order r.

`FullDirichletGroup(N)`

The group of Dirichlet characters modulo N taking values in the mth cyclotomic field, where m is the exponent of the unit group modulo N. (This is a shortcut for the previous command.)

`BaseExtend(G, R)`
`BaseExtend(G, R, z)`

The group of Dirichlet characters corresponding to G with values in the ring R. In the second form, the distinguished root of unity of the base ring of G is identified with the given element z.

`AssignNames(~G, S)`

Assign names to the generators of the Dirichlet group G.

19.8.2 Element Creation

`Elements(G)`

A sequence containing all Dirichlet characters in the Dirichlet group G.

`Random(G)`

A random element of the Dirichlet group G.

`G . i`

The ith generator of the group G.

`G ! x`

This coerces the given element x into the Dirichlet group G. Here x may be a Dirichlet character belonging to a different group, or a sequence of integers specifying an element of the `AbelianGroup` of G.

`KroneckerCharacter(D)`

`KroneckerCharacter(D, R)`

The Kronecker character $n \mapsto (d/n)$, where d is the fundamental discriminant associated to the integer D.

When a ring R is given, this is returned as a character with values in R.

19.8.3 Properties of Dirichlet Groups

`BaseRing(G)`

The ring in which characters in G take values.

`Modulus(G)`

The integer N such that G is a group of Dirichlet characters on $\mathbf{Z}/N$.

`Order(G)`

The order of the Dirichlet group G.

`Exponent(G)`

The exponent of the Dirichlet group G.

`AbelianGroup(G)`

This returns a finite abelian group isomorphic to the given group G of Dirichlet characters (as an abstract group), and secondly returns a map from the abstract group to G.

It is necessary to use this function in order to make group theoretic constructions involving G.

`NumberOfGenerators(G)`

The number of generators of the Dirichlet group G.

`Generators(G)`

A sequence containing generators for the Dirichlet group G.

`G . i`

The ith generator of the group G.

`UnitGenerators(G)`

This returns an ordered sequence of integers that reduce to "canonical" generators of the unit group of Z/N, where N is the modulus of G.

19.8.4 Properties of Elements

`BaseRing(chi)`

The ring in which the Dirichlet character χ takes values.

`Modulus(chi)`

The modulus of the group of Dirichlet characters that contains χ.

`Conductor(chi)`

The minimal conductor of the Dirichlet character χ. (That is, the smallest integer M such that `chi` is well-defined on the unit group of Z/M.)

`ElementToSequence(chi)`

A sequence of integers specifying the Dirichlet character χ (in terms of generators of the group containing χ).

`x eq y`

Return `true` iff the given characters have the same modulus and values.

`Order(chi)`

The order of the given element χ in a group of Dirichlet characters.

`IsTrivial(chi)`

Returns `true` if and only if the Dirichlet character χ has order 1.

`IsPrimitive(chi)`

Returns `true` iff the Dirichlet character χ is primitive (equivalently, if its conductor equals its modulus).

`AssociatedPrimitiveCharacter(chi)`

The primitive character modulo the conductor of χ which takes the same values (on units) as χ.

`IsEven(chi)`

Returns `true` if and only if `Evaluate(chi,-1)` is equal to 1. Note that in characteristic 0, the space of modular forms of weight k and character χ is zero if χ is even and k is odd.

`IsOdd(chi)`

Returns `true` if and only if `Evaluate(chi,-1)` is equal to -1. Note that in characteristic 0, the space of modular forms of weight k and character χ is zero if χ is odd and k is even.

`IsTotallyEven(chi)`

For a Dirichlet character χ, this is `true` if and only if every character in the `Decomposition` of χ (into prime power components) is even.

`Decomposition(chi)`

This decomposes the Dirichlet character χ as a product of characters with prime power moduli. The function returns a list (not a sequence) containing these characters (which do not belong to the same group).

`GaloisConjugacyRepresentatives(G)`

`GaloisConjugacyRepresentatives(seq)`

This returns a sequence containing one representative from each Galois conjugacy class (over $\mathbf{Q}$) of characters corresponding to a character in the given group or the given sequence.

`MinimalBaseRingCharacter(chi)`

The returns a character which is the same as χ, except which takes values in the smallest possible subring of the base ring of χ.

19.8.5 Evaluation

`Evaluate(chi,n)`

`chi(n)`

The value of the Dirichlet character χ at the integer n.

`ValueList(chi)`

A sequence containing the values $[\chi(1), .., \chi(N)]$ of the given character χ, where N is the modulus of χ.

The list of values is stored; then in later calls to `Evaluate`, the stored value is returned.

`ValuesOnUnitGenerators(chi)`

A sequence containing the values of χ on the ordered sequence of elements of $\mathbf{Z}/m$ given by `UnitGenerators(Parent(chi))`, where m is the modulus of χ.

`OrderOfRootOfUnity(r, n)`

Given an element r of some ring which is *assumed* to satisfy $r^n = 1$, this returns the smallest integer m such that $r^m = 1$.

(This provides a convenient way to calculate the order of values of non-real characters.)

19.8.6 Arithmetic

`x * y`

`x / y`

The product or quotient (respectively) of the Dirichlet characters x and y. This is a Dirichlet character of modulus equal to the least common multiple of the moduli of x and y. The base rings and chosen roots of unity of the parents of x and y are equal.

`x ^ n`

The Dirichlet character x raised to the power of n, where n is any integer.

`x ^ phi`

The image of the Dirichlet character x under the automorphism ϕ.

`Sqrt(x)`

Given a Dirichlet character x of odd order, this returns a square root of x (in the same group).

19.8.7 Example

Example H19E7

We begin by constructing the group of characters $(\mathbf{Z}/5\mathbf{Z})^* \to \mathbf{Q}^*$.

```
> G<a> := DirichletGroup(5);  G;  // The default base field is Q.
Group of Dirichlet characters of modulus 5 over Rational Field
> #G;
2
> [Evaluate(a, n) : n in [1..5]];
[ 1, -1, -1, 1, 0 ]
> Eltseq(a);
[ 2 ]
> a eq G![2];
true
> IsEven(a);
true
> IsOdd(a);
false
> IsTrivial(a);
false
```

Next we create a character by building it up "locally".

```
> G1<a4> := DirichletGroup(4);
> Conductor(a4);
4
> G2<a5> := DirichletGroup(25);
```

```
> Conductor(a5);
5
> eps := a4*a5;
> Modulus(eps);
100
> Conductor(eps);
20
> Evaluate(eps,7) eq Evaluate(a4,7)*Evaluate(a5,7);
true
```

Characters can be constructed over various fields.

```
> G<a> := DirichletGroup(7,GF(7));
> #G;
6
> Evaluate(a,2);
2
>
> G<a3,a5> := DirichletGroup(15,CyclotomicField(EulerPhi(15)));
> G;
Group of Dirichlet characters of modulus 15 over Cyclotomic Field of
order 8 and degree 4
> #G;
8
> Conductor(a3);
3
> Conductor(a5);
5
> Order(a5);
4
> Evaluate(a5,2);
zeta_8^2
```

If D is a fundamental discriminant, then `KroneckerCharacter(D)` is the quadratic Dirichlet character corresponding to the quadratic field $\mathbf{Q}(\sqrt{D})$. The following code verifies that `KroneckerCharacter` and `KroneckerSymbol` agree in the case $D = 209$.

```
> chi := KroneckerCharacter(209);
> for n in [1..209] do
>    assert Evaluate(chi,n) eq KroneckerSymbol(209,n);
> end for;
```

If E is an elliptic curve with newform f_E, then the twist E_D corresponds to f_E twisted by this character, as illustrated below.

```
> E := EllipticCurve(CremonaDatabase(),"11A");
> f := qEigenform(E,8); f;
q - 2*q^2 - q^3 + 2*q^4 + q^5 + 2*q^6 - 2*q^7 + O(q^8)
> chi := KroneckerCharacter(-7);
> qEigenform(QuadraticTwist(E,-7),8);
q - 2*q^2 + q^3 + 2*q^4 - q^5 - 2*q^6 + O(q^8)
```

```
> R<q> := Parent(f);
> &+[Evaluate(chi,n)*Coefficient(f,n)*q^n : n in [1..7]] + O(q^8);
q - 2*q^2 + q^3 + 2*q^4 - q^5 - 2*q^6 + O(q^8)
```

---

20 RATIONAL FIELD

Chapter 20
RATIONAL FIELD

20.1 Introduction

This Chapter describes functions relating to the field of rational numbers **Q**. Note that most functions for rational integers can be found in Chapter 18.

The rational field **Q** is automatically created when Magma is started up. That means that in **Q**, unlike most other structures, arithmetic can be done without the need to create the structure explicitly first. The same is true for the ring of integers.

In order to be compatible with the other rings and fields, `Q.1` will return 1.

20.1.1 Representation

Rational numbers are stored as pairs of numerator and denominator. Whenever a rational number is created, it will be put in reduced form (coprime numerator and denominator, positive denominator). It is well possible that a rational number has denominator 1, and thus represents a rational integer; in such cases it will however never automatically be converted into an integer (that is, its type will not be changed).

20.1.2 Coercion

The tables in Chapter 17 describe which coercions of rational numbers are allowed, and which will take place automatically when necessary. As a general rule, automatic coercion occurs between elements of **Q** and elements of any ring R of characteristic 0. That means, for example, that addition of any rational number and an element r of such ring can be performed without the need to coerce the elements first; the result will be in the larger of **Q** and R (usually R, unless R is a subring of **Q** such as **Z**). The most important exceptions to the above rule are those cases where the result would lie in a structure strictly larger than both **Q** and R. Examples of this are $R = \mathbf{Z}[x]$, and the result would generally be in $\mathbf{Q}(x)$, and $R = O_K$, an order in a number field (and the result could be in K).

Example H20E1

We give three examples of successful automatic coercion, and one where it does not work. Note that in the third case the result, although being integral, is still in the rational field.

```
> 1/2 + elt< CyclotomicField(3) | 1,2>;
1/2*(4*zeta_3 + 3)
> 1/2 - 0.12345;
0.37655
> 1/2 * 2;
1
> Parent(1/2 * 2);
```

```
Rational Field
>  R<x> := PolynomialRing(Integers());
>  // The following produces an error:
>  1/2 + x;
>> 1/2 + x;
       ^
Runtime error in '+': Bad argument types
```

20.1.3 Homomorphisms

Since homomorphisms are generally only allowed to be unitary, the specification of ring homomorphisms from $Q = \mathbf{Q}$ to a ring R is particularly simple: the image is completely determined by the image of 1, which we require to be 1 in R, so

```
hom< Q -> R | >
```

suffices.

Note that MAGMA allows the user to define maps with `hom` that are not proper homomorphisms; this is sometimes useful, as the example below shows.

Example H20E2

Suppose we wish to coerce rational numbers with denominator not divisible by 11 into the ring $\mathbf{Z}/11\mathbf{Z}$ in the obvious way by sending r/s to rs^{-1} mod 11. The coercion rules do not allow you to do so using `!`, but a simple 'homomorphism' will work.

```
> Z11 := Integers(11);
> Q := RationalField();
> h := hom< Q -> Z11 | >;
> h(1/2);
6
```

20.2 Creation Functions

20.2.1 Creation of Structures

The rational field **Q** is automatically created when MAGMA is started up. Nevertheless, it may be necessary to formally create the rational field, for instance if it is to be used as the coefficient ring for a polynomial ring. There is a unique rational field structure in MAGMA, that is, multiple calls to the creation function `RationalField()` will return the same object (and not an isomorphic copy), so no memory will be wasted.

`Rationals()`

`RationalField()`

Create the field **Q** of rational numbers.

`MaximalOrder(Q)`

`IntegerRing(Q)`

`IntegerRing()`

`Integers()`

`RingOfIntegers(Q)`

Create the field **Z** of rational integers.

`FieldOfFractions(Z)`

The function `FieldOfFractions` returns the field **Q** when R is either the ring **Z** of rational integers, or the field **Q** itself.

`Completion(Q, P)`

`Precision` RNGINTELT *Default :* ∞

Computes the completion of `Q` at the integral prime ideal `P` together with the injection into the completion.

The parameter `Precision` may be used to specify a particular precision.

20.2.2 Creation of Elements

Unlike elements of other structures, rational numbers and integers can be created as literals without the need to define the parent field **Q** or the parent ring **Z** first, since these structures are loaded whenever MAGMA is started up.

`a / b`

Given integers a and $b \neq 0$, form the rational number a/b (in reduced form). Of course a and be are allowed to be given as expressions defining integers.

`Q ! [a]`

The inverse function to `Eltseq`, returns `Q!a`.

```
Q ! [a, b]
```
```
elt< Q | a, b >
```

Given the rational field **Q**, and integers a, b (with $b \neq 0$), construct the rational number a/b, in reduced form.

```
Q ! a
```

Given the rational field **Q**, and an integer a, create the rational number $a = a/1$ in **Q**. Also, any element from a quadratic, cyclotomic or number field (or an order of such) that is rational can be coerced into the rational field this way.

```
One(Q)
```
```
Identity(Q)
```
```
Zero(Q)
```
```
Representative(Q)
```

These generic functions (cf. Chapter 17) create 1, 1, 0, and 0 respectively, in the rational field **Q**.

```
RootOfUnity(n, Q)
```

This function returns, in general, for a positive integer n and a cyclotomic field Q a primitive n-th root of unity in Q; if Q is the rational field, n must be 1 or 2, and the result will be 1 or -1 in Q accordingly.

```
Random(Q, m)
```

This function returns a random rational number with random numerator in $[-u..u]$ and random denominator in $[1..u]$, where u is the absolute value of m.

20.3 Structure Operations

20.3.1 Related Structures

```
Category(Q)
```
```
Parent(Q)
```
```
PrimeField(Q)
```
```
IntegralBasis(Q)
```

An integral basis for Q as a number field as a sequence of elements of Q (giving the sequence containing 1 for the rational field).

```
MinimalField(q)
```

Return the least cyclotomic field containing the cyclotomic field element q; if q is rational this returns the rational field.

`MinimalField(S)`

Returns the minimal cyclotomic field containing the cyclotomic field elements in the enumerated set S; this will return the rational field if all elements of S are rational numbers.

`BaseField(Q)`

In analogy to the number fields, returns the coefficient field of Q which will be $\mathbf{Q}$.

`Basis(Q)`

`AbsoluteBasis(Q)`

A basis for Q as a $\mathbf{Q}$-vector space, i.e. [1].

`UnitGroup(Q)`

The unit group of the maximal order of $\mathbf{Q}$ (i.e. of $\mathbf{Z}$).

`ClassGroup(Q)`

The class group of the ring of integers $\mathbf{Z}$ of $\mathbf{Q}$ (which is trivial).

`AutomorphismGroup(Q)`

`AutomorphismGroup(Q, Q)`

The group of $\mathbf{Q}$ automorphisms of $\mathbf{Q}$, ie. a trivial finitely presented group, the parent structure for $\mathbf{Q}$-automorphisms and a map from the group to actual field automorphisms. In this case, of course the only $\mathbf{Q}$-automorphism will be the identity.

`Algebra(Q, Q)`

The field of the rational number form canonically an algebra. This function returns an associative $\mathbf{Q}$-algebra isomorphic to $\mathbf{Q}$ and the map from the algebra to $\mathbf{Q}$.

`VectorSpace(Q, Q)`

The field of the rational number form canonically a vector space. This function returns a $\mathbf{Q}$-vector space isomorphic to $\mathbf{Q}$ and the map from the vector space to $\mathbf{Q}$.

`Decomposition(Q, p)`

For a prime p or for the "infinite prime" `Infinity()` compute the decomposition in $\mathbf{Q}$ as a number field. This returns a list of length one containing a 2-tuple describing the splitting behaviour: the first component contains p and the second it's ramification degree, ie. 1.

20.3.2 Numerical Invariants

The functions below are defined for the rational field **Q** mainly because it often arises as a degenerate case of quadratic or cyclotomic field constructions. See the corresponding Chapters 35 and 36 for more.

`Characteristic(Q)`

`Conductor(Q)`

The smallest positive integer n such that Q is contained in the cyclotomic field $\mathbf{Q}(\zeta_n)$. For the rational field this is 1.

`Degree(Q)`
`AbsoluteDegree(Q)`

The degree of Q as a number field (which is 1 for the rational field).

`Discriminant(Q)`
`AbsoluteDiscriminant(Q)`

The field discriminant of Q (which is 1 for the rational field).

`DefiningPolynomial(Q)`

An irreducible polynomial over **Q** a root of which generates Q as a number field (for the rational field this returns the linear polynomial $x - 1$).

`Signature(Q)`

The signature (number of real embeddings and pairs of complex embeddings) of **Q**.

20.3.3 Ring Predicates and Booleans

`IsCommutative(Q)` `IsUnitary(Q)`
`IsFinite(Q)` `IsOrdered(Q)`
`IsField(Q)` `IsEuclideanDomain(Q)`
`IsPID(Q)` `IsUFD(Q)`
`IsDivisionRing(Q)` `IsEuclideanRing(Q)`
`IsPrincipalIdealRing(Q)` `IsDomain(Q)`
`Q eq R` `Q ne R`

20.4 Element Operations

A variety of different types of operations are provided for rational elements including arithmetic operations, comparison and predicates and converting to a sequence.

20.4.1 Parent and Category

`Parent(r)` `Category(r)`

20.4.2 Arithmetic Operators

`+ a` `- a`

`a + b` `a - b` `a * b` `a ^ k` `a / b`

`a +:= b` `a -:= b` `a *:= b` `a /:= b` `a ^:= k`

20.4.3 Numerator and Denominator

`Numerator(q)`

The (integer) numerator of the rational number q in reduced form.

`Denominator(q)`

The (integer) denominator of the rational number q in reduced form. This will always be a positive integer.

Example H20E3

Rational numbers are always immediately put in reduced form, that is, the greatest common divisor of numerator and denominator is taken out, and the denominator will be positive.

```
> Numerator(10/-4);
-5
> Denominator(10/-4);
2
```

20.4.4 Equality and Membership

`a eq b` `a ne b`

`a in R` `a notin R`

20.4.5 Predicates on Ring Elements

`IsIntegral(q)`

Returns `true` if the rational number q is an element of the ring of integers, `false` otherwise.

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`

`IsNilpotent(a)` `IsIdempotent(a)`

`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`

`IsIrreducible(a)` `IsPrime(a)`

20.4.6 Comparison

`a gt b` `a ge b` `a lt b` `a le b`

`Maximum(a, b)` `Maximum(Q)`

`Minimum(a, b)` `Minimum(Q)`

20.4.7 Conjugates, Norm and Trace

`ComplexConjugate(q)`

The complex conjugate of q, which will be the rational number q itself.

`Conjugate(q)`

The conjugate of q, which will be the rational number q itself.

`Norm(q)`

`Norm(q)`

The norm (in $\mathbf{Q}$) of q, which will be the rational number q itself.

`Trace(q)`

The trace (in $\mathbf{Q}$) of q, which will be the rational number q itself.

`MinimalPolynomial(q)`

Returns the minimal polynomial of the rational number q, which is the monic linear polynomial with constant coefficient q in a univariate polynomial ring R over the rational field. (If R has not been created before with a name for its indeterminate, `$.1-q` will be returned.)

20.4.8 Absolute Value and Sign

`AbsoluteValue(q)`

`Abs(q)`

The absolute value $|q|$ of a rational number q.

`Sign(q)`

Returns the sign of the rational number q, which is one of the integers -1, 0, 1, corresponding to the cases $q < 0$, $q = 0$, and $q > 0$.

`Height(q)`

The height of $q = r/s$. For r and s coprime, the height is defined as the maximum of the absolute value of r and s.

20.4.9 Rounding and Truncating

`Ceiling(q)`

The ceiling of the rational number q, that is, the least integer greater than or equal to q.

`Floor(q)`

The floor of the rational number q, that is, the largest integer less than or equal to q.

`Round(q)`

This function returns the integer value of the rational number q rounded to the nearest integer. In the case of a tie, rounding is done away from zero (that is, $i + \frac{1}{2}$ is rounded to $i + 1$, for non-negative integers i and $i - \frac{1}{2}$ is rounded to $i - 1$, for non-positive integers i).

`Truncate(q)`

This function returns the integer truncation of the rational number q, that is the integral part of q. Thus the effect is that of rounding towards 0.

`Qround(q, M)`

`ContFrac` BoolElt *Default :* `false`

Finds an rational approximation d of q such that the denominator of d is bounded by M. If `ContFrac` is given then an optimal approximation is computed using the continued fraction process. By default d is obtained by some rounding procedure which is faster but gives worse results.

20.4.10 Rational Reconstruction

Under certain circumstances it is useful to have a partial inverse of the function $\psi_m : \mathbf{Q} \to \mathbf{Z}/m\mathbf{Z}$ of taking residues modulo m (where the obvious value of ψ_m is only defined for rational numbers with denominator in smallest terms coprime to m); the partial inverse of the function is sometimes referred to as 'rational reconstruction'. For $s \in \mathbf{Z}/m\mathbf{Z}$ the value of $\psi^{-1}(s)$ is the rational number r for which $\psi_m(r) = s$ and, in addition, the absolute values of both the numerator and denominator of r are at most $\sqrt{m/2}$; such r does not always exist, but if r exists it is unique.

`RationalReconstruction(s)`

Given an element s of a ring S of m elements, return a Boolean flag indicating whether or not a rational number r exists such that for the representation $r = n/d$ in minimal terms it holds that $n \cdot d^{-1} \equiv s \bmod m$, $|n| \leq \sqrt{m/2}$ and $0 < d \leq \sqrt{m/2}$. If the flag is true, the element r is also returned. The ring S is allowed to be a residue class ring `Integers(m)` or a finite field of prime cardinality $p = m$: `FiniteField(p)`.

In addition, s is allowed to be a matrix over a prime finite field, in which case the existence (and, if possible, value) of a rational reconstruction of the matrix is determined.

20.4.11 Valuation

`Valuation(x, p)`

`Valuation(x, I)`

The valuation v of the rational number x at the prime p (the prime ideal I). This is the difference of the valuations of the numerator and denominator of x. The optional second return value is the rational u such that $x = p^v u$.

20.4.12 Sequence Conversions

`ElementToSequence(a)`

`Eltseq(a)`

The sequence $[a]$ for compatibility with the other field types.

21 FINITE FIELDS

Chapter 21
FINITE FIELDS

21.1 Introduction

MAGMA provides a powerful environment for computing with lattices of finite fields. Complete freedom in the manner in which fields are constructed is allowed, while assuring compatibility. Finite fields of various kinds are supported, with optimized representations for each kind. For a detailed description of how finite fields are presented in MAGMA, see [BCS97].

21.1.1 Representation of Finite Fields

In MAGMA, arithmetic in small non-prime finite fields is carried out using tables of Zech logarithms. While this ensures that finite field arithmetic is fast, its use is limited to finite fields of small cardinality.

Larger finite fields are internally represented as polynomial rings over a small finite field. It is possible for the user to specify his own irreducible polynomial (although internally an alternative representation may well be used).

Although two finite fields of the same cardinality are isomorphic, in practical applications it is often important to be guaranteed to work in a field defined by a specific polynomial. Moreover, in passing between fields and subfields, choices regarding the embeddings have to be made, so that these embeddings are *compatible* (so that 'diagrams commute'). The scheme implemented in MAGMA and described in [BCS97] ensures that this is so.

21.1.2 Conway Polynomials

To avoid ambiguities when talking about (small) finite fields, *Conway polynomials* have been defined and calculated by R. Parker. The Conway polynomial $C_{p,n}$ is the lexicographically first monic irreducible, primitive polynomial of degree n over $\mathbf{F}_p$ with the property that it is consistent with all $C_{p,m}$ for m dividing n. Consistency of $C_{p,n}$ and $C_{p,m}$ for m dividing n means that for a root α of $C_{p,n}$ it holds that $\beta = \alpha^{\frac{p^n-1}{p^m-1}}$ is a root of $C_{p,m}$. Lexicographically first is with respect to the system of representatives $-\frac{p-1}{2}, \ldots, -1, 0, 1, \ldots, \frac{p-1}{2}$ for the residue classes modulo p, ordered via $0 < -1 < 1 < -2 < \cdots \frac{p-1}{2}$ (and we only need to compare polynomials of the same degree).

To compute the Conway polynomial $C_{p,n}$ one needs to know all Conway polynomials $C_{p,m}$ for m dividing n, and as far as we know, no essentially better method is known than enumerating and testing the primitive polynomials of degree n in lexicographical order.

Conway polynomials are used in MAGMA by default for the construction of $\mathbf{F}_{p^n}$ using `FiniteField(p, n)` or its synonyms, whenever the Conway polynomial is available. However, it must be stressed that Conway polynomials are **only** used in MAGMA to provide

standard defining polynomials for $\mathbf{F}_{p^n}$ – the special properties of Conway polynomials are never used because they are totally irrelevant in the scheme implemented in MAGMA!

21.1.3 Ground Field and Relationships

Throughout this Chapter we will use the notions of *ground field* and *prime field* in the following way. The prime field of a finite field F is the unique field of cardinality p, the characteristic of F. Here we mean unique not just in the mathematical sense, but in the sense that all prime fields of the same cardinality are identical in MAGMA, and their elements are denoted $0, 1, \ldots, p-1$. The ground field of F is the field over which F is created as an extension. If F was not explicitly created as an extension of a finite field E by using `ext`, its ground field will be the prime field. Printing in MAGMA always takes place with respect to the ground field, that is, elements of F are expressed as polynomials in the generator `F.1` of the field with coefficients in the ground field; there is one exception to this rule: if the field F is small enough to be represented by means of Zech logarithms, the printing of elements is in the form of powers of the primitive element (see the option on `AssertAttribute` below for ways of changing that).

It should be kept in mind that finite fields may be related mathematically without MAGMA being aware of the relation between them. This happens for example when two fields of dividing degrees are created as *extensions* of one field; although an isomorphic image of the smaller field will be contained in the larger, MAGMA will not establish this relation (unless the user explicitly asks for it, using the `Embed` function). However, all `subfields` of one common overfield in MAGMA will have their inclusion relations set up automatically.

21.2 Creation Functions

Since V2.13, a database of low-term irreducible polynomials over $\mathbf{F}_2$ is available for all degrees up to 90000 (see the function `IrreducibleLowTermGF2Polynomial` below). Thus one can create the finite field $\mathbf{F}_{2^k}$ for k within this range and compute within the field without any delay in the creation. Advantage is also taken of the special form of the defining polynomial.

Previous to V2.11, sparse trinomial/pentanomial irreducible polynomials (see the function `IrreducibleSparseGF2Polynomial`) were used by default for constructing $GF(2^k)$ when k is beyond the Conway range. To enable compatibility with older versions, one may select these sparse polynomials with the parameter `Sparse` in the creation functions.

21.2.1 Creation of Structures

`FiniteField(q)`

`GaloisField(q)`

`GF(q)`

`Optimize` BOOLELT *Default :* `true`

Sparse BoolElt *Default :* `false`

Given $q = p^n$, where p is a prime, create the finite field $\mathbf{F}_q$. If p is very big, it is advised to use the form `FiniteField(p, n)` described below instead, because Magma will first attempt to factor q completely.

The primitive polynomial used to construct $\mathbf{F}_q$ when $n > 1$ will be a Conway polynomial, if it is available. If the parameter `Optimize` is `false`, then no optimized representation (i.e., by using Zech logarithm tables or internal multi-step extensions) will be constructed for the new field which means that the time to create the field will be trivial but arithmetic operations in the field may be slower – this is useful if say one wishes to just compute a few trivial operations on a few elements of the field alone.

If $q = 2^k$ and k is beyond the Conway range, then a low-term irreducible is used (see `IrreducibleLowTermGF2Polynomial` below). Setting the parameter `Sparse` to `true` will cause a sparse polynomial to be used instead if possible (see `IrreducibleSparseGF2Polynomial` below).

`FiniteField(p, n)`

`GaloisField(p, n)`

`GF(p, n)`

Check BoolElt *Default :* `true`

Optimize BoolElt *Default :* `true`

Sparse BoolElt *Default :* `false`

Given a prime p and an exponent $n \geq 1$, create the finite field $\mathbf{F}_{p^n}$. The primitive polynomial used to construct $\mathbf{F}_q$ when $n > 1$ will be a Conway polynomial, if it is available.

By default p is checked to be a strong pseudoprime for 20 random bases b with $1 < b < p$; if the parameter `Check` is `false`, then no check is done on p at all (this is useful when p is very large and one does not wish to perform an expensive primality test on p).

The parameters are as above.

`ext< F | n >`

Optimize BoolElt *Default :* `true`

Sparse BoolElt *Default :* `false`

Given a finite field F and a positive integer n, create an extension G of degree n of F, as well as the embedding map $\phi : F \to G$. The parameter `Optimize` has the same behaviour as that for the `FiniteField` function. If F is a default field, then G will also be a default field (so its ground field will be the prime field). Otherwise, the ground field of G will be F.

The parameters are as above.

`ext< F | P >`

`Optimize` BoolElt *Default :* `true`

Given a finite field F and a polynomial P of degree n over F, create an extension $G = F[\alpha]$ of degree n of F, as well as the natural embedding map $\phi : F \to G$; the polynomial P must be irreducible over F, and α is one of its roots. Thus the defining polynomial of G over F will be P. The parameter `Optimize` has the same behaviour as that for the `FiniteField` function. The ground field of G will be F.

The parameter is as above.

`ExtensionField< F, x | P >`

Given a finite field F, a literal identifier x, and a polynomial P of degree n over F presented as a (polynomial) expression in x, create an extension $G = F[x]$ of degree n of F, as well as the natural embedding map $\phi : F \to G$; the polynomial P must be irreducible over F, and x is one of its roots. Thus the defining polynomial of G over F will be P. The parameter `Optimize` has the same behaviour as in the `FiniteField` function.

`RandomExtension(F, n)`

Given a finite field F and a degree n, return the extension of F by a random degree-n irreducible polynomial over F.

`SplittingField(P)`

Given a univariate polynomial P over a finite field F, create the minimal splitting field of P, that is, the smallest-degree extension field G of F such that P factors completely into linear factors over G.

`SplittingField(S)`

Given a set S of univariate polynomials each over a finite field F, create the minimal splitting field of S, that is, the smallest-degree extension field G of F such that for every polynomial P of S, P factors completely into linear factors over G.

`sub< F | d >`

`Optimize` BoolElt *Default :* `true`

`Sparse` BoolElt *Default :* `false`

Given a finite field F of cardinality p^n and a positive divisor d of n, create a subfield E of F of degree d, as well as the embedding map $\phi : E \to F$.

The parameters are as above.

`sub< F | f >`

`Optimize`	BoolElt	*Default :* `true`
`Sparse`	BoolElt	*Default :* `false`

Given a finite field F and an element f of F, create the subfield E of F generated by f, together with the embedding map $\phi : E \to F$. The map and field are constructed so that $\phi(w) = f$, where w is the generator of E (that is, `E.1`).

The parameters are as above.

`GroundField(F)`

`BaseField(F)`

Given a finite field F, return its ground field. If F was constructed as an extension of the field E, this function returns E; if F was not explicitly constructed as an extension then the prime field is returned.

`PrimeField(F)`

The subfield of F of prime cardinality.

`IsPrimeField(F)`

Returns whether field F is a prime field.

`F meet G`

Given finite fields F and G of the same characteristic p, return the finite field that forms the intersection $F \cap G$.

`CommonOverfield(K, L)`

Given finite fields K and L, both of characteristic p, return the smallest field which contains both of them.

Example H21E1

To define the field of 7 elements, use

```
> F7 := FiniteField(7);
```

We can define the field of 7^4 elements in several different ways. We can use the Conway polynomial:

```
> F<z> := FiniteField(7^4);
> F;
Finite field of size 7^4
```

We can define it as an extension of the field of 7 elements, using the internal polynomial:

```
> F<z> := ext< F7 | 4 >;
> F;
Finite field of size 7^4
```

We can supply our own polynomial, say $x^4 + 4x^3 + 2x + 3$:

```
> P<x> := PolynomialRing(F7);
```

```
> p := x^4+4*x^3+2*x+3;
> F<z> := ext< F7 | p >;
> F;
Finite field of size 7^4
```

We can define it as an extension of the field of 7^2 elements:

```
> F49<w> := ext< F7 | 2 >;
> F<z> := ext< F49 | 2 >;
> F;
Finite field of size 7^4
```

21.2.2 Creating Relations

`Embed(E, F)`

Given finite fields E and F of cardinality p^d and p^n, such that d divides n, assert the embedding relation between E and F. That is, an isomorphism between E and the subfield of F of cardinality p^d is chosen and set up, and can be used from then on to move between the fields E and F. See [BCS97] for details as to how this is done. If both E and F have been defined with Conway polynomials then the isomorphism will be such that the generator β of F is mapped to $\alpha^{\frac{p^n-1}{p^d-1}}$, where α is the generator of F.

`Embed(E, F, x)`

Given finite fields E and F of cardinality p^d and p^n such that d divides n, as well as an element $x \in F$, assert the embedding relation between E and F mapping the generator of E to x. The element x must be a root of the polynomial defining E over the prime field. Thus an isomorphism between E and the subfield of F of cardinality p^d is set up, and can be used from then on to move between the fields E and F.

21.2.3 Special Options

For finite fields for which the complete table of Zech logarithms is stored (and which must therefore be small), printing of elements can be done in two ways: either as powers of the primitive element or as polynomials in the generating element.

Note that power printing is not available in all cases where the logarithm table is stored however (the defining polynomial may not be primitive); for convenience element of a prime field are always printed as integers, and therefore power printing on prime fields will not work. Also, if a field is created with a generator that is not primitive, then power printing will be impossible.

`AssertAttribute(FldFin, "PowerPrinting", l)`

This attribute is used to change the *default* printing for all (small) finite fields created after the `AssertAttribute` command is executed. If l is `true` all elements of finite fields small enough for the Zech logarithms to be stored will be printed by default as a power of the primitive element – see `PrimitiveElement`). If l is `false` every finite field element is printed by default as a polynomial in the generator `F.1` of degree less than n over the ground field. The default can be overruled for a particular finite field by use of the `AssertAttribute` option listed below. The value of this attribute is obtained by use of `HasAttribute(FldFin, "PowerPrinting")`.

`SetPowerPrinting(F, l)`

`AssertAttribute(F, "PowerPrinting", l)`

Given a finite field F, the Boolean value l can be used to control the printing of elements of F, provided that F is small enough for the table of Zech logarithms to be stored. If l is `true` all elements will be printed as a power of the primitive element – see `PrimitiveElement`). If l is `false` (which is the only possibility for big fields), every element of F is printed as a polynomial in the generator `F.1` of degree less than n over the ground field of F, where n is the degree of F over its ground field. The function `HasAttribute(F, "PowerPrinting")` may be used to obtain the current value of this flag.

`HasAttribute(FldFin, "PowerPrinting", l)`

This function is used to find the current default printing style for all (small) finite fields. It returns `true` (since this attribute is always defined for FldFin), and also returns the current value of the attribute. The procedure `AssertAttribute(FldFin, "PowerPrinting", l)` may be used to control the value of this flag.

`HasAttribute(F, "PowerPrinting")`

Given a finite field F that is small enough for the table of Zech logarithms to be stored, returns `true` if the attribute `"PowerPrinting"` is defined, else returns `false`. If the attribute is defined, the function also returns the value of the attribute. The procedure `AssertAttribute(F, "PowerPrinting", l)` may be used to control the value of this flag.

`AssignNames(~F, [f])`

Procedure to change the name of the generating element in the finite field F to the contents of the string f. When F is created, the name will be `F.1`.

This procedure only changes the name used in printing the elements of F. It does *not* assign to an identifier called f the value of the generator in F; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies F, it is necessary to have a reference `~F` to F in the call to this function.

```
Name(F, 1)
```

Given a finite field F, return the element which has the name attached to it, that is, return the element `F.1` of F.

21.2.4 Homomorphisms

```
hom< F -> G | x >
```

Given a finite field F, create a homomorphism with F as its domain and G as its codomain. If F is a prime field, then the right hand side in the constructor must be empty; in this case the ring homomorphism is completely determined by the rule that the map must be unitary, that is, 1 of F is mapped to 1 of G. If F is not of prime cardinality, then the homomorphism must be specified by supplying one element x in the codomain, which serves as the image of the generator of the field F over its prime field. Note that it is the responsibility of the user that the map defines a homomorphism.

21.2.5 Creation of Elements

```
F . 1
```

The generator for F as an algebra over its ground field. Thus, if F was defined by the polynomial $P = P(X)$ over E, so $F \cong E[X]/P(X)$, then `F.1` is the image of X in F.

If F is a prime field, then $1 = 1_F$ will be returned.

```
elt< F | a >
F ! a
```

Given a finite field F create the element specified by a; here a is allowed to be an element coercible into F, which means that a may be

(i) an element of F;

(ii) an element of a subfield of F;

(iii) an element of an overfield of F that lies in F;

(iv) an integer, to be identified with a modulo the characteristic of F;

(v) a sequence of elements of the ground field E of F, of length equal to the degree of F over E. In this case the element $a_0 + a_1 w + \cdots + a_{n-1} w^{n-1}$ is created, where $a = [a_0, \ldots a_{n-1}]$ and w is the generator `F.1` of F over E.

`elt< F | a0, ..., an−1 >`

Given a finite field F with generator w of degree n over the ground field E, create the element $a_0 + a_1 w + \cdots + a_{n-1} w^{n-1} \in F$, where $a_i \in E$ $(0 \leq i \leq n-1)$. If the a_i are in some subfield of E or the a_i are integers, they will be coerced into the ground field.

`One(F)` `Identity(F)`

`Zero(F)` `Representative(F)`

These generic functions (cf. Chapter 17) create 1, 1, 0, and 0 respectively, in any finite field.

`Random(F)`

Create a 'random' element of finite field F.

21.2.6 Special Elements

`F . 1`

`Generator(F)`

Given a finite field F, this function returns the element f of F that generates F over its ground field E, so $F = E[f]$. This is the same as the element `F.1`.

`Generator(F, E)`

Given a finite field F and a subfield E of F, this function returns an element f of F that generates F over E, so $F = E[f]$. Note that this element may be different from the element `F.1`, but if `F.1` works it will be returned.

`PrimitiveElement(F)`

Given a finite field F, this function returns a primitive element for F, that is, a generator for the multiplicative group F^* of F. Note that this may be an element different from the generator `F.1` for the field as an algebra. This function will return the same element upon different calls with the same field; the primitive element that is returned is the one that is used as basis for the `Log` function.

`SetPrimitiveElement(F, x)`

(Procedure.) Given a finite field F and a *primitive* element x of F, set the internal primitive element p of F to be x. If the internal primitive element p of F has already been computed or set, x must equal it. The function `Log` (given one argument) returns the logarithm of its argument with respect to the base p; this function thus allows one to specify which base should be used. (One can also use `Log(x, b)` for a given base but setting the primitive element and using `Log(x)` will be faster if many logarithms are to be computed.)

`NormalElement(F)`

Given a finite field $F = \mathbf{F}_{p^n}$, this function returns a normal element for F over the ground field G, that is, an element $\alpha \in F$ such that $\alpha, \alpha^q, \ldots, \alpha^{q^{n-1}}$ forms a basis for F over G, where q is the cardinality of G, and n the degree for F over G. Two calls to this function with the same field may result in different normal elements.

`NormalElement(F, E)`

Given a finite field $F = \mathbf{F}_{q^n}$ and a subfield $E = \mathbf{F}_q$, this function returns a normal element for F over E, that is, an element $\alpha \in F$ such that $\alpha, \alpha^q, \ldots, \alpha^{q^{n-1}}$ forms a basis for F over E.

21.2.7 Sequence Conversions

`SequenceToElement(s, F)`

`Seqelt(s, F)`

Given a sequence $s = [s_0, \ldots, s_{n-1}]$ of elements of a finite field E, of length equal to the degree of the field F over its subfield E, construct the element $s = s_0 + s_1 w + \cdots + s_{n-1} w^{n-1}$ of F, where w is the generator `F.1` of F over E.

`ElementToSequence(a)`

`Eltseq(a)`

Given an element a of the finite field F, return the sequence of coefficients $[a_0, \ldots, a_{n-1}]$ in the ground field E of F such that $a = a_0 + a_1 w + \cdots + a_{n-1} w^{n-1}$, with w the generator of F over E, and n the degree of F over E.

`ElementToSequence(a, E)`

`Eltseq(a, E)`

Given an element a of the finite field F, return the sequence of coefficients $[a_0, \ldots, a_{n-1}]$ in the subfield E of F such that $a = a_0 + a_1 w + \cdots + a_{n-1} w^{n-1}$, with w the generator of F over E, and n the degree of F over E.

21.3 Structure Operations

21.3.1 Related Structures

`Category(F)` `Parent(F)` `Centre(F)`
`PrimeRing(F)` `PrimeField(F)`
`FieldOfFractions(F)`

`AdditiveGroup(F)`

Given $F = \mathbf{F}_q$, create the finite additive abelian group A of order $q = p^r$ that is the direct sum of r copies of the cyclic group of order p, together with the corresponding isomorphism from the group A to the field F.

`MultiplicativeGroup(F)`
`UnitGroup(F)`

Given $F = \mathbf{F}_q$, create the multiplicative group of R as an abelian group. This returns the (additive) cyclic group A of order $q-1$, together with a map from A to $F \setminus 0$, sending 1 to a primitive element of F.

`Set(F)`

Create the enumerated set consisting of the elements of finite field F.

`VectorSpace(F, E)`

Given a finite field F that is an extension of degree n of E, define the natural isomorphism between F and the n-dimensional vector space E^n. The function returns two values:

(a) A vector space $V \cong E^n$;

(b) The isomorphism $\phi : F \to V$.

The basis of V is chosen to correspond with the power basis α^0, α^1, ..., α^{n-1} of F, where α is the generator returned by `Generator(F, E)`, so that $V = E \cdot 1 \times E \cdot \alpha \times \cdots \times E \cdot \alpha^{n-1}$ and $\phi : \alpha^i \to e_{i+1}$, (for $i = 0, \ldots, n-1$), where e_i is the basis vector of V having all components zero, except the i-th, which is one.

`VectorSpace(F, E, B)`

Given a finite field F that is an extension of degree n of E, define the isomorphism between F and the n-dimensional vector space E^n defined by the basis B for F over E. The function returns two values:

(a) A vector space $V \cong E^n$;

(b) The isomorphism $\phi : F \to V$.

The basis of V is chosen to correspond with the basis $B = \beta_1, \beta_2, \ldots, \beta_n$ of F over E, as specified by the user, so that $V = E \cdot \beta_1 \times E \cdot \beta_2 \times \cdots \times E \cdot \beta_n$. $\phi : \beta_i \to e_i$, (for $i = 1, \ldots, n$), where e_i is the basis vector of V having all components zero, except the i-th, which is one.

`MatrixAlgebra(F, E)`

Let F be a finite field that is an extension of degree n of E. The function returns two values:

(a) A matrix algebra A of degree n, such that A is isomorphic to F;

(b) An isomorphism $\phi : F \to A$.

The matrix algebra A will be the subalgebra of the full algebra of $n \times n$ matrices over E generated by the companion matrix C of the defining polynomial of F over E. The generator `Generator(F, E)` of F over E is thus mapped to C.

`MatrixAlgebra(A, E)`

Let F be a finite field. Let A be a matrix algebra over F, and E be a subfield of F. The function returns two values:

(a) A matrix algebra N over E isomorphic to A, obtained from A by expanding each component of an element of A into the block matrix associated with it;

(b) An E-isomorphism $\phi : A \to N$.

N is A considered as an E-matrix algebra.

Example H21E2

Given the field F of 7^4 elements defined as an extension of the field $F49$ of 7^2 elements as above, we can construct two vector spaces, one of dimension 2, and the other of dimension 4:

```
> F7 := FiniteField(7);
> F49<w> := ext< F7 | 2 >;
> F<z> := ext< F49 | 2 >;
> v2, i2 := VectorSpace(F, F49);
> v2;
Full Vector space of degree 2 over GF(7^2)
> i2(z^12);
(   w w^28)
> v4, i4 := VectorSpace(F, PrimeField(F));
> v4;
Full Vector space of degree 4 over GF(7)
> i4(z^12);
(5 3 6 4)
```

`GaloisGroup(K, k)`

Compute the Galois group (which is of course cyclic) of K/k as a permutation group. The group is returned as well as the roots of the defining polynomial of K/k in a compatible ordering.

`AutomorphismGroup(K, k)`

Computes the (cyclic) group of k-automorphisms of K. The group is returned as well as a sequence of all automorphisms and a map sending an element of the abstract automorphism group to an explicit automorphism.

21.3.2 Numerical Invariants

`Characteristic(F)` `# F`

`Degree(F)`

The absolute degree of F, that is, the degree over its prime subfield.

`Degree(F, E)`

Given a finite field F that has been constructed as an extension of a field E, return the degree of F over E.

21.3.3 Defining Polynomial

`DefiningPolynomial(F)`

Given a finite field F that has been constructed as an extension of a field E, return the polynomial with coefficients in E that was used to define F as an extension of E. This is the minimum polynomial of `F.1`.

`DefiningPolynomial(F, E)`

Given a finite field F and a subfield E, return the polynomial with coefficients in E used to define F as an extension of E. This is the same as the minimum polynomial of the generator `Generator(F, E)` over E.

21.3.4 Ring Predicates and Booleans

`IsConway(F)`

Given a finite field F, this function returns `true` iff F is defined over its prime field using a Conway polynomial.

`IsDefault(F)`

Given a finite field F, this function returns `true` iff F is a default field.

`IsCommutative(F)` `IsUnitary(F)`

`IsFinite(F)` `IsOrdered(F)`

`IsField(F)` `IsEuclideanDomain(F)`

`IsPID(F)` `IsUFD(F)`

`IsDivisionRing(F)` `IsEuclideanRing(F)`
`IsPrincipalIdealRing(F)` `IsDomain(F)`
`F eq G` `F ne G`

21.3.5 Roots

`Roots(f)`

Given a polynomial f over a finite field F, this function finds all roots of f in F, and returns a sorted sequence of tuples (pairs), each consisting of a root of f in F and its multiplicity.

`RootsInSplittingField(f)`

Given a univariate polynomial f over a finite field K, compute the minimal splitting field S of f as an extension field of K, and return the roots of f in S, together with S. Using this function will be faster than computing the roots of f anew over the splitting field.

`FactorizationOverSplittingField(f)`

Given a univariate polynomial f over a finite field K, compute the minimal splitting field S of f as an extension field of K, and return the factorization (into linears) of f over S, together with S. Using this function will be faster than factorizing f anew over the splitting field.

`RootOfUnity(n, K)`

Return a primitive n-th root of unity in the smallest possible extension field of K.

Example H21E3

We compute the roots of a certain degree-20 polynomial f in its minimal splitting field.

```
> K := GF(2);
> P<x> := PolynomialRing(GF(2));
> f := x^20 + x^11 + 1;
> Factorization(f);
[
    <x^3 + x^2 + 1, 1>,
    <x^8 + x^7 + x^3 + x^2 + 1, 1>,
    <x^9 + x^7 + x^6 + x^4 + 1, 1>
]
> time r, S<w> := RootsInSplittingField(f);
Time: 0.040
```

We note that the splitting field S has degree 72 and there are 20 roots of f in S of course. We check that the evaluation of f at each root is zero.

```
> S;
```

```
Finite field of size 2^72
> DefiningPolynomial(S);
x^72 + x^48 + x^47 + x^44 + x^38 + x^35 + x^32 + x^31 + x^30 +
    x^29 + x^27 + x^25 + x^23 + x^22 + x^21 + x^18 + x^15 +
    x^12 + x^8 + x^4 + 1
> #r;
20
> r[1];
<w^68 + w^67 + w^64 + w^62 + w^60 + w^59 + w^56 + w^50 + w^49 +
    w^48 + w^47 + w^44 + w^43 + w^39 + w^37 + w^35 + w^33 + w^32
    + w^30 + w^29 + w^28 + w^25 + w^21 + w^19 + w^18 + w^16 +
    w^15 + w^14 + w^12 + w^10 + w^6 + w, 1>
> [IsZero(Evaluate(f, t[1])): t in r];
[ true, true, true, true, true, true, true, true, true, true, true, true,
true, true, true, true, true, true, true, true ]
```

21.4 Element Operations

See also Section 17.5.

21.4.1 Arithmetic Operators

`+ a` `- a`

`a + b` `a - b` `a * b` `a / b`

`a ^ k`

`a +:= b` `a -:= b` `a *:= b`

21.4.2 Equality and Membership

`a eq b` `a ne b`

`a in F` `a notin F`

21.4.3 Parent and Category

`Parent(a)` `Category(a)`

21.4.4 Predicates on Ring Elements

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`
`IsNilpotent(a)` `IsIdempotent(a)`
`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`
`IsIrreducible(a)` `IsPrime(a)`

`IsPrimitive(a)`

Returns `true` if and only if the element a of F is a primitive element for F (i.e., if and only if the multiplicative order of a is $\#F - 1$).

`IsPrimitive(f)`

Given a univariate polynomial $f \in F[x]$, over a finite field F, such that the degree of f is greater than or equal to 1, this function returns `true` if and only if f defines a primitive extension $G = F[x]/f$ of F (that is, x is primitive in G).

`IsNormal(a)`

Returns `true` if and only if the element a of F generates a normal basis for the field over the ground field, that is, if and only if $a, a^q, \ldots, a^{q^{n-1}}$ form a basis for F over the ground field $G = \mathbf{F}_q$.

`IsNormal(a, E)`

Returns `true` if and only if the element a of the finite field F with q^n elements generates a normal basis for F over its subfield E, that is, if and only if $a, a^q, \ldots, a^{q^{n-1}}$ form a basis for F over E for $q = \#E$.

`IsSquare(a)`

Given a finite field element $a \in F$, this function returns either `true` and an element $b \in F$ such that $b^2 = a$, or it returns `false` in the case that such an element does not exist.

21.4.5 Minimal and Characteristic Polynomial

`MinimalPolynomial(a)`

The minimal polynomial of the element a of the field F, relative to the ground field of F. This is the unique minimal-degree monic polynomial with coefficients in the ground field, having a as a root.

`MinimalPolynomial(a, E)`

The minimal polynomial of the element a of the field F, relative to the subfield E of F. This is the unique minimal-degree monic polynomial with coefficients in E, having a as a root.

`CharacteristicPolynomial(a)`

Given an element a of a finite field F, return the characteristic polynomial of a with respect to the ground field of F. (This polynomial is the characteristic polynomial of the companion matrix of a written as a polynomial over the ground field, and is a power of the minimal polynomial.)

`CharacteristicPolynomial(a, E)`

Given an element a of a finite field F, return the characteristic polynomial of a with respect to the subfield E of F. (This polynomial is the characteristic polynomial of the companion matrix of a written as a polynomial over E, and is a power of the minimal polynomial over E.)

21.4.6 Norm, Trace and Frobenius

`Norm(a)`

The norm of the element a from the field F to the ground field of F.

`Norm(a, E)`

The relative norm of the element a from the field F, with respect to the subfield E of F. The result is an element of E.

`AbsoluteNorm(a)`
`NormAbs(a)`

The absolute norm of the element a, that is, the norm to the prime subfield of the parent field F of a.

`Trace(a)`

The trace of the element a from the field F to the ground field of F.

`Trace(a, E)`

The relative trace of the element a from field F, with respect to the subfield E of F. The result is an element of E.

`AbsoluteTrace(a)`
`TraceAbs(a)`

The trace of the element a, that is, the trace to the prime subfield of the parent field F of a.

`Frobenius(a)`

The Frobenius image of a w.r.t. the ground field of K; i.e., $a^{\#G}$, where G is the ground field of the parent of a.

`Frobenius(a, r)`

The r-th Frobenius image of a w.r.t. the ground field of K; i.e., $a^{(\#G)^r}$, where G is the ground field of the parent of a.

`Frobenius(a, E)`

The Frobenius image of x w.r.t. E; i.e., $x^{\#E}$.

`Frobenius(a, E, r)`

The Frobenius image of x w.r.t. E; i.e., $x^{(\#E)^r}$.

`NormEquation(K, y)`

Given a finite field K and an element y of a subfield S of K, return whether an element $x \in K$ exists such that $\mathrm{Norm}(x, S) = y$, and, if so, such an element x (in K).

`Hilbert90(a, q)`

Given an element a of some finite field k and a power q of the characteristic of k, return a solution of the Hilbert 90 equation $x^q x^{-1} = a$. Note that the solution may be in an finite-degree extension of k.

`AdditiveHilbert90(a, q)`

Given an element a of some finite field k and a power q of the characteristic of k, return a solution of the additive Hilbert 90 equation $x^q - x = a$. Note that the solution may be in an finite-degree extension of k.

21.4.7 Order and Roots

`Order(a)`

The multiplicative order of the non-zero element a of the field F.

`FactoredOrder(a)`

The multiplicative order of the non-zero element a of the field F as a factorization sequence.

`SquareRoot(a)`

`Sqrt(a)`

The square root of the non-zero element a from the field F, i.e., an element y of F such that $y^2 = a$. An error results if a is not a square.

`Root(a, n)`

The n-th root of the non-zero element a from the field F, i.e., an element y of F such that $y^n = a$. An error results if no such root exists.

`IsPower(a, n)`

Given a finite field element $a \in F$, and an integer $n > 0$, this function returns either `true` and an element $b \in F$ such that $b^n = a$, or it returns `false` in the case that such an element does not exist.

`AllRoots(a, n)`

Given a finite field element $a \in F$, and an integer $n > 0$, return a sequence containing all of the n-th roots of a which lie in the same field F.

Example H21E4

Given the fields F and $F49$ defined above, we can use the following functions:

```
> F7 := FiniteField(7);
> F49<w> := ext< F7 | 2 >;
> F<z> := ext< F49 | 2 >;
> Root(z^73, 7);
z^1039
> Trace(z^73);
0
> Trace(z^73, F49);
w^44
> Norm(z^73);
3
> Norm(z^73, F49);
w^37
> Norm(w^37);
3
> MinimalPolynomial(z^73);
x^2 + w^20*x + w^43
> MinimalPolynomial(z^73, F7);
x^4 + 4*x^2 + 4*x + 3
```

We now demonstrate the `NormEquation` function.

```
> Norm(z);
3
> NormEquation(F, F7!3);
true z
> Norm(z^30, F49);
w^30
> Parent(z) eq F;
true
> NormEquation(F, w^30);
true z^30
```

21.5 Polynomials for Finite Fields

`IrreduciblePolynomial(F, n)`

Given a finite field F and a positive integer $n > 1$, return a polynomial of degree n that is irreducible over F. If a Conway polynomial or a sparse polynomial is available, then it is returned.

`RandomIrreduciblePolynomial(F, n)`

Given a finite field F and a positive integer $n > 1$, return a random irreducible polynomial of degree n that is irreducible over F. The polynomial will be dense in general (that is, a Conway or stored sparse polynomial is not used).

`IrreducibleLowTermGF2Polynomial(n)`

Given an integer n in the range $1 \leq n \leq 100000$, return the irreducible polynomial f of the form $x^n + g$ where the degree of g is minimal and g is the first such polynomial in lexicographical order.

This uses a database of low-term irreducible polynomials over $\mathbf{F}_2$, constructed by Allan Steel in 2004 (thanks are expressed to William Stein for providing machines for some of the computations).

`IrreducibleSparseGF2Polynomial(n)`

Given an integer n in the range $4 \leq n \leq 12800$, return the irreducible polynomial f of the form $x^n + g$ where g has 2 non-zero terms if possible and 4 non-zero terms if not; g is the first such polynomial in lexicographical order in either case.

This uses a database of sparse irreducible polynomials over $\mathbf{F}_2$ constructed by Allan Steel in 1998.

`PrimitivePolynomial(F, m)`

Given a finite field F and a positive integer $m > 1$, construct a polynomial f of degree m that is primitive over F. Thus, f is irreducible over F, and it has a primitive root of the degree m extension field of F as a root.

`AllIrreduciblePolynomials(F, m)`

Given a finite field F and a positive integer $m > 1$, construct the set of all monic polynomials of degree m that are irreducible over F.

`ConwayPolynomial(p, n)`

Given a prime p and an exponent $n \geq 1$, return the Conway polynomial of degree n over $\mathbf{F}_p$. The Conway polynomial is defined in the introduction. Note that this polynomial is read in from a table containing Conway polynomials for a limited range of p, n only.

`ExistsConwayPolynomial(p, n)`

Given a prime p and an exponent $n > 1$, return `true` and the Conway polynomial if it is known for the field $\mathbf{F}_p$, `false` otherwise.

21.6 Discrete Logarithms

Let K be a field of cardinality $q = p^k$, with p prime. MAGMA contains several advanced algorithms for computing discrete logarithms of elements of K. The two main kinds of algorithms used are as follows: (1) *Pohlig-Hellman* [PH78]: The running time is usually proportional to the square root of the largest prime l dividing $q - 1$; this is combined with the Shanks baby-step/giant-step algorithm (when l is very small) or the Pollard-ρ algorithm. (2) *Index-Calculus*: There is first a precomputation stage which computes and stores all the logarithms of a *factor base* (all the elements of the field corresponding to irreducible polynomials up to some bound) and then each subsequent individual logarithm is computed by expressing the given element in terms of the factor base.

The different kinds of finite fields in MAGMA are handled as follows (in this order):

(a) *Small Fields (any characteristic)*:

If the largest prime l dividing $q - 1$ is reasonably small (typically, less than 2^{36}), the Pohlig-Hellman algorithm is used (the characteristic p is irrelevant).

(b) *Large Prime* :

Suppose K is a prime field (so $q = p$). Then the *Gaussian integer sieve* [COS86, LO91a] is used if p has at least 4 bits but no more than 400 bits, $p - 1$ is not a square, and one of the following is a quadratic residue modulo p: -1, -2, -3, -7, or -11. If the Gaussian integer sieve cannot be used and if p is no more than 300-bits, then the *linear sieve* [COS86, LO91a] is used. The precomputation stage always takes place and typically requires a lot more time than for computing individual logarithms (and may also require a lot of memory for large fields). Thus, the first call to the function `Log` below may take much more time than for subsequent calls. Also, for large prime fields, in comparison to the Gaussian method the linear sieve requires much more time and memory than the Gaussian method for the precomputation stage, and therefore it is only used when the Gaussian integer algorithm cannot be used. See the example H27E3 in the chapter on sparse matrices for an explanation of the basic linear sieve algorithm and for more information on the sparse linear algebra techniques employed.

(c) *Small Characteristic, Non-prime* :

Since V2.19, if K is a finite field of characteristic p, where p is less than 2^{30}, then an implementation by Allan Steel of Coppersmith's index-calculus algorithm [Cop84, GM93, Tho01] is used. (Strictly speaking, Coppersmith's algorithm is for the case $p = 2$ only, but a straightforward generalization is used when $p > 2$.) A suite of external auxiliary tables boost the algorithm so that the precomputation stage computation to determine the logarithms of a factor base can be avoided for a large number of fields of very small characteristic. This means that logarithms of individual elements can be computed immediately if a relevant table is present for the specific field. By default, tables are included in the standard Magma distribution at least for all fields of characteristic 2, 3, 5 or 7 with cardinality up to 2^{200}. The user can optionally download a much larger suite of tables from the Magma optional downloads page `http://magma.maths.usyd.edu.au/magma/download/db/` (files `FldFinLog_2.tar.gz`, etc.; about 5GB total).

(d) *Large Characteristic, Non-prime* :

In all other cases, the Pohlig-Hellman algorithm is used.

`Log(x)`

The discrete logarithm of the non-zero element x from the field F, i.e., the unique integer k such that $x = w^k$ and $0 \leq k < (\#F - 1)$, where w is the primitive element of F (as returned by `PrimitiveElement`). Default parameters are automatically chosen if an index-calculus method is used (use `Sieve` below to set parameters). See also the procedure `SetPrimitiveElement`.

`Log(b, x)`

The discrete logarithm to the base b of the non-zero element x from the field F, i.e., the unique integer k such that $x = b^k$ and $0 \leq k < (\#F - 1)$. If b is not a primitive element, then in some unusual cases the algorithm may take much longer than normal.

`ZechLog(K, n)`

The Zech logarithm $Z(n)$ of the integer n for the field field F, which equals the logarithm to base w of $w^n + 1$, where w is the primitive element of F. If w^n is the minus one element of K, then -1 is returned.

`Sieve(K)`

`Lanczos` BoolElt *Default :* `false`

(Procedure.) Call the Gaussian integer sieve on the prime finite field K if possible; otherwise call the linear sieve on K (assuming K is not too small).

If the parameter `Lanczos` is set to `true`, then the *Lanczos* algorithm [LO91b, Sec. 3] will be used for the linear algebra phase. This is generally *very much slower* than the default method (often 10 to 50 times slower), but it will take considerably less memory, so may be preferable for extremely large fields. See also the function `ModularSolution` in the chapter on sparse matrices for more information.

`SetVerbose("FFLog", v)`

(Procedure.) Set the verbose printing level for the finite field logarithm algorithm to be v. Currently the legal values for v are 0, 1, and 2. If the level is 1, information is printed whenever the logarithm of an element is computed (unless the field is very small, in which case a lookup table is used). The value of 2 will print a very large amount of information.

Example H21E5

We demonstrate the Log function.

```
> F<z> := FiniteField(7^4);
> PrimitiveElement(F);
z;
> Log(z);
1
> Log(z^2);
2
> Log(z + 1);
419
> z^419 eq z + 1;
true
> b := z + 1;
> b;
z^419
> Log(b, b);
1
> Log(b, z);
779
> b^779 eq z;
true
```

We now do similar things for a larger field of characteristic 2, which will use Coppersmith's algorithm to compute the logarithms.

```
> F<z> := GF(2, 73);
> Factorization(#F-1);
[ <439, 1>, <2298041, 1>, <9361973132609, 1> ]
> PrimitiveElement(F);
z
> time Log(z + 1);
429570031703221890 8392
Time: 5.400
> z^429570031703221890 8392;
z + 1
> time Log(z + 1);
429570031703221890 8392
Time: 0.000
> time Log(z^2);
2
Time: 0.000
> time Log(z^2134914112412412);
2134914112412412
Time: 0.000
> b := z + 1;
> b;
z + 1
```

```
> time Log(b, b);
1
Time: 0.010
> time Log(b, z);
2260630912967574270198
Time: 0.000
> b^2260630912967574270198;
z
```

21.7 Permutation Polynomials

Let K be a finite field. A polynomial representing (by the evaluation map) a bijection of K into itself is known as a *permutation polynomial*. The Dickson polynomials of the first and second kind are permutation polynomials when certain conditions are satisfied.

`DicksonFirst(n, a)`

Given a positive integer n, this function constructs the Dickson polynomial of the first kind $D_n(x, a)$ of degree n, where $D_n(x, a)$ is defined by

$$D_n(x,a) = \sum_{i=0}^{\lfloor n/2 \rfloor} \frac{n}{n-i} \binom{n-i}{i} (-a)^i x^{n-2i}.$$

`DicksonSecond(n, a)`

Given a positive integer n, this function constructs the Dickson polynomial of the second kind $E_n(x, a)$ of degree n, where $E_n(x, a)$ is defined by

$$E_n(x,a) = \sum_{i=0}^{\lfloor n/2 \rfloor} \binom{n-i}{i} (-a)^i x^{n-2i}.$$

`IsProbablyPermutationPolynomial(p)`

`NumAttempts` RngIntElt *Default :* 100

Let p denote a polynomial defined over a finite field K. A probabilistic test is applied to determine whether the mapping on K defined by p is a bijection. The function returns `true` if the test succeeds for each of n attempts, otherwise `false`. By default, n is taken to be 100; a different value for n can be specified by use of the parameter `NumAttempts`.

Example H21E6

Let K be a finite field of cardinality q. By a theorem of Nöbauer, the Dickson polynomial of the first kind of degree n is a permutation polynomial for K if and only if $(n, q^2 - 1) = 1$. Consider $K = \mathbf{F}_{16}$.

```
> Factorization(16^2 - 1);
[ <3, 1>, <5, 1>, <17, 1> ]
```

Thus, $D_n(x, a)$ will be a permutation polynomial for K providing that n is coprime to 3, 5 and 17.

```
> K<w> := GF(16);
> R<x> := PolynomialRing(K);
> a := w^5;
> p1 := DicksonFirst(3, a);
> p1;
x^3 + w^5*x
> #{ Evaluate(p1, x) : x in K };
11
> IsProbablyPermutationPolynomial(p1);
false
```

So $D_3(x, a)$ is not a permutation polynomial. However, $D_4(x, a)$ is a permutation polynomial:

```
> p1 := DicksonFirst(4, a);
> p1;
x^7 + w^5*x^5 + x
> #{ Evaluate(p1, x) : x in K };
16
> IsProbablyPermutationPolynomial(p1);
true
```

22 NEARFIELDS

Chapter 22
NEARFIELDS

22.1 Introduction

In 1905, in the course of proving the independence of the field postulates, L. E. Dickson [Dic05a] (p. 203) introduced the first example of a nearfield. His example is a set of 9 elements with operations of addition and multiplication which satisfy all the axioms of a field except for the commutative law of multiplication and the right distributive law. Later that year Dickson [Dic05b] published a more extensive collection of examples: an infinite series obtained by twisting the multiplication of a Galois field and seven "irregular" examples.

The terminology 'nearfield' seems to have introduced by Zassenhaus in his 1935 paper [Zas35] where he showed that the only finite nearfields (endliche Fastkörper) are those due to Dickson.

The irregular nearfields are often referred to as Zassenhaus nearfields and the nearfields in the infinite series are called Dickson nearfields.

In the papers of Dickson and Zassenhaus the nearfields are left-distributive but for the purposes of the MAGMA implementation we consider only right-distributive nearfields.

Nearfields are important in group theory, geometry and a combination of these two fields. On the one hand, the finite sharply doubly transitive permutation groups are in one-to-one correspondence with the finite nearfields and on the other hand, nearfields coordinatise a class of translation planes [Hal59, L69] and they are the starting point for the construction of the Hughes planes [Dem71, Hug57]. Furthermore, every sharply transitive collineation group of projective space over a finite field is a quotient of the group of units of a nearfield [EK63] (see also, [Dem68, §1.4, n° 17]).

22.2 Nearfield Properties

A (right-distributive) *nearfield* is a set N containing elements 0 and 1 and with binary operations $+$ and $\circ$ such that

NF1: $(N, +)$ is an abelian group and 0 is its identity element. Let $N^\times$ denote the set of non-zero elements of N.

NF2: $(N^\times, \circ)$ is a group and 1 is its identity element.

NF3: $a \circ 0 = 0 \circ a = 0$ for all $a \in N$.

NF4: $(a + b) \circ c = a \circ c + b \circ c$ for all $a, b, c \in N$.

A subset S of a nearfield N is a *sub-nearfield* if $(S, +)$ and $(S \setminus \{0\}, \circ)$ are groups. The sub-nearfield *generated* by a subset X is the intersection of all sub-nearfields containing X. The *prime field* $\mathcal{P}(N)$ of N is the sub-nearfield generated by 1.

The inverse of $x \in N^\times$ is written $x^{[-1]}$. But where no confusion is possible we write multiplication of nearfield elements x and y as xy rather than $x \circ y$ and we write the inverse of x as x^{-1}. (In the MAGMA code we use "*" as the symbol for multiplication.)

If N is a finite nearfield, the prime field of N is a Galois field $\mathbf{F}_p$ for some prime p and p is the *characteristic* of N.

A nearfield of characteristic p is a vector space over its prime field and therefore its cardinality is p^n for some n. Every field is a nearfield.

If N is a nearfield, the *centre* of N is the set

$$\mathcal{Z}(N) = \{\, x \in N \mid xy = yx \text{ for all } y \in N \,\}$$

and the *kernel* of N is the subfield

$$\mathcal{K}(N) = \{\, x \in N \mid x(y+z) = xy + xz \text{ for all } y, z \in N \,\}.$$

It is clear that $\mathcal{Z}(N) \subseteq \mathcal{K}(N)$ but equality need not hold because, in general, $\mathcal{Z}(N)$ need not be closed under addition. Furthermore, the prime field $\mathcal{P}(N)$ need not be contained in $\mathcal{Z}(N)$. However, for the Dickson nearfields $\mathcal{Z}(N) = \mathcal{K}(N)$.

If N is a nearfield, then $\mathcal{Z}(N) = \bigcap\{\mathcal{K}(N)^x \mid x \in N,\ x \neq 0\}$.

22.2.1 Sharply Doubly Transitive Groups

A group G acting on a set Ω is *sharply doubly transitive* if G is doubly transitive on Ω and only the identity element fixes two points.

If G is a finite sharply doubly transitive group on Ω then

1. The set M consisting of the identity element and the elements of G without fixed points is an elementary abelian normal subgroup of G of order p^n for some n and some prime p.
2. Addition and multiplication between elements of Ω can be defined so that Ω becomes a nearfield and so that the group G is isomorphic to the group of all affine transformations $v \mapsto va + b$ of Ω, where $a \in \Omega^\times$ and $b \in \Omega$.

There is a converse to this theorem, namely if N is a nearfield, the group of all transformations $v \mapsto va + b$ acts sharply doubly transitively on N.

Let F be the prime field of N, regard N as a vector space over F and define $\mu : N^\times \to \mathrm{GL}(N)$ by $v^{\mu(a)} = va$. Then for all $a \in N^\times$, $a \neq 1$, the linear transformation $\mu(a)$ is fixed-point-free. Furthermore, μ defines an isomorphism between the multiplicative group $N^\times$ and its image in $\mathrm{GL}(N)$.

Suppose that $G = H \ltimes M$ is a sharply doubly transitive group of degree p^n, as above. The centre of G is trivial and M is a minimal normal subgroup. Thus if Ω' is a minimal permutation representation we may suppose that it is primitive. Then M is transitive on Ω' and since M is abelian, it acts regularly on Ω'. Thus p^n is the minimal degree of a faithful permutation representation of G.

22.3 Constructing Nearfields

There are two types of finite nearfield: the *regular* nearfields of Dickson and the *irregular* nearfields of Zassenhaus. In order to accommodate both types MAGMA has a 'virtual type' `Nfd` and types `NfdDck` and `NfdZss` which inherit from `Nfd`.

22.3.1 Dickson Nearfields

In order to begin exploring `Nfd` types in MAGMA we need a way to create instances of nearfields and their elements. As already mentioned there is a large class of nearfields first described by L. E. Dickson [Dic05a, Dic05b] in 1905 and in this section we describe how to construct them in MAGMA.

The nearfields resulting from this construction will be called *Dickson* (or *regular*) nearfields.

If p is a prime and if the positive integers h and v satisfy

- *if r is a prime or 4 and if r divides v, then r divides $p^h - 1$*
  then (p, h, v) is a *Dickson triple*.

If we write $q = p^h$, the condition above is equivalent to

- *All prime factors of v divide $q - 1$ and $q \equiv 3 \bmod 4$ implies $v \not\equiv 0 \bmod 4$.*
  We call (q, v) a *Dickson pair*.

`DicksonPairs(p, hlo, hhi, vlo, vhi )`

The list of Dickson pairs (q, v) for prime p, where `hlo` and `hhi` are the lower and upper bounds on h and where `vlo` and `vhi` are the lower and upper bounds on v.

`DicksonPairs(p, h1, v1)`

The list of Dickson pairs (p^h, v) for the prime p, where `h1` and `v1` are upper bounds on h and v.

`DicksonTriples(p, hb, vb)`

The list of Dickson triples (p, h, v) for the prime p, where `hb` and `vb` are bounds on h and v.

Example H22E1

For each Dickson pair (equivalently Dickson triple), there is at least one Dickson nearfield.

```
> DicksonPairs(5,3,4,4,5);
[
    [ 125, 4 ],
    [ 625, 4 ]
]
> DicksonPairs(5,4,5);
[
    [ 5, 1 ],
    [ 5, 2 ],
```

```
    [ 5, 4 ],
    [ 25, 1 ],
    [ 25, 2 ],
    [ 25, 3 ],
    [ 25, 4 ],
    [ 125, 1 ],
    [ 125, 2 ],
    [ 125, 4 ],
    [ 625, 1 ],
    [ 625, 2 ],
    [ 625, 3 ],
    [ 625, 4 ]
]
> DicksonTriples(5,4,5);
[
    [ 5, 1, 1 ],
    [ 5, 1, 2 ],
    [ 5, 1, 4 ],
    [ 5, 2, 1 ],
    [ 5, 2, 2 ],
    [ 5, 2, 3 ],
    [ 5, 2, 4 ],
    [ 5, 3, 1 ],
    [ 5, 3, 2 ],
    [ 5, 3, 4 ],
    [ 5, 4, 1 ],
    [ 5, 4, 2 ],
    [ 5, 4, 3 ],
    [ 5, 4, 4 ]
]
```

The isomorphism type of a Dickson nearfield depends on the choice of primitive element of the underlying Galois field. It has been shown by Lüneburg [L$\ddot{7}$1] that if ϕ is the Euler phi-function and g is the order of p modulo v, there are $\phi(v)/g$ isomorphism classes of Dickson nearfields with the same Dickson triple (p, h, v).

The default nearfield will use the 'standard' primitive element of the field. The other variants with the same Dickson pair can be obtained by providing an integer s coprime to v. Internally this is converted to a suitable integer e coprime to $q^v - 1$ such that $s \equiv e \pmod{v}$.

`NumberOfVariants(q, v)`

The number of non-isomorphic nearfields with Dickson pair (q, v).

`NumberOfVariants(N)`

The number of variants of the Dickson nearfield N.

`VariantRepresentatives(q, v)`

Representatives for the variant parameter of nearfields with Dickson pair (q, v).

Example H22E2

For each Dickson pair there can be several variants. The variant representative can be used when constructing the corresponding Dickson nearfield.

```
> NumberOfVariants(625,4);
2
> VariantRepresentatives(625,4);
[ 1, 3 ]
```

`DicksonNearfield(q, v : parameters)`

`Variant`	RngIntElt	*Default :* 1
`LargeMatrices`	BoolElt	*Default :* `false`

Create a Dickson nearfield from the Dickson pair (q, v). The `Variant` parameter is an integer s which can be used to specify the choice of primitive element (see the discussion following the intrinsic `DicksonTriples`). The parameter `LargeMatrices` is used only when the group of units of the nearfield is requested. The default is to represent the group of units as a matrix group defined over the kernel of the nearfield. But if `LargeMatrices` is `true`, the matrices are defined over the prime field.

Example H22E3

As indicated in the previous example, up to isomorphism, there are two Dickson nearfields with Dickson pair $(625, 4)$.

```
> D := DicksonNearfield(625,4);
> D3 := DicksonNearfield(625,4 : Variant := 3);
> D5 := DicksonNearfield(625,4 : Variant := 5);
> D eq D3;
false
> D3 eq D5;
false
> D eq D5;
true
> D;
Nearfield D of Dickson type defined by the pair (625, 4)
Order = 152587890625
```

22.3.2 Zassenhaus Nearfields

It was shown by Zassenhaus [Zas35] that in addition to the regular nearfields there are seven *irregular* nearfields. Zassenhaus gave constructions but did not prove their uniqueness. The proofs in [Zas35] are known to contain gaps. Perhaps the most reliable account of the existence and uniqueness of the irregular nearfields is the PhD thesis of Dancs-Groves [Gro74].

The seven finite nearfields which are not Dickson nearfields are the *Zassenhaus* nearfields.

Zassenhaus nearfields can be distinguished from regular nearfields by the fact that the multiplicative group of a finite nearfield N is metacyclic if and only if N is regular.

As a consequence, a Zassenhaus nearfield cannot occur as a subfield of a Dickson nearfield.

`ZassenhausNearfield(n)`

Creates the nth Zassenhaus nearfield.

Example H22E4

The orders of the Zassenhaus nearfields are 5^2, 11^2, 7^2, 23^2, 11^2, 29^2 and 59^2.

```
> for n := 1 to 7 do ZassenhausNearfield(n); end for;
Irregular nearfield Z with Zassenhaus number 1
Order = 25
Irregular nearfield Z with Zassenhaus number 2
Order = 121
Irregular nearfield Z with Zassenhaus number 3
Order = 49
Irregular nearfield Z with Zassenhaus number 4
Order = 529
Irregular nearfield Z with Zassenhaus number 5
Order = 121
Irregular nearfield Z with Zassenhaus number 6
Order = 841
Irregular nearfield Z with Zassenhaus number 7
Order = 3481
```

22.4 Operations on Elements

22.4.1 Nearfield Arithmetic

The operations of addition, subtraction and negation are inherited from the underlying Galois field.

The operation of multiplication distinguishes a nearfield from a field. In a nearfield, multiplication is not commutative and the left distributive law fails.

```
+ a
- a
a + b
a - b
a * b
a / b
a ^ k
a +:= b
a -:= b
a *:= b
```

```
Inverse(a)
```

The inverse of a.

22.4.2 Equality and Membership

```
a eq b
a ne b
a in N
a notin N
```

22.4.3 Parent and Category

```
Parent(a)
Category(a)
```

```
N ! x
```

```
Element(N, x)
```

Create a nearfield element from a finite field element.

```
ElementToSequence(x)
```

Create a sequence from an element x of a nearfield.

22.4.4 Predicates on Nearfield Elements

```
IsZero(a)
IsUnit(a)
IsIdentity(a)
```

Example H22E5

This example illustrates some of the basic operations available on nearfields and their elements. There is a strong connection with the arithmetic of the underlying Galois field of a nearfield D, which is available as the attribute D`gf.

```
> D := DicksonNearfield(3^2,2);
> K := D`gf;
> x := Element(D,K.1);
> x;
$.1
> Parent(x);
Nearfield D of Dickson type defined by the pair (9, 2)
Order = 81
> x^2;
$.1^10
> Identity(D);
1
> assert x ne Identity(D);
> assert x eq x;
> Zero(D);
0
> Parent(Zero(D));
Nearfield D of Dickson type defined by the pair (9, 2)
Order = 81
> assert not IsZero(D!1);
> assert not IsZero(x);
> assert IsZero(Zero(D));
> K<z> := GF(3,4);
> x := Element(D,z^61);
> y := Element(D,z^54);
> assert x + y eq Element(D,z^61+z^54);
> assert x - y eq Element(D,z^61-z^54);
> x*y;
z^35
> x/y;
z^7
> x^y;
z^29
```

Example H22E6

A nearfield is right-distributive, but unlike a Galois field, multiplication is not commutative and the left-distributive law may fail.

```
> N := DicksonNearfield(3^2,4);
> F<a> := N`gf;
> x := Element(N,a^5215);
> y := Element(N,a^5140);
```

```
> z := Element(N,a^5819);
> x*y eq y*x;
false
> x*(y+z) eq x*y+x*z;
false
> (y+z)*x eq y*x+z*x;
true
```

22.5 Operations on Nearfields

`N eq M` `N ne M`

`#N`

`Cardinality(N)`

The cardinality of the nearfield N.

`Random(N)`

A random element of the nearfield N.

`Identity(N)`

The multiplicative identity of the nearfield N.

`Zero(N)`

The additive identity of the nearfield N.

`PrimeField(N)`

The prime field of the nearfield N.

`Kernel(N)`

Return the kernel of the nearfield N as a finite field.

22.6 The Group of Units

If N is a nearfield and $F = \mathcal{K}(N)$ is its kernel, N is a vector space over F and for all $u \in N^\times$, the map $x \mapsto x \circ u$ is an F-linear transformation. This action of $N^\times$ on the non-zero elements of the vector space is transitive and fixed-point-free.

Similarly, we may regard N as a vector space over its prime field and again the elements of $N^\times$ act as linear transformations. In the following code the vector space E could be either a vector space over the kernel or a vector space of the prime field. The default setting is to use the kernel. But if the parameter `LargeMatrices` is set to `true` when a regular nearfield is first defined, the prime field will be used. For irregular nearfields the kernel coincides with the prime field.

Let (p, h, v) be the Dickson triple for N, let ζ be a primitive element of $K = \mathbf{F}_{q^v}$ and put $A = \langle \zeta^v \rangle$. Then A is a group of order $m = (q^v - 1)/v$ and the elements $s_i = \zeta^{(q^i-1)/(q-1)}$ $(1 \le i \le v)$ are coset representatives for A in $K^\times$. Let Φ denote the Frobenius automorphism $x \mapsto x^q$ of K and define $\rho : K^\times \to \mathrm{Gal}(K/\mathbf{F}_p)$ by $\rho(u) = \Phi^i$ if $u \in s_i A$; that is, letting automorphisms of K act on the right, we have $x^{\rho(u)} = x^{q^i}$. The map ρ is not a homomorphism. However, its image is the cyclic group of order v generated by $\Phi = \rho(\zeta)$ and the fixed field of $\mathrm{im}\rho$ is $\mathbf{F}_q$; thus $\mathrm{im}\rho$ may be identified with $\mathrm{Gal}(K/\mathbf{F}_q)$.

The underlying set of N is identified with K and multiplication in N is defined to be $w \circ u = w^{\rho(u)}u$.

The group U of units of the Dickson nearfield $D = D(p, h, v, \zeta)$ has generators a and b and relations $a^m = 1$, $b^v = a^t$ and $b^{-1}ab = a^q$, where $q = p^h$, $m = (q^v - 1)/v$ and $t = m/(q-1)$. Furthermore, Ellers and Karzel [EK64] show that $\gcd(v, t) = \gcd(q - 1, t) \le 2$. Equality holds if and only if $v \equiv 2 \pmod 4$ and $q \equiv 3 \pmod 4$ and this in turn is equivalent to the Sylow 2-subgroup of U being a generalised quaternion group.

The centre of D is $\mathbf{F}_q$ and its group of units is generated by ζ^{vt}.

`UnitGroup(N)`

`UnitGroup(GrpPerm, N)`

`UnitGroup(GrpPC, N)`

The unit group of the nearfield N.

Example H22E7

In this example we construct the group of units of a subnearfield.

```
> N := DicksonNearfield(3^3,13);
> zeta := N`prim;
> x := N!(zeta^((3^39-1) div (3^13-1)));
> S := sub< N | x >;
> U := UnitGroup(S);
> IsAbelian(U);
true
> Factorisation(#N);
[ <3, 39> ]
```

```
> Factorisation(#S);
[ <3, 13> ]
> Factorisation(#Kernel(N));
[ <3, 3> ]
> S;
Nearfield S of Dickson type defined by the pair (1594323, 1)
Order = 1594323
```

`Order(x)`

The order of the unit x of a nearfield.

As a matrix group, the unit group U of a nearfield acts regularly on the non-zero vectors of the underlying vector space E and consequently the affine group $E \cdot U$ is sharply two-transitive. All sharply two-transitive groups occur in this way.

`AffineGroup(N)`

`AffineGroup(GrpPerm, N)`

`AffineGroup(GrpPC, N)`

The sharply two-transitive affine group associated with a nearfield, returned as a matrix group.

If $\Gamma = \mathrm{Gal}(K/\mathbf{F}_p)$ and $S = \Gamma \ltimes K^\times$ is the semidirect product of Γ and $K^\times$, then $D^\times \to S : w \mapsto \rho(w)w$ is an embedding of the multiplicative group $D^\times$ of $D = D(p, h, v, \zeta)$ in S, where multiplication in S is defined by

$$(\gamma_1 a_1)(\gamma_2 a_2) = \gamma_1\gamma_2 a_1^{\gamma_2} a_2.$$

If U is the image of $D^\times$ in S, then $\Gamma \cap U = 1$, $\Gamma U = S$ and $K^\times \cap U = A = \langle \zeta^v \rangle$. In fact, from the definition of ρ, we have $UK^\times = \Gamma_0 \ltimes K^\times$, where $\Gamma_0 = \mathrm{Gal}(K/\mathbf{F}_q)$. This is the *extended unit group* of the Dickson nearfield D.

`ExtendedUnitGroup(D)`

The extended unit group of a Dickson nearfield.

22.7 Automorphisms

`IsIsomorphic(N1, N2)`

Test whether the regular nearfields N_1 and N_2 are isomorphic. If they are, return an isomorphism.

`AutomorphismGroup(N)`

The automorphism group A of the regular nearfield N and a map giving the action of A on N.

22.8 Nearfield Planes

A nearfield N is said to be *planar* if the mapping $x \mapsto -xa + xb$ is a permutation of N whenever $a \neq b$. Every finite nearfield is planar.

Given a finite nearfield N, there is an *affine* plane $\mathcal{A}$ with point set $N \times N$ and lines given by the equations

$$y = xm + b$$
$$x = c$$

Let $\mathcal{P}$ be the corresponding projective plane, obtained from $\mathcal{A}$ by adjoining a line L_∞ called the *line at infinity*. We label the points of $\mathcal{P}$ with triples of elements of N as follows.

(1) For every point (x, y) of $\mathcal{A}$ there is a point $[1, x, y]$ of $\mathcal{P}$.

(2) For every m there is an "ideal" point $[0, 1, m]$ of $\mathcal{P}$ which lies on every line $y = xm + b$ $(b \in N)$ and on L_∞.

(3) There is a point $[0, 0, 1]$ of $\mathcal{P}$ which lies on every line $x = c$ and on L_∞.

The lines of $\mathcal{P}$ may also be labelled by triples of elements of N: the line $y = xm + b$ corresponds to the triple $[-b, -m, 1]$ and the line $x = c$ corresponds to $[-c, 1, 0]$. The line L_∞ is labelled $[1, 0, 0]$. A point $\pi = [w, x, y]$ is incident with a line $L = [a, b, c]$ if and only if $wa + xb + yc = 0$.

Every collineation of $\mathcal{A}$ extends to a collineation of $\mathcal{P}$.

`ProjectivePlane( N : parameters)`

`Check` BoolElt *Default :* `false`

The finite projective plane coordinatised by the nearfield N. The points of the nearfield plane are represented as triples of Galois field elements.

Example H22E8

```
> N := DicksonNearfield(3,2);
> pl := ProjectivePlane(N);
> A := AutomorphismGroup(pl);
> #A;
311040
> CompositionFactors(A);
    G
    |  Cyclic(2)
    *
    |  Alternating(5)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
    |  Cyclic(2)
    *
```

```
|  Cyclic(2)
*
|  Cyclic(2)
*
|  Cyclic(3)
*
|  Cyclic(3)
*
|  Cyclic(3)
*
|  Cyclic(3)
1
```

22.8.1 Hughes Planes

In 1957 Hughes [Hug57] discovered a class of finite projective planes constructed from the Dickson nearfields which have rank 2 over their kernel. Neither these planes nor their duals are translation planes and therefore they cannot be obtained by the coordinatisation method of the previous section. Hughes' methods required the kernel to be central but in 1960 the construction was generalised by Rosati [Ros60] to include the Zassenhaus nearfields (see also Dembowski [Dem68, §5.4] and [Dem71]). For simplicity of notation we shall use the term 'Hughes plane' to include both Hughes planes and generalised Hughes planes.

`HughesPlane(N : parameters)`

`Check` BoolElt *Default :* `false`

The Hughes plane based on the nearfield N.

Example H22E9

We construct the Desarguesian projective plane `PG(2,49)` and then, using nearfields of order 49, we construct three non-Desarguesian projective planes. These four planes can be distinguished by the orders of their collineation groups.

```
> DP := FiniteProjectivePlane(49); // Desarguesian plane
> DP;
Projective Plane PG(2, 49)
> CD  := CollineationGroup(DP);
> FactoredOrder(CD);
[ <2, 10>, <3, 3>, <5, 2>, <7, 6>, <19, 1>, <43, 1> ]
> N := DicksonNearfield(7,2);
> NP := ProjectivePlane(N);
> NP;
Projective Plane of order 49
> CN := CollineationGroup(NP);
> FactoredOrder(CN);
```

```
[ <2, 10>, <3, 2>, <7, 4> ]
> Z := ZassenhausNearfield(3);
> #Z;
49
> ZP := ProjectivePlane(Z);
> CZ := CollineationGroup(ZP);
> FactoredOrder(CZ);
[ <2, 9>, <3, 3>, <7, 4> ]
> HP := HughesPlane(N);
> HP;
Projective Plane of order 49
> CH := CollineationGroup(HP);
> FactoredOrder(CH);
[ <2, 6>, <3, 3>, <7, 3>, <19, 1> ]
> CompositionFactors(CH);
    G
    |  Cyclic(3)
    *
    |  A(2, 7)               = L(3, 7)
    *
    |  Cyclic(2)
    1
```

23 UNIVARIATE POLYNOMIAL RINGS

Chapter 23
UNIVARIATE POLYNOMIAL RINGS

23.1 Introduction

Univariate polynomial rings may be defined over any ring R. Let us denote the univariate polynomial ring in indeterminate x over the coefficient ring R by $P = R[x]$.

There are two kinds of polynomials in MAGMA: *univariate* polynomials, represented as vectors of coefficients; and *multivariate polynomials* represented in distributive form (linear sums of coefficient-monomial pairs). In this chapter we discuss univariate polynomials.

23.1.1 Representation

The vector representation enables fast arithmetic on univariate polynomials, but it requires considerable amounts of memory for multivariate polynomials; therefore, only univariate polynomial rings using the vector representation can be created directly (but, if one insists, it is possible to create univariate polynomial rings over univariate polynomial rings, etc.). Multivariate polynomials can be stored efficiently in distributive form, but the arithmetic operations on polynomials of one variable stored in this way may be considerably slower.

23.2 Creation Functions

23.2.1 Creation of Structures

There are two different ways to create polynomial rings, corresponding to the different internal representations (vector versus distributive — see the introductory section): `PolynomialRing(R)` and `PolynomialRing(R, n)`. The latter should be used to create multivariate polynomials; the former should be used for univariate polynomials.

`PolynomialAlgebra(R)`

`PolynomialRing(R)`

`Global` BOOLELT *Default :* `true`

Create a univariate polynomial ring over the ring R. The ring is regarded as an R-algebra via the usual identification of elements of R and the constant polynomials. The polynomials are stored in vector form, which allows fast arithmetic. It is not recommended to use this function recursively to build multivariate polynomial rings. The angle bracket notation can be used to assign names to the indeterminate, e.g.: `P<x> := PolynomialRing(R)`.

By default, the unique *global* univariate polynomial ring over R will be returned; if the parameter `Global` is set to `false`, then a non-global univariate polynomial ring over R will be returned (to which a separate name for the indeterminate can be assigned).

Example H23E1

We demonstrate the difference between global and non-global rings. We first create the global univariate polynomial ring over **Q** twice.

```
> Q := RationalField();
> P<x> := PolynomialRing(Q);
> PP := PolynomialRing(Q);
> P;
Univariate Polynomial Ring in x over Rational Field
> PP;
Univariate Polynomial Ring in x over Rational Field
> PP.1;
x
```

PP is identical to P. We now create non-global univariate polynomial rings (which are also different to the global polynomial ring P). Note that elements of all the rings are mathematically equal by automatic coercion.

```
> Pa<a> := PolynomialRing(Q: Global := false);
> Pb<b> := PolynomialRing(Q: Global := false);
> Pa;
Univariate Polynomial Ring in a over Rational Field
> Pb;
Univariate Polynomial Ring in b over Rational Field
> a;
a
> b;
b
> P;
Univariate Polynomial Ring in x over Rational Field
> x;
x
> x eq a; // Automatic coercion
true
> x + a;
2*x
```

23.2.2 Print Options

The `AssignNames` and `Name` functions can be used to associate a name with the indeterminate of a polynomial ring after creation.

```
AssignNames(~P, s)
```

Procedure to change the name of the indeterminate of a polynomial ring P. The indeterminate will be given the name of the string in the sequence s.

This procedure only changes the name used in printing the elements of P. It does *not* assign to identifiers corresponding to the strings the indeterminates in P; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies P, it is necessary to have a reference ~P to P in the call to this function.

```
Name(P, i)
```

Given a polynomial ring P, return the i-th indeterminate of P (as an element of P).

23.2.3 Creation of Elements

The easiest way to create polynomials in a given ring is to use the angle bracket construction to attach names to the indeterminates, and to use these names to express polynomials (see the examples). Below we list other options.

```
P . 1
```

Return the indeterminate for the polynomial ring P, as an element of P.

```
elt< P | a0, ..., ad >
```

Given a polynomial ring $P = R[x]$ and elements $a_0, \ldots, a_d$ coercible into the coefficient ring R, return the polynomial $a_0 + a_1 x_n + \cdots + a_d x_n^d$ as an element of P.

```
P ! s
```

```
elt< P | s >
```

Coerce the element s into the polynomial ring $P = R[x]$. The following possibilities for s exist.

(a) s is an element of P: it is returned unchanged;

(b) s is an element of a ring that can be coerced into the coefficient ring R of P: the constant polynomial s is returned;

(c) $s = \sum_j s_j y^j$ is an element of a univariate polynomial ring whose coefficient ring elements s_j can be coerced into R: the polynomial $\sum_j r_j x^j$ is returned, where r_j is the result of coercing s_j into R;

(c) s is a sequence: if s is empty then the zero element of P is returned, and if it is non-empty but the elements of the sequence can be coerced into R then the polynomial $\sum_j s[j] x_n^{j-1}$ is returned.

Note that constant polynomials may be coerced into their coefficient rings.

`Polynomial(Q)`

Given a sequence Q of elements from a ring R, create the polynomial over R whose coefficients are given by Q. This is equivalent to `PolynomialRing(Universe(Q))!Q`.

`Polynomial(R, Q)`

Given a ring R and sequence Q of elements from a ring S, create the polynomial over R whose coefficients are given by the elements of Q, coerced into S. This is equivalent to `PolynomialRing(R)!ChangeUniverse(Q, R)`.

`Polynomial(R, f)`

Given a ring R and a polynomial f over a ring S, create the polynomial over R obtained from f by coercing its coefficients into S. This is equivalent to `PolynomialRing(R)!f`.

`One(P)` `Identity(P)` `Zero(P)` `Representative(P)`

Example H23E2

The easiest way to create the polynomial $x^3 + 3x + 1$ (over the integers) is as follows.

```
> P<x> := PolynomialRing(Integers());
> f := x^3+3*x+1;
> f;
x^3 + 3*x + 1
```

Alternative ways to create polynomials are given by the element constructor (rarely used) and the `!` operator:

```
> P<x> := PolynomialAlgebra(Integers());
> f := elt< P | 2, 3, 0, 1 >;
> f;
x^3 + 3*x + 2
> P ! [ 2, 3, 0, 1 ];
x^3 + 3*x + 2
```

Note that it is important to realize that a sequence is coerced into a polynomial ring by coercing its entries into the coefficient ring, and it is not attempted first to coerce the sequence as a whole into the coefficient ring:

```
> Q := RationalField();
> Q ! [1, 2];
1/2
> P<x> := PolynomialRing(Q);
> P ! [1,2];
2*x + 1
> P ! Q ! [1,2];
1/2
> P ! [ [1,2], [2,3] ];
2/3*x + 1/2
```

23.3 Structure Operations

23.3.1 Related Structures

The main structure related to a polynomial ring is its coefficient ring. Univariate polynomial rings belong to the MAGMA category `RngUPol`.

`BaseRing(P)`

`CoefficientRing(P)`

`CoefficientRing(f)`

Return the coefficient ring of polynomial ring P (the parent of f).

`Category(P)` `Parent(P)` `PrimeRing(P)`

23.3.2 Changing Rings

The `ChangeRing` function enables changing coefficient rings on a polynomial ring.

`ChangeRing(P, S)`

Given a polynomial ring $P = R[x]$, together with a ring S, construct the polynomial ring $Q = S[y]$, together with the homomorphism h from P to Q. It is necessary that all elements of the old coefficient ring R can be automatically coerced into the new coefficient ring S. The homomorphism h will apply this coercion to the coefficients of elements in P to return elements of Q. The usual angle bracket notation can be used for indeterminate names on the result.

`ChangeRing(P, S, f)`

Given a polynomial ring $P = R[x]$, together with a ring S and a map $f : R \to S$, construct the polynomial ring $Q = S[y]$ together with the homomorphism h from P to Q obtained by applying h to the coefficients of elements of P. The usual angle bracket notation can be used for indeterminate names on the result.

Example H23E3

In the first example of `ChangeRing` below we use automatic coercion of integers to rationals to go from $\mathbf{Z}[x]$ to $\mathbf{Q}[y]$. In fact `!` can be used for this as well. In the second example we use a map to obtain a non-standard embedding (not mapping 1 to 1) of $\mathbf{Z}$ in $\mathbf{Q}$.

```
> Z := Integers();
> Q := RationalField();
> P<x> := PolynomialRing(Z);
> S<y>, h := ChangeRing(P, Q);
> h(x^3-2*x+5);
y^3 - 2*y + 5
> S ! (x^3-2*x+5);
y^3 - 2*y + 5
> m := hom< Z -> Q | x :-> 3*x >;
```

```
> S<y>, h := ChangeRing(P, Q, m);
> h(x^3-2*x+5);
3*y^3 - 6*y + 15
```

23.3.3 Numerical Invariants

The characteristic can be obtained for any polynomial ring, the rank for free polynomial rings and the cardinality only for finite quotients.

`Rank(P)`

Return the rank of the polynomial ring P, defined as the maximal number of independent indeterminates in P over its coefficient ring; for univariate polynomial rings this will therefore always return 1.

`#P`

Return the number of elements of P; this will only return an integer value if P is finite, which for polynomial rings can only happen for quotients of polynomial rings over finite coefficient rings.

`Characteristic(P)`

23.3.4 Ring Predicates and Booleans

The usual ring functions returning Boolean values are available on polynomial rings.

`IsCommutative(P)` `IsUnitary(P)` `IsFinite(P)` `IsOrdered(P)`
`IsField(P)` `IsEuclideanDomain(P)` `IsPID(P)` `IsUFD(P)`
`IsDivisionRing(P)` `IsEuclideanRing(P)` `IsDomain(P)`
`IsPrincipalIdealRing(P)` `P eq Q` `P ne Q` `P lt Q`
`P gt Q` `P le Q` `P ge Q`

23.3.5 Homomorphisms

A ring homomorphism taking a polynomial ring $R[x]$ as its domain requires 2 pieces of information, namely, a map (homomorphism) telling how to map the coefficient ring R, together with the image of the indeterminate x. The map may be omitted.

`hom< P -> S | f, y >`
`hom< P -> S | y >`

Given a polynomial ring $P = R[x]$, a ring S, a map $f : R \to S$ and an element $y \in S$, create the homomorphism $g : P \to S$ given by that $g(\sum s_i x^i) = \sum f(s_i) y^i$.

The coefficient ring map may be omitted, in which case the coefficients are mapped into S by the unitary homomorphism sending 1_R to 1_S. Also, the image y is allowed to be from a structure that allows automatic coercion into S.

Example H23E4

In this example we map $\mathbf{Z}[x]$ into the reals by sending x to $1/2$. Note that we do not have a choice for the coefficient map (since we require it to be unitary), and also that we give the image of x as a rational number that is automatically coerced into the reals.

```
> Z := Integers();
> P<x> := PolynomialRing(Z);
> Re := RealField(20);
> half := hom< P -> Re | 1/2 >;
> half(x^3-3*x+5);
3.625
```

23.4 Element Operations

The categories for elements in univariate polynomial rings and their quotients are are `RngUPolElt` and `RngUPolResElt`

23.4.1 Parent and Category

`Parent(p)` `Category(p)`

23.4.2 Arithmetic Operators

The usual unary and binary ring operations are available for univariate polynomials, with the following notable restrictions.

Since inverses cannot generally be obtained in polynomial rings, division (using `/`) of polynomials is not allowed, and neither are negative powers. For polynomial rings over fields division by elements of the coefficient field are allowed.

The operators `div` and `mod` give results corresponding to the quotient and the remainder of division of the arguments. See the section on quotient and remainder for details.

`+ a` `- a`

`a + b` `a - b` `a * b` `a ^ k` `a / b`

`a div b` `a mod b`

`a +:= b` `a -:= b` `a *:= b`

23.4.3 Equality and Membership

`a eq b` `a ne b`

`a in R` `a notin R`

23.4.4 Predicates on Ring Elements

The list belows contains the general ring element predicates. Note that not all functions are available for every coefficient ring.

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`
`IsNilpotent(a)` `IsIdempotent(a)`
`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`
`IsIrreducible(a)` `IsPrime(a)` `IsMonic(a)`

23.4.5 Coefficients and Terms

`Coefficients(p)`
`ElementToSequence(p)`
`Eltseq(p)`

The coefficients of the polynomial $p \in R[x]$ in ascending order, as a sequence of elements of R.

`Coefficient(p, i)`

Given a polynomial $p \in R[x]$ and an integer $i \geq 0$, return the coefficient of the i-th power of x in f. (If i exceeds the degree of f then zero is returned.) The return value is an element of R.

`MonomialCoefficient(p, m)`

Given elements p and m of a polynomial ring $P = R[x]$, where m is a monomial (that is, has exactly one non-zero base coefficient, which must be 1), return the coefficient of m in p, as an element of the coefficient ring R.

`LeadingCoefficient(p)`

Return the coefficient of the highest occurring power of x in $p \in R[x]$, as an element of the coefficient ring R.

`TrailingCoefficient(p)`

Return the coefficient of the lowest occurring power of x in $p \in R[x]$, as an element of the coefficient ring R.

`ConstantCoefficient(p)`

Return the constant term, ie. the coefficient of x^0 as an element of the coefficient ring R.

`Terms(p)`

Return the non-zero terms of the polynomial $p \in P = R[x]$ in ascending order with respect to the degree, as a sequence of elements of P with ascending degrees.

`LeadingTerm(p)`

Return the term of $p \in P = R[x]$ with the highest occurring power of x, as an element of P. The coefficient of the result will be the leading coefficient of p.

`TrailingTerm(p)`

Return the term of $p \in P = R[x]$ with the lowest occurring power of x, as an element of P. The coefficient of the result will be the trailing coefficient of p.

`Monomials(p)`

The monomials of the univariate p, matching up with `Coefficients(p)`, that is a sequence of powers of the indeterminate up to the degree of p.

`Support(p)`

Given a polynomial $p \in R[x]$, return the positions in p for which there are non-zero coefficients, and the corresponding coefficients.

`Round(p)`

Given a polynomial $p \in P = R[x]$ where R is a subring of the real field (the ring of integers $\mathbf{Z}$, the rational field $\mathbf{Q}$, or a real field), return the polynomial in $Z[x]$ obtained from p by rounding all the coefficients of p.

`Valuation(p)`

The valuation of a polynomial $p \in R[x]$, that is, the exponent of the largest power of x which divides p. Note that the zero polynomial has valuation ∞.

23.4.6 Degree

`Degree(p)`

The degree of a polynomial $p \in R[x]$, that is, the exponent of the largest power of x that occurs with non-zero coefficient. Note that the zero polynomial has degree -1.

23.4.7 Roots

`Roots(p)`

`Max` RngIntElt *Default :*

Given a polynomial p over one of a certain collection of coefficient rings, this function returns a sorted sequence of pairs of coefficient ring element and integer, where the ring element is a root of p in the coefficient ring, and the integer its multiplicity. Currently the coefficient rings that are allowed comprise complex and real fields, integers and rationals, finite fields and residue class rings with prime modulus. If the parameter `Max` is set to a non-negative number m, at most m roots are returned.

`Roots(p, S)`

Given a polynomial p over one of a certain collection of coefficient rings as well as a ring S into which the coefficients of p can be coerced automatically, this function returns a sorted sequence of pairs of ring element and integer, where the ring element is a root of p in the ring S, and the integer its multiplicity. Currently the coefficient rings that are allowed comprise complex and real fields, integers and rationals, finite fields and residue class rings with prime modulus.

`HasRoot(p)`

Given a polynomial p over the coefficient ring R this function returns `true` iff p has a root in R. If the result is `true`, the function also returns a root of p as a second return value. Currently the coefficient rings that are allowed comprise complex and real fields, integers and rationals, finite fields and residue class rings with prime modulus. Note that particularly for finite fields, this method may be much faster than the computation of all roots of the polynomial.

`HasRoot(p, S)`

Given a polynomial p over the coefficient ring R and a ring S which contains R, this function returns `true` iff p has a root in S. If the result is `true`, the function also returns a root of p in S as a second return value. Currently the coefficient rings that are allowed comprise complex and real fields, integers and rationals, finite fields and residue class rings with prime modulus. Note that particularly for finite fields, this method may be much faster than the computation of all roots of the polynomial.

`SmallRoots(p, N, X)`

`Bits`	BoolElt	*Default :* `false`
`Beta`	RngElt	*Default :* 1.0
`Exponent`	RngElt	*Default :*
`Finalshifts`	RngElt	*Default :*
`Direct`	BoolElt	*Default :* `false`

Given a monic non-zero univariate integer polynomial p and two positive integers N and X, this function returns all x_0's such that $|x_0| \leq X$ and $P(x_0) = 0$ $[N]$, as long as $X \leq 0.5 \cdot N^{1/d}$, where d is the degree of p.

This function implements Coppersmith's algorithm to compute the small roots of a univariate polynomial modulo an integer [Cop96], as described in Alexander May's PhD thesis [May03]. It relies upon the LLL algorithm for reducing euclidean lattices [LLL82]. It is frequently used for cryptanalysing public-key cryptosystems (see the example below).

When `Bits` is set to `true`, the input X is read as 2^X.

The parameter `Beta` can be set to any value in $(0.0, 1.0]$. The routine will then find all x_0's such that $|x_0| \leq X$ and $P(x_0) = 0 \cong N'$, as long as $X \leq 0.5 \cdot N^{\beta^2/d}$, where d is the degree of p and $N' \geq N^\beta$ is any divisor of N.

The `Exponent` and `Finalshifts` specify the shape of the lattice basis to be reduced. If `Exponent` is m, then p^m will be the highest power of p used to build the lattice basis, and if `Finalshifts` is t, t shifts of p^m will be used. Unless requested by the user, these parameters are chosen automatically.

Finally, the `Direct` option allows the user to require the lattice basis to be reduced at once, and not progressively while constructed. This is can be slower.

Example H23E5

We show how to use the `SmallRoots` routine to factor an RSA modulus when some most significant bits of one of the factors is known. We first generate an RSA modulus.

```
> SetSeed(1);
> F<x> := PolynomialRing (Integers());
> length := 1024;
> p:=NextPrime (2^(Round(length/2)): Proof:=false);
> pi:=Pi(RealField());
> q:=NextPrime (Round (pi*p): Proof:=false);
> N := p*q;
```

Suppose that N is known, as well as an approximation of the factor q:

```
> hidden:=220;
> approxq := q+Random(2^hidden-1);
```

Our goal is to recover `q` from our knowledge of `approxq`. We are therefore interested in the small roots of the polynomial $x - approxq$ modulo q, whose multiple N is known.

```
> A:=x-approxq;
> time perturb:=SmallRoots (A, N, hidden : Bits, Beta:=0.5)[1];
Time 0.050
> q eq approxq-perturb;
true
```

`SetVerbose("SmallRoots", v)`

(Procedure.) Set the verbose printing level for the `SmallRoots` routine to be v. Currently the legal values for v are `true`, `false`, 0, 1 or 2 (`false` is the same as 0, and `true` is the same as 1).

23.4.8 Derivative, Integral

`Derivative(p)`

Given a polynomial $p \in P$, return the derivative of p as an element of P.

`Derivative(p, n)`

Given a polynomial $p \in P$ and an integer $n \geq 0$, return the n-th derivative of p as an element of P.

`Integral(p)`

Given a polynomial $p \in P$ over a field of characteristic zero, return the formal integral of p as an element of P.

23.4.9 Evaluation, Interpolation

`Evaluate(p, r)`

Given an element p of a polynomial ring P and an element r of a ring S, return the value of p evaluated at r. If r can be coerced into the coefficient ring R of P, the result will be an element of R. If r cannot be coerced to the coefficient ring, then an attempt is made to do a generic evaluation of p at r. In this case, the result will be an element of S.

`Interpolation(I, V)`

This function finds a univariate polynomial that evaluates to the values V in the interpolation points I. Let K be a field and $n > 0$ an integer; given sequences I and V, both consisting of n elements of K, return the unique univariate polynomial p over K of degree less than n such that $p(I[i]) = V[i]$ for each $1 \leq i \leq n$.

23.4.10 Quotient and Remainder

`Quotrem(f, g)`

Given elements f and g of the polynomial ring $P = R[x]$, this function returns polynomials q (quotient) and r (remainder) in P such that $f = q \cdot g + r$, and the degree of r is minimal. The leading coefficient of g has to be a non-zero divisor in R. If the leading coefficient of g is a unit, then the degree of r will be strictly less than that of g (taking the degree of 0 to be -1). Over the integers ($R = \mathbf{Z}$) this will be true in general when the leading coefficient of g divides that of f.

`f div g`

The quotient of the polynomial f by g, which is the first return value of `Quotrem` described above.

`IsDivisibleBy(a, b)`

Return whether the polynomial f is exactly divisible by the polynomial g; that is, whether there exists q with $f = qg$. If so, return also the exact divisor q.

`ExactQuotient(f, g)`

Assuming that the polynomial f is exactly divisible by the polynomial g, return the exact quotient of f by g (as a polynomial in the same polynomial ring). An error results if g does not divide f exactly.

`f mod g`

The remainder of division of the polynomial f by g, which is the second return value of `Quotrem` described above.

`Valuation(f, g)`

The exponent of the highest power of the polynomial g which divides the polynomial f.

`Reductum(f)`

The reductum of a polynomial f, which is the polynomial obtained by removing the leading term of f.

`PseudoRemainder(f, g)`

Given polynomials f, g in $P = R[x]$, where R is an integral domain, this function returns the pseudo-remainder r of f and g defined as follows. Let d be the maximum of 0 and $\deg(f) - \deg(g) + 1$, and let c be the leading coefficient of g; then r will be the unique polynomial in P such that $c^d \cdot f = q \cdot g + r$ and the degree of r is less than that of g (possibly -1 for $r = 0$).

`EuclideanNorm(p)`

Return the Euclidean norm of the univariate polynomial $p \in P$, where the Euclidean norm is the function that makes P into a Euclidean ring, which is the degree function.

23.4.11 Modular Arithmetic

The following functions allow modular arithmetic for univariate polynomials over a field without the need to move into the quotient ring. See also the description of `mod` in the section on quotient and remainder.

`Modexp(f, n, g)`

Given univariate polynomials f and g in $K[x]$ over a field K, return $f^n \bmod g$ as an element of $K[x]$. Here n must be a non-negative integer, and g is allowed to be a constant polynomial.

`ChineseRemainderTheorem(X, M)`

`CRT(X, M)`

Given two sequences X and M of polynomials where the elements in M are assumed to be pairwise coprime, find a single polynomial t that solve the modular equation $X_i = t$ modulo M_i.

23.4.12 Other Operations

`ReciprocalPolynomial(f)`

The reciprocal of the given univariate polynomial.

`PowerPolynomial(f,n)`

The polynomial whose roots are the nth powers of the roots of the given polynomial (which should have coefficients in some field).

`f ^ M`

The transformation of the univariate polynomial f under the linear fractional transformation given by the 2 by 2 matrix M (obtained by homogenizing f and making a linear substitution).

23.5 Common Divisors and Common Multiples

The functions in this section are restricted to univariate polynomials over a field, over the integers, or over a residue class ring of integers with prime modulus, or any polynomial ring over these.

23.5.1 Common Divisors and Common Multiples

```
GreatestCommonDivisor(f, g)
```
```
Gcd(f, g)
```
```
GCD(f, g)
```

Given univariate polynomials f and g over the ring R, this function returns the greatest common divisor (GCD) of f and g. The valid coefficient rings are those which themselves have a GCD algorithm for their elements (which includes most commutative rings in MAGMA).

If either of the inputs is zero, then the result is the other input (and if the inputs are both zero then the result is zero). The result is normalized (see the function Normalize), so the result is always unique.

For polynomials over finite fields, the simple Euclidean algorithm is used, since this is efficient (there is no intermediate coefficient blowup).

For polynomials over the integers or rationals, a combination of two algorithms is used: (1) the heuristic evaluation 'GCDHEU' algorithm of Char et al. ([CGG89] and [GCL92, section 7.7]), suitable for small to moderate-degree dense polynomials; (2) a modular algorithm similar to that presented in [vzGG99, Algorithm 6.38] or [GCL92, section 7.4] (although lifting all the way up to a bound is not used since it is completely unnecessary for correctness in this algorithm!).

For polynomials over an algebraic number field, quadratic field, or cyclotomic field, a fast modular algorithm is used, which maps the field to a residue class polynomial ring modulo a small prime.

Since V2.10, for polynomials over an algebraic function field or polynomial quotient ring over a function field, a new fast modular algorithm of Allan Steel (to be published) is used, which evaluates and interpolates for each base transcendental variable.

For polynomials over another polynomial ring or function field, the polynomials are first "flattened" to be inside a multivariate polynomial ring over the base coefficient ring, then the appropriate (multivariate) algorithm is used for that base coefficient ring.

For polynomials over any other ring, the generic subresultant algorithm [Coh93, section 3.3] is used.

```
ExtendedGreatestCommonDivisor(f, g)
```
```
Xgcd(f, g)
```
```
XGCD(f, g)
```

The extended greatest common divisor of polynomials f and g in a univariate polynomial ring P: the function returns polynomials c, a and b in P with $\deg(a) < \deg(g)$ and $\deg(b) < \deg(f)$ such that c is the monic GCD of f and g, and $c = a \cdot f + b \cdot g$. The multipliers a and b are unique if f and g are both non-zero. The coefficient ring must be a field.

For polynomials over the rational field, a modular algorithm due to Allan Steel (unpublished) is used; over other fields the basic Euclidean algorithm is used.

`LeastCommonMultiple(f, g)`

`Lcm(f, g)`

`LCM(f, g)`

The least common multiple of polynomials f and g in a univariate polynomial ring P. The LCM of zero and anything else is zero. The result is normalized (see the function `Normalize`), so the result is always unique. The valid coefficient rings are as for the function `GCD`, above.

The LCM is effectively computed as `Normalize((F div GCD(F, G)) * G)`, for non-zero inputs.

`Normalize(f)`

Given a univariate polynomial f over the ring R, this function returns the unique normalized polynomial g which is associate to f (so $g = uf$ for some unit in R). This is chosen so that if R is a field then g is monic, if R is $\mathbf{Z}$ then the leading coefficient of g is positive, if R is a polynomial ring itself, then the leading coefficient of g is recursively normalized, and so on for other rings.

23.5.2 Content and Primitive Part

`Content(p)`

The content of p, that is, the greatest common divisor of the coefficients of p as an element of the coefficient ring.

`PrimitivePart(p)`

The primitive part of p, being p divided by the content of p.

`ContentAndPrimitivePart(p)`

`Contpp(p)`

The content (the greatest common divisor of the coefficients) of p, as an element of the coefficient ring, as well as the primitive part (p divided by the content) of p.

23.6 Polynomials over the Integers

The functions in this section are available for univariate polynomials over the integers only.

`Sign(p)`

The sign of the leading coefficient of p.

`AbsoluteValue(p)`

`Abs(p)`

Returns either p or $-p$ according to which one has non-negative leading coefficient.

`MaxNorm(p)`

The maximum of the absolute values of the coefficients of p.

`SumNorm(p)`

The sum of the coefficients of p.

`DedekindTest(p, m)`

Given a monic polynomial p (univariate or multivariate in one variable) and a prime number m, this returns true if p satisfies the Dedekind criterion at m, and false otherwise. The Dedekind criterion is satisfied at m if and only if the equation order corresponding to p is locally maximal at m [PZ89, p. 295].

23.7 Polynomials over Finite Fields

The functions in this section are available for univariate polynomials over finite fields only.

`PrimePolynomials(R, d)`

`PrimePolynomials(R, d, n)`

A sequence of all monic prime polynomials of R of degree d, resp. a sequence of n monic prime polynomials of R of degree d.

`RandomPrimePolynomial(R, d)`

A random monic prime polynomial of R of degree d.

`NumberOfPrimePolynomials(q, d)`

`NumberOfPrimePolynomials(K, d)`

`NumberOfPrimePolynomials(R, d)`

The number of monic prime polynomials of degree d over the respective finite field.

`JacobiSymbol(a,b)`

The Jacobi symbol (a/b) of the two polynomials $a, b \in \mathbf{F}_q[x]$ where q must be odd. If b is irreducible, the symbol equals 0 if b divides a. It equals 1 if a is a square mod b and -1 otherwise. The symbol then extends multiplicatively to all non-constant polynomials b.

23.8 Factorization

This section describes the functions for polynomial factorization and associated computations. These are available for several kinds of coefficient rings.

23.8.1 Factorization and Irreducibility

`Factorization(f)`
`Factorisation(f)`

`Al` MonStgElt *Default : "Default"*

Given a univariate polynomial f over the ring R, this function returns the factorization of f as a factorization sequence Q, that is, a sequence of pairs, each consisting of an irreducible factor q_i a positive integer k_i (its multiplicity). Each irreducible factor is normalized (see the function `Normalize`), so the expansion of the factorization sequence is the unique canonical associate of f. The function also returns the unit u of R giving the normalization, so $f = u \cdot \prod_i q_i^{k_i}$.

The coefficient ring R must be one of the following: a finite field $\mathbf{F}_q$, the ring of integers $\mathbf{Z}$, the field of rationals $\mathbf{Q}$, an algebraic number field $\mathbf{Q}(\alpha)$, a local ring, or a polynomial ring, function field (rational or algebraic) or finite-dimensional affine algebra (which is a field) over any of the above.

For factorization over very small finite fields, the Berlekamp algorithm is used by default, which depends on fast linear algebra (see, for example, [Knu97, section 4.6.2] or [vzGG99, section 14.8]). For medium to large finite fields, the von zur Gathen/Kaltofen/Shoup algorithm ([vzGS92, KS95, Sho95]) is used by default. The parameter `Al` may be used to specify the factorization algorithm over finite fields. The possible values are:

(1) `"Default"`: The default strategy, whereby an appropriate choice will be made.

(2) `"BerlekampSmall"` or `"BerlekampLarge"` for the Berlekamp algorithm (see [Knu97, pp. 446–447] for the difference between these two variants).

(3) `"GKS"` for the von zur Gathen/Kaltofen/Shoup algorithm.

Since V2.8 (July 2001), Magma uses the algorithm of Mark van Hoeij [vH02, vH01] to factor polynomials over the integers or rationals. First a factorization of f is found modulo a suitable small prime, then Hensel lifting is applied, as in the standard Berlekamp-Zassenhaus (BZ) algorithm [Knu97, p. 452]. The Hensel lifting is performed using Victor Shoup's 'tree lifting' algorithm, as described in [vzGG99, Sec. 15.5]. Easy factors are also detected at various stages, if possible, using heuristics developed by Allan Steel. But the final search for the correct combination of modular factors (which has exponential worst-case complexity in the standard BZ algorithm) is now performed by van Hoeij's algorithm, which efficiently finds the correct combinations by solving a Knapsack problem via the LLL lattice-basis reduction algorithm [LLL82].

van Hoeij's new algorithm is *much* more efficient in practice than the original lattice-based factoring algorithm proposed in [LLL82]: the lattice constructed in

van Hoeij's algorithm has dimension equal to the number of modular factors (not the degree of the input polynomial), and the entries of the lattice are very much smaller. Many polynomials can now be easily factored which were out of reach for any previous algorithm (see the examples below).

For polynomials over algebraic number fields, algebraic function fields and affine algebras, the norm-based algorithm of Trager [Tra76] is used, which performs a suitable substitution and resultant computation, and then factors the resulting polynomial with one less variable. In characteristic zero, the difficult case (where there are very many factors of this integral polynomial modulo any prime) is now easily handled by van Hoeij's combination algorithm above. In small characteristic, where inseparable field extensions may occur, an algorithm of Allan Steel ([Ste05]) is used.

`HasPolynomialFactorization(R)`

Given a ring R, return whether factorization of polynomials over R is allowed in MAGMA.

`SetVerbose("PolyFact", v)`

(Procedure.) Change the verbose printing level for all polynomial factorization algorithms to be v. Currently the legal levels are 0, 1, 2 or 3.

`FactorisationToPolynomial(f)`

`Facpol(f)`

Given a sequence of tuples, each consisting of pairs of irreducible polynomials and positive integer exponents, return the product polynomial.

Example H23E6

To demonstrate the power of the van Hoeij combination algorithm, in this example we factor Swinnerton-Dyer polynomials, which are worse-case inputs for the Berlekamp-Zassenhaus factorization algorithm for polynomials over $\mathbf{Z}$.

The n-th Swinnerton-Dyer polynomial is defined to be

$$\prod(x \pm \sqrt{2} \pm \sqrt{3} \pm \sqrt{5} \pm \cdots \pm \sqrt{p_n}),$$

where p_i is the i-th prime and the product runs over all 2^n possible combinations of $+$ and $-$ signs. This polynomial lies in $\mathbf{Z}[x]$, has degree 2^n, is irreducible over $\mathbf{Z}$, and has at least 2^{n-1} factors modulo any prime. This last fact is easy to see, since, given any finite field K, the polynomial must split into linear factors over a quadratic extension of K, so it will have only linear or quadratic factors over K. See also [vzGG99, section 15.3] for further discussion.

In this example, we use the function `SwinnertonDyerPolynomial` to construct the polynomials (see Example H40E2 in the chapter on algebraically closed fields for an explanation of how this function works).

First we display the first 4 polynomials.

```
> P<x> := PolynomialRing(IntegerRing());
```

```
> SwinnertonDyerPolynomial(1);
x^2 - 2
> SwinnertonDyerPolynomial(2);
x^4 - 10*x^2 + 1
> SwinnertonDyerPolynomial(3);
x^8 - 40*x^6 + 352*x^4 - 960*x^2 + 576
> SwinnertonDyerPolynomial(4);
x^16 - 136*x^14 + 6476*x^12 - 141912*x^10 + 1513334*x^8 - 7453176*x^6 +
    13950764*x^4 - 5596840*x^2 + 46225
> IsIrreducible($1);
true
```

We note the degree patterns of the factorizations of the first eight Swinnerton-Dyer polynomials over the three finite fields $\mathbf{F}_3$, $\mathbf{F}_{23}$ and $\mathbf{F}_{503}$. There are only linear or quadratic factors, as expected.

```
> for i := 1 to 8 do
>    f := SwinnertonDyerPolynomial(i);
>    printf "%o:", i;
>    for p in [3, 23, 503] do
>         L := Factorization(PolynomialRing(GF(p)) ! f);
>         printf " %o", {* Degree(t[1])^^t[2]: t in L *};
>     end for;
>     "";
> end for;
1: {* 2 *} {* 1^^2 *} {* 1^^2 *}
2: {* 2^^2 *} {* 1^^4 *} {* 1^^4 *}
3: {* 1^^4, 2^^2 *} {* 2^^4 *} {* 2^^4 *}
4: {* 1^^8, 2^^4 *} {* 2^^8 *} {* 2^^8 *}
5: {* 1^^8, 2^^12 *} {* 2^^16 *} {* 2^^16 *}
6: {* 1^^16, 2^^24 *} {* 2^^32 *} {* 2^^32 *}
7: {* 1^^48, 2^^40 *} {* 2^^64 *} {* 2^^64 *}
8: {* 1^^96, 2^^80 *} {* 1^^16, 2^^120 *} {* 2^^128 *}
```

We now construct the 6-th polynomial, note its largest coefficient, and then factor it; it takes only a second to prove that it is irreducible, even though there are 32 modular factors.

```
> sd6 := SwinnertonDyerPolynomial(6);
> Degree(sd6);
64
> Max([Abs(x): x in Coefficients(sd6)]);
177108072043062916168515897889215259945 6
> time L := Factorization(sd6);
Time: 1.009
> #L;
1
```

Now we factor the 7-th polynomial!

```
> sd7 := SwinnertonDyerPolynomial(7);
> Degree(sd7);
```

```
128
> Max([Abs(x): x in Coefficients(sd7)]);
85783447140360187781662744163364252674665633803596496806969245 87\
4401145842570683324825619
> time L := Factorization(sd7);
Time: 11.670
> #L;
1
```

We now factor the product of the 6-th and 7-th polynomials. This has degree 192 and has at least 96 factors modulo any prime! But the van Hoeij algorithms easily finds the correct factors over the integers.

```
> p := sd6*sd7;
> Degree(p);
192
> Max([Abs(x): x in Coefficients(p)]);
46178075233031441597519883536198372339486796800578859978206259 79\
48178917111255021010981707011266628489195528524859249200516300 8
31
> time L := Factorization(p);
Time: 16.840
> #L;
2
> L[1,1] eq sd6;
true
> L[2,1] eq sd7;
true
```

See also Example H40E2 in the chapter on algebraically closed fields for a generalization of the Swinnerton-Dyer polynomials.

`SquarefreeFactorization(f)`

Given a univariate polynomial f over the ring R, this function returns the square-free factorization of f as a sequence of pairs, each consisting of a (not necessarily irreducible) factor and an integer indicating the multiplicity. The factors do not contain the square of any non-constant polynomial.

The coefficient ring R must be the integer ring or any field. The algorithm works by computing the GCD of f with its derivative and repeating as necessary (special considerations are also necessary for characteristic p).

`DistinctDegreeFactorization(f)`

`Degree` RngIntElt *Default :* 0

Given a squarefree univariate polynomial $f \in F[x]$ with F a finite field, this function returns the distinct-degree factorization of f as a sequence of pairs, each consisting of a degree d, together with the product of the degree-d irreducible factors of f.

If the optional parameter `Degree` is given a value $L > 0$, then only (products of) factors up to degree L are returned.

`EqualDegreeFactorization(f, d, g)`

Given a squarefree univariate polynomial $f \in F[x]$ with F a finite field, and integer d and another polynomial $g \in F[x]$ such that F is known to be the product of distinct degree-d irreducible polynomials alone, and g is x^q mod f, where q is the cardinality of F, this function returns the irreducible factors of f as a sequence of polynomials (no multiplicities are needed).

If the conditions are not satisfied, the result is unpredictable. This function allows one to split f, assuming that one has computed f in some special way.

`IsIrreducible(f)`

Given a univariate polynomial f over the ring R, this function returns returns `true` if and only f is irreducible over R. The conditions on R are the same as for the function `Factorization` above.

`IsSeparable(f)`

Given a polynomial $f \in K[x]$ such that f is a polynomial of degree ≥ 1 and K is a field allowing polynomial factorization, this function returns `true` iff f is separable.

`QMatrix(f)`

Given a univariate polynomial f of degree d over a finite field F this function returns the Berlekamp Q-matrix associated with f, which is an element of the degree $d-1$ matrix algebra over F.

23.8.2 Resultant and Discriminant

`Discriminant(f)`

The discriminant D of $f \in R[x]$ is returned. The discriminant is an element of R that can be defined by $D = c_n^{2n-2} \prod_{i \neq j}(\alpha_i - \alpha_j)$, where c_n is the leading coefficient of f and the α_i are the zeros of f (in some algebraic closure of R). The coefficient ring R must be a domain.

`Resultant(f, g)`

The resultant of univariate polynomials f and g (of degree m and n) in $R[x]$, which is by definition the determinant of the Sylvester matrix for f and g (a matrix of rank $m+n$ containing coefficients of f and g as entries). The resultant is an element of R. The coefficient ring R must be a domain.

`CompanionMatrix(f)`

Given a monic univariate polynomial f of degree d over some ring R, return the companion matrix of f as an element of the full matrix algebra of degree $d-1$ over R. The companion matrix for $f = a_0 + a_1 x + \cdots + a_{d-1}x^{d-1} + x^d$ is given by

$$\begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \\ -a_0 & -a_1 & -a_2 & \cdots - a_{d-2} & -a_{d-1} \end{pmatrix}.$$

23.8.3 Hensel Lifting

`HenselLift(f, s, P)`

Given the sequence of irreducible factors s modulo some prime p of the univariate integer polynomial f, return the Hensel lifting into the polynomial ring P, which must be the univariate polynomial ring over a residue class ring modulo some power of p. Thus given $f \equiv \prod_i s_i \bmod p$, this returns $f \equiv \prod_i t_i \bmod p^k$ for some $k \geq 1$, as a sequence of polynomials in $\mathbf{Z}/p^k\mathbf{Z}$. The factorization of f modulo p must be squarefree, that is, s should not contain repeated factors.

Example H23E7

```
> R<x> := PolynomialRing(Integers());
> b := x^5 - x^3 + 2*x^2 - 2;
> F<f> := PolynomialRing(GF(5));
> s := [ w[1] : w in Factorization( F ! b ) ];
> s;
[
    f + 1,
    f + 3,
    f + 4,
    f^2 + 2*f + 4
]
> T<t> := PolynomialRing(Integers(5^3));
> h := HenselLift(b, s, T);
> h;
[
    t + 1,
    t + 53,
    t + 124,
    t^2 + 72*t + 59
]
> &*h;
t^5 + 124*t^3 + 2*t^2 + 123
```

23.9 Ideals and Quotient Rings

Currently it is only possible to create ideals and quotient rings in univariate polynomial rings over fields. Note that these are principal ideal domains: all ideals can be generated by a single element.

23.9.1 Creation of Ideals and Quotients

`ideal< R | a1, ..., ar >`

Given a univariate polynomial ring R over a field K, this function returns the ideal of R generated by the elements $a_1, \ldots, a_r \in R$. This is the same as the ideal generated by the greatest common divisor of the elements a_i in R. The function returns the ideal as a subring of R, generated by a single element.

`quo< R | I >`

`quo< R | a1, ..., ar >`

Given an ideal I in the univariate polynomial ring R (over a field), return the quotient R/I, as well as the projection map $h : R \to R/I$. The ideal I may either be specified as an ideal or by a list a_1, a_2, ..., a_r, of generators. The angle bracket notation can be used to assign names to the indeterminates: `Q<q> := quo< I | I >;`.

23.9.2 Ideal Arithmetic

Since ideals of R are regarded as subrings of R, the ring R itself is a valid ideal as well.

`I + J`

Given ideals I and J in the same polynomial ring R, this function returns the sum of the ideals I and J, which is the ideal generated by the generators of I and those of J. Since we require R to be a principal ideal domain, the resulting ideal will be simply generated by the greatest common divisor of `I.1` and `J.1`.

`I * J`

Given ideals I and J in the same polynomial ring R, this function returns the product of the ideals I and J, which is the ideal generated by the products of the generators of I and those of J. Since we require R to be a principal ideal domain, the resulting ideal will be simply generated by `I.1 * J.1`.

`I meet J`

Given ideals I and J in the same polynomial ring R, this function returns the intersection of the ideals I and J. Since we require R to be a principal ideal domain, the resulting ideal will equal the product of I and J and be simply generated by `I.1 * J.1`.

`a in I`

Given an element a of a polynomial ring P as well as an ideal I of P, this function returns `true` if and only if a is contained in I, and `false` otherwise.

`a notin I`

Given an element a of a polynomial ring P as well as an ideal I of P, this function returns `false` if and only if a is contained in I, and `true` otherwise.

`I eq J`

Given two ideals I and J in the same polynomial ring R this returns `true` if and only if I and J are the same, and `false` otherwise.

`I ne J`

Given two ideals I and J in the same polynomial ring R this returns `false` if and only if I and J are the same, and `true` otherwise.

`I subset J`

Given two ideals I and J in the same polynomial ring R this returns `true` if and only if I is contained in J, and `false` otherwise.

`I notsubset J`

Given two ideals I and J in the same polynomial ring R this returns `false` if and only if I is contained in J, and `true` otherwise.

23.9.3 Other Functions on Ideals

Since ideals are considered as subrings of polynomial rings, and in particular are in the same MAGMA category as polynomial rings, most of the function listed in this chapter for polynomial rings do also apply to ideals, but some restrictions apply. Thus it will be possible to get the coefficient ring but it will not be possible to use `ChangeRing` to change it. We list some functions here that additional comments.

`I . 1`

Given an ideal I in a univariate polynomial ring R, return the generator of I in R as an element of I.

23.9.4 Other Functions on Quotients

Contrary to ideals, quotient rings form a separate MAGMA category. Only very few functions are available on these rings; however most element functions for polynomial rings apply to elements of quotients as well, in particular the coefficient, term and degree functions.

`Modulus(Q)`

Given a quotient ring $Q = R[x]/I$ of the univariate polynomial ring $R[x]$ obtained by factoring out by the ideal I, return the generator for I as an element of R.

`PreimageRing(Q)`

If Q is the quotient $Q = R/I$ for some univariate polynomial ring R, this function returns R.

23.10 Special Families of Polynomials

23.10.1 Orthogonal Polynomials

`ChebyshevFirst(n)`

`ChebyshevT(n)`

Given a positive integer n, this function constructs the Chebyshev polynomial of the first kind $T_n(x)$, where $T_n(x)$ is defined by $T_n(x) = \cos n\theta$ with $x = \cos\theta$.

`ChebyshevSecond(n)`

`ChebyshevU(n)`

Given a positive integer n, this function constructs the Chebyshev polynomial of the second kind, $U_n(x)$, of degree $n-1$. The polynomial is defined by

$$U_n(x) = \frac{1}{n}T_n'(x) = \frac{\sin n\theta}{\sin\theta}$$

where $x = \cos\theta$.

`LegendrePolynomial(n)`

Given a positive integer n, this function constructs the Legendre polynomial $P_n(x)$ of degree n, where $P_n(x)$ is defined by

$$P_0(x) = 1,\ P_1(x) = x,$$
$$P_n(x) = \frac{1}{n}((2n-1)xP_{n-1}(x) - (n-1)P_{n-2}(x)).$$

`LaguerrePolynomial(n)`

`LaguerrePolynomial(n, m)`

Given a positive integer n, this function constructs the Laguerre polynomial $L_n^m(x)$ of degree n with parameter m. If m is omitted, it is assumed to be zero if it is not specified. The polynomial satisfies the recurrence relation

$$L_0(x) = 1,\ L_1(x) = 1 + m - x,$$
$$L_n(x) = \frac{1}{n}(((2n + m - 1) - x)L_{n-1}^m(x) - (n - 1 + m)L_{n-2}^m(x)).$$

`HermitePolynomial(n)`

Given a positive integer n, this function constructs the Hermite polynomial $H_n(x)$ of degree n, where $H_n(x)$ is defined by

$$H_0(x) = 1,\ H_1(x) = 2x,$$
$$H_n(x) = 2xH_{n-1}(x) - 2nH_{n-2}(x).$$

`GegenbauerPolynomial(n, m)`

Given a positive integer n and an integer m, this function constructs the Gegenbauer polynomial $C_n^m(x)$ of degree n with parameter m, where $C_n^m(x)$ is defined by

$$C_0^m(x) = 1,\ C_1^m(x) = 2mx,$$
$$C_n^m(x) = \frac{1}{n}(2(n - 1 + m)xC_{n-1}^m(x) - (n + 2m - 2)C_{n-2}^m(x)).$$

23.10.2 Permutation Polynomials

`DicksonFirst(n, a)`

Given a positive integer n, this function constructs the Dickson polynomial of the first kind $D_n(x, a)$ of degree n, where $D_n(x, a)$ is defined by

$$D_n(x, a) = \sum_{i=0}^{\lfloor n/2 \rfloor} \frac{n}{n - i}\binom{n - i}{i}(-a)^i x^{n-2i}.$$

`DicksonSecond(n, a)`

Given a positive integer n, this function constructs the Dickson polynomial of the second kind $E_n(x, a)$ of degree n, where $E_n(x, a)$ is defined by

$$E_n(x, a) = \sum_{i=0}^{\lfloor n/2 \rfloor} \binom{n - i}{i}(-a)^i x^{n-2i}.$$

23.10.3 The Bernoulli Polynomial

`BernoulliPolynomial(n)`

Given a positive integer n, this function constructs the n-th Bernoulli polynomial.

23.10.4 Swinnerton-Dyer Polynomials

`SwinnertonDyerPolynomial(n)`

Given a positive integer n, this function constructs the n-th Swinnerton-Dyer polynomial, which is defined to be

$$\prod(x \pm \sqrt{2} \pm \sqrt{3} \pm \sqrt{5} \pm \cdots \pm \sqrt{p_n}),$$

where p_i is the i-th prime and the product runs over all 2^n possible combinations of $+$ and $-$ signs. This polynomial lies in $\mathbf{Z}[x]$, has degree 2^n, and is irreducible over $\mathbf{Z}$.

See Example H23E6 above which explains more about this class of polynomials, and see also Example H40E2 in the chapter on algebraically closed fields to see how these polynomials are constructed and also for a generalization.

24 MULTIVARIATE POLYNOMIAL RINGS

Chapter 24
MULTIVARIATE POLYNOMIAL RINGS

24.1 Introduction

This chapter describes multivariate polynomial rings in MAGMA. A multivariate polynomial ring in any number of variables $n \geq 1$ can be created over an arbitrary coefficient ring R, and we will denote it by $P = R[x_1, \ldots, x_n]$. Certain functions, however, will only apply for coefficient rings satisfying certain conditions.

MAGMA contains a powerful system for computing with ideals of multivariate polynomial rings. This is based on the construction of Gröbner bases of such ideals. This chapter only deals with polynomial rings and operations on their elements; see Chapter 105 for the details concerning ideals and Gröbner bases.

Permutation and matrix groups have a natural action on multivariate polynomial rings. This leads to the subject of invariant rings of finite groups, which is covered in Chapter 110. See also the chapters on affine algebras (Chapter 108) and on modules over affine algebras (Chapter 109).

24.1.1 Representation

Let P be the polynomial ring $R[x_1, \ldots, x_n]$ of rank n over a ring R. A *monomial* (or *power product*) of P is a product of powers of the variables of P, that is, an expression of the form $x_1^{e_1} \cdots x_n^{e_n}$ with $e_i \geq 0$ for $1 \leq i \leq n$. Multivariate polynomials in MAGMA are stored efficiently in distributive form, using arrays of coefficient-monomial pairs, where the coefficient is in the base ring R. The word 'term' will always refer to a coefficient multiplied by a monomial.

Various orders can be applied to the monomials, and these are of great importance when dealing with Gröbner bases. A polynomial ring in MAGMA may defined with a certain monomial order, but as this does not affect the basic arithmetic operations in the polynomial ring, these orders are not described here but in the chapter dealing with Gröbner bases (see Section 105.2).

Since V2.7 (June 2000), a new generalized monomial representation has been developed, which uses differing byte sizes for monomials depending on the size of the monomials encountered. Monomial overflow is rigorously detected, and the system automatically extends the byte size of the monomials in the background if possible. Thus there is no need for the user to know beforehand the maximum degree which may occur, and much memory is also saved for low- to medium-degree computations. The total degree of any monomial may now be anything up to $2^{30} - 1 = 1073741823$.

It is possible but not advised to use distributive 'multivariate' polynomials in one single variable. (See Chapter 23 which devoted to univariate polynomial rings.)

24.2 Polynomial Rings and Polynomials

24.2.1 Creation of Polynomial Rings

Multivariate polynomial rings are created from a coefficient ring, the number of indeterminates, and a monomial order. If no order is specified, the monomial order is taken to be the lexicographical order (see Section 105.2 for details).

`PolynomialRing(R, n)`

`PolynomialAlgebra(R, n)`

`Global` BoolElt *Default :* `false`

Create a multivariate polynomial ring in $n > 0$ indeterminates over the ring R. The ring is regarded as an R-algebra via the usual identification of elements of R and the constant polynomials. The lexicographical ordering on the monomials is used for this default construction (see Section 105.2). The angle bracket notation can be used to assign names to the indeterminates; e.g.: `P<x, y> := PolynomialRing(R, 2);` etc.

By default, a *non-global* polynomial ring will be returned; if the parameter `Global` is set to `true`, then the unique global polynomial ring over R with n variables will be returned. This may be useful in some contexts, but a non-global result is returned by default since one often wishes to have several rings with the same numbers of variables but with different variable names (and create mappings between them, for example). Explicit coercion is always allowed between polynomial rings having the same number of variables (and suitable base rings), whether they are global or not, and the coercion maps the i-variable of one ring to the i-th variable of the other ring.

`PolynomialRing(R, n, order)`

`PolynomialAlgebra(R, n, order)`

Create a multivariate polynomial ring in $n > 0$ indeterminates over the ring R with the given order *order* on the monomials. See Section 105.2 for details.

Example H24E1

We show the use of angle brackets for generator names.

```
> Z := IntegerRing();
> S := PolynomialRing(Z, 2);
```

If we define S this way, we can only refer to the indeterminates by $S.1$ and $S.2$ (see below). So we could assign these generators to variables, say x and y, as follows:

```
> x := S.1;
> y := S.2;
```

In this case it is easy to construct polynomials, but printing is slightly awkward:

```
> f := x^3*y +3*y^2;
```

```
> f;
$.1^3*$.2 + 3*$.2^2
```

To overcome that, it is possible to assign names to the indeterminates that are used in the printing routines, using the `AssignNames` function, before assigning to x and y.

```
> AssignNames(~S, ["x", "y"]);
> x := S.1; y := S.2;
> f := x^3*y +3*y^2;
> f;
x^3*y + 3*y^2
```

Alternatively, we use the angle brackets to assign generator names that will be used in printing as well:

```
> S<x, y> := PolynomialRing(Z, 2);
> f := x^3*y +3*y^2;
> f;
x^3*y + 3*y^2
```

Example H24E2

We demonstrate the difference between global and non-global rings. We first create the global multivariate polynomial ring over $\mathbf{Q}$ with 3 variables twice.

```
> Q := RationalField();
> P<x,y,z> := PolynomialRing(Q, 3: Global);
> PP := PolynomialRing(Q, 3: Global);
> P;
Polynomial ring of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
> PP;
Polynomial ring of rank 3 over Rational Field
Lexicographical Order
Variables: x, y, z
> PP.1;
x
```

PP is identical to P. We now create default (non-global) multivariate polynomial rings (which are also different to the global polynomial ring P). Explicit coercion is allowed, and maps the i-variable of one ring to the i-th variable of the other ring.

```
> P1<a,b,c> := PolynomialRing(Q, 3);
> P2<d,e,f> := PolynomialRing(Q, 3);
> P1;
Polynomial ring of rank 3 over Rational Field
Lexicographical Order
Variables: a, b, c
> P2;
Polynomial ring of rank 3 over Rational Field
```

```
Lexicographical Order
Variables: d, e, f
> a;
a
> d;
d
> P1 ! d;
a
> P ! e;
y
```

24.2.2 Print Names

The `AssignNames` and `Name` functions can be used to associate names with the indeterminates of polynomial rings after creation.

`AssignNames(~P, s)`

Procedure to change the name of the indeterminates of a polynomial ring P. The i-th indeterminate will be given the name of the i-th element of the sequence of strings s (for $1 \leq i \leq \#s$); the sequence may have length less than the number of indeterminates of P, in which case the remaining indeterminate names remain unchanged.

This procedure only changes the name used in printing the elements of P. It does *not* assign to identifiers corresponding to the strings the indeterminates in P; to do this, use an assignment statement, or use angle brackets when creating the polynomial ring.

Note that since this is a procedure that modifies P, it is necessary to have a reference `~P` to P in the call to this function.

`Name(P, i)`

Given a polynomial ring P, return the i-th indeterminate of P (as an element of P).

24.2.3 Graded Polynomial Rings

It is possible within MAGMA to assign weights to the variables of a multivariate polynomial ring. This means that monomials of the ring then have a *weighted degree* with respect to the weights of the variables. Such a multivariate polynomial ring is called *graded* or *weighted*. Since this subject is intimately related to ideals, it is covered in the chapter on ideals and Gröbner bases (see Subsection 105.3.2).

24.2.4 Creation of Polynomials

The easiest way to create polynomials in a given ring is to use the angle bracket construction to attach variables to the indeterminates, and then to use these variables to create polynomials (see the examples). Below we list other options.

```
P . i
```

Return the i-th indeterminate for the polynomial ring P in n variables ($1 \leq i \leq n$) as an element of P.

```
elt< R | a >
```

```
R ! s
```

```
elt< R | s >
```

This element constructor can only be used for trivial purposes in multivariate polynomial rings: given a polynomial ring $P = R[x_1, \ldots, x_n]$ and an element a that can be coerced into the coefficient ring R, the constant polynomial a is returned; if a is in P already it will be returned unchanged.

```
MultivariatePolynomial(P, f, i)
```

```
MultivariatePolynomial(P, f, v)
```

Given a multivariate polynomial ring $P = R[x_1, \ldots, x_n]$, as well as a polynomial f in a univariate polynomial ring $R[x]$ over the same coefficient ring R, return an element q of P corresponding to f in the indeterminate $v = x_i$; that is, $q \in P$ is defined by $q = \sum_j f_j x_i^j$ where $f = \sum_j f_j x^j$. The indeterminate x_i can either be specified as a polynomial $v = x_i$ in P, or by simply providing the integer i with $1 \leq i \leq n$.

The inverse operation is performed by the `UnivariatePolynomial` function.

```
One(P)
```

```
Identity(P)
```

```
Zero(P)
```

```
Representative(P)
```

24.3 Structure Operations

24.3.1 Related Structures

The main structure related to a polynomial ring is its coefficient ring. Multivariate polynomial rings belong to the MAGMA category `RngMPol`.

```
BaseRing(P)
```

```
CoefficientRing(P)
```

Return the coefficient ring of polynomial ring P.

```
Category(P)
```

```
Parent(P)
```

```
PrimeRing(P)
```

24.3.2 Numerical Invariants

Note that the # operator only returns a value for finite (quotients of) polynomial rings.

```
Rank(P)
```

Return the number of indeterminates of polynomial ring P over its coefficient ring.

```
Characteristic(P)
```
```
# P
```

24.3.3 Ring Predicates and Booleans

The usual ring functions returning Boolean values are available on polynomial rings.

```
IsCommutative(P)
```
```
IsUnitary(P)
```
```
IsFinite(P)
```
```
IsOrdered(P)
```
```
IsField(P)
```
```
IsEuclideanDomain(P)
```
```
IsPID(P)
```
```
IsUFD(P)
```
```
IsDivisionRing(P)
```
```
IsEuclideanRing(P)
```
```
IsDomain(P)
```
```
IsPrincipalIdealRing(P)
```
```
P eq Q
```
```
P ne Q
```

24.3.4 Changing Coefficient Ring

The ChangeRing function enables the changing of the coefficient ring of a polynomial ring.

```
ChangeRing(P, S)
```

Given a polynomial ring $P = R[x_1, \ldots, x_n]$ of rank n with coefficient ring R, together with a ring S, construct the polynomial ring $Q = S[x_1, \ldots, x_n]$. It is necessary that all elements of the old coefficient ring R can be automatically coerced into the new coefficient ring S.

24.3.5 Homomorphisms

In its general form, a ring homomorphism taking a polynomial ring $R[x_1, \ldots, x_n]$ as domain requires $n + 1$ pieces of information, namely, a map (homomorphism) telling how to map the coefficient ring R together with the images of the n indeterminates.

```
hom< P -> S | f, y1, ..., yn >
```
```
hom< P -> S | y1, ..., yn >
```

Given a polynomial ring $P = R[x_1, \ldots, x_n]$, a ring S, a map $f : R \to S$ and n elements $y_1, \ldots, y_n \in S$, create the homomorphism $g : P \to S$ by applying the rules that $g(rx_1^{a_1} \cdots x_n^{a_n}) = f(r)y_1^{a_1} \cdots y_n^{a_n}$ for monomials and linearity, that is, $g(M + N) = g(M) + g(N)$.

The coefficient ring map may be omitted, in which case the coefficients are mapped into S by the unitary homomorphism sending 1_R to 1_S. Also, the images y_i are allowed to be from a structure that allows automatic coercion into S.

Example H24E3

In this example we map $\mathbf{Q}[x, y]$ into the number field $\mathbf{Q}(\sqrt[3]{2}, \sqrt{5})$ by sending x to $\sqrt[3]{2}$ and y to $\sqrt{5}$ and the identity map on the coefficients (which we omit).

```
> Q := RationalField();
> R<x, y> := PolynomialRing(Q, 2);
> A<a> := PolynomialRing(IntegerRing());
> N<z, w> := NumberField([a^3-2, a^2+5]);
> h := hom< R -> N | z, w >;
> h(x^11*y^3-x+4/5*y-13/4);
-40*w*z^2 - z + 4/5*w - 13/4
```

24.4 Element Operations

24.4.1 Arithmetic Operators

The usual unary and binary ring operations are available for multivariate polynomials.

For polynomial rings over fields division by elements of the coefficient field are allowed (with the result in the original polynomial ring). The operator `div` has slightly different semantics from the univariate case: if b divides a, that is, if there exists a polynomial $q \in P$ such that $a = b \cdot q \in P$ then q will be the result of `a div b`, but if such polynomial does not exist an error results.

`+ a` `- a`

`a + b` `a - b` `a * b` `a ^ k` `a / b` `a div b`

`a +:= b` `a -:= b` `a *:= b` `a div:= b`

24.4.2 Equality and Membership

`a eq b` `a ne b`

`a in R` `a notin R`

24.4.3 Predicates on Ring Elements

The list belows contains the general ring element predicates. Also, the `IsDivisibleBy` function allows a divisibility test, and the `IsAlgebraicallyDependent` function determines if a set of ring elements is algebraically dependent. Note that not all functions are available for every coefficient ring.

`IsDivisibleBy(a, b)`

Given elements a, b in a multivariate polynomial ring P, this function returns whether the polynomial a is divisible by b in P, that is, if and only if there exists $q \in P$ such that $a = q \cdot b$. If `true` is returned, the quotient polynomial q is also returned.

`IsAlgebraicallyDependent(S)`

Returns `true` iff the set S of multivariate polynomials is algebraically dependent.

`IsZero(f)` `IsOne(f)` `IsMinusOne(f)`

`IsNilpotent(f)` `IsIdempotent(f)`

`IsUnit(f)` `IsZeroDivisor(f)` `IsRegular(f)`

`IsIrreducible(f)` `IsPrime(f)`

24.4.4 Coefficients, Monomials and Terms

Many of the functions in this subsection come in three different forms: one in which no variable is specified, which usually returns values in the coefficient ring, and two in which a particular variable is referred, either by name or by number, and these usually return values in the polynomial ring itself.

`Coefficients(f)`

Given a multivariate polynomial f with coefficients in R, this function returns a sequence of 'base' coefficients, that is, a sequence of elements of R occurring as coefficients of the monomials in f. Note that the monomials are ordered, and that the sequence of coefficients corresponds exactly to the sequence of monomials returned by `Monomials(f)`.

`Coefficients(f, i)`

`Coefficients(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns a sequence of coefficients with respect to a given variable $v = x_i$, that is, the function returns a sequence of elements of P that form the coefficients of the powers of v (in ascending order) when f is regarded as a polynomial $\sum_j c_j x_i^j$; note that the variable x_i itself will not occur in the coefficients. There are two ways to indicate with respect to which variable the coefficients are to be taken: either one specifies

i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Coefficient(f, i, k)`

`Coefficient(f, v, k)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the coefficient of $v^k = x_i^k$, that is, the function returns the element of P that forms the coefficient of the k-th power of x_i, when f is regarded as a polynomial $\sum_j c_j x_i^j$; note that the variable x_i itself will not occur in the coefficient. There are two ways to indicate with respect to which variable the coefficient is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`LeadingCoefficient(f)`

Given a multivariate polynomial f with coefficients in R, this function returns the leading coefficient of f as an element of R; this is the coefficient of the leading monomial of f, that is, the first among the monomials occurring in f with respect to the ordering of monomials used in P.

`LeadingCoefficient(f, i)`

`LeadingCoefficient(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the element of P that forms the coefficient of the largest power of $v = x_i$ that occurs with non-zero coefficient in f, when f is regarded as a polynomial $\sum_j c_j x_i^j$; note that the variable x_i itself will not occur in the coefficient. There are two ways to indicate with respect to which variable the leading coefficient is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Length(f)`

Given a multivariate polynomial f, return the length of f, i.e., the number of terms of f.

`TrailingCoefficient(f)`

Given a multivariate polynomial f with coefficients in R, this function returns the trailing coefficient of f as an element of R; this is the coefficient of the trailing monomial of f, that is, the last among the monomials occurring in f with respect to the ordering of monomials used in P.

`TrailingCoefficient(f, i)`

`TrailingCoefficient(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the element of P that forms the coefficient of the least power of $v = x_i$ that occurs with non-zero coefficient in f, when f is regarded as a polynomial $\sum_j c_j x_i^j$; note that the variable x_i itself will not occur in the coefficient. There are two ways to indicate with respect to which variable the leading coefficient is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`MonomialCoefficient(f, m)`

Given a multivariate polynomial f and a monomial m, both in $P \in R[x_1, \ldots, x_n]$, this function returns the coefficient with which m occurs in f as an element of R.

`Monomials(f)`

Given a multivariate polynomial $f \in P$, this function returns a sequence of monomials, that is, a sequence of monomial elements of P occurring in f. Note that the monomials in P are ordered, and that the sequence of monomials corresponds exactly to the sequence of coefficients returned by `Coefficients(f)`.

`CoefficientsAndMonomials(f)`

Given a multivariate polynomial $f \in P$, this function returns parallel sequences C and M of the coefficients and monomials, respectively, of f. Thus this function is equivalent to calling `Coefficients` and `Monomials` separately, but is more efficient (particularly for large polynomials) since only one scan of the polynomial needs to be done.

`LeadingMonomial(f)`

Given a multivariate polynomial $f \in P$ this function returns the leading monomial of f, that is, the first monomial element of P that occurs in f, with respect to the ordering of monomials used in P.

`Terms(f)`

Given a multivariate polynomial $f \in P$, this function returns the sequence of (non-zero) terms of f as elements of P. The terms are ordered according to the ordering on the monomials in P. Consequently the i-th element of this sequence of terms will be equal to the product of the i-th element of the sequence of coefficients and the i-th element of the sequence of monomials.

`Terms(f, i)`

`Terms(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns a sequence of terms with respect to a given variable $v = x_i$, that is, the function returns a sequence of elements of P that form the terms (ascending order) of f regarded as a polynomial $\sum_j c_j x_i^j$. There are two ways to indicate with respect to which variable the terms are to be ordered: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Term(f, i, k)`

`Term(f, v, k)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the k-th term of f (with $k \geq 0$), that is, the function returns the term of f involving the k-th power of x_i, when f is regarded as a polynomial $\sum_j c_j x_i^j$. There are two ways to indicate with respect to which variable the term is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`LeadingTerm(f)`

Given a multivariate polynomial $f \in P$, this function returns the leading term of f as an element of P; this is the product of the leading monomial and the leading coefficient that is, the first among the monomial terms occurring in f with respect to the ordering of monomials used in P.

`LeadingTerm(f, i)`

`LeadingTerm(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the element of P that forms the leading term of f when f is regarded as a polynomial $\sum_j c_j x_i^j$. Thus it is the term involving the largest power of x_i that occurs with non-zero coefficient. There are two ways to indicate with respect to which variable the leading coefficient is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`TrailingTerm(f)`

Given a multivariate polynomial $f \in P$, this function returns the trailing term of f as an element of P; this is the last among the monomial terms occurring in f with respect to the ordering of monomials used in P.

`TrailingTerm(f, i)`

`TrailingTerm(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the element of P that forms the trailing term of f when f is regarded as a polynomial $\sum_j c_j x_i^j$. Thus it is the term involving the least power of x_i that occurs with non-zero coefficient. There are two ways to indicate with respect to which variable the leading coefficient is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Exponents(f)`

Given a single term f (a polynomial having exactly one term) in a polynomial ring of rank n, return the exponents of the monomial of f, as a sequence of length n of integers. (The coefficient of f is ignored; it need not be 1.)

`Monomial(P, E)`

Given a multivariate polynomial ring $P = R[x_1, \ldots, x_n]$, and a sequence E of non-negative integers, return the monomial ${x_1}^{E[1]} \ldots {x_n}^{E[n]}$ in P. This function is a semi-inverse of `Exponents`.

`Polynomial(C, M)`

Given a length-k sequence C of coefficients in a ring R and a length-k sequence M of monomials of a polynomial ring R, return the multivariate polynomial $f \in R$ whose coefficients are C and monomials are M. (Thus for any $f \in R$, `Polynomial(Coefficients(f), Monomials))` equals f.)

Example H24E4

In this and the next example we illustrate the coefficient and term functions, using the polynomial in three variables x, y, z over the rational field that is given by $f = (2x + y)z^3 + 11xyz + x^2y^2$.

```
> R<x, y, z> := PolynomialAlgebra(RationalField(), 3);
> f := (2*x+y)*z^3+11*x*y*z+x^2*y^2;
> f;
x^2*y^2 + 11*x*y*z + 2*x*z^3 + y*z^3
> Coefficients(f);
[ 1, 11, 2, 1 ]
> Monomials(f);
[
   x^2*y^2,
   x*y*z,
   x*z^3,
   y*z^3
]
> CoefficientsAndMonomials(f);
[ 1, 11, 2, 1 ]
```

```
[
    x^2*y^2,
    x*y*z,
    x*z^3,
    y*z^3
]
> Terms(f);
[
   x^2*y^2,
   11*x*y*z,
   2*x*z^3,
   y*z^3
]
> Coefficients(f, y);
[
   2*x*z^3,
   11*x*z + z^3,
   x^2
]
> Terms(f, 2);
[
   2*x*z^3,
   11*x*y*z + y*z^3,
   x^2*y^2
]
> MonomialCoefficient(f, x*y*z);
11
> LeadingTerm(f);
x^2*y^2
> LeadingTerm(f, z);
2*x*z^3 + y*z^3
> LeadingCoefficient(f, z);
2*x + y
> Polynomial([1, 2, 3], [x*y, y, z^2]);
x*y + 2*y + 3*z^2
```

24.4.5 Degrees

`Degree(f, i)`

`Degree(f, v)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the degree of f in $v^k = x_i^k$, that is, the function returns the degree of f when it is regarded as a polynomial $\sum_j c_j x_i^j$. The resulting integer is thus the largest power of x_i occurring in any monomial of f. There are two ways to indicate with respect to

which variable the degree is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P). If f is the zero polynomial, the return value is always -1.

`TotalDegree(f)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the total degree of f, which is the maximum of the total degrees of all monomials that occur in f. The total degree of a monomial m is the sum of the exponents of the indeterminates that make up m. Note that this ignores the weights on the variables if there are any (see the section on graded polynomial rings below). If f is the zero polynomial, the return value is -1.

`LeadingTotalDegree(f)`

Given a multivariate polynomial $f \in P = R[x_1, \ldots, x_n]$, this function returns the leading total degree of f, which is the total degree of the leading monomial of f. If f is the zero polynomial, the return value is -1.

24.4.6 Univariate Polynomials

`IsUnivariate(f)`

Given a multivariate polynomial $f \in R[x_1, \ldots, x_n]$, this function returns whether f is in fact a univariate polynomial in one of its indeterminates $x_1, \ldots, x_n$. If true is returned, then the function also returns a univariate version u of f and (the first) i such that f is univariate in x_i. Note that there will only be ambiguity about i if f is a constant polynomial. The univariate polynomial u will be an element of $R[x]$ with the same coefficients as f.

`IsUnivariate(f, i)`
`IsUnivariate(f, v)`

Given a multivariate polynomial $f \in R[x_1, \ldots, x_n]$, this function returns whether f is in fact a univariate polynomial in x_i. If true is returned, then the function also returns a univariate version u of f, which will be an element of the univariate polynomial ring $R[x]$ with the same coefficients as f. The indeterminate x_i should either be specified as a (polynomial) argument v or as an integer i.

`UnivariatePolynomial(f)`

Given a multivariate polynomial $f \in R[x_1, \ldots, x_n]$, which is known to be a univariate polynomial in x_i for some i with $1 \leq i \leq n$, return a univariate version u of f, which will be an element of the univariate polynomial ring $R[x]$ with the same coefficients as f.

Example H24E5

Suppose we have two bivariate polynomials f and g over some ring.

```
> P<x,y> := PolynomialRing(GF(5), 2);
> f := x^2 - y + 3;
> g := y^3 - x*y + x;
```

If we compute the resultant in either variable of the two polynomials, then we can apply `UnivariatePolynomial` to this to obtain a univariate version of it, from which we can compute the roots.

```
> ry := Resultant(f, g, y);
> ry;
4*x^6 + x^4 + x^3 + 3*x^2 + 2*x + 3
> Roots(UnivariatePolynomial(ry));
[ <3, 1> ]
> Evaluate(f, x, 3);
4*y + 2
> Evaluate(g, x, 3);
y^3 + 2*y + 3
> GCD($1, $2);
y + 3
> rx := Resultant(f, g, x);
> rx;
y^6 + 4*y^3 + 3*y + 3
> Roots(UnivariatePolynomial(rx));
[ <2, 1> ]
> Evaluate(f, y, 2);
x^2 + 1
> Evaluate(g, y, 2);
4*x + 3
> GCD($1, $2);
x + 2
```

24.4.7 Derivative, Integral

`Derivative(f, i)`

`Derivative(f, v)`

Given a multivariate polynomial $f \in P$, return the derivative of f with respect to the variable $v = x_i$, as an element of P. There are two ways to indicate with respect to which variable the derivative is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Derivative(f, k, i)`

`Derivative(f, k, v)`

Given a multivariate polynomial $f \in P$ and an integer $k > 0$, return the k-th derivative of f with respect to the variable $v = x_i$, as an element of P. There are two ways to indicate with respect to which variable the derivative is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`Integral(f, i)`

`Integral(f, v)`

Given a multivariate polynomial $f \in P$ over a field of characteristic zero, return the formal integral of f with respect to $v = x_i$ as an element of P. There are two ways to indicate with respect to which variable the integral is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

`JacobianMatrix( [ f ] )`

Creates the matrix with (i, j)'th entry the partial derivative of the i'th polynomial in the list with the j'th indeterminate of its parent ring.

24.4.8 Evaluation, Interpolation

`Evaluate(f, s)`

Given an element f of a polynomial ring $P = R[x_1, \ldots, x_n]$ and a sequence or tuple s of ring elements of length n, return the value of f at s, that is, obtained by substituting $x_i = s[i]$. If the elements of s can be lifted into the coefficient ring R, then the result will be an element of R. If the elements of s cannot be lifted to the coefficient ring, then an attempt is made to do a generic evaluation of f at s. In this case, the result will be of the same type as the elements of s.

`Evaluate(f, i, r)`

`Evaluate(f, v, r)`

Given an element f of a multivariate polynomial ring P and a ring element r return the value of f when the variable $v = x_i$ is evaluated at r. If r can be coerced into the coefficient ring of P, the result will be an element in P again. Otherwise the other variables of P must be coercible into the parent of r, and the result will have the same parent as r.

`Interpolation(I, V, i)`

`Interpolation(I, V, v)`

Let K be a field, and $P = K[x_1, \ldots, x_n]$ a multivariate polynomial ring over K; let $v = x_i$ be the i-th indeterminate of P. Given a sequence I of elements of K (the interpolation points) and a sequence V of elements of P (the interpolation values), both sequences of length $k > 0$, return the unique polynomial $f \in P$ of degree less than k in the variable x_i such that $f(I[j]) = V[j]$, for $j = 1, \ldots, k$. The variable x_i may not occur anywhere in the values V. There are two ways to indicate with respect to which variable to interpolate: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable or the variable v itself (as a polynomial).

Example H24E6

We define $P = \mathbf{Q}[x, y, z]$, and give an example of interpolation. We find a polynomial which, when evaluated in the first variable x in the rational points $1, 2, 3$, yields $y, z, y + z$ respectively. We check the result by evaluating.

```
> Q := RationalField();
> P<x, y, z> := PolynomialRing(Q, 3);
> f := Interpolation([Q | 1, 2, 3], [y, z, y + z], 1);
> f;
x^2*y - 1/2*x^2*z - 4*x*y + 5/2*x*z + 4*y - 2*z
> [ Evaluate(f, 1, v) : v in [1, 2, 3] ];
[
   y,
   z,
   y + z
]
```

24.4.9 Quotient and Reductum

`f div g`

`ExactQuotient(f, g)`

The quotient of the multivariate polynomial f by g in $R[x_1, \ldots, x_n]$, provided the result lies in P again. Here R must be a domain. If a polynomial q in P exists such that $f = q \cdot g$ then it will be returned, but if does not exist an error results.

`Reductum(f)`

The reductum of a polynomial f, which is the polynomial obtained by removing the leading term of f.

`Reductum(f, i)`

`Reductum(f, v)`

The reductum of a multivariate polynomial $f \in R[x_1, \ldots, x_n]$ obtained by removing the leading term with respect to the variable $v = x_i$. Here either v must be specified as a polynomial, or x_i must be specified by providing the integer i, with $1 \leq i \leq n$.

24.4.10 Diagonalizing a Polynomial of Degree 2

We provide two basic tools that deal with polynomial diagonalization.

`SymmetricBilinearForm(f)`

The symmetric bilinear form (as a matrix) of a multivariate polynomial of degree 2.

`DiagonalForm(f)`

The diagonal form of the multivariate polynomial of degree 2. Also returns the transformation matrix.

Example H24E7

```
> Q := RationalField();
> PR<x, y, z> := PolynomialRing(Q, 3);
> g := 119/44*x^2 - 93759/41440*x*y + 390935/91427*x*z
>      + 212/243*x - 3/17*y^2 + 52808/172227*y*z
>      - 287/227*y + 537/934*z^2 - 127/422*z;
> SymmetricBilinearForm(g);
[       119/44  -93759/82880 390935/182854       106/243]
[ -93759/82880         -3/17  26404/172227      -287/454]
[390935/182854  26404/172227       537/934      -127/844]
[      106/243      -287/454      -127/844             0]
> DiagonalForm(g);
119/44*x^2 - 15798558582429/4*y^2 +
34932799628335074761085292707227419544217/934*z^2 -
17658873286101893452437121055688364561927521739811614723483771045740414637 1/2
>
> bl := SymmetricBilinearForm(g);
> NBL := Matrix(PR, bl);
> D, T := OrthogonalizeGram(bl);
> NT := Matrix(PR, T);
> C := Matrix(PR, [[x,y,z,1]]);
> NC := C * NT;
> NCT := Transpose(NC);
> (NC * NBL * NCT)[1][1] eq DiagonalForm(g);
true
```

The last few statements demonstrate how the polynomial's diagonal form is obtained from its symmetric bilinear form. Note also that since the polynomial g is not homogeneous its symmetric bilinear form is given on four variables, the fourth variable being a homogenizing variable.

24.5 Greatest Common Divisors

The functions in this section can be applied to multivariate polynomials over any ring which has a GCD algorithm.

24.5.1 Common Divisors and Common Multiples

`GreatestCommonDivisor(f, g)`

`Gcd(f, g)`

`GCD(f, g)`

The greatest common divisor of f and g in a multivariate polynomial ring P. If either of the inputs is zero, then the result is the other input (and if the inputs are both zero then the result is zero). The result is normalized (see the function `Normalize`), so the result is always unique.

The valid coefficient rings are those which themselves have a GCD algorithm for their elements (which includes most commutative rings in MAGMA).

For polynomials over the integers or rationals, a combination of three algorithms is used: (1) the heuristic evaluation 'GCDHEU' algorithm of Char et al. ([CGG89] and [GCL92, section 7.7]), suitable for moderate-degree dense polynomials with several variables; (2) the EEZ-GCD algorithm of Wang ([Wan80, MY73] and [GCL92, section 7.6]), based on evaluation and sparse ideal-adic multivariate Hensel lifting ([Wan78] and [GCL92, section 6.8]), suitable for sparse polynomials; (3) a recursive multivariate evaluation-interpolation algorithm (similar to that in [GCL92, section 7.4]), which in fact works generically over $\mathbf{Z}$ or most fields.

For polynomials over any finite field or any field of characteristic zero besides $\mathbf{Q}$, the generic recursive multivariate evaluation-interpolation algorithm (3) above is used, which effectively takes advantage of any fast modular algorithm for the base univariate polynomials (e.g., for number fields). See the function `GreatestCommonDivisor` in the univariate polynomials chapter for details of univariate GCD algorithms.

For polynomials over another polynomial ring or rational function field, the polynomials are first "flattened" to be inside a multivariate polynomial ring over the base coefficient ring, then the appropriate algorithm is used for that base coefficient ring.

For polynomials over any other ring, the generic subresultant algorithm [Coh93, section 3.3] is called recursively on a subring with one less variable.

`GCD(Q)`

Given a sequence Q of polynomials, return the GCD of the elements of Q. If Q has length 0 and universe P, then the zero element of P is returned.

`LeastCommonMultiple(f, g)`

`Lcm(f, g)`

`LCM(f, g)`

The least common multiple of f and g in a multivariate polynomial ring P. The LCM of zero and anything else is zero. The result is normalized (see the function `Normalize`), so the result is always unique. The valid coefficient rings are as for the function `GCD`, above.

The LCM is effectively computed as `Normalize((F div GCD(F, G)) * G)`, for non-zero inputs.

`LCM(Q)`

Given a sequence Q of polynomials, return the LCM of the elements of Q. If Q has length 0 and universe P, then the one element of P is returned.

`Normalize(f)`

Given a polynomial f over the base ring R, this function returns the unique normalized polynomial g which is associate to f (so $g = uf$ for some unit in R). This is chosen so that if R is a field then g is monic, if R is $\mathbf{Z}$ then the leading coefficient of g is positive, if R is a polynomial ring itself, then the leading coefficient of g is recursively normalized, and so on for other rings.

`ClearDenominators(f)`

`ClearDenominators(Q)`

Given a polynomial f over a field K such that K is the field of fractions of a domain D, the first function computes the lowest common denominator L of the coefficients of f and returns the polynomial $g = L \cdot f$ over D with cleared denominators, and L. The second function returns the sequence of polynomials derived from independently clearing the denominators in each polynomial in the given sequence Q.

24.5.2 Content and Primitive Part

`Content(f)`

The content of f, that is, the greatest common divisor of the coefficients of f as an element of the coefficient ring.

`PrimitivePart(f)`

The primitive part of f, being f divided by the content of f.

`ContentAndPrimitivePart(f)`

`Contpp(f)`

The content (the greatest common divisor of the coefficients) of f, as an element of the coefficient ring, as well as the primitive part (f divided by the content) of f.

24.6 Factorization and Irreducibility

We describe the functions for multivariate polynomial factorization and associated computations.

`Factorization(f)`

Given a multivariate polynomial f over the ring R, this function returns the factorization of f as a factorization sequence Q, that is, a sequence of pairs, each consisting of an irreducible factor q_i a positive integer k_i (its multiplicity). Each irreducible factor is normalized (see the function `Normalize`), so the expansion of the factorization sequence is the unique canonical associate of f. The function also returns the unit u of R giving the normalization, so $f = u \cdot \prod_i q_i^{k_i}$.

The coefficient ring R must be one of the following: a finite field $\mathbf{F}_q$, the ring of integers $\mathbf{Z}$, the field of rationals $\mathbf{Q}$, an algebraic number field $\mathbf{Q}(\alpha)$, or a polynomial ring, function field (rational or algebraic) or finite-dimensional affine algebra (which is a field) over any of the above.

For bivariate polynomials, a polynomial-time algorithm in the same spirit as van Hoeij's Knapsack factoring algorithm [vH02] is used.

For polynomials over the integers or rationals, an algorithm similar to that presented in [Wan78] and [GCL92, section 6.8], based on evaluation and sparse ideal-adic multivariate Hensel lifting, is used.

For polynomials over any finite field, a similar algorithm is used, with a few special modifications for non-zero characteristic (see, for example, [BM97]).

For polynomials over algebraic number fields and affine algebras, a multivariate version of the norm-based algorithm of Trager [Tra76] is used, which performs a suitable substitution and multivariate resultant computation, and then factors the resulting integral multivariate polynomial.

Each of these algorithms reduces to univariate factorization over the base ring; for details of how this factorization is done in each case, see the function `Factorization` in the univariate polynomial rings chapter.

For polynomials over another polynomial ring or function field, the polynomials are first "flattened" to be inside a multivariate polynomial ring over the base coefficient ring, then the appropriate algorithm is used for that base coefficient ring.

`SquarefreeFactorization(f)`

Return the squarefree factorization of the multivariate polynomial f as a sequence of tuples of length 2, each consisting of a (not necessarily irreducible) factor and an integer indicating the multiplicity. The factors do not contain the square of any polynomial of degree greater than 0. The allowable coefficient rings are the same as those allowable for the function `Factorization`.

`SquarefreePart(f)`

Return the squarefree part of the multivariate polynomial f, which is the largest (normalized) divisor g of f which is squarefree.

`IsIrreducible(f)`

Given a multivariate polynomial f over a ring R, this function returns whether f is irreducible over R. The allowable coefficient rings are the same as those allowable for the function `Factorization`.

`SetVerbose("PolyFact", v)`

(Procedure.) Change the verbose printing level for all polynomial factorization algorithms to be v. Currently the legal levels are 0, 1, 2 or 3.

Example H24E8

We create a polynomial f in the polynomial ring in three indeterminates over the ring of integers by multiplying together various trinomials. The resulting product f has 461 terms and total degree 15. We then factorize f to recover the trinomials.

```
> P<x, y, z> := PolynomialRing(IntegerRing(), 3);
> f := &*[x^i+y^j+z^k: i,j,k in [1..2]];
> #Terms(f);
461
> TotalDegree(f);
15
> time Factorization(f);
[
    <x + y + z, 1>,
    <x + y + z^2, 1>,
    <x + y^2 + z, 1>,
    <x + y^2 + z^2, 1>,
    <x^2 + y + z, 1>,
    <x^2 + y + z^2, 1>,
    <x^2 + y^2 + z, 1>,
    <x^2 + y^2 + z^2, 1>
]
Time: 0.290
```

Example H24E9

We construct a Vandermonde matrix of rank 6, find its determinant, and factorize that determinant.

```
> // Create polynomial ring over R of rank n
> PRing := function(R, n)
>     P := PolynomialRing(R, n);
>     AssignNames(~P, ["x" cat IntegerToString(i): i in [1..n]]);
>     return P;
> end function;
>
> // Create Vandermonde matrix of rank n
> Vandermonde := function(n)
```

```
>     P := PRing(IntegerRing(), n);
>     return MatrixRing(P, n) ! [P.i^(j - 1): i, j in [1 .. n]];
> end function;
>
> V := Vandermonde(6);
> V;
[   1   x1 x1^2 x1^3 x1^4 x1^5]
[   1   x2 x2^2 x2^3 x2^4 x2^5]
[   1   x3 x3^2 x3^3 x3^4 x3^5]
[   1   x4 x4^2 x4^3 x4^4 x4^5]
[   1   x5 x5^2 x5^3 x5^4 x5^5]
[   1   x6 x6^2 x6^3 x6^4 x6^5]
> D := Determinant(V);
> #Terms(D);
720
> TotalDegree(D);
15
> time Factorization(D);
[
    <x5 - x6, 1>,
    <x4 - x6, 1>,
    <x4 - x5, 1>,
    <x3 - x6, 1>,
    <x3 - x5, 1>,
    <x3 - x4, 1>,
    <x2 - x6, 1>,
    <x2 - x5, 1>,
    <x2 - x4, 1>,
    <x2 - x3, 1>,
    <x1 - x6, 1>,
    <x1 - x5, 1>,
    <x1 - x4, 1>,
    <x1 - x3, 1>,
    <x1 - x2, 1>
]
Time: 0.030
```

Example H24E10

We construct a polynomial $A2$ in three indeterminates a, b, and c over the rational field such that $A2$ is the square of the area of the triangle with side lengths a, b, c. Using elementary trigonometry one can derive the expression $(4 * a^2 * b^2 - (a^2 + b^2 - c^2)^2)/16$ for $A2$. Factorizing $A2$ gives a nice formulation of the square of the area which is similar to that given by *Heron's formula*.

```
> P<a, b, c> := PolynomialRing(RationalField(), 3);
> A2 := 1/16 * (4*a^2*b^2 - (a^2 + b^2 - c^2)^2);
> A2;
-1/16*a^4 + 1/8*a^2*b^2 + 1/8*a^2*c^2 - 1/16*b^4 + 1/8*b^2*c^2 - 1/16*c^4
```

```
> F, u := Factorization(A2);
> F;
[
    <a - b - c, 1>,
    <a - b + c, 1>,
    <a + b - c, 1>,
    <a + b + c, 1>
]
> u;
-1/16
```

Example H24E11

We factorize a multivariate polynomial over a finite field.

```
> Frob := function(G)
>     n := #G;
>     I := {@ g: g in G @};
>     P := PolynomialRing(GF(2), n);
>     AssignNames(~P, [CodeToString(96 + i): i in [1 .. n]]);
>     M := MatrixRing(P, n);
>     return M ! &cat[
>         [P.Index(I, I[i] * I[j]): j in [1 .. n]]: i in [1 .. n]
>     ];
> end function;
> A := Frob(Sym(3));
> A;
[a b c d e f]
[b c a f d e]
[c a b e f d]
[d e f a b c]
[e f d c a b]
[f d e b c a]
> Determinant(A);
a^6 + a^4*d^2 + a^4*e^2 + a^4*f^2 + a^2*b^2*c^2 +
    a^2*b^2*d^2 + a^2*b^2*e^2 + a^2*b^2*f^2 + a^2*c^2*d^2 +
    a^2*c^2*e^2 + a^2*c^2*f^2 + a^2*d^4 + a^2*d^2*e^2 +
    a^2*d^2*f^2 + a^2*e^4 + a^2*e^2*f^2 + a^2*f^4 + b^6 +
    b^4*d^2 + b^4*e^2 + b^4*f^2 + b^2*c^2*d^2 + b^2*c^2*e^2
    + b^2*c^2*f^2 + b^2*d^4 + b^2*d^2*e^2 + b^2*d^2*f^2 +
    b^2*e^4 + b^2*e^2*f^2 + b^2*f^4 + c^6 + c^4*d^2 +
    c^4*e^2 + c^4*f^2 + c^2*d^4 + c^2*d^2*e^2 + c^2*d^2*f^2
    + c^2*e^4 + c^2*e^2*f^2 + c^2*f^4 + d^6 + d^2*e^2*f^2 +
    e^6 + f^6
> time Factorization(Determinant(A));
[
    <a + b + c + d + e + f, 2>,
    <a^2 + a*b + a*c + b^2 + b*c + c^2 + d^2 + d*e + d*f +
```

```
        e^2 + e*f + f^2, 2>
]
Time: 0.049
```

24.7 Resultants and Discriminants

`Resultant(f, g, i)`

`Resultant(f, g, v)`

The resultant of multivariate polynomials f and g in $P = R[x_1, \ldots, x_n]$ with respect to the variable $v = x_i$, which is by definition the determinant of the Sylvester matrix for f and g when considered as polynomials in the single variable x_i. The result will be an element of P again. The coefficient ring R must be a domain. There are two ways to indicate with respect to which variable the integral is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

The algorithm used is the modular interpolation method, as given in [GCL92, pp. 412–413].

`Discriminant(f, i)`

`Discriminant(f, v)`

The discriminant D of $f \in R[x_1, \ldots, x_n]$ is returned, where f is considered as a polynomial in $v = x_i$. The result will be an element of P again. The coefficient ring R must be a domain. There are two ways to indicate with respect to which variable the integral is to be taken: either one specifies i, the integer $1 \leq i \leq n$ that is the number of the variable (upon creation of P, corresponding to `P.i`) or the variable v itself (as an element of P).

24.8 Polynomials over the Integers

The functions in this section are available for multivariate polynomials over the integers only.

`Sign(f)`

The sign of the leading coefficient of f.

`AbsoluteValue(f)`

`Abs(f)`

Return either f or $-f$ according to which one has non-negative leading coefficient.

`MaxNorm(f)`

The maximum of the absolute values of the coefficients of f.

`SumNorm(f)`

The sum of the base coefficients of f.

25 REAL AND COMPLEX FIELDS

Chapter 25
REAL AND COMPLEX FIELDS

25.1 Introduction

Real and complex numbers can only be stored in the computer effectively in approximations. MAGMA provides a number of facilities for calculating with such approximations. Most of these facilities are based upon the C libraries MPFR, which provides algorithms for manipulating real numbers with *exact rounding*, and MPC, an extension of MPFR to handle complex numbers. More specifically, the MFPR library extends the semantics of the ANSI/IEEE-754 standard for double-precision numbers — which are used in virtually all major programming languages — to handle real numbers of arbitrary precision. The precise semantics of MPFR give the user fine control over precision loss, which is a tremendous advantage when working with reals and complexes. MAGMA currently uses MPFR 2.4.1 and MPC 0.8. Documentation for algorithms used in MPFR can be found at `mpfr.org`.

As MPFR and MPC are works in progress, they do not yet provide a complete framework for working with the reals and complexes. For those functions that these libraries are missing, Magma falls back to algorithms taken from PARI. The documentation of MFPR and MPC provide a list of the functions that they provide. Assume that each intrinsic uses MPFR unless otherwise stated.

Although we use the terms *real field* and *complex field* for MAGMA structures containing real or complex approximations, it should be noted that such a subset of the real or complex field may not even form a commutative ring. Never the less, the real and complex fields are considered to be fields by MAGMA, they comprise objects of type `FldRe` and `FldCom` with elements of type `FldReElt` and `FldComElt` respectively.

25.1.1 Overview of Real Numbers in MAGMA

Real numbers are stored internally as expansions $\sum b_i 2^i$. Complex numbers consist of a pair of real numbers of identical precision. Each real or complex number is associated with a corresponding field structure, which has the same precision as all of its elements. MAGMA stores a list of real and complex fields that have been created during a session, and it is guaranteed that any two fields of the same fixed precision are the same. This means in particular that changing the name of $\sqrt{-1}$ (see `AssignNames` below) on one of the complex fields of precision r will change the name on every complex field of that same precision. As a convenience, MAGMA allows real and complex numbers of differing precisions to be used in the same expression; internally, MAGMA implicitly reduces the precision of the higher precision element to the precision of the lower element.

While internally we store real numbers in base two, when creating real or complex fields the precision is by default specified in the number of *decimal* digits, not binary digits, required. It is possible to specify the precision in binary digits if needed (see the documentation for `RealField` for details).

Example H25E1

We show how to create and manipulate real numbers. In particular, note that there is an inherent loss of precision in the conversion between base 10 and base 2 representations of some real numbers.

```
> S1 := RealField(20);
> S2 := RealField(10);
> a := S1 ! 0.5;
> a;
0.50000000000000000000
> b := S2 ! 0.05;
> b;
0.05000000000
> a + b;
0.5500000000
> Precision(a + b);
10
```

A warning is in place here; in the examples above, the real number on the right hand side had to be constructed in some real field *before* it could be coerced into S_1 and S_2. That real field is the so-called *default real field*. In these examples it is assumed that the default field has sufficiently large precision to store the real numbers on the right accurately to the last digit.

25.1.2 Coercion

Automatic coercion ensures that all functions listed below that take an element of some real field as an argument, will also accept an integer or a rational number as an argument; in this case the integer or rational number will be coerced automatically into the default real field. For the binary operations (such as `+, *`) coercion also takes place: if one argument is real and the other is integral or rational, automatic coercion will put them both in the parent field of the real argument. If the arguments are real numbers of different fixed precision, the result will have the smaller precision of the two.

The same coercion rules apply for functions taking a complex number as an argument; in that case real numbers will be valid input as well: if necessary reals, rationals or integers will be coerced into the appropriate complex field.

Elements of quadratic and cyclotomic fields that are real can be coerced into any real field using `!`; any quadratic or cyclotomic field element can be coerced by `!` into any complex field. Functions taking real or complex arguments will not *automatically* coerce such arguments though.

25.1.3 Homomorphisms

The only homomorphisms that have a real field or a complex field as domain are the coercion functions. Therefore, homomorphisms from the reals or complexes may be specified as follows.

```
hom< R -> S | >
```

Here S must be a structure into which all elements of the real or complex field R are coercible, such as another real or complex field, or a polynomial ring over one of these. These homomorphisms can also be obtained as map by using the function `Coercion`, also called `Bang`.

Example H25E2

Here are two equivalent ways of creating the embedding function from a real field into a polynomial ring over some complex field.

```
> Re := RealField(20);
> PC<x, y> := PolynomialRing(ComplexField(8), 2);
> f := hom< Re -> PC | >;
> bangf := Bang(Re, PC);
> f(Pi(Re));
3.1415927
> f(Pi(Re)) eq bangf(Pi(Re));
true
```

25.1.4 Special Options

When MAGMA is started up, real and complex fields of precision 30 are created by default. They serve (among other things) as a parent for reals that are created as literals, such as 1.2345, in the same way as the default ring of integers is the parent for literal integers. It is possible to change this default real field with `SetDefaultRealField`.

Finally, `AssignNames` can be used to change the name for $\sqrt{-1}$ in a complex field.

```
SetDefaultRealField(R)
```

Procedure to change the default parent for literal real numbers to the real field R. This parent is the real field of precision 30 by default.

```
GetDefaultRealField()
```

Return the current parent for literal real numbers.

`AssignNames(~C, [s])`

Procedure to change the name of the purely imaginary element $\sqrt{-1}$ in the complex field C to the contents of the string s. When C is created, the name is "C.1"; suitable choices of s might be `"i"`, `"I"` or `"j"`.

This procedure only changes the name used in printing the elements of C. It does *not* assign to an identifier called s the value of $\sqrt{-1}$ in C; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies C, it is necessary to have a reference `~C` to C in the call to this function.

`Name(C, 1)`

Given a complex field C, return the element which has the name attached to it, that is, return the purely imaginary element $\sqrt{-1}$ of C.

25.1.5 Version Functions

The following intrinsics retrieve the versions of MPFR, MPC and GMP which the current MAGMA is using.

`GetGMPVersion()`
`GetMPFRVersion()`
`GetMPCVersion()`

The version of GMP, MPFR or MPC being used.

25.2 Creation Functions

We describe the creation of real and complex fields and their elements.

25.2.1 Creation of Structures

At the time MAGMA is loaded, a real field is automatically created. This is used as the default parent for literal reals and real values returned by MAGMA.

`RealField(p)`

`Bits` BOOLELT *Default :* `false`

Given a positive integer p, create and return a version R of the real field $\mathbf{R}$ in which all calculations are correct to precision p. If the parameter `Bits` is `true`, then the precision p is specified as the number of binary digits. If `Bits` is `false`, then the precision is given as the number of decimal digits — this is translated into a binary precision of $\lceil \log_2 10^p \rceil$.

`RealField()`

Return the default real field.

`ComplexField(p)`

`Bits` BoolElt *Default :* `false`

Given a positive integer p, create and return a version C of the complex field $\mathbf{C}$ in which all calculations are correct to precision p. If the parameter `Bits` is `true`, then the precision p is specified as the number of binary digits. If `Bits` is `false`, then the precision is given as the number of decimal digits — this is translated into a binary precision of $\lceil \log_2 10^p \rceil$.

By default no name is given to $\sqrt{-1}$; this may be changed with `AssignNames`. Angle brackets, e.g. `C<i> := ComplexField(20)`, may be used to assign $\sqrt{-1}$ to an identifier.

`ComplexField()`

Return the default complex field.

By default no name is given to $\sqrt{-1}$; this may be changed with `AssignNames`. Angle brackets, e.g. `C<i> := ComplexField()`, may be used to assign $\sqrt{-1}$ to an identifier.

`ComplexField(R)`

Return the complex field which has real subfield R; in other words, return the complex field with the same precision as the real field R.

Example H25E3

It is convenient to use i to define elements of a complex field. It is also possible to change the default printing of i, using `AssignNames`, as follows. Note that the latter procedure does not assign to an identifier, it only changes the printing.

```
> C<i> := ComplexField(20);
> Pi(C)+ 1/4*i;
3.14159265358979323850 + 0.25000000000000000000*i
> AssignNames(~C, ["k"]);
> Pi(C)+ 1/4*i;
3.14159265358979323850 + 0.25000000000000000000*k
> k := Name(C, 1);
> Pi(C)+ 1/4*k;
3.14159265358979323850 + 0.25000000000000000000*k
```

25.2.2 Creation of Elements

`d . eefpg`

`d . eEfPg`

Given a succession of literal decimal digits d, a succession of literal decimal digits e, a succession of literal decimal digits f, and an integer g, construct the real number $r = d.e \times 10^f$. If specified, the effect of g is to create r as an element of the real field of precision g.

If g is omitted (together with `p` or `P`), the real number will be created as an element of the default real field.

Both d and f may include a leading sign `+` or `-`; leading zeroes in d and f are ignored. If e consists entirely of zeroes it may be omitted together with the `.` and if f is zero it may be omitted together with `E` (or `e`). But note that if all of e, f and g are omitted the result will be an integer.

```
elt< R | m, n >
```

Given the real field R, an element m coercible into R and an integer n, construct the real number $m \times 2^n$ in R.

```
elt< C | x, y >
```

```
C ! [x, y]
```

Given the complex field C and elements x and y coercible into the real field underlying C, construct the complex number $x + y$i.

```
R ! a
```

Given an integer, a rational number, a quadratic or cyclotomic number field element a, this returns an element from the real field R that best approximates a. An error results if a is a non-real quadratic or cyclotomic field element.

If R is a field of precision r and a is an element of a real field S of precision s then:

if a is an element of a real field S of precision $s \geq r$, then an element of R approximating a to r digits is returned;

if a is an element of a real field S of precision $s < r$, then an element of R is returned approximating a, obtained by padding with zeroes until the required precision r is reached;

```
C ! a
```

Given an integer, a rational number, a quadratic or cyclotomic number field element a, this returns an element from the complex field C that best approximates a. The rules of coercion for the real and imaginary parts are the same as those for coercion into a real field.

Example H25E4

We create the real number 1.2345 in many ways. We assume that the default real field has not been changed.

```
> x := 1.2345;
> x, Parent(x);
1.234500000000000000000000000000 Real field of precision 30
> SetDefaultRealField(RealField(20));
> x1 := 1.2345;
> x1, Parent(x1);
1.2345000000000000000 Real field of precision 20
> x2 := 12345e-4;
> x2, Parent(x2);
1.2345000000000000000 Real field of precision 20
> x3 := 1.2345p10;
> x3, Parent(x3);
1.234500000 Real field of precision 10
> x4 := 12345e-4p8;
> x4, Parent(x4);
1.2345000 Real field of precision 8
> x5 := RealField(12) ! 1.2345;
> x5, Parent(x5);
1.23450000000 Real field of precision 12
```

The following generic element constructions are available; they return the 1 and 0 element of a real or complex field.

`One(R)` `Identity(R)`
`Zero(R)` `Representative(R)`

25.3 Structure Operations

25.3.1 Related Structures

`Category(R)` `Parent(R)`
`PrimeField(R)`

25.3.2 Numerical Invariants

`Characteristic(R)`

25.3.3 Ring Predicates and Booleans

IsCommutative(R) IsUnitary(R)
IsFinite(R) IsOrdered(R)
IsField(R) IsEuclideanDomain(R)
IsPID(R) IsUFD(R)
IsDivisionRing(R) IsEuclideanRing(R)
IsPrincipalIdealRing(R) IsDomain(R)
R eq S R ne S

25.3.4 Other Structure Functions

Precision(R)

Return the decimal precision p to which calculations are performed in the real or complex field R.

BitPrecision(R)

Return the (internally used) bit precision p to which calculations are performed in the real or complex field R.

25.4 Element Operations

25.4.1 Generic Element Functions and Predicates

All predicates on real or complex numbers that check whether these numbers are equal to an integer do so within the given precision of the parent field. Thus `IsOne(c)` for an element of a complex domain of precision 20 returns true if and only if the real part equals one and the imaginary part equals 0 up to 20 decimals.

Parent(r) Category(r)
IsZero(r) IsOne(r) IsMinusOne(r)
IsUnit(r) IsZeroDivisor(r)
IsIdempotent(r) IsNilpotent(r)
IsIrreducible(r) IsPrime(r)

25.4.2 Comparison of and Membership

The (in)equality test on real numbers of only test for equality up to the given precision. Equality testing on complex numbers is done by testing the real and imaginary parts.

The comparison functions `gt, ge, lt, le` are not defined for complex numbers.

```
a eq b    a ne b
a in R    a notin R
a gt b    a ge b    a lt b    a le b
Maximum(a, b)    Minimum(a, b)
Maximum(Q)    Minimum(Q)
```

25.4.3 Other Predicates

`IsIntegral(c)`

Returns `true` if and only if the real or complex number c is a rational integer.

`IsReal(c)`

Returns `true` if the complex number c is real, `false` otherwise. This checks whether the digits of the imaginary part of c are 0 up to the precision of the parent complex field.

25.4.4 Arithmetic

The binary operations `+, -, *, /` allow combinations of arguments from the integers, the rationals, and real and complex fields; automatic coercion is applied where necessary (see the Introduction).

```
+ r    - r
r + s    r - s    r * s    r / s    r ^ k
r +:= s    r -:= s    r *:= s    r /:= s    r ^:= s
```

25.4.5 Conversions

Here we list various ways to convert between integers, reals of fixed precision, complexes and their various representations, other than by the creation functions and `!`. See also the rounding functions in a later section.

`MantissaExponent(r)`

Given a real number r, this function returns a real number m (the mantissa of r) and an integer e (the exponent of r) such that $1 \leq m < 10$ and $r = m \times 2^e$.

`ComplexToPolar(c)`

Given a complex number c, return the modulus $m \geq 0$ and the argument a (with $-\pi \leq a \leq \pi$) of c as real numbers to the same precision as c.

`PolarToComplex(m, a)`

Given real numbers m and a, construct the complex number me^{ia}. The result will have the smaller of the precisions of m and a; each of m and a is allowed to be an integer or rational number; if both are integral or rational then the result will have the default precision, otherwise the result will be of the same precision as the real argument.

`Argument(c)`

`Arg(c)`

Given a complex number c, return the real number (to the same precision) that is the argument (in radians between $-\pi$ and π) of c.

`Modulus(c)`

Given a complex number c, return the real number (to the same precision as c) that is the modulus of c.

`Real(c)`

`Re(c)`

Given a complex number $c = x + y\mathrm{i}$, return the real part x of c (as a real number to the same precision as c).

`Imaginary(c)`

`Im(c)`

Given a complex number $c = x + y\mathrm{i}$, return the imaginary part y of c (as a real number to the same precision as c).

25.4.6 Rounding

`Round(r)`

Given a real number r, return the integer i for which $|r - i|$ is a minimum. i.e., the integer closest to r. If there are two such integers, the one of larger magnitude is chosen (rounding away from zero). Given a (non-real) complex number r, return the Gaussian integer i for which $|r - i|$ is a minimum, i.e. the Gaussian integer closest to r.

`Truncate(r)`

Given a real number r, return $\lfloor r \rfloor$ if r is positive, and return $-\lfloor -r \rfloor + 1$ if r is negative. Thus, the effect of this function is to round towards zero.

`Ceiling(r)`

`Ceiling(r)`

The ceiling of the real number r, i.e. the smallest integer greater than or equal to r.

`Floor(r)`

`Floor(r)`

The floor of the real number r, i.e. the greatest integer less than or equal to r.

25.4.7 Precision

`Precision(c)`

Given a real or complex number c belonging to the real or complex field C, return the decimal precision p to which calculations are performed in C.

`BitPrecision(c)`

Given a real or complex number c belonging to the real or complex field C, return the (internally used) bit precision p to which calculations are performed in C.

`Precision(L)`

`Precision(L)`

Gives a sequence of real or complex numbers, return the precision p of their parent field.

`ChangePrecision(r, n)`

`ChangePrecision(c, n)`

Coerces the real (r) or complex (c) number into a field of precision n.

25.4.8 Constants

Let R denote a real or complex field. The functions described below will return an approximation of certain constants to the precision associated with a given real or complex field R. If R is real, a real number is returned; if R is complex, a complex number with imaginary part zero is returned.

`Catalan(R)`

The value of Catalan's constant computed to the accuracy associated with the real or complex field R. Catalan's constant is the sum

$$\sum_{k=0}^{\infty}(-1)^k(2k+1)^{-2}.$$

MPFR calculates this constant using formula (31) of Victor Adamchik's document "33 representations for Catalan's constant"*, for more information see `mpfr.org`.

---

* `http://www-2.cs.cmu.edu/~adamchik/articles/catalan/catalan.htm`

`EulerGamma(R)`

The value of Euler's constant

$$\gamma = \lim_{n\to\infty}(1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{n} - \log n) \approx 0.57721566$$

computed to the precision of R.

`Pi(R)`

The value of π computed to the precision of R.

25.4.9 Simple Element Functions

`AbsoluteValue(r)`

`Abs(r)`

The absolute value of the real or complex number r.

`Sign(r)`

Return one of the integer values $+1$, 0, -1 depending upon whether the real number r is positive, zero or negative, respectively.

`ComplexConjugate(c)`

`Conjugate(c)`

The complex conjugate $x - y\mathrm{i}$ of a complex number $x + y\mathrm{i}$.

`Norm(c)`

The real norm of a real or complex number c; note that for complex $c = x + y\mathrm{i}$ this returns $x^2 + y^2$, while for elements of real domains it just returns the absolute value. The result lies in the same field as the argument.

`Root(r, n)`

Given a real number R and a positive integer n, calculate $\sqrt[n]{r}$ (using Newton's method without divisions) with the same precision. If n is even then r must be non-negative.

`SquareRoot(c)`

`Sqrt(c)`

Given a real or complex number c, return the square root of r as an element of the same field to which r belongs.

```
Distance(x, L)
Distance(x, L)
Distance(x, L)
Distance(x, L)
```

Given a sequence L of real or complex numbers and an additional number x compute the distance between x and L, ie. $\min_{y \in L} |x-y|$, that is the shortest distance between x and any element of L. Furthermore, the index in L of an element realising the distance is returned as a second argument.

```
Diameter(L)
Diameter(L)
```

Given a sequence L of real of complex numbers, compute the diameter of the set defined by L, ie. the smallest distance between distinct elements of L.

25.4.10 Roots

MAGMA contains a very powerful algorithm for finding highly accurate approximations to the complex roots of a polynomial; it is based on Xavier Gourdon's implementation of Schönhage's algorithm, which we will summarize below.

Given a polynomial $p = a_0 + a_1 z + \cdots + a_n z^n \in \mathbf{C}[z]$, define the norm of p, $|p|$, by

$$|p| = |a_0| + |a_1| + \cdots + |a_n|.$$

Schönhage's algorithm (given in his technical report of 1982 [Sch82]) takes as input a univariate polynomial p in $\mathbf{C}[z]$ and a positive real number ε, and finds linear factors $L_j = u_j z - v_j$ $(j = 1, \ldots, n = \deg(p))$ such that

$$|p - L_1 \cdots L_n| < \varepsilon |p|.$$

The parameter ε may be chosen so as to find the roots of p to within a certain ε', and this is how the function `Roots` described below works (when run with Schönhage's algorithm).

The algorithm uses the concept of a 'splitting circle' to find polynomials F and G such that $|p - FG| < \varepsilon_1 |p|$ for some ε_1 depending on ε.

This splitting circle method can then be applied recursively to F and G until we have only linear factors, as required.

The splitting circle method works as follows. For the purposes of this discussion assume that p is monic. Suppose we know a circle Γ such that, for some integer k with $0 < k < n$, there are k roots of p (say $u_1, \ldots, u_k$) which lie inside Γ, and the other $n - k$ roots $(u_{k+1}, \ldots, u_n)$ lie outside Γ. Note that the circle Γ is chosen so that the roots of p are not too close to it. Then we can write $p = FG$, where $F = (z - u_1) \ldots (z - u_k)$ and $G = (z - u_{k+1}) \ldots (z - u_n)$. Through shifts and scalings, we may assume that $\Gamma = \{c \in \mathbf{C} : \|z\| = 1\}$.

For m in $\{1, \ldots, k\}$, let s_m denote the m-th power sum of the roots of p which lie inside the splitting circle. That is,

$$s_m = u_1^m + \cdots + u_k^m.$$

The residue theorem can then be used to calculate s_m $(1 \leq m \leq k)$:

$$s_m = \frac{1}{2\pi i} \int_\Gamma z^m \frac{p'(z)}{p(z)}\, dz.$$

where the integration can be computed to the required precision by the discrete sum

$$s_m \approx \frac{1}{N} \sum_{j=0}^{N-1} \frac{p'(\omega^j)}{p(\omega^j)} \omega^{(m+1)j}.$$

for a large enough integer N, where $\omega = \exp(2\pi i/N)$.

The coefficients of the polynomial F can then be computed from the Newton sums s_m $(1 \leq m \leq k)$ using the classical Newton formulae. Then set $G = p/F$.

The integer N above needed to get F and G to the required precision can be quite large. It is more efficient to use a smaller value of N to give an approximation F_0 of F, and then use the following refining technique.

Define G_0 (an approximation of G) by $p = F_0 G_0 + r$, where $\deg(r) < \deg(F_0)$. We want polynomials f and g such that $F_1 = F_0 + f$ and $G_1 = G_0 + g$ are better approximations of F and G. Now

$$p - F_1 G_1 = p - F_0 G_0 - f G_0 - g F_0 - fg.$$

Hence choosing f and g such that

$$p - F_0 G_0 = f G_0 + g F_0$$

will lead to a second order error.

The Euclidean algorithm could be used to find f and g, but this is numerically unstable. It suffices to find polynomials H (called the auxiliary polynomial) and L such that

$$1 = H G_0 + L F_0,$$

where $\deg(H) < \deg(F_0)$ and $\deg(L) < \deg(G_0)$.

The polynomial H can be calculated using the formula

$$H(z) = \frac{1}{2\pi i} \int_\Gamma \frac{1}{(F_0 G_0)(t)} \frac{F_0(z) - F_0(t)}{z - t}\, dt.$$

Again, rather than computing the integral to the required precision directly, we find only an approximation H_0 and then refine it using Newton iteration:

$$H_{m+1} \equiv H_m(2 - H_m G_0) \pmod{F_0}.$$

Assuming that $|H - H_0|$ is small, the sequence (H_m) converges quadratically to H.

Once H is known to a large enough precision, f can be computed by

$$f \equiv H(p - F_0 G_0) \pmod{F_0}.$$

This gives us the new approximation F_1 of F, and G_1 is computed by division of p by F_1. We repeat this process until

$$|p - FG| < \varepsilon_1 |p|$$

and we are done.

The problem remains to find the splitting circle.

This relies mainly on the computation of the moduli of the roots of p. Let

$$r_1(p) \leq r_2(p) \leq \cdots \leq r_n(p)$$

denote the moduli of the roots of p in ascending order. For each k, the computation of $r_k(p)$ with a small number of digits can be achieved in a reliable way using the Graeffe process. The Graeffe process is a root squaring step transforming any given polynomial p into a polynomial q of the same degree whose roots are the square of the roots of p.

By the use of a suitable shift, we may assume that the sum of the roots of p is zero. If $p(0) = 0$, then we have found a factorization $p \approx FG$ with $F = z$ and $G = p/z$. If not, then the computation of the maximum root modulus $r_n(p)$ allows us to scale p so that its maximum root modulus is now close to 1. For $j = 0, 1, 2, 3$, set

$$q_j(z) = p(z + 2i^j).$$

Then amongst these four polynomials there exists q such that

$$\frac{r_n(q)}{r_1(q)} = \exp(\Delta),$$

with $\Delta > 0.3$. A dichotomic process from the computation of some $r_j(q)$ can then be applied to find k $(1 \leq k \leq n-1)$ such that

$$\frac{r_{k+1}(q)}{r_k(q)} > \exp(\frac{\Delta}{n-1}).$$

Then the circle $\{c : \|c\| = \sqrt{r_k(q) r_{k+1}(q)}\}$ is a suitable splitting circle, with the roots not too close to it.

`Roots(p)`

`Al`	MonStgElt	*Default :* "*Schonhage*"
`Digits`	RngIntElt	*Default :*

Given a univariate polynomial p over a real or complex field, this returns a sequence of complex approximations to the roots of p. The elements of this sequence are of the form $< r, m >$, where r is a root and m its multiplicity.

The algorithm used to find the roots of p may be specified by using the optional argument `Al`. This must be one of `"Schonhage"` (which is the default), `"Laguerre"`, `"NewtonRaphson"` or `"Combination"` (a combination of Laguerre and Newton-Raphson). When using the (default) Schönhage algorithm, the roots given are correct to within an absolute error of 10^{-d}, where d is the value of `Digits`. This algorithm gives correct results in all cases. When using the other algorithms (for which correct answers are not guaranteed in all cases), the results are found with `Digits` significant figures. The default value for `Digits` is the current precision of the free real field.

PARI is used here for complex polynomials.

Warning: Beware of the problems of floating point numbers. Because real numbers are stored in the computer with finite precision, you may not be finding the roots of the polynomial you want. If you know the polynomial exactly, you should enter it with exact (that is, integer or rational) coefficients. This is illustrated in the following example.

Example H25E5

```
> P<z> := PolynomialRing(ComplexField());
> p := (z-1.1)^6;
> p;
z^6 - 6.60000000000000000000000000001*z^5 +
    18.15000000000000000000000000000*z^4 -
    26.62000000000000000000000000000*z^3 +
    21.96150000000000000000000000000*z^2 -
    9.66306000000000000000000000003*z +
    1.77156100000000000000000000001
> R := Roots(p);
> R;
[ <1.100013305965906054216519998 57, 1>,

1.152315096132698580046691677 11E-5*i, 1> ]
> P<x> := PolynomialRing(Rationals());
> q := (x-11/10)^6;
> Roots(q);
[ <11/10, 6> ]
```

The function `RootsNonExact` (below) is more suitable for non-exact polynomials.

`RootsNonExact(p)`

Given a polynomial p of degree n defined over a real or complex field, returns a sequence $[v_1, \ldots, v_n]$ of complex numbers such that

$$|p - a(z - v_1) \ldots (z - v_n)| < 10^{-d}|p|,$$

where a is the leading coefficient of p, and d is the precision of the field.

A second sequence $[e_1, \ldots, e_n]$ of (free) real numbers may also be returned. Given any polynomial $\hat{p}$ such that $|p - \hat{p}| < 10^{-d}|p|$, we can write $\hat{p} = a(z - u_1) \ldots (z - u_n)$ with $|v_i - u_i| < e_i$. In some cases, such error bounds cannot be derived, because the value d of `Digits` is too small for the given polynomial. In these cases, this second sequence is not returned.

This function acknowledges the fact that the polynomial p may not be the exact polynomial wanted, but only an approximation (to a certain number of decimal places), and so the roots of the true polynomial can only be found to a limited number of decimal places. Increasing the precision will decrease the errors on the 'roots'.

Example H25E6

```
> P<z> := PolynomialRing(ComplexField());
> p := (z-1.1)^6;
> R, E := RootsNonExact(p);
> R;
[ 1.10001483296913451410370191006 -

`HenselLift(f, R, k)`

`HenselLift(f, R, k)`

Let f be a real or complex polynomial and x an approximation to a single zero of f. This function will apply the Newton-iteration to improve the accuracy of the root to the precision indicated by k.

25.4.11 Continued Fractions

The following functions use the continued fraction expansion of real numbers to get Diophantine approximations. They were obtained from corresponding PARI implementations.

`ContinuedFraction(r)`

`ContinuedFraction(r)`

`Bound` RNGINTELT *Default :* -1

Given an element r from a real field, return a sequence of integers s that form the partial quotient for the (regular) continued fraction expansion for r, so r is approximately equal to

$$s_1 + \cfrac{1}{s_2 + \cfrac{1}{s_3 + \cdots + \cfrac{1}{s_n}}}.$$

The length n of the sequence is determined in such a way that the last significant partial quotient is obtained (determined by the precision with which r is known), unless the optional integer argument `Bound` is used to limit the length.

`BestApproximation(r, n)`

Given an element r from a real field and a positive integer n, this function determines a rational approximation to r with denominator not exceeding n. The approximation is at least as close as the best continued fraction convergent with denominator not exceeding n. PARI is used here.

`Convergents(s)`

Given a sequence s of n non-negative integers (forming the partial fractions of a real number r, say), this function returns a 2×2 matrix with integer coefficients

$$\begin{pmatrix} p_n & p_{n-1} \\ q_n & q_{n-1} \end{pmatrix};$$

the quotients p_{n-1}/q_{n-1} and p_n/q_n form the last two convergents for r as provided by s.

25.4.12 Algebraic Dependencies

`LinearRelation(q: parameters)`

`LinearRelation(v: parameters)`

`Al`	MonStgElt	*Default :* "*Hastad*"

Given a sequence q or a vector v with entries from a complex field, return an integer sequence or vector forming the coefficients for a (small) linear dependency among the entries. The algorithm used may be specified by the optional parameter `Al`. The default is `"Hastad"`, which uses a variation of the LLL algorithm due to Hastad, Lagarias and Schnorr; the alternative is `"LLL"`, which uses a straight LLL algorithm. Pari is used here. The new version of this function is `IntegerRelation`.

`AllLinearRelations(q,p)`

Given a sequence q with entries from a real or complex field, return the lattice of all (small) integer linear dependencies among the entries. The precision, p, given as second argument is used for two purposes. First "small" is defined to be any relation such that the sum of the digits of the coefficients is less than p. Second, a linear relation must be zero to within 10^{-p}.

`PowerRelation(r, k: parameters)`

`Al`	MonStgElt	*Default :* "*Hastad*"
`Precision`	RngIntElt	*Default :*

Given an element r from a real or complex field, and an integer $k > 0$, return a univariate integer polynomial of degree at most k having r as an approximate root. The parameters here have the same usage and meaning as for `LinearRelation`. Pari is used here. The new version of this function is `MinimalPolynomial`.

25.5 Transcendental Functions

25.5.1 Exponential, Logarithmic and Polylogarithmic Functions

In this section the exponential and logarithmic functions to the natural base e are described, as well as the conversion to the logarithm with respect to any base.

The power series expansions are

$$e^z = \sum_{n=0}^{\infty} \frac{z^n}{n!}, \quad \ln(1+z) = \sum_{n=1}^{\infty} (-1)^{n-1} \frac{z^n}{n}.$$

Further information on the Dilog and Polylog functions can be found in Lewin [Lew81].

`Exp(f)`

Given a power series f defined over a real or complex field, return the exponential power series of f.

`Exp(c)`

Given an arbitrary real or complex number c, return the exponential e^c of c. Here c is allowed to be free or of fixed precision, and the result is in the same field as c.

`Log(f)`

Given a power series f defined over a real or complex field, return the logarithm of f. The valuation of f must be zero.

`Log(c)`

Given a non-zero real or complex number c, return the logarithm of c (to the natural base e). The principal value with imaginary part in $(-\pi, \pi]$ is chosen. The result will be a complex number, unless the argument is real and positive, in which case a real number is returned.

`Log(b, r)`

Given non-negative real numbers b and r, return the logarithm $\log_b(r)$ of a to the base b. Automatic coercion is applied if necessary.

`Dilog(s)`

For a given complex s, this returns the value of the principal branch of the *dilogarithm* $\mathrm{Li}_2(s)$, which can be defined by

$$\mathrm{Li}_2(s) = -\int_0^s \frac{\log(1-s)}{s} ds,$$

and forms the analytic continuation of the power series

$$\sum_{n=1}^{\infty} \frac{s^n}{n^2},$$

(which is convergent for $|s| \leq 1$). For large values of the argument a functional equation like

$$\mathrm{Li}_2(\frac{-1}{s}) + \mathrm{Li}_2(-s) = 2\mathrm{Li}_2(-1) - \frac{1}{2}\log^2(s)$$

should be used.

`Polylog(m, f)`

For an integer $m \geq 2$ and power series f defined over a real or complex field, return the m-th polylogarithm of the series f. The valuation of f must be positive for $m > 1$.

`Polylog(m, s)`

For given integer $m \geq 2$ and complex s this returns the value of the principal branch of the *polylogarithm* $\mathrm{Li}_m(s)$, defined for $m \geq 3$ by

$$\mathrm{Li}_m(s) = \int_0^s \frac{\mathrm{Li}_{m-1}(s)}{s} ds$$

(and for $m = 2$ as the dilogarithm Li_2). Then Li_m is the analytic continuation of

$$\sum_{n=1}^{\infty} \frac{s^n}{n^m},$$

(which is convergent for $|s| \leq 1$). For large values of the argument a functional equation like

$$(-1)^m \mathrm{Li}_m(\frac{-1}{s}) + \mathrm{Li}_m(-s) = -\frac{1}{m!}\log^m(s) + 2\sum_{r=1}^{\lfloor m/2 \rfloor} \frac{\log^{m-2r}(s)}{(m-2r)!}\mathrm{Li}_{2r}(-1)$$

should be used. PARI is used here.

`PolylogD(m, s)`

`PolylogDold(m, s)`

`PolylogP(m, s)`

Given integer $m \geq 2$ and complex s, this returns the value of the principal branch of the modified versions $\tilde{D}_m, D_m$ and P_m of the polylogarithm $\mathrm{Li}_m(s)$; all of these satisfy functional equations of the form $f_m(1/s) = (-1)^m f_m(s)$. For their definition and main properties, see Zagier [Zag91]. PARI is used here.

25.5.2 Trigonometric Functions

The trigonometric functions may be computed for real and complex arguments or for power series defined over a real or complex field. The basic power series expansions are

$$\sin(z) = \sum_{n=0}^{\infty} \frac{(-1)^{n+1} z^{2n+1}}{(2n+1)!}, \quad \cos(z) = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n}}{(2n)!}.$$

Euler's formulas relate these with the exponential functions via

$$\sin(z) = \frac{e^{\mathrm{i}z} - e^{-\mathrm{i}z}}{2\mathrm{i}}, \quad \cos(z) = \frac{e^{\mathrm{i}z} + e^{-\mathrm{i}z}}{2}.$$

`Sin(f)`

Given a power series f defined over a real or complex field, return the power series $\sin(f)$.

`Sin(c)`

Given a real or complex number c, return the value $\sin(c)$.

`Cos(f)`

Given a power series f defined over a real or complex field, return the power series $\cos(f)$.

`Cos(c)`

Given a real or complex number c, return the value $\cos(c)$.

`Sincos(f)`

Given a power series f defined over a real or complex field, return the two power series $\sin(f)$ and $\cos(f)$.

`Sincos(s)`

Given a real or complex number s, return the two values $\sin(s)$ and $\cos(s)$.

`Tan(f)`

Given a power series f defined over the real or complex field, return the power series $\tan(f)$.

`Tan(c)`

Given a real or complex number c, return the value $\tan(c) = \frac{\sin(c)}{\cos(c)}$. Note that c should not be too close to one of the zeroes $(\pi/2 + n \cdot \pi)$ of $\cos(z)$.

`Cot(f)`

Given a power series f defined over a real or complex field having valuation zero, return the power series $\cot(f)$.

`Cot(c)`

Given a real or complex number c, return the value $\cot(c) = \cos(c)/\sin(c)$. Note that c should not be too close to one of the zeroes $n \cdot \pi$ of $\sin(z)$.

`Sec(f)`

Given a power series f defined over a real or complex field, return the power series $\sec(f)$.

`Sec(c)`

Given a real or complex number c, return the value $\sec(c) = 1/\cos(c)$. Note that c should not be too close to one of the zeroes $(\pi/2 + n \cdot \pi)$ of $\cos(z)$.

`Cosec(f)`

Given a power series f defined over a real or complex field having valuation zero, return the power series $\mathrm{cosec}(f)$.

`Cosec(c)`

Given a real or complex number c, return the value $\mathrm{cosec}(c) = 1/\sin(c)$. Note that c should not be too close to one of the zeroes $n \cdot \pi$ of $\sin(z)$.

25.5.3 Inverse Trigonometric Functions

The inverse trigonometric functions are all available for arbitrary real or complex arguments. The principal values are chosen as indicated.

We mention the power series expansions for the inverse of the sine and tangent functions (for $|z| \leq 1$):

$$\arcsin(z) = \sum_{n=0}^{\infty} \left(\prod_{k=1}^{2n} k^{(-1)^{k-1}}\right) \frac{z^{2n+1}}{2n+1},$$

$$\arctan(z) = \sum_{n=1}^{\infty} (-1)^n \frac{z^{2n+1}}{2n+1}.$$

The important relations with the logarithmic function include

$$\arcsin(z) = \frac{1}{\mathrm{i}} \log(\mathrm{i}z + \sqrt{1-z^2}),$$

$$\arccos(z) = \frac{1}{\mathrm{i}} \log(z + \sqrt{z^2-1}),$$

$$\arctan(z) = \frac{1}{2\mathrm{i}} \log\left(\frac{1+\mathrm{i}z}{1-\mathrm{i}z}\right).$$

`Arcsin(f)`

Given a power series f defined over a real or complex field. return the inverse sine of the power series f.

`Arcsin(r)`

Given a real or complex number s, return a value t such that $\sin(t) = s$. The principal value with real part in $[-\pi/2, \pi/2]$ is chosen. The return value is a complex number, unless s is real and $-1 \leq s \leq 1$, in which case a free real number is returned.

`Arccos(f)`

Given a power series f defined over a real or complex field. return the inverse cosine of the power series f.

`Arccos(r)`

Given a real or complex number s, return a value t such that $\cos(t) = s$. The principal value with real part in $[0, \pi]$ is chosen. The return value is a complex number, unless s is real and $-1 \leq s \leq 1$, in which case a free real number is returned.

`Arctan(f)`

Given a power series f defined over the real or complex field, return the inverse tangent of the power series f.

`Arctan(r)`

Given a real or complex number s, return a value t such that $\tan(t) = s$. The principal value with real part in $(-\pi/2, \pi/2)$ is chosen. The return value is a complex number, unless s is real, in which case a free real number is returned.

`Arctan(x, y)`

`Arctan2(x, y)`

Given the real numbers x and y, return the value v of $\arctan(y/x)$ determined by the choice of signs for x and y. That is, the value v is chosen in $(-\pi, \pi)$ in such a way that the signs of x and $\sin(v)$ coincide, as well as the signs of y and $\cos(v)$. An error occurs if x and y are both zero; if y is zero and x non-zero, the value returned is $\text{sign}(x) \cdot \pi/2$.

The arguments are allowed to be in any real field (automatic coercion is used whenever necessary).

`Arccot(r)`

Given a real or complex number s, return a value t such that $\cot(t) = s$. The principal value with real part in $(-\pi/2, \pi/2)$ is chosen. The return value is a complex number, unless s is real, in which case a real number is returned.

`Arcsec(r)`

Given a real or complex number s, return a value t such that $\sec(t) = s$. The principal value with real part in $[0, \pi/2) \cup (\pi/2, \pi]$ is chosen. The return value is a complex number, unless s is real, in which case a real number is returned.

`Arccosec(r)`

Given a real or complex number s, return a value t such that $\text{cosec}(t) = s$. The principal value with real part in $[-\pi/2, 0) \cup (0, \pi/2]$ is chosen. The return value is a complex number, unless s is real, in which case a real number is returned.

25.5.4 Hyperbolic Functions

The hyperbolic functions are available for real and complex arguments, as specified below.

The hyperbolic functions are defined using

$$\sinh(z) = \frac{e^z - e^{-z}}{2},$$
$$\cosh(z) = \frac{e^z + e^{-z}}{2}.$$

`Sinh(f)`

Given a power series f defined over a real or complex field, return the hyperbolic sine of the power series f.

`Sinh(s)`

Given a real or complex number s, return $\sinh(s)$. The result will be a real or complex value, in accordance with the argument.

`Cosh(f)`

Given a power series f defined over a real or complex field, return the hyperbolic cosine of the power series f.

`Cosh(r)`

Given a real or complex number s, return $\cosh(s)$. The result will be a real or complex value, in accordance with the argument.

`Tanh(f)`

Given a power series f defined over a real or complex field, return the hyperbolic tangent of the power series f.

`Tanh(r)`

Given a real or complex number s, return $\tanh(s) = \frac{\sinh(s)}{\cosh(s)}$. The result will be a real or complex value, in accordance with the argument.

`Coth(r)`

Given a real or complex number s, return $\coth(s) = \frac{\cosh(s)}{\sinh(s)}$. The result will be a real or complex value, in accordance with the argument.

`Sech(r)`

Given a real or complex number s, return $\mathrm{sech}(s) = 1/\cosh(s)$. The result will be a real or complex value, in accordance with the argument.

`Cosech(r)`

Given a real or complex number s, return $\mathrm{cosech}(s) = 1/\sinh(s)$. The result will be a real or complex value, in accordance with the argument.

25.5.5 Inverse Hyperbolic Functions

The inverse hyperbolic functions are available for real or complex arguments. The principal values are chosen as indicated.

`Argsinh(f)`

Given a power series f defined over a real or complex field, return the inverse hyperbolic sine of the power series f.

`Argsinh(r)`

Given a real or complex number s, return t such that $\sinh(t) = s$; the principal value with imaginary part in $[\pi/2, \pi/2]$ is chosen. The return value is a complex number, unless the argument is real, in which case a real number is returned.

`Argcosh(f)`

Given a power series f defined over a real or complex field, return the inverse hyperbolic cosine of the power series f.

`Argcosh(r)`

Given a real or complex number s, return t such that $\cosh(t)) = s$; the principal value with imaginary part in $[0, \pi]$ is chosen. The return value is a complex number, unless the argument is real and $s \geq 1$, in which case a real number is returned.

`Argtanh(f)`

Given a power series f defined over a real or complex field, return the inverse hyperbolic tangent of the power series f.

`Argtanh(s)`

Given a real or complex number s, return t such that $\tanh(t) = s$; the principal value with imaginary part in $[\pi/2, \pi/2]$ is chosen. The return value is a complex number, unless the argument is real and $-1 < s < 1$, in which case a real number is returned.

`Argsech(s)`

Given a real or complex number s, return t such that $\mathrm{sech}(t)) = s$; the principal value with imaginary part in $[0, \pi]$ is chosen. The return value is a complex number, unless the argument is real and $|s| \geq 1$, in which case a real number is returned.

`Argcosech(s)`

Given a real or complex number s, return t such that $\mathrm{cosech}(t)) = s$; the principal value with imaginary part in $[-\pi/2, \pi/2]$ is chosen. The return value is a complex number, unless the argument is real, in which case a real number is returned.

`Argcoth(s)`

Given a real or complex number s, return t such that $\coth(t)) = s$; the principal value with imaginary part in $[-\pi/2, \pi/2]$ is chosen. The return value is a complex number, unless the argument is real and $0 < s \leq 1$, in which case free real number is returned.

25.6 Elliptic and Modular Functions

More information on elliptic functions can be found for example in Chandrasekharan [Cha85], and for modular functions and their use see Koblitz [Kob84].

25.6.1 Eisenstein Series

Let $f(z)$ be a modular function. Then $f(z)$ may be written as a Fourier series

$$f(z) = \sum_{n \in \mathbf{Z}} a_n q^n,$$

where $q = e^{2\pi i z}$, which has at most finitely many nonzero coefficients a_n with $n < 0$. Such a Fourier expansion of a modular function is called its *q-expansion*. In this and the next section we present intrinsics for q-expansions of the Eisenstein series and the Weierstrass $\wp$-function.

Let z be a point in the upper half-plane and let L be a lattice in $\mathbf{C}$. The Eisenstein series are defined as the coefficients of the Laurent Series expansion of the Weierstrass $\wp$-function:

$$\wp(z, L) = \frac{1}{z^2} + \sum_{2 \leq k} G_k(L)(2k-1)z^{2k-2}$$

where $G_k(L)$ are the Eisenstein series. The normalization $E_{2n}(z) = \frac{1}{2\zeta(2n)} G_{2n}(z)$ ensures that $E_{2n}(z)$ has a *rational* q-expansion.

`Eisenstein(k, z)`

`Precision` RngIntElt *Default :*

Given a positive even integer $k = 2n$ and a complex power series z with positive valuation, return the q-expansion of the normalized Eisenstein series $E_{2n}(z)$. If z has finite precision this is the default for `Precision` otherwise the default precision of the parent of z is used.

`Eisenstein(k, t)`

Given a positive even integer $k = 2n$ and a point t in the upper half plane, return the value of $E_{2n}(z)$ at t.

`Eisenstein(k, L)`

Given a positive even integer $k = 2n$ and a lattice $L = [a, b]$ in the complex plane, return the value of the Eisenstein series $E_{2n}(z)$ relative to the lattice L.

`Eisenstein(k, F)`

Given a positive even integer $k = 2n$ and a binary quadratic form $F = ax^2 + bxy + cy^2$, return the value of the Eisenstein series $E_{2n}(z)$ at the point $\tau = \left(-b + \sqrt{b^2 - 4ac}\right)/(2a)$ where z is $e^{2\pi * \mathrm{i} * \tau}$.

Example H25E7

We compute the q-expansion for the normalized Eisenstein series $E_4(z)$.

```
> C<i> := ComplexField();
> R<z> := PowerSeriesRing(C);
> E4<q> := Eisenstein(4, z);
> E4;
1.0000000000000000000000000000 +
    240.0000000000000000000000000000*q +
    2160.0000000000000000000000000000*q^2 +
    6720.0000000000000000000000000000*q^3 +
    17520.0000000000000000000000000000*q^4 +
    30240.0000000000000000000000000000*q^5 +
    60480.0000000000000000000000000000*q^6 +
    82560.0000000000000000000000000000*q^7 +
    140400.0000000000000000000000000000*q^8 +
    181680.0000000000000000000000000000*q^9 +
    272160.0000000000000000000000000000*q^10 +
    319680.0000000000000000000000000000*q^11 +
    490560.0000000000000000000000000000*q^12 +
    527520.0000000000000000000000000000*q^13 +
    743040.0000000000000000000000000000*q^14 +
    846720.0000000000000000000000000000*q^15 +
    1123440.0000000000000000000000000000*q^16 +
    1179360.0000000000000000000000000000*q^17 +
    1635120.0000000000000000000000000000*q^18 +
    1646400.0000000000000000000000000000*q^19 + O(q^20)
```

We now evaluate this series at the point $z1 = 2.5 + i$. Since the expansion is in terms of q rather than z we first must calculate the point $q1$ that corresponds to $z1$.

```
> q1 := Exp(2*Pi(RealField())*i*(2.5 +i));
> Evaluate(E4, q1);
0.55930285285619077376676241 1942 +
3.67329046709782088758389413820E-31*i
```

If we are interested only in the value of E_4 at a single point, then we can compute it directly:

```
> Eisenstein(4, 2.5 + i);
```

```
0.55930285285619077376676241 1942 +
3.67329046709782088758389413820E-31*i
```

25.6.2 Weierstrass Series

`WeierstrassSeries(z, q)`

`Precision` RngIntElt *Default :*

Return a normalized q-expansion of the Weierstrass $\wp$-function:

$$\wp(z, L) = \frac{1}{z^2} + \sum_{2 \leq k} G_k(L)(2k-1)z^{2k-2}$$

where $G_k(L)$ are the Eisenstein series and

$$\texttt{WeierstrassSeries}(z, q) = (2\pi i)^{-2}\wp(q, z/(2\pi i))$$

Each term is an Eisenstein series, calculated to precision `Precision`, which is by default the precision of q.

`WeierstrassSeries(z, t)`

Given a complex power series z with positive valuation and a point $t = \tau$ in the upper-half complex plane, return the normalized q-expansion of the Weierstrass $\wp$-function. This is equivalent to evaluating the q-series expansion at $q = e^{2\pi i\tau}$.

`WeierstrassSeries(z, L)`

Given a complex power series z with positive valuation and a lattice $L = [a, b]$ in the complex plane, returns the normalized q-expansion of the Weierstrass $\wp$-function relative to the lattice L.

`WeierstrassSeries(z, F)`

Given a complex power series z with positive valuation and a binary quadratic form $F = ax^2 + bxy + cy^2$, this function returns the q-expansion of the Weierstrass $\wp$-function at $\tau = \left(-b + \sqrt{b^2 - 4ac}\right)/(2a)$

25.6.3 The Jacobi θ and Dedekind η-functions

The first Jacobi θ-function, $\theta(q,z)$, is defined by

$$\theta(q,z) = \frac{1}{\mathrm{i}} \sum_{n=-\infty}^{\infty} (-1)^n q^{(n+\frac{1}{2})^2} e^{(2n+1)\mathrm{i}z} = 2\sum_{n=0}^{\infty} (-1)^n q^{(n+\frac{1}{2})^2} \sin(2n+1)z.$$

Defined this way, θ satisfies $\theta(q,-z) = -\theta(q,z)$, it is periodic with period 2π in the second variable: $\theta(q,z+2\pi) = \theta(q,z)$, and its zeroes are of the form $m_1\pi + m_2\frac{\log x}{\mathrm{i}}$ for any integers m_1, m_2.

`JacobiTheta(q, z)`

For a real or complex number q satisfying $|q| < 1$, return the first of Jacobi's theta functions $\theta(q,z)$ as a power series expansion in z, a series over the complex numbers. PARI is used here.

`JacobiTheta(q, z)`

For real or complex numbers q, z satisfying $|q| < 1$, return the value of $\theta(q,z)$, the first of Jacobi's theta functions. PARI is used here.

`JacobiThetaNullK(q, k)`

For integer $k \geq 0$, return the k-th derivative $\theta^{(k)}(q,0)$ of $\theta(q,z)$ at $z = 0$. PARI is used here.

`DedekindEta(z)`

Given a complex power series z with positive valuation, return the q-expansion of Dedekind's η-function. Note that the unnormalized series is returned, that is, the factor $q^{1/24}$ is *not* removed. See [Lan87].

`DedekindEta(s)`

For complex argument s with positive imaginary part, this returns the actual value of Dedekind's η-function which is defined by

$$\eta(s) = e^{\frac{2\pi\mathrm{i}s}{24}} \left(1 + \sum_{n=1}^{\infty} (-1)^n (q^{n(3n-1)/2} + q^{n(3n+1)/2})\right)$$

where $q = e^{2\pi\mathrm{i}s}$.

25.6.4 The j-invariant and the Discriminant

The discriminant of the elliptic curve corresponding to the complex lattice L_τ, spanned by 1 and τ is given by

$$\Delta(\tau) = q\left(1 + \sum_{n=1}^{\infty}(-1)^n(q^{n(3n-1)/2} + q^{n(3n+1)/2})\right)$$

where $q = e^{2\pi i\tau}$.

`jInvariant(q)`

Given a power series q over a real or complex field with positive valuation, return the q-expansion of the elliptic j-invariant. The expansion begins with

$$j(q) = q^{-1} + 744 + 196884q + \cdots.$$

Note that:

$$j(q) = \frac{E_4(q)^3}{\Delta(q)}$$

where $E_4(q) =$ `Eisenstein(4, q)` and $\Delta(q) =$ `Delta(q)`.

`jInvariant(s)`

For complex argument s with positive imaginary part, this returns the value of the elliptic j-invariant at s. This is a modular function of weight 0 whose Fourier expansion starts with

$$j(s) = e^{-2\pi is} + 744 + 196884e^{2\pi is} + \cdots.$$

`jInvariant(L)`

Given a lattice $L = [a, b]$ in the complex plane, this function returns the value of the elliptic j-invariant of L. This is the j-invariant of τ where $\tau = a/b$ or $\tau = b/a$, whichever is in the upper half complex plane.

`jInvariant(F)`

For a binary quadratic form $F = ax^2 + bxy + cy^2$ with negative discriminant, this returns the elliptic j-invariant of F. This is the j-invariant of τ where $\tau = \left(-b + \sqrt{b^2 - 4ac}\right)/(2a)$.

`Delta(z)`

Given a complex power series z, this function returns a q-series expansion of the discriminant $\Delta(z)$.

`Delta(t)`

Given a point t in the upper half plane, return the q-series expansion of the discriminant $\Delta(q)$ evaluated at $q = e^{2\pi i t}$.

`Delta(L)`

Given a pair $L = [a,b]$ of complex numbers generating a lattice in $\mathbf{C}$, return the q-series expansion of the discriminant $\Delta(q)$ evaluated at $q = e^{2\pi i \tau}$ where $\tau = a/b$ or $\tau = b/a$, whichever is in the upper half complex plane.

25.6.5 Weber's Functions

`WeberF(s)`

For complex argument s in the upper half-plane, this returns the value of Weber's function f, defined in such a way that

$$j(s) = \frac{(f(s)^{24} - 16)^3}{f(s)^{24}}.$$

`WeberF2(g)`

For a complex power series g having positive valuation, this function returns the q-expansion of Weber's f_2 function

$$f_2(x) = \frac{\eta(2x)\sqrt{2}}{\eta(x)}$$

defined in such a way that

$$j(s) = \frac{(f_2(s)^{24} + 16)^3}{f_2(s)^{24}}.$$

`WeberF1(s)`
`WeberF2(s)`

For complex number s lying in the upper half-plane, these return the value of Weber's functions f_1 and f_2, defined in such a way that

$$j(s) = \frac{(f_{1/2}(s)^{24} + 16)^3}{f_{1/2}(s)^{24}}.$$

In fact, f_2 is as defined above and

$$f_1(x) = f_2(-1/x) = \eta(x/2)/\eta(x)$$

Example H25E8

We compute the q-expansion for the Weber function $f_2(z)$.

```
> C<i> := ComplexField();
> R<x> := PowerSeriesRing(C);
> f2<q> := WeberF2(x);
> f2;
1.41421356237309504880168872421 +
    (1.41421356237309504880168872421 +
    0.37024024484653052058465674917 2*i)*q +
    (1.36574922765338060759226121771 +

    ...
```

25.7 Theta Functions

One of the main tools for working with analytic Jacobians is the theta function. For instance it is used by FromAnalyticJacobian on page 4209 and RosenhainInvariants on page 4216. For $c \in \mathbf{R}^{2g}$ let c' be the first g entries and c'' the second g entries of c. For such a c, $z \in \mathbf{C}^g$ and τ an element of Siegel upper half-space the classical multi-variable theta function is defined by

$$\theta[c](z,\tau) = \sum_{m \in \mathbf{Z}^g} \exp(\pi i^t (m+c')\tau(m+c') + 2\pi i^t (m+c')(z+c'')).$$

The vector c is called the characteristic of the theta function.

`Theta(char, z, tau)`

This computes the multidimensional theta function with characteristic *char* (a $2g \times 1$ matrix) at z (a $g \times 1$ matrix) and τ (a symmetric $g \times g$ matrix with positive definite imaginary part).

`Theta(char, z, A)`

This computes the multidimensional theta function with characteristic *char* (a $2g \times 1$ matrix) at z (a $g \times 1$ matrix) and τ, the small period matrix of the analytic Jacobian A. This function caches the values of theta null values ($z = 0$) at half-integer characteristics.

25.8 Gamma, Bessel and Associated Functions

As a general reference to the functions described in this section (and much more), we refer the reader to Whittaker and Watson [WW15].

`Gamma(f)`

Return the Gamma function $\Gamma(f)$ of the series f. f must be defined over the free real or complex field, the valuation of f must be 0 and the constant term of f must be 1.

`Gamma(r)`

`Gamma(r)`

Given a real or complex number s (not equal to $0, -1, -2, \ldots$), calculate the value $\Gamma(s)$ of the *gamma function* at s. For s with positive real part this is the value of

$$\Gamma(s) = \int_0^\infty u^{s-1} e^{-u} du.$$

For other s (not a non-positive integer) the function is defined by analytic continuation, and it satisfies the product formula

$$\frac{1}{s\Gamma(s)} = e^{\gamma s} \prod_{n=1}^{\infty} (1 + \frac{s}{n}) e^{-s/n}.$$

The function Γ also satisfies

$$\Gamma(s)\Gamma(1-s) = \frac{\pi}{\sin(\pi s)},$$

and

$$\Gamma(s+1) = s\Gamma(s).$$

`Gamma(r, s)`

`Complementary`	BoolElt	*Default :* `false`
`Gamma`	FldReElt	*Default :*

For real numbers s, t this returns the value of the incomplete gamma function

$$\gamma(s,t) = \int_0^t u^{s-1} e^{-u} du.$$

The optional argument `Complementary` can be used to find the complement

$$\int_t^\infty u^{s-1} e^{-u} du$$

instead. There is a second optional argument that may be used in the computation of the incomplete gamma value; the free real value of `Gamma` should be the value of $\Gamma(s)$, in which case $\gamma(s,t)$ may be computed as the difference between the given value for $\Gamma(s)$ and that of the complementary γ at s, t. Pari is used here.

`GammaD(s)`

For free real s (such that $s + \frac{1}{2}$ is not a non-positive integer) this returns the value of $\Gamma(s + \frac{1}{2})$. For integer values of s this is faster than `Gamma(s+(1/2))`, because Legendre's doubling formula

$$\Gamma(s + \frac{1}{2}) = 2^{1-2s}\sqrt{\pi}\frac{\Gamma(2s)}{\Gamma(s)}$$

is used. PARI is used here.

`LogGamma(f)`

Return the Log-Gamma function $\mathrm{Log}(\Gamma(f))$ of the series f. f must be defined over a real or complex field, the valuation of f must be 0 and the constant term of f must be 1.

`LogGamma(r)`

For real or complex s (not a non-positive integer) return the value of the principal branch of the logarithm of the gamma function of s.

`LogDerivative(s)`

`Psi(s)`

For real or complex s (not a non-positive integer) return the principal value of the logarithmic derivative

$$\Psi(s) = \frac{d\log\Gamma(s)}{ds} = \frac{\Gamma'(s)}{\Gamma(s)},$$

of the gamma function, which allows the expansion

$$\Psi(s) = -\gamma - \frac{1}{s} + s\sum_{n=1}^{\infty}\frac{1}{n(s+n)};$$

here γ is Euler's gamma. PARI is used here.

`BesselFunction(n, r)`

Given a small integer n and a real number r, calculate the value of the *Bessel function* $y = J_n(r)$, of the first kind of order n. Results for negative arguments are defined by: $J_{-n}(r) = J_n(-r) = (-1)^n J_n(r)$. The Bessel function of the first kind of order n is defined by

$$J_n(x) = \frac{1}{2\pi\mathrm{i}}\left(\frac{z}{2}\right)^n \int_{-\infty}^{0^+} u^{-n-1}e^{u-\frac{z^2}{4t}}\,du,$$

and satisfies

$$J_n(x) = \sum_{k=0}^{\infty} \frac{(-1)^k z^{n+2k}}{2^{n+2k} k! \Gamma(n+k+1)}.$$

`BesselFunctionSecondKind(n, r)`

Given a small integer n and a real number r, calculate the value of the *Bessel function* $y = Y_n(r)$, of the second kind of order n. Results for negative arguments are defined by: $Y_{-n}(r) = -(-1)^n Y_n(r)$, $Y_n(-r)$ is not a real number. The Bessel function of the second kind of order n satisfies the Bessel differential equation.

`JBessel(n, s)`

Given a small integer n and a real number s, calculate the value of the *Bessel function* of the first kind of half integral index $n + \frac{1}{2}$, $J_{n+\frac{1}{2}}$, defined as above. PARI is used here.

`KBessel(n, s)`

`KBessel2(n, s)`

Given a complex n and a positive real s, compute the value of the *modified Bessel function of the second kind* $K_n(s)$, which may be defined by

$$K_n(s) = \frac{\pi}{2} \left(\mathrm{i}^n J_{-n}(\mathrm{i}s) - \mathrm{i}^{-n} J_n(s) \right) \cot(n\pi).$$

The function `KBessel2` is an alternative (often faster) implementation of this function. PARI is used here.

25.9 The Hypergeometric Function

For more information on the Hypergeometric Series, see Husemöller [Hus87], page 176.

`HypergeometricSeries(a,b,c, z)`

Return the hypergeometric series $F(a, b, c; z)$ defined by

$$F(a, b, c; z) = \sum_{0 \le n} \frac{(a)_n (b)_n}{n! (c)_n z^n}$$

where $(a)_n = a(a+1)\cdots(a+n-1)$.

`HypergeometricU(a, b, s)`

For positive real s and complex arguments a and b this function returns the value of the confluent hypergeometric function $U(a, b, s)$. This can be defined by

$$U(a, b, s) = \frac{1}{\Gamma(a)} \int_{u=0}^{\infty} e^{-su} u^{a-1} (1+u)^{b-a-1)} du.$$

PARI is used here.

25.10 Other Special Functions

`ArithmeticGeometricMean(x, y)`

`AGM(f, g)`

Return the hyperbolic arithmetic-geometric mean of the series f and g defined over a field. The valuations of f and g must be equal.

`ArithmeticGeometricMean(x, y)`

`AGM(x, y)`

Returns the arithmetic-geometric mean of the real or complex numbers x and y, defined as the limit of either of the sequences x_i, y_i where $x_0 = x$, $y_0 = y$ and $x_{i+1} = (x_i + y_i)/2, y_{i+1} = \sqrt{x_i y_i}$. The function calculates both sequences, and when the numbers are within the desired precision of each other, it returns one of them.

`BernoulliNumber(n)`

For a non-negative integer n, return the value of the n-th Bernoulli number B_n, defined by

$$\frac{t}{e^t - 1} = \sum_{n=0}^{\infty} B_n \frac{t^n}{n!}.$$

`BernoulliApproximation(n)`

For a non-negative integer n, return an approximation in the field of real numbers to the value of the n-th Bernoulli number B_n, defined by

$$\frac{t}{e^t - 1} = \sum_{n=0}^{\infty} B_n \frac{t^n}{n!}.$$

`DawsonIntegral(r)`

Given a real number r, compute the value of *Dawson's integral*,

$$e^{-x^2} \cdot \int_0^x e^{u^2} du,$$

at $x = r$. The mp real package is used here.

`ErrorFunction(r)`

`Erf(r)`

Given a real number r, calculate the value of the *error function* erf. This is the value of

$$\sqrt{\frac{4}{\pi}} \cdot \int_0^x e^{-u^2} du,$$

at $x = r$ for $r > 0$, and for $r < 0$ it is defined by $\mathrm{erf}(x) = -\mathrm{erf}(-x)$, while $\mathrm{erf}(0) = 0$.

`ComplementaryErrorFunction(r)`

`Erfc(r)`

Given a real number r, calculate the value of the *complementary error function*. This is the value of $y = \operatorname{erfc}(x) = 1 - \operatorname{erf}(x)$. for the error function erf as defined above.

`ExponentialIntegral(r)`

Given a real number r, calculate the value of the *exponential integral*, that is, the principal value of

$$\int_{-\infty}^{x} \frac{e^u}{u} du$$

at $x = r$.

`ExponentialIntegralE1(r)`

Given a real number r, calculate the value of the *exponential integral E1*, that is, the principal value of

$$\int_{x}^{\infty} \frac{e^u}{u} du$$

at $x = r$.

`LogIntegral(r)`

Given a non-negative real number r that is not equal to 1, evaluate the *logarithmic integral* $y = \operatorname{li}(x)$ at $x = r$. This integral is defined to be the principal value of

$$\int_{0}^{x} \frac{1}{\log(u)} du.$$

The mp real package is used here.

`ZetaFunction(s)`

`ZetaFunction(R, n)`

These functions calculate values of the Riemann ζ-function, which is the analytic continuation of

$$\zeta(z) = \sum_{i=1}^{\infty} \frac{1}{i^z}$$

(convergent for $\operatorname{Re}(z) > 1$). The version with one argument takes a real or complex number $r \neq 1$ and returns a real or complex number.

The version with two arguments is much more restricted; it takes a real field R and an integer $n \neq 1$, and returns $\zeta(n)$ in R.

MPFR uses the algorithm of Jean-Luc Rémy and Sapphorain Pétermann [PR06].

25.11 Numerical Functions

This section contains some functions for numerical analysis, taken from Pari.

25.11.1 Summation of Infinite Series

There are three functions for evaluating infinite sums of real numbers. The sum should be specified as a map m from the integers to the real field, such that $m(n)$ is the n^{th} term of the sum. The summation begins at term i. The precision of the result will be the default precision of the real field.

`InfiniteSum(m, i)`

An approximation to the infinite sum $m(i)+m(i+1)+m(i+2)+\cdots$. This function also works for maps to the complex field.

`PositiveSum(m, i)`

An approximation to the infinite sum $m(i)+m(i+1)+m(i+2)+\cdots$. Designed for series in which every term is positive, it uses van Wijngaarden's trick for converting the series into an alternating one. Due to the stopping criterion, terms equal to 0 will create problems and should be removed.

`AlternatingSum(m, i)`

`Al`	MonStgElt	*Default :* "*Villegas*"

An approximation to the infinite sum $m(i)+m(i+1)+m(i+2)+\cdots$. Designed for series in which the terms alternate in sign. The optional argument `Al` can be used to specify the algorithm used. The possible values are `"Villegas"` (the default), and `"EulerVanWijngaarden"`. Due to the stopping criterion, terms equal to 0 will create problems and should be removed.

25.11.2 Integration

A number of 'Romberg-like' integration methods have been taken from Pari. The precision should not be made too large for this, and singularities are not allowed in the interval of integration (including its boundaries).

`Interpolation(P, V, x)`

Using Neville's algorithm, interpolate the value of x under a polynomial p such that $p(P[i]) = V[i]$. An estimate of the error is also returned.

`RombergQuadrature(f, a, b: parameters)`

`Precision`	FldReElt	*Default :* $1.0e-6$
`MaxSteps`	RngIntElt	*Default :* 20
`K`	RngIntElt	*Default :* 5

Using Romberg's method of order $2K$, approximate the integral of f from a to b. The desired accuracy may be specified by setting the `Precision` parameter, and the order of the algorithm by changing `K`. The algorithm ceases after `MaxSteps` iterations if the desired accuracy has not been achieved.

`SimpsonQuadrature(f, a, b, n)`

Using Simpson's rule on n sub-intervals, approximate the integral of f from a to b.

`TrapezoidalQuadrature(f, a, b, n)`

Using the trapezoidal rule on n sub-intervals, approximate the integral of f from a to b.

25.11.3 Numerical Derivatives

There is also a function to compute the NumericalDerivative of a function. This works via computing enough interpolation points and using a Taylor expansion.

`NumericalDerivative(f, n, z)`

Given a suitably nice function f, compute a numerical approximation to the nth derivative at the point z.

Example H25E9

```
> f := func<x|Exp(2*x)>;
> NumericalDerivative(f, 10, ComplexField(30)! 1.0) / f (1.0);
1024.000000000000000000000000000
> NumericalDerivative(func<x|LogGamma(x)>,1,ComplexField()!3.0);
0.92278433509846713939348790991 8
> Psi(3.0); // Psi is Gamma'/Gamma
0.92278433509846713939348790991 8
```

PART IV
MATRICES AND LINEAR ALGEBRA

26 MATRICES

Chapter 26
MATRICES

26.1 Introduction

This chapter describes all the basic operations available for creating and working with matrices. Matrices arise in many different contexts and there are several types of matrix within MAGMA, but most of the operations listed here apply to all types of matrix.

The parent of any matrix will be one of several types of matrix-structure (module, matrix algebra, matrix group, etc.), and each of these matrix-structure types are described in other chapters, together with operations peculiar to their elements.

26.2 Creation of Matrices

This section describes the elementary constructs provided for creating a matrix or vector. For each of the following functions, the parent of the result will be as follows:

(a) If the result is a vector then its parent will be the appropriate R-space (of type `ModTupRng` or `ModTupFld`).

(b) If the result is a square matrix then its parent will be the appropriate matrix algebra (of type `AlgMatElt`).

(c) If the result is a non-square matrix then its parent will be the appropriate R-matrix space (of type `ModMatRng` or `ModMatFld`).

A matrix or a vector may also be created by coercing a sequence of ring elements into the appropriate parent matrix structure. There is also a virtual type `Mtrx` and all matrix types inherit from `Mtrx`. While writing package intrinsics, an argument should be declared to be of type `Mtrx` if it is a general matrix.

26.2.1 General Matrix Construction

`Matrix(R, m, n, Q)`

Given a ring R, integers $m, n \geq 0$ and a sequence Q, return the $m \times n$ matrix over R whose entries are those specified by Q, coerced into R. Either of m and n may be 0, in which case Q must have length 0 (and may even be null), and the $m \times n$ zero matrix over R is returned. There are several possibilities for Q:

(a) The sequence Q may be a sequence of length mn containing elements of a ring S, in which case the entries are given in row-major order. In this case, the function is equivalent to `MatrixRing(R, n)!Q` if $m = n$ and `RMatrixSpace(R, m, n)!Q` otherwise.

(b) The sequence Q may be a sequence of tuples, each of the form `<i, j, x>`, where $1 \leq i \leq m$, $1 \leq j \leq n$, and $x \in S$ for some ring S. Such a tuple specifies that

the (i, j)-th entry of the matrix is x. If an entry position is not given then its value is zero, while if an entry position is repeated then the last value overrides any previous value(s). This case is useful for creating sparse matrices.

(c) The sequence Q may be a sequence of m sequences, each of length n and having entries in a ring S, in which case the rows of the matrix are specified by the inner sequences.

(d) The sequence Q may be a sequence of m vectors, each of length n and having entries in a ring S, in which case the rows of the matrix are specified by the vectors.

Example H26E1

This example demonstrates simple ways of creating matrices using the general `Matrix(R, m, n, Q)` function.

(a) Defining a 2×2 matrix over $\mathbf{Z}$:

```
> X := Matrix(IntegerRing(), 2, 2, [1,2, 3,4]);
> X;
[1 2]
[3 4]
> Parent(X);
Full Matrix Algebra of degree 2 over Integer Ring
```

(b) Defining a 2×3 matrix over $\mathbf{F}_{23}$:

```
> X := Matrix(GF(23), 2, 3, [1,-2,3, 4,100,-6]);
> X;
[ 1 21  3]
[ 4  8 17]
> Parent(X);
Full KMatrixSpace of 2 by 3 matrices over GF(23)
```

(c) Defining a sparse 5×10 matrix over $\mathbf{Q}$:

```
> X := Matrix(RationalField(), 5, 10, [<1,2,23>, <3,7,11>, <5,10,-1>]);
> X;
[ 0 23  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0 11  0  0  0]
[ 0  0  0  0  0  0  0  0  0  0]
[ 0  0  0  0  0  0  0  0  0 -1]
> Parent(X);
Full KMatrixSpace of 5 by 10 matrices over Rational Field
```

(c) Defining a sparse 10×10 matrix over $\mathbf{F}_{101}$:

```
> X := Matrix(GF(101), 10, 10, [<2*i-1, 2*j-1, i*j>: i, j in [1..5]]);
> X;
[  1   0   2   0   3   0   4   0   5   0]
[  0   0   0   0   0   0   0   0   0   0]
```

```
[  2   0   4   0   6   0   8   0  10   0]
[  0   0   0   0   0   0   0   0   0   0]
[  3   0   6   0   9   0  12   0  15   0]
[  0   0   0   0   0   0   0   0   0   0]
[  4   0   8   0  12   0  16   0  20   0]
[  0   0   0   0   0   0   0   0   0   0]
[  5   0  10   0  15   0  20   0  25   0]
[  0   0   0   0   0   0   0   0   0   0]
> Parent(X);
Full Matrix Algebra of degree 10 over GF(101)
```

26.2.2 Shortcuts

The following functions are "shortcut" versions of the previous general creation function, where some of the arguments are omitted since they can be inferred by MAGMA.

`Matrix(m, n, Q)`

Given integers $m, n \geq 0$ and a sequence Q of length mn containing elements of a ring R, return the $m \times n$ matrix over R whose entries are the entries of Q, in row-major order. Either of m and n may be 0, in which case Q must have length 0 and some universe R. This function is equivalent to `MatrixRing(Universe(Q), n)!Q` if $m = n$ and `RMatrixSpace(Universe(Q), m, n)!Q` otherwise.

`Matrix(m, n, Q)`

Given integers m and n, and a sequence Q consisting of m sequences, each of length n and having entries in a ring R, return the $m \times n$ matrix over R whose rows are given by the inner sequences of Q.

`Matrix(Q)`

Given a sequence Q of m vectors, each of length n over a ring R, return the $m \times n$ matrix over R whose rows are the entries of Q.

`Matrix(R, n, Q)`

Given a ring R, an integer $n \geq 0$ and a sequence Q of length l containing elements of a ring S, such that n divides l, return the $(l/n) \times n$ matrix over R whose entries are the entries of Q, coerced into R, in row-major order. The argument n may be 0, in which case Q must have length 0 (and may even be null), in which case the 0×0 matrix over R is returned. This function is equivalent to `MatrixRing(R, n)!Q` if $l = n^2$ and `RMatrixSpace(R, #Q div n, n)!Q` otherwise.

`Matrix(n, Q)`

Given an integer $n \geq 0$ and a sequence Q of length l containing elements of a ring R, such that n divides l, return the $(l/n) \times n$ matrix over R whose entries are the entries of Q, in row-major order. The argument n may be 0, in which case Q must have length 0 and some universe R, in which case the 0×0 matrix over R is returned. This function is equivalent to `MatrixRing(Universe(Q), n)!Q` if $l = n^2$ and `RMatrixSpace(Universe(Q), #Q div n, n)!Q` otherwise.

`Matrix(Q)`

Given a sequence Q consisting of m sequences, each of length n and having entries in a ring R, return the $m \times n$ matrix over R whose rows are given by the inner sequences of Q.

`Matrix(R, Q)`

Given a sequence Q consisting of m sequences, each of length n and having entries in a ring S, return the $m \times n$ matrix over R whose rows are given by the inner sequences of Q, with the entries coerced into R.

Example H26E2

The first matrix in the previous example may be created thus:

```
> X := Matrix(2, [1,2, 3,4]);
> X;
[1 2]
[3 4]
> X := Matrix([[1,2], [3,4]]);
> X;
[1 2]
[3 4]
```

The second matrix in the previous example may be created thus:

```
> X := Matrix(GF(23), 3, [1,-2,3, 4,100,-6]);
> X;
[ 1 21  3]
[ 4  8 17]
> Parent(X);
Full KMatrixSpace of 2 by 3 matrices over GF(23)
> X := Matrix(GF(23), [[1,-2,3], [4,100,-6]]);
> X;
[ 1 21  3]
[ 4  8 17]
> X := Matrix([[GF(23)|1,-2,3], [4,100,-6]]);
> X;
[ 1 21  3]
[ 4  8 17]
```

26.2.3 Construction of Structured Matrices

`ZeroMatrix(R, m, n)`

Given a ring R and integers $m, n \geq 0$, return the $m \times n$ zero matrix over R.

`ScalarMatrix(n, s)`

Given an integer $n \geq 0$ and an element s of a ring R, return the $n \times n$ scalar matrix over R which has s on the diagonal and zeros elsewhere. The argument n may be 0, in which case the 0×0 matrix over R is returned. This function is equivalent to `MatrixRing(Parent(s), n)!s`.

`ScalarMatrix(R, n, s)`

Given a ring R, an integer $n \geq 0$ and an element s of a ring S, return the $n \times n$ scalar matrix over R which has s, coerced into R, on the diagonal and zeros elsewhere. n may be 0, in which case in which case the 0×0 matrix over R is returned. This function is equivalent to `MatrixRing(R, n)!s`.

`DiagonalMatrix(R, n, Q)`

Given a ring R, an integer $n \geq 0$ and a sequence Q of n ring elements, return the $n \times n$ diagonal matrix over R whose diagonal entries correspond to the entries of Q, coerced into R.

`DiagonalMatrix(R, Q)`

Given a ring R and a sequence Q of n ring elements, return the $n \times n$ diagonal matrix over R whose diagonal entries correspond to the entries of Q, coerced into R.

`DiagonalMatrix(Q)`

Given a sequence Q of n elements from a ring R, return the $n \times n$ diagonal matrix over R whose diagonal entries correspond to the entries of Q.

`Matrix(A)`

Given a matrix A of any type, return the same matrix but having as parent the appropriate matrix algebra if A is square, or the appropriate R-matrix space otherwise. This is useful, for example, if it is desired to convert a matrix group element or a square R-matrix space element to be an element of a general matrix algebra.

`LowerTriangularMatrix(Q)`

Given a sequence Q of length l containing elements of a ring R, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ lower-triangular matrix F over R such that the entries of Q describe the lower triangular part of F, in row major order.

`LowerTriangularMatrix(R, Q)`

Given a ring R and a sequence Q of length l containing elements of a ring S, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ lower-triangular matrix F over R such that the entries of Q, coerced into R, describe the lower triangular part of F, in row major order.

`UpperTriangularMatrix(Q)`

Given a sequence Q of length l containing elements of a ring R, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ upper-triangular matrix F over R such that the entries of Q describe the upper triangular part of F, in *row major* order.

`UpperTriangularMatrix(R, Q)`

Given a ring R and a sequence Q of length l containing elements of a ring S, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ upper-triangular matrix F over R such that the entries of Q, coerced into R, describe the upper triangular part of F, in *row major* order.

`SymmetricMatrix(Q)`

Given a sequence Q of length l containing elements of a ring R, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ symmetric matrix F over R such that the entries of Q describe the lower triangular part of F, in row major order. This function allows the creation of symmetric matrices without the need to specify the redundant upper triangular part.

`SymmetricMatrix(R, Q)`

Given a ring R and a sequence Q of length l containing elements of a ring S, such that $l = \binom{n+1}{2} = n(n+1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ symmetric matrix F over R such that the entries of Q, coerced into R, describe the lower triangular part of F, in row major order. This function allows the creation of symmetric matrices without the need to specify the redundant upper triangular part.

`AntisymmetricMatrix(Q)`

Given a sequence Q of length l containing elements of a ring R, such that $l = \binom{n}{2} = n(n-1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ antisymmetric matrix F over R such that the entries of Q describe the proper lower triangular part of F, in row major order. The diagonal of F is zero and the proper upper triangular part of F is the negation of the proper lower triangular part of F.

`AntisymmetricMatrix(R, Q)`

Given a ring R and a sequence Q of length l containing elements of a ring S, such that $l = \binom{n}{2} = n(n-1)/2$ for some integer n (so l is a triangular number), return the $n \times n$ antisymmetric matrix F over R such that the entries of Q, coerced into R, describe the proper lower triangular part of F, in row major order.

`PermutationMatrix(R, Q)`

Given a ring R and a sequence Q of length n, such that Q is a permutation of $[1, 2, \ldots, n]$, return the n by n permutation matrix over R corresponding Q.

`PermutationMatrix(R, x)`

Given a ring R and a permutation x of degree n, return the n by n permutation matrix over R corresponding x.

Example H26E3

This example demonstrates ways of creating special matrices.
(a) Defining a 3×3 scalar matrix over $\mathbf{Z}$:

```
> S := ScalarMatrix(3, -4);
> S;
[-4  0  0]
[ 0 -4  0]
[ 0  0 -4]
> Parent(S);
Full Matrix Algebra of degree 3 over Integer Ring
```

(b) Defining a 3×3 diagonal matrix over $\mathbf{F}_{23}$:

```
> D := DiagonalMatrix(GF(23), [1, 2, -3]);
> D;
[ 1  0  0]
[ 0  2  0]
[ 0  0 20]
> Parent(D);
Full Matrix Algebra of degree 3 over GF(23)
```

(c) Defining a 3×3 symmetric matrix over $\mathbf{Q}$:

```
> S := SymmetricMatrix([1, 1/2,3, 1,3,4]);
> S;
[  1 1/2   1]
[1/2   3   3]
[  1   3   4]
> Parent(S);
Full Matrix Algebra of degree 3 over Rational Field
```

(d) Defining $n \times n$ lower- and upper-triangular matrices for various n:

```
> low := func<n | LowerTriangularMatrix([i: i in [1 .. Binomial(n + 1, 2)]])>;
```

```
> up := func<n | UpperTriangularMatrix([i: i in [1 .. Binomial(n + 1, 2)]])>;
> sym := func<n | SymmetricMatrix([i: i in [1 .. Binomial(n + 1, 2)]])>;
> low(3);
[1 0 0]
[2 3 0]
[4 5 6]
> up(3);
[1 2 3]
[0 4 5]
[0 0 6]
> sym(3);
[1 2 4]
[2 3 5]
[4 5 6]
> up(6);
[ 1  2  3  4  5  6]
[ 0  7  8  9 10 11]
[ 0  0 12 13 14 15]
[ 0  0  0 16 17 18]
[ 0  0  0  0 19 20]
[ 0  0  0  0  0 21]
```

26.2.4 Construction of Random Matrices

`RandomMatrix(R, m, n)`

Given a *finite* ring R and positive integers m and n, construct a random $m \times n$ matrix over R.

`RandomUnimodularMatrix(M, n)`

Given positive integers M and n, construct a random integral $n \times n$ matrix having determinant 1 or -1. Most entries will lie in the range $[-M, M]$.

`RandomSLnZ(n, k, l)`

A random element of $SL_n(\mathbf{Z})$, obtained by multiplying l random matrices of the form $I + E$, where E has exactly one nonzero entry, which is off the diagonal and has absolute value at most k.

`RandomGLnZ(n, k, l)`

A random element of $GL_n(\mathbf{Z})$, obtained in a similar way to `RandomSLnZ`.

`RandomSymplecticMatrix(g, m)`

Given positive integers n and m, construct a (somewhat) random $2n \times 2n$ symplectic matrix over the integers. The entries will have the same order of magnitude as `m`.

26.2.5 Creating Vectors

`Vector(n, Q)`

Given an integer n and a sequence Q of length n containing elements of a ring R, return the vector of length n whose entries are the entries of Q. The integer n may be 0, in which case Q must have length 0 and some universe R. This function is equivalent to `RSpace(Universe(Q), n)!Q`.

`Vector(Q)`

Given a sequence Q of length l containing elements of a ring R, return the vector of length l whose entries are the entries of Q. The argument Q may have length 0 if it has a universe R (i.e., it may not be null). This function is equivalent to `RSpace(Universe(Q), #Q)!Q`.

`Vector(R, n, Q)`

Given a ring R, an integer n, and a sequence Q of length n containing elements of a ring S, return the vector of length n whose entries are the entries of Q, coerced into R. The integer n may be 0, in which case Q must have length 0 (and may even be null). This function is equivalent to `RSpace(R, n)!Q`.

`Vector(R, Q)`

Given a ring R and a sequence Q of length l containing elements of a ring S, return the vector of length l whose entries are the entries of Q, coerced into R. The argument Q may have length 0 and may be null. This function is equivalent to `RSpace(R, #Q)!Q`.

26.3 Elementary Properties

The following functions yield elementary properties of matrices and may be applied to matrices of any type, including vectors.

`NumberOfRows(A)`
`Nrows(A)`

Given an $m \times n$ matrix A, return m, the number of rows of A.

`NumberOfColumns(A)`
`Ncols(A)`

Given an $m \times n$ matrix A, return n, the number of columns of A.

`NumberOfNonZeroEntries(A)`
`NNZEntries(A)`

Given a matrix A, return the number of non-zero entries in A.

`Density(A)`

Given a matrix A, return the density of A as a real number, which is the number of non-zero entries in A divided by the product of the number of rows of A and the number of columns of A (or zero if A has zero rows or columns).

`BaseRing(A)`

`CoefficientRing(A)`

Given a matrix A with entries lying in a ring R, return R.

`ElementToSequence(A)`

`Eltseq(A)`

Given a matrix A over the ring R having m rows and n columns, return the entries of A, in row-major order, as a sequence of mn elements of R.

`RowSequence(A)`

Returns the entries of A as a sequence of rows where a row is represented as a sequence of entries of A.

26.4 Accessing or Modifying Entries

26.4.1 Indexing

The following functions and operators enable one to access individual entries or rows of matrices or vectors.

`A[i]`

Given a matrix A over the ring R having m rows and n columns, and an integer i such that $1 \leq i \leq m$, return the i-th row of A, as a vector of length n.

`A[i, j]`

Given a matrix A over the ring R having m rows and n columns, integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, return the (i, j)-th entry of A, as an element of the ring R.

`A[Q]`

`A[i .. j]`

Given a matrix A over the ring R having m rows and n columns, and a sequence Q of integers in the range $[1..m]$, return the sequence consisting of the rows of A specified by Q. This is equivalent to `[A[i]: i in Q]]`. If Q is a range, then the second form `A[i .. j]` may be used to specify the range directly.

`A[i] := v`

Given a matrix A over the ring R having m rows and n columns, an integer i such that $1 \leq i \leq m$, and a vector v over R of length n, modify the i-th row of A to be v. The integer 0 may also be given for v, indicating the zero vector.

`A[i, j] := x`

Given a matrix A over the ring R having m rows and n columns, integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, and a ring element x coercible into R, modify the (i, j)-th entry of A to be x.

Example H26E4

This example demonstrates simple ways of accessing the entries of matrices.

```
> X := Matrix(4, [1,2,3,4, 5,4,3,2, 1,2,3,4]);
> X;
[1 2 3 4]
[5 4 3 2]
[1 2 3 4]
> X[1];
(1 2 3 4)
> X[1, 2];
2
> X[1, 2] := 23;
> X;
[ 1 23  3  4]
[ 5  4  3  2]
[ 1  2  3  4]
> X[3] := Vector([9,8,7,6]);
> X[2] := 0;
> X;
[ 1 23  3  4]
[ 0  0  0  0]
[ 9  8  7  6]
```

26.4.2 Extracting and Inserting Blocks

The following functions enable the extraction of certain rows, columns or general submatrices, or the replacement of a block by another matrix.

`Submatrix(A, i, j, p, q)`

`ExtractBlock(A, i, j, p, q)`

Given an $m \times n$ matrix A and integers i, j, p and q such that $1 \leq i \leq i + p \leq m + 1$ and $1 \leq j \leq j + q \leq n + 1$, return the $p \times q$ submatrix of A rooted at (i, j). Either or both of p and q may be zero, while i may be $m + 1$ if p is zero and j may be $n + 1$ if q is zero.

`SubmatrixRange(A, i, j, r, s)`

`ExtractBlockRange(A, i, j, r, s)`

Given an $m \times n$ matrix A and integers i, j, r and s such that $1 \leq i$, $i - 1 \leq r \leq m$, $1 \leq j$, and $j - 1 \leq s \leq n$, return the $r - i + 1 \times s - j + 1$ submatrix of A rooted at the (i, j)-th entry and extending to the (r, s)-th entry, inclusive. r may equal $i - 1$ or s may equal $j - 1$, in which case a matrix with zero rows or zero columns, respectively, will be returned.

`Submatrix(A, I, J)`

Given an $m \times n$ matrix A and integer sequences I and J, return the submatrix of A given by the row indices in I and the column indices in J.

`InsertBlock(A, B, i, j)`

`InsertBlock(~A, B, i, j)`

Given an $m \times n$ matrix A over a ring R, a $p \times q$ matrix B over R, and integers i and j such that $1 \leq i \leq i + p \leq m + 1$ and $1 \leq j \leq j + q \leq n + 1$, insert B at position (i, j) in A. In the functional version (A is a value argument), this function returns the new matrix and leaves A untouched, while in the procedural version ($\sim A$ is a reference argument), A is modified in place so that the $p \times q$ submatrix of A rooted at (i, j) is now equal to B.

`RowSubmatrix(A, i, k)`

Given an $m \times n$ matrix A and integers i and k such that $1 \leq i \leq i + k \leq m + 1$, return the $k \times n$ submatrix of X consisting of rows $[i \ldots i + k - 1]$ inclusive. The integer k may be zero and i may also be $m + 1$ if k is zero, but the result will always have n columns.

`RowSubmatrix(A, i)`

Given an $m \times n$ matrix A and an integer i such that $0 \leq i \leq m$, return the $i \times n$ submatrix of X consisting of the first i rows. The integer i may be 0, but the result will always have n columns.

`RowSubmatrixRange(A, i, j)`

Given an $m \times n$ matrix A and integers i and j such that $1 \leq i$ and $i - 1 \leq j \leq m$, return the $j - i + 1 \times n$ submatrix of X consisting of rows $[i \ldots j]$ inclusive. The integer j may equal $i - 1$, in which case a matrix with zero rows and n columns will be returned.

`ColumnSubmatrix(A, i, k)`

Given an $m \times n$ matrix A and integers i and k such that $1 \leq i \leq i + k \leq n + 1$, return the $m \times k$ submatrix of X consisting of columns $[i \ldots i + k - 1]$ inclusive. The integer k may be zero and i may also be $n + 1$ if k is zero, but the result will always have m rows.

`ColumnSubmatrix(A, i)`

Given an $m \times n$ matrix A and an integer i such that $0 \leq i \leq n$, return the $m \times i$ submatrix of X consisting of the first i columns. The integer i may be 0, but the result will always have m rows.

`ColumnSubmatrixRange(A, i, j)`

Given an $m \times n$ matrix A and integers i and j such that $1 \leq i$ and $i - 1 \leq j \leq n$, return the $m \times j - i + 1$ submatrix of X consisting of columns $[i \ldots j]$ inclusive. The integer j may equal $i - 1$, in which case a matrix with zero columns and n rows will be returned.

Example H26E5

The use of the submatrix operations is illustrated by applying them to a 6×6 matrix over the ring of integers **Z**.

```
> A := Matrix(6,
>     [ 9, 1, 7, -3, 2, -1,
>       3, -4, -5, 9, 2, 7,
>       7, 1, 0, 1, 8, 22,
>       -3, 3, 3, 8, 8, 37,
>       -9, 0, 7, -1, 2, 3,
>       7, 2, -2, 4, 3, 47 ]);
> A;
[ 9  1  7 -3  2 -1]
[ 3 -4 -5  9  2  7]
[ 7  1  0  1  8 22]
[-3  3  3  8  8 37]
[-9  0  7 -1  2  3]
[ 7  2 -2  4  3 47]
> Submatrix(A, 2,2, 3,3);
[-4 -5  9]
[ 1  0  1]
[ 3  3  8]
> SubmatrixRange(A, 2,2, 3,3);
[-4 -5]
[ 1  0]
> S := $1;
> InsertBlock(~A, S, 5,5);
> A;
[ 9  1  7 -3  2 -1]
[ 3 -4 -5  9  2  7]
[ 7  1  0  1  8 22]
[-3  3  3  8  8 37]
[-9  0  7 -1 -4 -5]
[ 7  2 -2  4  1  0]
> RowSubmatrix(A, 5, 2);
```

```
[-9  0  7 -1 -4 -5]
[ 7  2 -2  4  1  0]
> RowSubmatrixRange(A, 2, 3);
[ 3 -4 -5  9  2  7]
[ 7  1  0  1  8 22]
> RowSubmatrix(A, 2, 0);
Matrix with 0 rows and 6 columns
```

26.4.3 Row and Column Operations

The following functions and procedures provide elementary row or column operations on matrices. For each operation, there is a corresponding function which creates a new matrix for the result (leaving the input matrix unchanged), and a corresponding procedure which modifies the input matrix in place.

`SwapRows(A, i, j)`

`SwapRows(~A, i, j)`

Given an $m \times n$ matrix A and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq m$, swap the i-th and j-th rows of A.

`SwapColumns(A, i, j)`

`SwapColumns(~A, i, j)`

Given an $m \times n$ matrix A and integers i and j such that $1 \leq i \leq n$ and $1 \leq j \leq n$, swap the i-th and j-th columns of A.

`ReverseRows(A)`

`ReverseRows(~A)`

Given a matrix A, reverse all the rows of A.

`ReverseColumns(A)`

`ReverseColumns(~A)`

Given a matrix A, reverse all the columns of A.

`AddRow(A, c, i, j)`

`AddRow(~A, c, i, j)`

Given an $m \times n$ matrix A over a ring R, a ring element c coercible into R, and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq m$, add c times row i of A to row j of A.

`AddColumn(A, c, i, j)`

`AddColumn(~A, c, i, j)`

Given an $m \times n$ matrix A over a ring R, a ring element c coercible into R, and integers i and j such that $1 \leq i \leq n$ and $1 \leq j \leq n$, add c times column i of A to column j.

`MultiplyRow(A, c, i)`

`MultiplyRow(~A, c, i)`

Given an $m \times n$ matrix A over a ring R, a ring element c coercible into R, and an integer i such that $1 \leq i \leq m$, multiply row i of A by c (on the left).

`MultiplyColumn(A, c, i)`

`MultiplyColumn(~A, c, i)`

Given an $m \times n$ matrix A over a ring R, a ring element c coercible into R, and an integer i such that $1 \leq i \leq n$, multiply column i of A by c (on the left).

`RemoveRow(A, i)`

`RemoveRow(~A, i)`

Given an $m \times n$ matrix A and an integer i such that $1 \leq i \leq m$, remove row i from A (leaving an $(m-1) \times n$ matrix).

`RemoveColumn(A, j)`

`RemoveColumn(~A, j)`

Given an $m \times n$ matrix A and an integer j such that $1 \leq j \leq n$, remove column j from A (leaving an $m \times (n-1)$ matrix).

`RemoveRowColumn(A, i, j)`

`RemoveRowColumn(~A, i, j)`

Given an $m \times n$ matrix A and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, remove row i and column j from A (leaving an $(m-1) \times (n-1)$ matrix).

`RemoveZeroRows(A)`

`RemoveZeroRows(~A)`

Given a matrix A, remove all the zero rows of A.

Example H26E6

The use of row and column operations is illustrated by applying them to a 5×6 matrix over the ring of integers $\mathbf{Z}$.

```
> A := Matrix(5, 6,
>     [ 3, 1, 0, -4, 2, -12,
>       2, -4, -5, 5, 23, 6,
>       8, 0, 0, 1, 5, 12,
>       -2, -6, 3, 8, 9, 17,
>       11, 12, -6, 4, 2, 27 ]);
> A;
[  3   1   0  -4   2 -12]
[  2  -4  -5   5  23   6]
[  8   0   0   1   5  12]
[ -2  -6   3   8   9  17]
[ 11  12  -6   4   2  27]
> SwapColumns(~A, 1, 2);
> A;
[  1   3   0  -4   2 -12]
[ -4   2  -5   5  23   6]
[  0   8   0   1   5  12]
[ -6  -2   3   8   9  17]
[ 12  11  -6   4   2  27]
> AddRow(~A, 4, 1, 2);
> AddRow(~A, 6, 1, 4);
> AddRow(~A, -12, 1, 5);
> A;
[  1   3   0  -4   2 -12]
[  0  14  -5 -11  31 -42]
[  0   8   0   1   5  12]
[  0  16   3 -16  21 -55]
[  0 -25  -6  52 -22 171]
> RemoveRow(~A, 1);
> A;
[ 2 -4 -5  5 23  6]
[ 8  0  0  1  5 12]
[-2 -6  3  8  9 17]
[11 12 -6  4  2 27]
> RemoveRowColumn(~A, 4, 6);
> A;
[ 2 -4 -5  5 23]
[ 8  0  0  1  5]
[-2 -6  3  8  9]
```

26.5 Building Block Matrices

Block matrices can be constructed either by listing the blocks, or by joining together smaller matrices horizontally, vertically or diagonally.

`BlockMatrix(m, n, blocks)`

The matrix constructed from the given block matrices, which should all have the same dimensions, and should be given as a sequence of $m \cdot n$ block matrices (given in row major order, in other words listed across rows).

`BlockMatrix(m, n, rows)`

`BlockMatrix(rows)`

The matrix constructed from the given block matrices, which should all have the same dimensions, and should be given as a sequence of m rows, each containing n block matrices.

`HorizontalJoin(X, Y)`

Given a matrix X with r rows and c columns, and a matrix Y with r rows and d columns, both over the same coefficient ring R, return the matrix over R with r rows and $(c + d)$ columns obtained by joining X and Y horizontally (placing Y to the right of X).

`HorizontalJoin(Q)`

`HorizontalJoin(T)`

Given a sequence Q or tuple T of matrices, each having the same number of rows and being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q or T horizontally in order.

`VerticalJoin(X, Y)`

Given a matrix X with r rows and c columns, and a matrix Y with s rows and c columns, both over the same coefficient ring R, return the matrix with $(r + s)$ rows and c columns over R obtained by joining X and Y vertically (placing Y underneath X).

`VerticalJoin(Q)`

`VerticalJoin(T)`

Given a sequence Q or tuple T of matrices, each having the same number of columns and being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q or T vertically in order.

`DiagonalJoin(X, Y)`

Given matrices X with a rows and b columns and Y with c rows and d columns, both over the same coefficient ring R, return the matrix with $(a+c)$ rows and $(b+d)$ columns over R obtained by joining X and Y diagonally (placing Y diagonally to the right of and underneath X, with zero blocks above and below the diagonal).

`DiagonalJoin(Q)`

`DiagonalJoin(T)`

Given a sequence Q or tuple T of matrices, each being over the same coefficient ring R, return the matrix over R obtained by joining the elements of Q or T diagonally in order.

`KroneckerProduct(A, B)`

Given an $m \times n$ matrix A and a $p \times q$ matrix B, both over a ring R, return the Kronecker product of A and B, which is the $mp \times nq$ matrix C over R such that the $((i-1)p+r, (j-1)q+s)$-th entry of C is the (i,j)-th entry of A times the (r,s)-th entry of B, for $1 \leq i \leq m$, $1 \leq j \leq n$, $1 \leq r \leq p$ and $1 \leq s \leq q$.

26.6 Changing Ring

`ChangeRing(A, R)`

`Matrix(R, A)`

Given a matrix A over a ring S having m rows and n columns, and another ring R, return the $m \times n$ matrix over R obtained by coercing the entries of A from S into R. The argument order to `ChangeRing(A, R)` here is consistent with other forms of `ChangeRing`, while the `Matrix(R, A)` form of this function is provided to be consistent with the matrix creation functions above, for which the destination ring is the first argument, if supplied.

`ChangeRing(A, R, f)`

`ChangeRing(A, f)`

Given a matrix A over a ring S having m rows and n columns, another ring R, and a map $f : S \to R$, return the $m \times n$ matrix over R obtained by applying f to each of the entries of A. R may be omitted, in which case it is taken to be the codomain of f.

26.7 Elementary Arithmetic

`A + B`

Given $m \times n$ matrices A and B over a ring R, return $A + B$.

`A - B`

Given $m \times n$ matrices A and B over a ring R, return $A - B$.

`A * B`

Given an $m \times n$ matrix A over a ring R and an $n \times p$ matrix B over R, return the $m \times p$ matrix $A \cdot B$ over R. This function attempts to preserve the maximal amount of information in the choice of parent for the product. For example, if A and B are both square and have the same matrix algebra M as parent, then the product will also have M as parent. Similarly, if the parents of A and B are R-matrix spaces such that the codomain of B equals the domain A, then the product will have domain equal to that of A and codomain equal to that of B.

`x * A`
`A * x`

Given an $m \times n$ matrix A over a ring R and a ring element x coercible into R, return the scalar product $x \cdot A$.

`-A`

Given a matrix A, return $-A$.

`A ^ -1`

Given a invertible square matrix A over a ring R, return the inverse B of A so that $A \cdot B = B \cdot A = 1$. The coefficient ring R must be either a field, a Euclidean domain, or a ring with an exact division algorithm and having characteristic equal to zero or greater than m (this includes most commutative rings).

`A ^ n`

Given a square matrix A over a ring R and an integer n, return the matrix power A^n. A^0 is defined to be the identity matrix for any square matrix A (even if A is zero). If n is negative, A must be invertible (see the previous function), and the result is $(A^{-1})^{-n}$.

`Transpose(A)`

Given an $m \times n$ matrix A over a ring R, return the transpose of A, which is simply the $n \times m$ matrix over R whose (i, j)-th entry is the (j, i)-th entry of A.

`AddScaledMatrix(A, s, B)`

Given a matrix A over a ring R, a scalar s coercible into R, and a matrix B over R with the same shape as A, return $A + s \cdot B$. This is generally quicker than the call `A + s*B`.

`AddScaledMatrix(~A, s, B)`

Given a matrix A over a ring R, a scalar s coercible into R, and a matrix B over R with the same shape as A, set A to $A + s \cdot B$. This is generally quicker than the statement `A := A + s*B;`.

26.8 Nullspaces and Solutions of Systems

The following functions compute nullspaces of matrices (solving equations of the form $V \cdot A = 0$), or solve systems of the form $V \cdot A = W$, for given A and W.

Magma possesses a very rich suite of internal algorithms for computing nullspaces of matrices efficiently, including a fast p-adic algorithm for matrices over $\mathbf{Z}$ and $\mathbf{Q}$, and also algorithms which take advantage of sparsity if it is present.

`Nullspace(A)`

`Kernel(A)`

Given an $m \times n$ matrix A over a ring R, return the nullspace of A (or the kernel of A, considered as a linear transformation or map), which is the R-space consisting of all vectors v of length m such that $v \cdot A = 0$. If the parent of A is an R-matrix space, then the result will be the appropriate submodule of the domain of A. The function `Kernel(A)` also returns the inclusion map from the kernel into the domain of A, to be consistent with other forms of the `Kernel` function.

`NullspaceMatrix(A)`

`KernelMatrix(A)`

Given an $m \times n$ matrix A over a ring R, return a basis matrix of the nullspace of A. This is a matrix N having m columns and the maximal number of independent rows subject to the condition that $N \cdot A = 0$. This function has the advantage that the nullspace is not returned as a R-space, so echelonization of the resulting nullspace may be avoided.

`NullspaceOfTranspose(A)`

This function is equivalent to `Nullspace(Transpose(A))`, but may be more efficient in space for large matrices, since the transpose may not have to be explicitly constructed to compute the nullspace.

`IsConsistent(A, W)`

Given an $m \times n$ matrix A over a ring R, and a vector W of length n over R or a $r \times n$ matrix W over R, return `true` iff and only if the system of linear equations $V \cdot A = W$ is consistent. If the system is consistent, then the function will also return:

(a) A particular solution V so that $V \cdot A = W$;

(b) The nullspace N of A so that adding any elements of N to any rows of V will yield other solutions to the system.

`IsConsistent(A, Q)`

Given an $m \times n$ matrix A over a ring R, and a sequence Q of vectors of length n over R, return `true` if and only if the system of linear equations $V[i] * A = Q[i]$ for all i is consistent. If the system is consistent, then the function will also return:

(a) A particular solution sequence V;

(b) The nullspace N of A so that $(V[i] + u) * A = Q[i]$ for $u \in N$ for all i.

`Solution(A, W)`

Given an $m \times n$ matrix A over a ring R, and a vector W of length n over R or a $r \times n$ matrix W over R, solve the system of linear equations $V \cdot A = W$ and return:

(a) A particular solution V so that $V \cdot A = W$;

(b) The nullspace N of A so that adding any elements of N to any rows of V will yield other solutions to the system.
If there is no solution, an error results.

`Solution(A, Q)`

Given an $m \times n$ matrix A over a ring R, and a sequence Q of vectors of length n over R, solve the system of linear equations $V[i] * A = Q[i]$ for each i and return:

(a) A particular solution sequence V;

(b) The nullspace N of A so that $(V[i] + u) * A = Q[i]$ for $u \in N$ for all i.
If there is no solution, an error results.

Example H26E7

We compute the nullspace of a 301×300 matrix over $\mathbf{Z}$ with random entries in the range [0..10]. The nullity is 1 and the entries of the non-zero null vector are integers, each having about 455 decimal digits.

```
> m := 301; n := 300;
> X := Matrix(n, [Random(0, 10): i in [1 .. m*n]]);
> time N := NullspaceMatrix(X);
Time: 9.519
> Nrows(N), Ncols(N);
1 301
> time IsZero(N*X);
true
Time: 0.429
> {#Sprint(N[1,i]): i in [1..301]};
{ 452, 455, 456, 457, 458 }
```

Example H26E8

We show how one can enumerate all solutions to the system $V \cdot X = W$ for a given matrix X and vector W over a finite field. The `Solution` function gives a particular solution for V, and then adding this to every element in the nullspace N of X, we obtain all solutions.

```
> K := GF(3);
> X := Matrix(K, 4, 3, [1,2,1, 2,2,2, 1,1,1, 1,0,1]);
> X;
[1 2 1]
[2 2 2]
[1 1 1]
[1 0 1]

26.9 Predicates

The functions in this section test various properties of matrices. See also the Lattices chapter for a description of the function `IsPositiveDefinite` and related functions.

`IsZero(A)`

Given an $m \times n$ matrix A over the ring R, return `true` iff A is the $m \times n$ zero matrix.

`IsOne(A)`

Given a square $m \times m$ matrix A over the ring R, return `true` iff A is the $m \times m$ identity matrix.

`IsMinusOne(A)`

Given a square $m \times m$ matrix A over the ring R, return `true` iff A is the negation of the $m \times m$ identity matrix.

`IsScalar(A)`

Given a square $m \times m$ matrix A over the ring R, return `true` iff A is scalar, i.e., iff A is the product of some element of R and the $m \times m$ identity matrix.

`IsDiagonal(A)`

Given a square matrix A over the ring R, return `true` iff A is diagonal, i.e., iff the only non-zero entries of A are on the diagonal.

`IsSymmetric(A)`

Given a square matrix A over the ring R, return `true` iff A is symmetric, i.e., iff A equals its transpose.

`IsUpperTriangular(A)`

Given a matrix A over the ring R, return `true` iff A is upper triangular, i.e., iff the only non-zero entries of A are on or above the diagonal.

`IsLowerTriangular(A)`

Given a matrix A over the ring R, return `true` iff A is lower triangular, i.e., iff the only non-zero entries of A are on or below the diagonal.

`IsUnit(A)`

Given a square matrix A over the ring R, return `true` iff A is a unit, i.e., iff A has an inverse. The coefficient ring R may be any commutative ring (since the computation depends on testing if the determinant is a unit – a calculation which is supported in all commutative rings).

`IsSingular(A)`

Given a square $m \times m$ matrix A over the ring R, return `true` iff A is singular, i.e., iff the determinant of A is zero (or, equivalently, iff the rank of A is less than m). Note that `(not IsSingular(A))` is *not* equivalent to `IsUnit(A)` whenever R is not a field: if the determinant of A is non-zero but not a unit, then A is non-singular but not invertible. The coefficient ring R may be any commutative ring (since the computation involves only computing the determinant and testing whether it is zero).

`IsSymplecticMatrix(A)`

Given an $m \times m$ matrix A over the integers, return `true` if and only if A is an integer symplectic matrix, that is, $AJ^tA = J$, where $J = \begin{pmatrix} 0 & \mathbf{1}_g \\ -\mathbf{1}_g & 0 \end{pmatrix}$.

26.10 Determinant and Other Properties

`Determinant(A: parameters)`

`MonteCarloLevel`	RngIntElt	*Default :* 0
`Proof`	BoolElt	*Default :* `true`
`pAdic`	BoolElt	*Default :* `true`
`Divisor`	RngIntElt	*Default :* 0

Given a square matrix A over the ring R, return the determinant of A as an element of R. R may be any commutative ring. The determinant of the 0×0 matrix over R is defined to be `R!1`.

If the coefficient ring is the integer ring $\mathbf{Z}$ or the rational field $\mathbf{Q}$ then a modular algorithm based on that of Abbott et al. [ABM99] is used, which first computes a divisor d of the determinant D using a fast p-adic nullspace computation, and then computes the quotient D/d by computing the determinant D modulo enough small primes to cover the Hadamard bound divided by d. This always yields a correct answer.

If the parameter `MonteCarloLevel` is set to a small positive integer s, then a probabilistic Monte-Carlo modular technique is used. Rather than using sufficient primes to cover the Hadamard bound divided by the divisor d, this version of the algorithm terminates when the constructed residue remains constant for s steps. The probability of this being wrong is non-zero but extremely small, even if s is only 1 or 2. If the level is set to 0, then the normal deterministic algorithm is used. Setting the parameter `Proof` to `false` is equivalent to setting `MonteCarloLevel` to 2.

If the coefficient ring is $\mathbf{Z}$ and the parameter `Divisor` is set to an integer d, then d must be a known exact divisor of the determinant (the sign does not matter), and the algorithm may be sped up because of this knowledge.

`Trace(A)`

Given a square matrix A over the ring R, return the trace of A as an element of R, which is simply the sum of the diagonal elements of A.

`TraceOfProduct(A, B)`

Given square matrices A and B over the ring R, with the same size, return the trace of $A \cdot B$ as an element of R. This is in general much faster than the call `Trace(A*B)`.

`Rank(A)`

Given an $m \times n$ matrix A over a ring R, return the rank of A. This is defined to be the largest r such that there exists a non-zero $r \times r$ subdeterminant of A, so $r \leq m$ and $r \leq n$. The rank may have to be obtained by computing the Smith form or echelon form of A, and this computation may be quite expensive over some rings.

`Minor(M, i, j)`

The determinant of the submatrix of M (which must be square) formed by removing the i-th row and j-th column.

`Minor(M, I, J)`

The determinant of the submatrix of M given by the row indices in I and the column indices in J.

`Minors(M, r)`

Returns a sequence of all the r by r minors of the matrix M.

`Cofactor(M, i, j)`

The appropriate cofactor of M, equal to $(-1)^{i+j}$ times the corresponding minor.

`Cofactors(M)`

Returns a sequence of all the cofactors of the matrix M.

`Cofactors(M, r)`

Returns a sequence of all the r by r cofactors of the matrix M.

`Pfaffian(M)`

`Pfaffian(M, I, J)`

`Pfaffians(M, r)`

Let M be an anti-symmetric square matrix. Then its determinant is always a square and a particular square-root of this, which can be described by a universal polynomial in its entries, is called the Pfaffian of M. The first function returns this. The second function returns the Pfaffian of the submatrix of M described by the indices in I and J. The third function returns the sequence of Pfaffians of the $\binom{n}{r}$ principal r by r submatrices of M (n = the number of rows of M).

These are primarily convenience functions and are computed naively by Pfaffian row-expansion.

26.11 Minimal and Characteristic Polynomials and Eigenvalues

The functions in this section deal with minimal and characteristic polynomials.

`MinimalPolynomial(A: parameters)`

`Proof` BoolElt *Default :* `true`

Given a square matrix A over a ring R, return the minimal polynomial of A. This is defined to be the unique monic univariate polynomial $f(x)$ of minimal degree such that $f(A) = 0$, and $f(x)$ always divides the characteristic polynomial of A. The coefficient ring R is currently restricted to being a field or the integer ring $\mathbf{Z}$.

Setting the parameter `Proof` to false suppresses proof of correctness.

`CharacteristicPolynomial(A: parameters)`

`Al` MonStg *Default :* "*Modular*"

`Proof` BoolElt *Default :* `true`

Given a square matrix A over a ring R, return the characteristic polynomial of A. This is defined to be the monic univariate polynomial $\mathrm{Det}(x - A) \in R[x]$ where $R[x]$ is the univariate polynomial ring over R. R may be any commutative ring.

The parameter `Al` allows the user to specify which algorithm that is to be employed. The algorithm `"Modular"` (the default) may be used for matrices over $\mathbf{Z}$ and $\mathbf{Q}$—in such a case the parameter `Proof` can also be used to suppress proof of correctness.

The algorithm `"Hessenberg"`, available for matrices over fields, works by first reducing the matrix to Hessenberg form. The algorithm `"Interpolation"`, available for matrices over Z and Q, works by evaluating the characteristic matrix of a at various points and then interpolating. The algorithm `"Trace"`, available for matrices over fields, works by calculating the traces of powers of a.

Since V2.8, none of these algorithms are now recommended for matrices over $\mathbf{Z}$ or $\mathbf{Q}$, as the new p-adic modular algorithm over the integers is extremely fast.

`MinimalAndCharacteristicPolynomials(A: parameters)`

`MCPolynomials(A)`

`Proof` BoolElt *Default :* `true`

Given a square matrix A over a ring R, return the minimal and characteristic polynomials of A. For some rings, both polynomials can be computed at the same time, so in such cases it will be more efficient to use this function than to call `MinimalPolynomial` and `CharacteristicPolynomials` separately.

Setting the parameter `Proof` to false suppresses proof of correctness.

`FactoredMinimalPolynomial(A:` *parameters*`)`

`Proof`	BoolElt	*Default :* `true`

Given a square matrix A over a ring R, return the factorization of the minimal polynomial of A. This is equivalent to `Factorization(MinimalPolynomial(A))`, but may be faster than that for some coefficient rings (in particular, $\mathbf{Z}$ and $\mathbf{Q}$). Setting the parameter `Proof` to false suppresses proof of correctness.

`FactoredCharacteristicPolynomial(A:` *parameters*`)`

`Al`	MonStg	*Default :* "*Modular*"
`Proof`	BoolElt	*Default :* `true`

Given a square matrix A over a ring R, return the factorisation of the characteristic polynomial of A. This function returns the same result as the command `Factorisation(CharacteristicPolynomial(A))`, but may be faster than that for some coefficient rings (in particular, $\mathbf{Z}$ and $\mathbf{Q}$). The parameters are as for the function `CharacteristicPolynomial` above (setting the parameter `Proof` to false suppresses proof of correctness).

`FactoredMinimalAndCharacteristicPolynomials(A:` *parameters*`)`

`FactoredMCPolynomials(A:` *parameters*`)`

`Al`	MonStg	*Default :* "*Modular*"
`Proof`	BoolElt	*Default :* `true`

Given a square matrix A over a ring R, return the factorizations of the minimal and characteristic polynomials of A, respectively. For some rings, both polynomials can be computed and factored at the same time, so in such cases it will be more efficient to use this function than to call the above functions separately. Setting the parameter `Proof` to false suppresses proof of correctness.

`Eigenvalues(A)`

Given a square matrix A over a ring R, return the eigenvalues of A as a set of pairs, each of which gives the value of a distinct eigenvalue and its multiplicity. Factorization of polynomials over the base ring R must be possible.

`Eigenspace(A, e)`

Given a square matrix A over a ring R, and an element e of R, return the eigenspace of A corresponding to e, which is `Nullspace(A - e)`. If the ring element e is not a eigenvalue for the matrix A then the trivial nullspace is returned.

26.12 Canonical Forms

26.12.1 Canonical Forms over General Rings

The functions defined here apply to matrices defined over fields or Euclidean domains. See also the section on Reduction in the Lattices chapter for a description of the function `LLL` and related basis-reduction functions for matrices.

`EchelonForm(A)`

Given an $m \times n$ matrix A over the ring R, return the (reduced) row echelon form E of A, and also an invertible $m \times m$ transformation matrix T over R such that $T \cdot A = E$. Recall that T is a product of elementary matrices that transforms A into the echelon form E. If R is a Euclidean domain, the function `HermiteForm` (described below) is invoked. Note however, that the the user cannot set the parameters for `HermiteForm` when invoking it via `EchelonForm`.

`Adjoint(A)`

Given a square $m \times m$ matrix A over the ring R, return the adjoint of A as an $m \times m$ matrix. The base ring R must be a ring with exact division whose characteristic is zero or greater than m (this includes most commutative rings).

26.12.2 Canonical Forms over Fields

The functions described in this section apply to square matrices defined over fields which support factorization of univariate polynomials. See [Ste97] for a description of the single algorithm which is the basis of most of these functions.

`PrimaryRationalForm(A)`

Given a square matrix A over a field K such that factorization of polynomials is possible over K, return the primary rational form of A. Each block in the form is the companion matrix of a power of an irreducible polynomial. This function returns three values:

(a) The primary rational canonical form F of A;

(b) An invertible matrix T such that $T \cdot A \cdot T^{-1} = F$;

(c) A sequence of pairs corresponding to the blocks of F where each pair consists of the irreducible polynomial and the multiplicity making up the block. This is the value returned by `PrimaryInvariantFactors(A)`.

`JordanForm(A)`

Given a square matrix A over a field K such that factorization of polynomials is possible over K, return the generalized Jordan form of A. Each block in the form is a Jordan block (which itself is derived from a power of an irreducible polynomial), and the generalized Jordan form corresponds to the usual Jordan form if the minimal polynomial splits over K. This function returns three values:

(a) The Jordan canonical form F of A;

(b) An invertible matrix T such that $T \cdot A \cdot T^{-1} = F$;

(c) A sequence of pairs corresponding to the blocks of F where each pair consists of the irreducible polynomial and the multiplicity making up the block. This is the value returned by `PrimaryInvariantFactors(A)`.

`RationalForm(A)`

Given a square matrix A over a field K such that factorization of polynomials is possible over K, return the rational form of A. For each block other than the final block, the polynomial corresponding to that block divides the polynomial corresponding to the next block. This function returns three values:

(a) The rational form F of A;

(b) An invertible matrix T such that $T \cdot A \cdot T^{-1} = F$;

(c) A sequence containing the polynomials corresponding to the successive blocks (where each polynomial, other than the last, divides the next polynomial). This is the value returned by `InvariantFactors(A)`.

`PrimaryInvariantFactors(A)`

Given a square matrix A over a field K such that factorization of polynomials is possible over K, return the primary invariant factors of A. This is the same as the third return value of `PrimaryRationalForm(A)` or `JordanForm(A)`.

`InvariantFactors(A)`

Given a square matrix A over a field K such that factorization of polynomials is possible over K, return the invariant factors of A. This is the same as the third return value of `RationalForm(A)`.

`IsSimilar(A, B)`

Given square $m \times m$ matrices A and B, both over a field K such that factorization of polynomials is possible over K, return `true` iff and only if A is similar to B, and if so, return also an invertible $m \times m$ transformation matrix T such that $T \cdot A \cdot T^{-1} = B$.

`HessenbergForm(A)`

Given a square $m \times m$ matrix A over the ring R, return the Hessenberg form of A as an $m \times m$ matrix. The form has zero entries above the super-diagonal. (This form is used in one of the characteristic polynomial algorithms.) The base ring R must be a field.

`FrobeniusFormAlternating(A)`

Given an non-singular $2n \times 2n$ alternating matrix A over the integers, this function returns the (alternating) Frobenius form F of A. That is, a block matrix $F = \begin{pmatrix} 0 & D \\ -D & 0 \end{pmatrix}$, where D is a diagonal matrix with positive diagonal entries, d_i, satisfying $d_1 | d_2 | \cdots | d_n$. The second return value is the change of basis matrix B, such that $BA^tB = F$.

Example H26E9

We construct a 5×5 matrix over the finite field with 5 elements and then calculate various canonical forms. We verify the correctness of the polynomial invariant factors corresponding to the rational form by calculating the Smith form of the characteristic matrix of the original matrix (see below).

```
> K := GF(5);
> A := Matrix(K, 5,
>     [ 0, 2, 4, 2, 0,
>       2, 2, 2, 3, 3,
>       3, 4, 4, 1, 3,
>       0, 0, 0, 0, 1,
>       0, 0, 0, 1, 0 ]);
> A;
[0 2 4 2 0]
[2 2 2 3 3]
[3 4 4 1 3]
[0 0 0 0 1]
[0 0 0 1 0]
> PrimaryInvariantFactors(A);
[
    <x + 1, 1>,
    <x + 1, 1>,
    <x + 4, 1>,
    <x + 4, 1>,
    <x + 4, 1>
]
> JordanForm(A);
[4 0 0 0 0]
[0 4 0 0 0]
[0 0 1 0 0]
[0 0 0 1 0]
[0 0 0 0 1]
> R, T, F := RationalForm(A);
> R;
[1 0 0 0 0]
[0 0 1 0 0]
[0 1 0 0 0]
[0 0 0 0 1]
[0 0 0 1 0]
> T;
[1 3 0 2 1]
[2 1 2 2 0]
[3 4 3 4 1]
[1 0 0 0 0]
[0 2 4 2 0]
> T*A*T^-1 eq R;
true;
```

```
> F;
[
    x + 4,
    x^2 + 4,
    x^2 + 4
]
> P<x> := PolynomialRing(K);
> PM := MatrixAlgebra(P, 5);
> Ax := PM ! x - PM ! A;
> Ax;
[    x     3     1     3     0]
[    3 x + 3     3     2     2]
[    2     1 x + 1     4     2]
[    0     0     0     x     4]
[    0     0     0     4     x]
> SmithForm(Ax);

[      0       1       0       0       0]
[      0       0   x + 4       0       0]
[      0       0       0 x^2 + 4       0]
[      0       0       0       0 x^2 + 4]
> ElementaryDivisors(Ax);
[
    1,
    1,
    x + 4,
    x^2 + 4,
    x^2 + 4
]
```

26.12.3 Canonical Forms over Euclidean Domains

The functions defined here apply to matrices defined over Euclidean domains. See also the section on Reduction in the Lattices chapter for a description of the function LLL and related functions, which are very useful for integer matrices.

`HermiteForm(A)`

`Al`	MonStg	*Default :* "*Default*"
`Optimize`	BoolElt	*Default :* `true`
`Integral`	BoolElt	*Default :* `true`

Given an $m \times n$ matrix A over the Euclidean ring R, return the Hermite form H of A, and also an invertible $m \times m$ transformation matrix T over R such that $T \cdot A = H$.

The basic algorithm used is the classical Kannan-Bachem algorithm [KB79, CC82], which has classical complexity (but does not suffer from bad coefficient growth).

Since V2.13, for matrices over the integers there is also a fast modular algorithm by Allan Steel. By default, MAGMA chooses between these two algorithms, usually favouring the new modular algorithm. But one may set the parameter `Al` to `"Modular"` to force the modular algorithm to be used, and to `"Classical"` to force the classical algorithm to be used.

If R is the ring of integers $\mathbf{Z}$ and the matrix T is requested (i.e., if an assignment statement is used with two variables on the left side), then the LLL algorithm will also be used by default to improve T (using the kernel of A) so that the size of its entries are very small. If the parameter `Optimize` is set to `false`, then this will not happen (which will be faster but the entries of T will not be as small). If the parameter `Integral` is set to `true`, then the integral (de Weger) LLL method will be used in the LLL step, instead of the default floating point method.

`SmithForm(A)`

Given an $m \times n$ matrix A over the Euclidean ring R, return the Smith normal form of A. This function returns three values:

(a) The Smith normal form S of A; and

(b) Unimodular matrices P and Q such that $P \cdot A \cdot Q = S$, i.e., P and Q are matrices which transform A into Smith normal form.

The algorithm implemented first uses the sparse techniques described in [HHR93] to reduce the matrix to a dense submatrix, then, if this is non-trivial, it either repeatedly calls the Hermite normal form algorithm (see above) and transposes until a diagonal form is obtained, or uses the modular algorithm of F. Lübeck [Lüb02].

Unless one wishes one or both of the transformation matrices, it is preferable to use the following function `ElementaryDivisors` since it gives the same information, but saves memory since the matrix S does not need to be constructed.

`ElementaryDivisors(A)`

Given an $m \times n$ matrix A over the Euclidean ring or field R, return the elementary divisors of A. These are simply the non-zero diagonal entries of the Smith form of A, in order. The divisors are returned as a sequence $[e_1, \ldots, e_r]$ of r elements of R (which may include ones), where r is the rank of A and $e_i | e_{i+1}$ for $i = 1, \ldots, r-1$. The divisors are normalized, so the result is unique. If R is a field, the result is always the sequence of r ones, where r is the rank of A.

Note that if $m = n = r$, then the determinant of A is the product of the e_i and if R is also a domain, then e_r is the lowest common denominator of the inverse of A over the field of fractions of R.

`Saturation(A)`

Given an $m \times n$ matrix A over the integer ring $\mathbf{Z}$, having rank r, return an $m \times n$ matrix S over $\mathbf{Z}$ whose first r rows form a basis of the saturation w.r.t. $\mathbf{Q}$ of the $\mathbf{Q}$-vector space spanned by the rows of A. The rows of S thus span the same space over $\mathbf{Q}$ as those of A, while the $\mathbf{Z}$-module spanned by the rows of S is the set of all

v such that for some non-zero scalar s, $s \cdot v$ is in the $\mathbf{Z}$-module spanned by the rows of A.

Example H26E10

We illustrate some of these operations for a 4×3 matrix over $\mathbf{F}_8$.

```
> K<w> := GF(8);
> A := Matrix(K, 4, 3, [1,w,w^5, 0,w^3,w^4, w,1,w^6, w^3,1,w^4]);
> A;
[  1   w w^5]
[  0 w^3 w^4]
[  w   1 w^6]
[w^3   1 w^4]
> EchelonForm(A);
[  1   0   0]
[  0   1   0]
[  0   0   1]
[  0   0   0]
```

We now illustrate some of these operations for a 4×5 matrix over $\mathbf{Z}$.

```
> A := Matrix(4, 5,
>     [ 2,-4,12,7,0,
>       3,-3,5,-1,4,
>       2,-1,-4,-5,-12,
>       0,3,6,-2,0]);
> A;
[  2  -4  12   7   0]
[  3  -3   5  -1   4]
[  2  -1  -4  -5 -12]
[  0   3   6  -2   0]
> Rank(A);
4
> HermiteForm(A);
[   1    1    1    6 -164]
[   0    3    0   16 -348]
[   0    0    2   13 -200]
[   0    0    0   19 -316]
> SmithForm(A);
[1 0 0 0 0]
[0 1 0 0 0]
[0 0 1 0 0]
[0 0 0 2 0]
> ElementaryDivisors(A);
[ 1, 1, 1, 2 ]
```

26.13 Orders of Invertible Matrices

The functions defined here apply to invertible square matrices. MAGMA can efficiently compute the order of an invertible matrix over a finite field, using the Cunningham database to factorize the numbers of the form $p^n - 1$ which arise. The algorithm employed is that described in [CLG97a].

MAGMA also contains efficient algorithms for rigorously proving whether a matrix over the ring of integers $\mathbf{Z}$, the rational field $\mathbf{Q}$, an algebraic number field, a cyclotomic field or a quadratic field has finite order or not, and for determining the order if it is finite.

`HasFiniteOrder(A)`

Given a square invertible matrix A over a ring R, return `true` iff A has finite order, i.e., iff there exists a positive integer n such that $A^n = 1$. The coefficient ring R is currently restricted to being either a finite field, the ring of integers $\mathbf{Z}$, the rational field $\mathbf{Q}$, an algebraic number field, a cyclotomic field or a quadratic field. For matrices over any of these rings, the function rigorously proves its result (over other rings, an error results).

`Order(A)`

`Proof` BOOLELT *Default :* `true`

Given a square invertible matrix A over any commutative ring, return the order of A. If R is a ring for which a finite order proof exists (see `HasFiniteOrder` above), then an error results if A has infinite order. Over other rings, if A has infinite order then the function may loop indefinitely since it may not be able to prove the infinitude of the order.

`FactoredOrder(A)`

`Proof` BOOLELT *Default :* `true`

Given a square invertible matrix A over a finite field, return the order of A in factored form. This returns the same value as `Factorization(Order(A))`, but since the order computation must compute the factorization of the order anyway, it involves no more effort to have it return the factorization. The conditions on the ring are as for `Order`.

`ProjectiveOrder(A)`

`Proof` BOOLELT *Default :* `true`

Given a square invertible matrix A over a finite field K, return the projective order n of A and a scalar $s \in K$ such that $A^n = sI$. The projective order of A is the smallest n such that A^n is a scalar matrix (not just the identity matrix), and it always divides the true order of A. The parameter `Proof` is as for `Order`.

`FactoredProjectiveOrder(A)`

`Proof` BoolElt *Default :* `true`

Given a square invertible matrix A over a finite field K, return the projective order n of A in factored form and a scalar $s \in K$ such that $A^n = sI$. The parameter `Proof` is as for `FactoredOrder`.

26.14 Miscellaneous Operations on Matrices

`FrobeniusImage(A, e)`

Given a matrix A over a finite field K of characteristic p, return the matrix obtained from A by mapping each entry $A_{i,j}$ to $(A_{i,j})^{p^e}$.

`NumericalEigenvectors(M, e)`

Given a square matrix M that is coercible into the complexes, and an approximation e to an eigenvalue of it, attempt to find eigenvectors. This function is for cases for which there are no numerical worries.

27 SPARSE MATRICES

Chapter 27
SPARSE MATRICES

27.1 Introduction

A separate type is provided for sparse matrices to allow the user to construct such matrices and apply algorithms which take advantage of sparsity. Sparse matrices are distinct from normal matrices in MAGMA, which have a dense representation. This chapter describes the operations available for creating and working with sparse matrices.

The operations provided for sparse matrices include dynamic construction, simple properties, and the calculation of a number of non-trivial and important invariants (such as rank, determinant, or computing a non-zero vector in the nullspace). In particular, this datatype supports the class of *index-calculus* algorithms which involve generating a very large sparse system and then solving the system or finding the elementary divisors of the corresponding matrix (for example, to compute the abelian group structure). An extended example presented at the end of the chapter (H27E3) illustrates how an index-calculus method may be implemented in practice in the MAGMA language using the sparse matrix facilities.

The type name for the category of sparse matrices is `MtrxSprs`. All sparse matrices over a given ring R lie in the same *sparse matrix structure*, whose type name is `MtrxSprsStr`. The user will, in practice, rarely need to refer explicitly to the parent structure.

27.2 Creation of Sparse Matrices

This section describes the constructs provided for creating sparse matrices.

27.2.1 Construction of Initialized Sparse Matrices

```
SparseMatrix(R, m, n, Q)
```

```
SparseMatrix(m, n, Q)
```

Given a ring R (optional), integers $m, n \geq 0$ and a sequence Q, return the $m \times n$ sparse matrix over R whose non-zero entries are those specified by Q, coerced into R. If R is not given, it is derived from the entries in Q. Either of m and n may be 0, in which case Q must have length 0 (and may be null if R is given), and the $m \times n$ zero sparse matrix over R is returned. There are two possibilities for Q:

(a) The sequence Q is a sequence of tuples, each of the form `<i, j, x>`, where $1 \leq i \leq m$, $1 \leq j \leq n$, and $x \in S$ for some ring S. Such a tuple specifies that the (i, j)-th entry of the matrix is x. If R is given, then x is coerced into R; otherwise the matrix is created over S. If an entry position is not given then its value is zero, while if an entry position is repeated then the last value overrides any previous values.

(b) The sequence Q is a "flat" sequence of integers, giving the entries of the matrix in compact form. To be precise, Q begins with the number of non-zero entries n for the first row, then $2 \cdot n$ integers giving column-entry pairs for the first row, and this format is immediately followed for the second row and so on. A zero row is specified by a zero value for n. If R is given, the integer entries are coerced into R; otherwise the matrix is defined over $\mathbf{Z}$. (Thus this method will not allow elements of R which cannot be created by coercing integers into R alone; another way of saying this is that the entries must all lie in the prime ring of R). This allows a very compact way to create (and store) sparse matrices. The examples below illustrate this format.

`SparseMatrix(R, m, n)`

Given a ring R, and integers $m, n \geq 0$, create the $m \times n$ sparse matrix over R.

`SparseMatrix(m, n)`

Given integers $m, n \geq 0$, create the $m \times n$ sparse matrix over the integer ring $\mathbf{Z}$.

27.2.2 Construction of Trivial Sparse Matrices

`SparseMatrix(R)`

`SparseMatrix()`

Create the 0×0 sparse matrix over R. If R is omitted (so there are no arguments), then R is taken to be the integer ring $\mathbf{Z}$. These functions will usually be called when the user wishes to create a sparse matrix whose final dimensions are initially unknown, and for which the SetEntry procedure below will be used to extend the matrix automatically, as needed.

Example H27E1

This example demonstrates simple ways of creating matrices using the general `SparseMatrix(R, m, n, Q)` function. Sparse matrices may be displayed in the sparse representation using the `Magma` print-format. Also, the function Matrix (described below) takes a sparse matrix and returns a normal (dense-representation) matrix, so this function provides a means of printing a small sparse matrix as a normal matrix.

(a) A sparse 2×2 matrix is defined over $\mathbf{Z}$, using the first (sequence of tuples) method. We specify that there is a 3 in the $(1, 2)$ position and a -1 in the $(2, 3)$ position. The ring need not be given since the entries are in $\mathbf{Z}$ already.

```
> A := SparseMatrix(2, 3, [<1,2,3>, <2,3,-1>]);
> A;
Sparse matrix with 2 rows and 3 columns over Integer Ring
> Matrix(A);
[ 0  3  0]
```

```
[ 0  0 -1]
```

(b) The same matrix is now defined over $\mathbf{F}_{23}$. We could also coerce the 3rd component of each tuple into $\mathbf{F}_{23}$ and thus omit the first argument.

```
> A := SparseMatrix(GF(23), 2, 3, [<1,2,3>, <2,3,-1>]);
> A;
Sparse matrix with 2 rows and 3 columns over GF(23)
> Matrix(A);
[ 0  3  0]
[ 0  0 22]
```

(c) A similar sparse matrix is defined over $\mathbf{F}_{2^4}$. When A is printed in `Magma` format, the sequence-of-tuples form is used (because the entries cannot be printed as integers).

```
> K<w> := GF(2^4);
> A := SparseMatrix(K, 2, 3, [<1,2,3>, <2,3,w>]);
> A;
Sparse matrix with 2 rows and 3 columns over GF(2^4)
> Matrix(A);
[   0    1    0]
[   0    0    w]
> A: Magma;
SparseMatrix(GF(2, 4), 2, 3, [
    <1, 2, 1>,
    <2, 3, w>
])
```

(d) A sparse 4×5 matrix A is defined over $\mathbf{Z}$, using the second (flat integer sequence) method. Here row 1 has one non-zero entry: -1 at column 3; then row 2 has three non-zero entries: 9 at column 2, 7 at column 3, and -3 at column 4; row 3 has no non-zero entries (so we give a 0 at this point); and finally row 4 has one non-zero entry 3 at column 4. Note that when A is printed in `Magma` format, this time the compact "flat" sequence of integers form is used, since this is possible.

```
> A := SparseMatrix(4,5, [1,3,-1, 3,2,9,3,7,4,-3, 0, 1,4,3]);
> A;
Sparse matrix with 4 rows and 5 columns over Integer Ring
> Matrix(A);
[ 0  0 -1  0  0]
[ 0  9  7 -3  0]
[ 0  0  0  0  0]
[ 0  0  0  3  0]
> A: Magma;
SparseMatrix(4, 5, \[
    1, 3,-1,
    3, 2,9, 3,7, 4,-3,
    0,
    1, 4,3
])
```

27.2.3 Construction of Structured Matrices

`IdentitySparseMatrix(R, n)`

Given a ring R, and an integer $n \geq 0$, return the $n \times n$ identity sparse matrix over R.

`ScalarSparseMatrix(n, s)`

Given an integer $n \geq 0$ and an element s of a ring R, return the $n \times n$ scalar sparse matrix over R which has s on the diagonal and zeros elsewhere. The argument n may be 0, in which case the 0×0 sparse matrix over R is returned.

`ScalarSparseMatrix(R, n, s)`

Given a ring R, an integer $n \geq 0$ and an element s of a ring S, return the $n \times n$ scalar sparse matrix over R which has s, coerced into R, on the diagonal and zeros elsewhere. n may be 0, in which case in which case the 0×0 sparse matrix over R is returned.

`DiagonalSparseMatrix(R, n, Q)`

Given a ring R, an integer $n \geq 0$ and a sequence Q of n ring elements, return the $n \times n$ diagonal sparse matrix over R whose diagonal entries correspond to the entries of Q, coerced into R.

`DiagonalSparseMatrix(R, Q)`

Given a ring R and a sequence Q of n ring elements, return the $n \times n$ diagonal sparse matrix over R whose diagonal entries correspond to the entries of Q, coerced into R.

`DiagonalSparseMatrix(Q)`

Given a sequence Q of n elements from a ring R, return the $n \times n$ diagonal sparse matrix over R whose diagonal entries correspond to the entries of Q.

27.2.4 Parents of Sparse Matrices

`SparseMatrixStructure(R)`

Create the structure containing all sparse matrices (of any shape) over ring R. This structure does not need to be created explicitly by the user (it will be the parent of any sparse matrix over R), but it may be useful to create it in this way occasionally.

27.3 Accessing Sparse Matrices

The following functions access basic properties of sparse matrices.

27.3.1 Elementary Properties

`BaseRing(A)`

`CoefficientRing(A)`

Given a sparse matrix A with entries lying in a ring R, return R.

`NumberOfRows(A)`

`Nrows(A)`

Given an $m \times n$ sparse matrix A, return m, the number of rows of A.

`NumberOfColumns(A)`

`Ncols(A)`

Given an $m \times n$ sparse matrix A, return n, the number of columns of A.

`ElementToSequence(A)`

`Eltseq(A)`

Given a sparse matrix A over the ring R having m rows and n columns, return the entries of A as a sequence of all tuples of the form `<i, j, x>` such that the $[i, j]$-th entry of A equals x and x is non-zero. It is always true that `SparseMatrix(Nrows(A), Ncols(A), Eltseq(A))` equals A.

`NumberOfNonZeroEntries(A)`

`NNZEntries(A)`

Given a sparse matrix A, return the number of non-zero entries in A.

`Density(A)`

Given a sparse matrix A, return the density of A as a real number, which is the number of non-zero entries in A divided by the product of the number of rows of A and the number of columns of A (or zero if A has zero rows or columns).

`Support(A, i)`

Given a sparse matrix A having r rows, and an integer i such that $1 \leq i \leq r$, return the support of row i of A; i.e., the column numbers of the non-zero entries of row i of A.

`Support(A)`

Given a sparse matrix A, return the sequence of all pairs `<i, j>` such that the $[i, j]$-th entry of A is non-zero.

27.3.2 Weights

`RowWeight(A, i)`

Given a sparse matrix A with m rows and an integer i such that $1 \leq i \leq m$, return the weight (number of non-zero entries) of the i-th row of A.

`RowWeights(A)`

Given a sparse matrix A with m rows, return the length m sequence of integers whose i-th entry is the weight of the i-th row of A.

`ColumnWeight(A, j)`

Given a sparse matrix A with n columns and an integer j such that $1 \leq j \leq n$, return the weight (number of non-zero entries) of the j-th column of A.

`ColumnWeights(A)`

Given a sparse matrix A with n columns, return the length n sequence of integers whose j-th entry is the weight of the j-th column of A.

27.4 Accessing or Modifying Entries

The following functions and procedures enable the user to access or set individual entries of sparse matrices.

`A[i]`

Given a sparse matrix A over a ring R having m rows and n columns, and an integer i such that $1 \leq i \leq m$, return the i-th row of A, as a dense vector of length n (lying in R^n).

`A[i, j]`

Given a sparse matrix A over a ring R having m rows and n columns, integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, return the (i, j)-th entry of A, as an element of the ring R.

`A[i, j] := x`

Given a sparse matrix A over a ring R having m rows and n columns, integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, and a ring element x coercible into R, modify the (i, j)-th entry of A to be x. Here i and j must be within the ranges given by the current dimensions of A; see `SetEntry` below for a procedure to automatically extend A if necessary.

`SetEntry(~A, i, j, x)`

(Procedure.) Given a sparse matrix A over a ring R, integers $i, j \geq 1$, and a ring element x coercible into R, modify the (i, j)-th entry of A to be x. The entry specified by i and j is allowed to be beyond the current dimensions of A; if so, A is automatically extended to have at least i rows and j columns.

This procedure will be commonly used in situations where the final size of the matrix is not known as an algorithm proceeds (e.g., in index-calculus methods). One can create the 0×0 sparse matrix over $\mathbf{Z}$, say, and then call `SetEntry` to build up the matrix dynamically. See the example H27E3 below, which uses this technique.

Note that extending the dimensions of A with a very large i or j will not in itself consume much memory, but if A then becomes dense or is passed to some algorithm, then the memory needed may of course be proportional to the dimensions of A.

Example H27E2

This example demonstrates simple ways of accessing the entries of sparse matrices.

```
> A := SparseMatrix(2, 3, [<1,2,3>, <2,3,-1>]);
> A;
Sparse matrix with 2 rows and 3 columns over Integer Ring
> Matrix(A);
[ 0  3  0]
[ 0  0 -1]
> A[1];
(0 3 0)
> A[1, 3]:=5;
> A[1];
(0 3 5)
```

We next extend A using the procedure `SetEntry`.

```
> SetEntry(~A, 1, 5, -7);
> A;
Sparse matrix with 2 rows and 5 columns over Integer Ring
> Matrix(A);
[ 0  3  5  0 -7]
[ 0  0 -1  0  0]
```

A common situation is to start with the empty 0×0 matrix over $\mathbf{Z}$ and then to extend it dynamically.

```
> A := SparseMatrix();
> A;
Sparse matrix with 0 rows and 0 columns over Integer Ring
> SetEntry(~A, 1, 4, -2);
> A;
Sparse matrix with 1 row and 4 columns over Integer Ring
> SetEntry(~A, 2, 3, 8);
> A;
```

```
Sparse matrix with 2 rows and 4 columns over Integer Ring
> Matrix(A);
[ 0  0  0 -2]
[ 0  0  8  0]
> SetEntry(~A, 200, 319, 1);
> SetEntry(~A, 200, 3876, 1);
> A;
Sparse matrix with 200 rows and 3876 columns over Integer Ring
> Nrows(A);
200
> Ncols(A);
3876
> NNZEntries(A);
4
> Density(A);
0.00000515995872033023735810113519 0
> Support(A, 200);
[ 319, 3876 ]
```

27.4.1 Extracting and Inserting Blocks

The following functions enable the extraction of certain rows, columns or general submatrices, or the replacement of a block by another sparse matrix.

`Submatrix(A, i, j, p, q)`

`ExtractBlock(A, i, j, p, q)`

Given an $m \times n$ sparse matrix A and integers i, j, p and q such that $1 \leq i \leq i+p \leq m+1$ and $1 \leq j \leq j+q \leq n+1$, return the $p \times q$ submatrix of A rooted at (i, j). Either or both of p and q may be zero, while i may be $m+1$ if p is zero and j may be $n+1$ if q is zero.

`SubmatrixRange(A, i, j, r, s)`

`ExtractBlockRange(A, i, j, r, s)`

Given an $m \times n$ sparse matrix A and integers i, j, r and s such that $1 \leq i$, $i-1 \leq r \leq m$, $1 \leq j$, and $j-1 \leq s \leq n$, return the $r-i+1 \times s-j+1$ submatrix of A rooted at the (i, j)-th entry and extending to the (r, s)-th entry, inclusive. r may equal $i-1$ or s may equal $j-1$, in which case a sparse matrix with zero rows or zero columns, respectively, will be returned.

`Submatrix(A, I, J)`

Given an $m \times n$ sparse matrix A and integer sequences I and J, return the submatrix of A given by the row indices in I and the column indices in J.

`InsertBlock(A, B, i, j)`

`InsertBlock(~A, B, i, j)`

Given an $m \times n$ sparse matrix A over a ring R, a $p \times q$ sparse matrix B over R, and integers i and j such that $1 \leq i \leq i + p \leq m + 1$ and $1 \leq j \leq j + q \leq n + 1$, insert B at position (i, j) in A. In the functional version (A is a value argument), this function returns the new sparse matrix and leaves A untouched, while in the procedural version ($\sim A$ is a reference argument), A is modified in place so that the $p \times q$ submatrix of A rooted at (i, j) is now equal to B.

`RowSubmatrix(A, i, k)`

Given an $m \times n$ sparse matrix A and integers i and k such that $1 \leq i \leq i+k \leq m+1$, return the $k \times n$ submatrix of X consisting of rows $[i \ldots i + k - 1]$ inclusive. The integer k may be zero and i may also be $m + 1$ if k is zero, but the result will always have n columns.

`RowSubmatrix(A, i)`

Given an $m \times n$ sparse matrix A and an integer i such that $0 \leq i \leq m$, return the $i \times n$ submatrix of X consisting of the first i rows. The integer i may be 0, but the result will always have n columns.

`RowSubmatrixRange(A, i, j)`

Given an $m \times n$ sparse matrix A and integers i and j such that $1 \leq i$ and $i - 1 \leq j \leq m$, return the $j - i + 1 \times n$ submatrix of X consisting of rows $[i \ldots j]$ inclusive. The integer j may equal $i - 1$, in which case a sparse matrix with zero rows and n columns will be returned.

`ColumnSubmatrix(A, i, k)`

Given an $m \times n$ sparse matrix A and integers i and k such that $1 \leq i \leq i+k \leq n+1$, return the $m \times k$ submatrix of X consisting of columns $[i \ldots i+k-1]$ inclusive. The integer k may be zero and i may also be $n + 1$ if k is zero, but the result will always have m rows.

`ColumnSubmatrix(A, i)`

Given an $m \times n$ sparse matrix A and an integer i such that $0 \leq i \leq n$, return the $m \times i$ submatrix of X consisting of the first i columns. The integer i may be 0, but the result will always have m rows.

`ColumnSubmatrixRange(A, i, j)`

Given an $m \times n$ sparse matrix A and integers i and j such that $1 \leq i$ and $i-1 \leq j \leq n$, return the $m \times j - i + 1$ submatrix of X consisting of columns $[i \ldots j]$ inclusive. The integer j may equal $i - 1$, in which case a sparse matrix with zero columns and n rows will be returned.

27.4.2 Row and Column Operations

The following functions and procedures provide elementary row or column operations on sparse matrices. For each operation, there is a corresponding function which creates a new sparse matrix for the result (leaving the input sparse matrix unchanged), and a corresponding procedure which modifies the input sparse matrix in place.

`SwapRows(A, i, j)`

`SwapRows(~A, i, j)`

Given an $m \times n$ sparse matrix A and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq m$, swap the i-th and j-th rows of A.

`SwapColumns(A, i, j)`

`SwapColumns(~A, i, j)`

Given an $m \times n$ sparse matrix A and integers i and j such that $1 \leq i \leq n$ and $1 \leq j \leq n$, swap the i-th and j-th columns of A.

`ReverseRows(A)`

`ReverseRows(~A)`

Given a sparse matrix A, reverse all the rows of A.

`ReverseColumns(A)`

`ReverseColumns(~A)`

Given a sparse matrix A, reverse all the columns of A.

`AddRow(A, c, i, j)`

`AddRow(~A, c, i, j)`

Given an $m \times n$ sparse matrix A over a ring R, a ring element c coercible into R, and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq m$, add c times row i of A to row j of A.

`AddColumn(A, c, i, j)`

`AddColumn(~A, c, i, j)`

Given an $m \times n$ sparse matrix A over a ring R, a ring element c coercible into R, and integers i and j such that $1 \leq i \leq n$ and $1 \leq j \leq n$, add c times column i of A to column j.

`MultiplyRow(A, c, i)`

`MultiplyRow(~A, c, i)`

Given an $m \times n$ sparse matrix A over a ring R, a ring element c coercible into R, and an integer i such that $1 \leq i \leq m$, multiply row i of A by c (on the left).

`MultiplyColumn(A, c, i)`

`MultiplyColumn(~A, c, i)`

Given an $m \times n$ sparse matrix A over a ring R, a ring element c coercible into R, and an integer i such that $1 \leq i \leq n$, multiply column i of A by c (on the left).

`RemoveRow(A, i)`

`RemoveRow(~A, i)`

Given an $m \times n$ sparse matrix A and an integer i such that $1 \leq i \leq m$, remove row i from A (leaving an $(m-1) \times n$ sparse matrix).

`RemoveColumn(A, j)`

`RemoveColumn(~A, j)`

Given an $m \times n$ sparse matrix A and an integer j such that $1 \leq j \leq n$, remove column j from A (leaving an $m \times (n-1)$ sparse matrix).

`RemoveRowColumn(A, i, j)`

`RemoveRowColumn(~A, i, j)`

Given an $m \times n$ sparse matrix A and integers i and j such that $1 \leq i \leq m$ and $1 \leq j \leq n$, remove row i and column j from A (leaving an $(m-1) \times (n-1)$ sparse matrix).

`RemoveZeroRows(A)`

`RemoveZeroRows(~A)`

Given a sparse matrix A, remove all the zero rows of A.

27.5 Building Block Matrices

`HorizontalJoin(A, B)`

Given a sparse matrix A with r rows and c columns, and a sparse matrix B with r rows and d columns, both over the same coefficient ring R, return the sparse matrix over R with r rows and $(c+d)$ columns obtained by joining A and B horizontally (placing B to the right of A).

`VerticalJoin(A, B)`

Given a sparse matrix A with r rows and c columns, and a sparse matrix B with s rows and c columns, both over the same coefficient ring R, return the sparse matrix with $(r+s)$ rows and c columns over R obtained by joining A and B vertically (placing B underneath A).

`DiagonalJoin(A, B)`

Given matrices A with a rows and b columns and B with c rows and d columns, both over the same coefficient ring R, return the sparse matrix with $(a + c)$ rows and $(b + d)$ columns over R obtained by joining A and B diagonally (placing B diagonally to the right of and underneath A, with zero blocks above and below the diagonal).

27.6 Conversion to and from Dense Matrices

The following functions convert between sparse matrices and normal (dense-representation) matrices.

`Matrix(A)`

Given a sparse matrix A, return the normal (dense-representation) matrix equal to A. This function should only be used if the size of A is reasonably small since otherwise the amount of memory needed to represent the dense-representation matrix may be huge. Printing the result of this operation is a convenient way to display A as a normal (dense) matrix if A is small.

`SparseMatrix(A)`

Given a normal (dense-representation) matrix A, return the sparse matrix equal to A. Note that if there is a fast algorithm available for the sparse matrix type, there is no need to convert a dense-representation matrix to the sparse matrix type first and then to use that algorithm, since MAGMA does this automatically.

27.7 Changing Ring

`ChangeRing(A, R)`

`SparseMatrix(R, A)`

Given a sparse matrix A over a ring S having m rows and n columns, and another ring R, return the $m \times n$ sparse matrix over R obtained by coercing the entries of A from S into R.

The argument order to `ChangeRing(A, R)` here is consistent with other forms of `ChangeRing`, while the `SparseMatrix(R, A)` form of this function is provided to be consistent with the sparse matrix creation functions above, for which the destination ring is the first argument, if supplied.

27.8 Predicates

The functions in this section test various properties of sparse matrices.

`A eq B`

Given sparse matrices A and B, return `true` if and only if A and B are equal.

`IsZero(A)`

Given an $m \times n$ sparse matrix A over the ring R, return `true` iff A is the $m \times n$ zero sparse matrix.

`IsOne(A)`

Given a square $m \times m$ sparse matrix A over the ring R, return `true` iff A is the $m \times m$ identity sparse matrix.

`IsMinusOne(A)`

Given a square $m \times m$ sparse matrix A over the ring R, return `true` iff A is the negation of the $m \times m$ identity sparse matrix.

`IsScalar(A)`

Given a square $m \times m$ sparse matrix A over the ring R, return `true` iff A is scalar, i.e., iff A is the product of some element of R and the $m \times m$ identity sparse matrix.

`IsDiagonal(A)`

Given a square sparse matrix A over the ring R, return `true` iff A is diagonal, i.e., iff the only non-zero entries of A are on the diagonal.

`IsSymmetric(A)`

Given a square sparse matrix A over the ring R, return `true` iff A is symmetric, i.e., iff A equals its transpose.

`IsUpperTriangular(A)`

Given a sparse matrix A over the ring R, return `true` iff A is upper triangular, i.e., iff the only non-zero entries of A are on or above the diagonal.

`IsLowerTriangular(A)`

Given a sparse matrix A over the ring R, return `true` iff A is lower triangular, i.e., iff the only non-zero entries of A are on or below the diagonal.

27.9 Elementary Arithmetic

`A + B`

Given $m \times n$ sparse matrices A and B over a ring R, return $A + B$.

`A - B`

Given $m \times n$ sparse matrices A and B over a ring R, return $A - B$.

`A * B`

Given an $m \times n$ sparse matrix A over a ring R and an $n \times p$ sparse matrix B over R, return the $m \times p$ sparse matrix $A \cdot B$ over R.

`x * A`
`A * x`

Given an $m \times n$ sparse matrix A over a ring R and a ring element x coercible into R, return the scalar product $x \cdot A$.

`-A`

Given a sparse matrix A, return $-A$.

`A ^-1`

Given a invertible square sparse matrix A over a ring R, return the inverse B of A so that $A \cdot B = B \cdot A = 1$. The coefficient ring R must be either a field, a Euclidean domain, or a ring with an exact division algorithm and having characteristic equal to zero or greater than m (this includes most commutative rings).

`A ^ n`

Given a square sparse matrix A over a ring R and an integer n, return the matrix power A^n. A^0 is defined to be the identity matrix for any square matrix A (even if A is zero). If n is negative, A must be invertible (see the previous function), and the result is $(A^{-1})^{-n}$.

`Transpose(A)`

Given an $m \times n$ sparse matrix A over a ring R, return the transpose of A, which is simply the $n \times m$ sparse matrix over R whose (i, j)-th entry is the (j, i)-th entry of A.

27.10 Multiplying Vectors or Matrices by Sparse Matrices

These functions allow the multiplication of a normal (dense-representation) vector by a sparse matrix.

`v * A`

`V * A`

Given a dense-representation vector v or dense-representation matrix V with c columns, together with a sparse $c \times n$ matrix A, both over a ring R, return the product $v \cdot A$ or $V \cdot A$.

This is generally fast if A is sparse and uses minimal memory.

`MultiplyByTranspose(v, A)`

`MultiplyByTranspose(V, A)`

Given a dense-representation vector v or dense-representation matrix V with c columns, together with a sparse $n \times c$ matrix A, both over a ring R, return the product of v or V by the transpose of A.

This is generally fast if A is sparse, and is much faster than computing the transpose of A first. For example, if the vector-matrix product $v \cdot A \cdot A^{tr}$ is required, then the function call `MultiplyByTranspose(v*A, A)` should be used to avoid forming the matrix $A \cdot A^{tr}$ which is usually dense. This product occurs in iterative algorithms such as Lanzcos.

27.11 Non-trivial Properties

The following functions compute non-trivial properties of sparse matrices.

27.11.1 Nullspace and Rowspace

The following functions compute nullspaces (solving equations of the form $V \cdot A = 0$) or rowspaces of sparse matrices.

`Nullspace(A)`

`Kernel(A)`

Given an $m \times n$ sparse matrix A over a ring R, return the nullspace of A (or the kernel of A, considered as a linear transformation or map), which is the R-space consisting of all vectors v of length m such that $v \cdot A = 0$. Since the result will be given in the dense representation, both the nullity of A and the number of rows of A must both be reasonably small.

The algorithm first performs sparse elimination using Markowitz pivoting ([DEJ84, Sec. 9.2]) to obtain a smaller dense matrix, then the nullspace algorithm for dense-representation matrices is applied to this matrix.

`NullspaceMatrix(A)`

`KernelMatrix(A)`

Given an $m \times n$ sparse matrix A over a ring R, return a (dense-representation) basis matrix of the nullspace of A. This is a matrix N having m columns and the maximal number of independent rows subject to the condition that $N \cdot A = 0$. This function has the advantage that the nullspace is not returned as a R-space, so echelonization of the resulting nullspace may be avoided.

`NullspaceOfTranspose(A)`

This function is equivalent to `Nullspace(Transpose(A))`, but will be more efficient in space for large matrices, since the transpose may not have to be explicitly constructed to compute the nullspace.

`Rowspace(A)`

Given an $m \times n$ sparse matrix A over a ring R, return the rowspace of A, which is the R-space generated by the rows of A. Since the result will be given in the dense representation, the rank and the number of columns of A must both be reasonably small.

27.11.2 Rank

`Rank(A)`

Given an $m \times n$ sparse matrix A over a ring R, return the rank of A. The algorithm first performs sparse elimination using Markowitz pivoting ([DEJ84, Sec. 9.2]) to obtain a smaller dense matrix, then the rank algorithm for dense-representation matrices is applied to this matrix.

27.12 Determinant and Other Properties

`Determinant(A:` *parameters*`)`

`MonteCarloSteps` RngIntElt *Default :*

Given a square sparse matrix A over the ring R, return the determinant of A as an element of R. R may be any commutative ring.

The algorithm first performs sparse elimination using Markowitz pivoting ([DEJ84, Sec. 9.2]) to obtain a smaller dense matrix, then the determinant algorithm for dense-representation matrices is applied to this matrix. If the parameter `MonteCarloSteps` is given, then this is passed to the dense algorithm for the dense matrix.

27.12.1 Elementary Divisors (Smith Form)

`ElementaryDivisors(A)`

Given an $m \times n$ matrix A over the Euclidean ring or field R, return the elementary divisors of A. These are simply the non-zero diagonal entries of the Smith form of A, in order.

The divisors are returned as a sequence $Q = [e_1, \ldots, e_d]$, $e_i | e_{i+1}$ $(i = 1, \ldots, d-1)$ of d elements of R (which may include ones), where d is the rank of A. If R is a field, the result is always a sequence of r ones, where r is the rank of A.

A function for computing the Smith normal form is not supplied for sparse matrices since the form may be trivially derived from the elementary divisors, and the sequence Q containing the divisors is often more convenient (and takes less memory). As transformation matrices are dense in general, they are not supported for the sparse representation.

The algorithm first performs sparse elimination using Markowitz pivoting to obtain a smaller dense matrix ([DEJ84, Sec. 9.2]; this is similar to the techniques described in [HHR93]). Then it invokes the dense Smith normal form algorithm for normal (dense-representation) matrices (`SmithForm`).

27.12.2 Verbosity

`SetVerbose("SparseMatrix", v)`

(Procedure.) Set the verbose printing level for all sparse matrix algorithms to be v. Currently the legal values for v are `true`, `false`, 0, 1, 2, and 3 (`false` has the same effect as 0, and `true` has the same effect as 1).

27.13 Linear Systems (Structured Gaussian Elimination)

`ModularSolution(A, M)`

`ModularSolution(A, L)`

`Lanczos` BoolElt *Default :* `false`

Given a sparse $m \times n$ matrix A, defined over the integer ring $\mathbf{Z}$, and a positive integer M, compute a vector v such that v satisfies the equation $v \cdot A^{tr} = 0$ modulo M. v will be non-zero with high probability.

This function is designed for index-calculus-type algorithms where a large sparse linear system defined by the matrix A is first constructed and then a vector satisfying the above equation modulo M is required. For this reason it is natural that the transpose of A appears in this equation. The example H27E3 below illustrates such a situation in detail.

The first version of the function takes the actual integer M as the second argument given and so must be factored as part of the calculation, while the second

version of the function takes the factorization sequence L of M. If possible, the solution vector is multiplied by a unit modulo M so that its first entry is 1.

The function uses the *Structured Gaussian Elimination* algorithm [LO91b, Sec. 5]. This reduces the linear system to be solved to a much smaller but denser system. By default, the function recurses on the smaller system until it is almost completely dense, and then this dense system is solved using the fast dense modular nullspace algorithm of MAGMA.

If the parameter `Lanczos` is set to `true`, then the *Lanczos* algorithm [LO91b, Sec. 3] will be used instead. This is generally *very much* slower than the default method (it is often 10 to 50 times slower), but it will take considerably less memory, so may be preferable in the case of extremely large matrices.

For typical matrices arising in index-calculus problems, and for most machines, the default method (reducing to a completely dense system) should solve a linear system of size roughly $100,000 \times 100,000$ using about 500MB of memory while a linear system of size roughly $200,000 \times 200,000$ should require about 1.5GB to 2.0GB of memory.

Example H27E3

In this extended example, we demonstrate the application of the function `ModularSolution` to a sparse matrix arising in an index-calculus algorithm. We present MAGMA code which performs the first stage of the basic linear sieve [COS86, LO91a] for computing discrete logarithms in a prime finite field $\mathbf{F}_p$. This first stage determines most of the logarithms of the elements of the *factor basis* (which is the set of small primes up to a given limit) by using a *sieve* to compute a sparse linear system which is then solved modulo $p-1$.

Even though the following sieving code is written in the MAGMA language and so is *much* slower than a serious C implementation, it is sufficiently powerful to be able to compute the first stage logarithms in less than a minute for fields $\mathbf{F}_p$ where p is about 10^{20} and $(p-1)/2$ is prime. In comparison, the standard Pohlig-Hellman algorithm based on the Pollard-Rho method would take many hours for such fields. This MAGMA code can also be adapted for other index-calculus methods.

Suppose p is an odd prime and let $K = \mathbf{F}_p$. Let Q be the *factor base*, an ordered set consisting of all positive primes from 2 to a given limit `qlimit`. Fix a primitive element α of K which is also *prime* as an integer, so α is in Q. We wish to compute the discrete logarithms of most of the elements of Q with respect to α; i.e., we wish to compute l_q with $\alpha^{l_q} = q$ for most $q \in Q$.

The algorithm uses a *sieve* to search for linear relations involving the logarithms of the elements of Q. Let $H = \lfloor \sqrt{p} \rfloor + 1$ and $J = H^2 - p$. We search for pairs of integers (c_1, c_2) with $1 \le c_1, c_2 \le$ `climit` (where `climit` is a given limit which is much less than H) such that

$$[(H + c_1)(H + c_2)] \bmod p = J + (c_1 + c_2)H + c_1 c_2$$

is *smooth* with respect to Q (i.e., all of its prime factors are in Q). If we include these $H + c_i$ in the factor base, then this gives a linear relation modulo $(p-1)$ among the logarithms of the elements of the extended factor base.

Fix c_1 with $1 \leq c \leq$ `climit` and suppose we initialize a sieve array (to be indexed by c_2) to have zero in each position. For each prime power q^h with $q \in Q$ and h sufficiently small, we compute

$$d = [(J + c_1 H)(H + c_1)^{-1}] \bmod q^h.$$

Then for all $c_2 \equiv d \pmod{q^h}$, it turns out that

$$(H + c_1)(H + c_2) \equiv 0 \pmod{q^h}.$$

So for each c_2 with $c_1 \leq c_2 \leq$ `climit` and $c_2 \equiv d \pmod{q^h}$, we add $\log(q)$ to the position of the sieve corresponding to c_2. (Ensuring that $c_2 \geq c_1$ avoids redundant relations.) When we have done this for each $q \in Q$, we perform trial division to obtain relations for each of the c_2 whose sieve values are beneath a suitable threshold.

We repeat this with a new c_1 value until we have more relations than elements of the factor base (typically we make the ratio be 1.1 or 1.2), then we solve the corresponding linear system modulo $M = p - 1$ to obtain the desired logarithms. We ensure that α is the first element of Q so that when the vector is normalized modulo M (so that its first entry is 1), the logarithms will be with respect to α. For derivations of the above equations and for further details concerning the sieving, see [LO91a].

In practice, one first writes $M = p - 1 = M_1 \cdot M_2$ where M_1 contains the maximal powers of all the small primes dividing M (say, for primes ≤ 10000). The solution space modulo M_1 will often have high dimension, so the logarithms modulo M_1 usually cannot be correctly computed from the linear system alone. So we only compute the solution of the linear system modulo M_2. It is still possible that some logarithms cannot be determined modulo M_2 (e.g., if 2 unknowns occur only in one equation), but usually most of the logarithms will be correctly computed modulo M_2. Then the logarithm of each factor basis element can be easily computed modulo M_1 by the Pohlig-Hellman algorithm, and the Chinese Remainder Theorem can be used to combine these with the correct modulo-M_2 logarithms to compute the logarithms modulo M of most elements of the factor basis.

Similar index-calculus-type algorithms should have techniques for handling small prime divisors of the modulus M when the solution of the linear system has high nullity modulo these small primes.

The following function `Sieve` has been developed by Allan Steel, based on code by Benjamin Costello. Its arguments are the field $K = \mathbf{F}_p$, the factor base prime limit `qlimit`, the c_1, c_2 range limit `climit`, and the desired stopping ratio of relations to unknowns. The function returns the sparse relation matrix A together with an indexed set containing the corresponding extended factor base (the small primes and the $H + c_i$ values which yield relations).

```
> function Sieve(K, qlimit, climit, ratio)
>     p := #K;
>     Z := Integers();
>     H := Iroot(p, 2) + 1;
>     J := H^2 - p;
>
>     // Get factor basis of all primes <= qlimit.
>     fb_primes := [p: p in [2 .. qlimit] | IsPrime(p)];
```

```
>
>     printf "Factor base has %o primes, climit is %o\n", #fb_primes, climit;
>
>     // Ensure that the primitive element of K is prime (as an integer).
>     a := rep{x: x in [2..qlimit] | IsPrime(x) and IsPrimitive(K!x)};
>     SetPrimitiveElement(K,K!a);
>
>     // Initialize extended factor base FB to fb_primes (starting with a).
>     FB := {@ Z!a @};
>     for x in fb_primes do
>         Include(~FB, x);
>     end for;
>
>     // Initialize A to 0 by 0 sparse matrix over Z.
>     A := SparseMatrix();
>
>     // Get logs of all factor basis primes.
>     log2 := Log(2.0);
>     logqs := [Log(q)/log2: q in fb_primes];
>
>     for c1 in [1 .. climit] do
>
>         // Stop if ratio of relations to unknowns is high enough.
>         if Nrows(A)/#FB ge ratio then break; end if;
>
>         if c1 mod 50 eq 0 then
>             printf "c1: %o, #rows: %o, #cols: %o, ratio: %o\n",
>                 c1, Nrows(A), #FB, RealField(8)!Nrows(A)/#FB;
>         end if;
>
>         // Initialize sieve.
>         sieve := [z: i in [1 .. climit]] where z := Log(1.0);
>         den := H + c1;                  // denominator of relation
>         num := -(J + c1*H);             // numerator
>
>         for i := 1 to #fb_primes do
>             // For each prime q in factor base...
>             q := fb_primes[i];
>             logq := logqs[i];
>
>             qpow := q;

>                 // For all powers qpow of q up to qlimit...
>
>                 if den mod qpow eq 0 then break; end if;
>                 c2 := num * Modinv(den, qpow) mod qpow;
>                 if c2 eq 0 then c2 := qpow; end if;
>
```

```
>                 nextqpow := qpow*q;
>                 // Ensure c2 >= c1 to remove redundant relations.
>                 while c2 lt c1 do
>                     c2 +:= qpow;
>                 end while;
>
>                 while c2 le #sieve do
>                     // Add logq into sieve for c2.
>                     sieve[c2] +:= logq;
>
>                     // Test higher powers of q if nextqpow is too large.
>                     if nextqpow gt qlimit then
>                         prod := (J + (c1 + c2)*H + c1*c2) mod p;
>                         nextp := nextqpow;
>                         while prod mod nextp eq 0 do
>                             sieve[c2] +:= logq;
>                             nextp *:= q;
>                         end while;
>                     end if;
>                     c2 +:= qpow;
>                 end while;
>                 qpow := nextqpow;
>             end while;
>         end for;
>
>         // Check sieve for full factorizations.
>         rel := den * (H + 1);   // the relation
>         relinc := H + c1;       // add to relation to get next relation
>         count := 0;
>         for c2 in [1 .. #sieve] do
>             n := rel mod p;
>             if Abs(sieve[c2] - Ilog2(n)) lt 1 then
>                 fact, r := TrialDivision(n, qlimit);
>                 if r eq [] and (#fact eq 0 or fact[#fact][1] lt qlimit) then
>                     // Include each H + c_i in extended factor basis.
>                     Include(~FB, H + c1);
>                     Include(~FB, H + c2);
>
>                     // Include relation (H + c1)*(H + c2) = fact.
>                     row := Nrows(A) + 1;
>                     for t in fact do
>                         SetEntry(~A, row, Index(FB, t[1]), t[2]);
>                     end for;
>                     if c1 eq c2 then
>                         SetEntry(~A, row, Index(FB, H + c1), -2);
>                     else
>                         SetEntry(~A, row, Index(FB, H + c1), -1);
>                         SetEntry(~A, row, Index(FB, H + c2), -1);
```

```
>                     end if;
>                 end if;
>             end if;
>             rel +:= relinc;
>         end for;
>     end for;
>
>     // Check matrix by multiplying out relations in field.
>     assert {&*[(K!FB[j])^A[k, j]: j in Support(A, k)]: k in [1..Nrows(A)]}
>             eq {1};
>
>     return A, FB;
> end function;
```

We first apply the function to a trivial example to illustrate the main points. We let K be $\mathbf{F}_{103}$, and we make the factor basis include primes up to 35, the c_i range be up to 27, and the stopping ratio be 1.1. We first compute the relation matrix A and the extended factor basis F.

```
> K := GF(103);
> A, F := Sieve(K, 35, 27, 1.1);
Factor base has 11 primes, climit is 27
> A;
Sparse matrix with 33 rows and 30 columns over Integer Ring
```

We examine a few rows of A and the extended factor basis F. Note that 5 is the smallest prime which is primitive in K, so it has been inserted first in F.

```
> A[1]; A[2]; A[30];
(1 0 0 0 0 1 0 0 0 0 0 -1 -1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
(0 0 0 1 1 0 0 0 0 0 0 -1 0 -1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
(0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 -1 0 0 -1 0 0 0 0 0)
> F;
{@ 5, 2, 3, 7, 11, 13, 17, 19, 23, 29, 31, 12, 14, 15, 16, 21, 38,
20, 26, 35, 22, 33, 34, 24, 25, 28, 30, 37, 32, 36 @}
```

Next we compute a solution vector v such that $v \cdot A^{tr} = 0$ modulo $M = \#K - 1$.

```
> Factorization(#K-1);
[ <2, 1>, <3, 1>, <17, 1> ]
> v := ModularSolution(A, #K - 1);
> v;
(1 44 39 4 61 72 70 80 24 86 57 25 48 40 74 43 22 0 1 5 3 100 12 69 2
    92 84 93 16 64)
```

Notice that 0 occurs in v, so the corresponding logarithm is not known. The vector is normalized so that the logarithm of 5 is 1, as desired. We finally compute the powers of the primitive element of K by each element of v and check that all of these match the entries of F except for the one missed entry. Note also that because M has small prime divisors, it is fortunate that the logarithms are all correct, apart from the missed one.

```
> a := PrimitiveElement(K);
```

```
> a;
5
> Z := IntegerRing();
> [a^Z!x: x in Eltseq(v)];
[ 5, 2, 3, 7, 11, 13, 17, 19, 23, 29, 31, 12, 14, 15, 16, 21, 38, 1,
5, 35, 22, 33, 34, 24, 25, 28, 30, 37, 32, 36 ]
> F;
{@ 5, 2, 3, 7, 11, 13, 17, 19, 23, 29, 31, 12, 14, 15, 16, 21, 38, 20,
26, 35, 22, 33, 34, 24, 25, 28, 30, 37, 32, 36 @}
```

Finally, we take $K = \mathbf{F}_p$, where p is the smallest prime above 10^{20} such that $(p-1)/2$ is prime. The sparse matrix constructed here is close to 1000×1000, but the solution vector is still found in less than a second.

```
> K := GF(100000000000000000763);
> Factorization(#K - 1);
[ <2, 1>, <50000000000000000381, 1> ]
> time A, F := Sieve(K, 2200, 800, 1.1);

Time: 3.990
> A;
Sparse matrix with 1141 rows and 1036 columns over Integer Ring
> time v := ModularSolution(A, #K - 1);
Time: 0.170
```

We observe that the list consisting of the primitive element powered by the computed logarithms agrees with the factor basis for at least the first 30 elements.

```
> a := PrimitiveElement(K);
> a;
2
> v[1], v[2];
1 71610399209536789314
> a^71610399209536789314;
3
> P := [a^x: x in Eltseq(v)];
> [P[i]: i in [1 .. 30]];
[ 2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43, 47, 53, 59, 61,
67, 71, 73, 79, 83, 89, 97, 101, 103, 107, 109, 113 ]
> [F[i]: i in [1 .. 30]];
[ 2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43, 47, 53, 59, 61,
```

```
67, 71, 73, 79, 83, 89, 97, 101, 103, 107, 109, 113 ]
```

There are in fact 8 logarithms which could not be computed correctly.

```
> [i: i in [1..#F] | P[i] ne F[i]];
[ 671, 672, 673, 737, 738, 947, 1024, 1025 ]
```

A zero value appearing in the place of a logarithm indicates that the nullity of the system was larger than 1, even considered modulo $(\#K - 1)/2$.

```
> [v[i]: i in [1..#F] | P[i] ne F[i]];
[ 0, 22076788376647522787, 73252391663364176895, 0,
33553634905886614528, 42960107136526083388, 0, 57276316725691590267 ]
> [P[i]: i in [1..#F] | P[i] ne F[i]];
[ 1, 7480000052677, 7960000056517, 1, 5220000041437,

```

However, we have found the correct logarithms for nearly all factor basis elements. As pointed out above, the Pollard-Rho method applied to an element of the factor basis for this field would take many hours!

28 VECTOR SPACES

Chapter 28
VECTOR SPACES

28.1 Introduction

In this chapter we will discuss vector spaces and their linear transformations. Let K be a field. In Magma, the standard K-vector space is taken to be the set of n-tuples over the field K, which we shall write as $K^{(n)}$.

A rectangular matrix over a field K is considered to be an element of the vector space consisting of all $m \times n$ matrices over K. This vector space will be written as $K^{(m\times n)}$. Let U and V be K-vector spaces of dimensions m and n, respectively. The set of all linear transformations with domain U and codomain V will be denoted by $\mathrm{Hom}_K(U, V)$. Once bases have been chosen for U and V, we may identify $\mathrm{Hom}_K(U, V)$ with $K^{(m\times n)}$. Thus, $K^{(m\times n)}$ is first of all a vector space and all the normal vector space operations apply. However, since it is also a set of mappings, some additional operations arising from this characterization apply.

We shall use the term *vector space* or *K-vector space* (if we wish to emphasize the coefficient field) to refer to both the space $K^{(n)}$ and the space $K^{(m\times n)}$. If we wish to differentiate between the two, we shall use the term *tuple space* when referring to $K^{(n)}$ and the term *matrix space* referring to $K^{(m\times n)}$.

28.1.1 Vector Space Categories

The family of all finite dimensional vector spaces over a given field K forms a category, while the set of all finite dimensional vector spaces forms a family of categories indexed by the field K. In this family of categories, objects are vector spaces and the morphisms are linear transformations. The (indexed family of) categories consisting of vector spaces of n-tuples has the name `ModTupFld`, while the (indexed family of) categories consisting of vector spaces of $m \times n$-matrices has the name `ModMatFld`.

28.1.2 The Construction of a Vector Space

Every vector space V defined over a field K is created either as a subspace of the row space $K^{(n)}$ (tuple spaces) or as a subspace of $K^{(m\times n)}$ (matrix modules). Thus, the construction of a general vector space is a two step process:

(i) The appropriate row space $K^{(n)}$, is constructed;

(ii) The required vector space V is then defined as a subspace or quotient space of $K^{(n)}$.

28.2 Creation of Vector Spaces and Arithmetic with Vectors

28.2.1 Construction of a Vector Space

`VectorSpace(K, n)`

`KSpace(K, n)`

Given a field K and a non-negative integer n, create the n-dimensional vector space $V = K^{(n)}$, consisting of all n-tuples over K. The vector space is created with respect to the standard basis, $e_1, \ldots, e_n$, where e_i $(i = 1, \ldots, n)$ is the vector containing a 1 in the i-th position and zeros elsewhere.

Use of the functions `VectorSpace` and `KSpace` ensures that subspaces of V will be presented in embedded form.

`KModule(K, n)`

Given a field K and a non-negative integer n, create the n-dimensional vector space $V = K^{(n)}$, consisting of all n-tuples over K. The vector space is created with respect to the standard basis, $e_1, \ldots, e_n$, where e_i $(i = 1, \ldots, n)$ is the vector containing a 1 in the i-th position and zeros elsewhere.

Use of the function `KModule` ensures that subspaces of V will be presented in reduced form. In all other respects, a vector space created by this function is identical to one created by `KSpace`.

`KMatrixSpace(K, m, n)`

Given a field K and integers m and n greater than one, create the vector space $K^{(m \times n)}$, consisting of all $m \times n$ matrices over K. The vector space is created with the standard basis, $\{E_{ij} \mid i = 1 \ldots, m, j = 1 \ldots, n\}$, where E_{ij} is the matrix having a 1 in the (i, j)-th position and zeros elsewhere.

Note that for a matrix space, subspaces will always be presented in embedded form, i.e. there is no reduced mode available for matrix spaces.

`Hom(V, W)`

If V is the vector space $K^{(m)}$ and W is the vector space $K^{(n)}$, create the matrix space $\mathrm{Hom}_K(V, W)$ as the vector space $K^{(m \times n)}$, represented as the set of all $m \times n$ matrices over K. The vector space is created with the standard basis, $\{E_{ij} \mid i = 1 \ldots, m, j = 1 \ldots, n\}$, where E_{ij} is the matrix having a 1 in the (i, j)-th position and zeros elsewhere.

Example H28E1

We construct the vector space V consisting of 6-tuples over the rational field.

```
> Q := RationalField();
> V := VectorSpace(Q, 6);
> V;
Vector space of dimension 6 over Rational Field
```

Example H28E2

We construct the matrix space M consisting of 3×5 matrices over the field $\mathbf{Q}(\sqrt{5})$.

```
> K<w> := QuadraticField(5);
> V := KMatrixSpace(K, 3, 5);
> V;
Full Vector Space of 3 by 5 matrices over Quadratic Field Q(w)
```

28.2.2 Construction of a Vector Space with Inner Product Matrix

`VectorSpace(K, n, F)`

`KSpace(K, n, F)`

Given a field K, a non-negative integer n and a square $n \times n$ symmetric matrix F, create the n-dimensional vector space $V = K^{(n)}$ (in embedded form), with inner product matrix F. This is the same as `VectorSpace(K, n)`, except that the functions `Norm` and `InnerProduct` (see below) will be with respect to the inner product matrix F.

28.2.3 Construction of a Vector

`elt< V | L >`

(1) Suppose V is a subspace of the vector space $K^{(n)}$. Given elements $a_1, \ldots, a_n$ belonging to K, construct the vector $v = (a_1, \ldots, a_n)$ as a vector of V. Note that if v is not an element of V, an error will result.

(2) Suppose V is a subspace of the matrix space $K^{(m \times n)}$. Given elements $a_1, \ldots, a_{mn}$ belonging to K, construct the matrix $m = (a_1, \ldots, a_{mn})$ as an element of V. Note that if m is not an element of V, an error will result.

`V ! Q`

(1) Suppose V is a subspace of the vector space $K^{(n)}$. Given elements $a_1, \ldots, a_n$ belonging to K, construct the vector $v = (a_1, \ldots, a_n)$ as a vector of V. Note that if v is not an element of V, an error will result.

(2) Suppose V is a subspace of the matrix space $K^{(m \times n)}$. Given elements $a_1, \ldots, a_{mn}$ belonging to K, construct the matrix $m = (a_1, \ldots, a_{mn})$ as an element of V. Note that if m is not an element of V, an error will result.

`CharacteristicVector(V, S)`

Given a subspace V of the vector space $K^{(n)}$ together with a set S of integers lying in the interval $[1, n]$, return the characteristic number of S as a vector of V.

`V ! 0`

`Zero(V)`

The zero element for the vector space V.

`Random(V)`

Given a vector space V defined over a finite field, return a random vector.

Example H28E3

We create the 5-dimensional vector space V over $\mathbf{F}_4$ and define the vector $u = (1, w, 1 + w, 0, 0)$, where w is a primitive element of $\mathbf{F}_4$.

```
> K<w> := GaloisField(4);
> V    := VectorSpace(K, 5);
> u    := V ! [1, w, 1+w, 0, 0];
> u;
(1 w w + 1 0 0)
> zero := V ! 0;
> zero;
(0 0 0 0 0)
r := Random(V);
(1 0 w 1 w + 1)
```

Example H28E4

We create an element belonging to the space of 3×4 matrices over the number field $\mathbf{Q}(w)$, where w is a root of $x^7 - 7x + 3$.

```
> R<x> := PolynomialRing(RationalField());
> L<w> := NumberField(x^7 - 7*x + 3);
> L34 := KMatrixSpace(L, 3, 4);
> a := L34 ! [ 1, w, 0, -w, 0, 1+w, 2, -w^3, w-w^3, 2*w, 1/3, 1 ];
> a;
[1    w    0    -1 * w]
```

```
[0    w + 1    2    -1 * w^3]
[-1 * w^3 + w    2 * w    1/3    1]
```

28.2.4 Deconstruction of a Vector

`ElementToSequence(u)`

`Eltseq(u)`

Given an element u belonging to the K-vector space V, return u in the form of a sequence Q of elements of V. Thus, if u is an element of $K^{(n)}$, then $Q[i] = u[i]$, $1 \leq i \leq n$.

28.2.5 Arithmetic with Vectors

For the following operations the vectors u and v must belong to the same vector space i.e. the same tuple space $K^{(n)}$ or the same matrix space $K^{(m \times n)}$. The scalar a must belong to the field K.

`u + v`

Sum of the vectors u and v, where u and v lie in the same vector space.

`-u`

Additive inverse of the vector u.

`u - v`

Difference of the vectors u and v, where u and v lie in the same vector space.

`x * u`

`u * x`

The scalar product of the vector u belonging to the K-vector space and the field element x belonging to K.

`u / x`

The scalar product of the vector u belonging to the K-vector space and the field element $1/x$ belonging to K where x is non-zero.

`NumberOfColumns(u)`

`Ncols(u)`

The number of columns in the vector u.

`Depth(u)`

The index of the first non-zero entry of the vector u (0 if none such).

`(u, v)`

`InnerProduct(u, v)`

Return the inner product of the vectors u and v with respect to the inner product defined on the space. If an inner product matrix F is given when the space is created, then this is defined to be $u \cdot F \cdot v^{tr}$. Otherwise, this is simply $u \cdot v^{tr}$.

`IsZero(u)`

Returns `true` iff the vector u belonging to a vector space is the zero element.

`Norm(u)`

Return the norm product of the vector u with respect to the inner product defined on the space. If an inner product matrix F is given when the space is created, then this is defined to be $u \cdot F \cdot u^{tr}$. Otherwise, this is simply $u \cdot u^{tr}$.

`Normalise(u)`

`Normalize(u)`

Given an element u, not the zero element, belonging to the K-vector space V, return $\frac{1}{a} * u$, where a is the first non-zero component of u. If u is the zero vector, it is returned. The net effect is that `Normalize(u)` always returns a vector v in the subspace generated by u, such that the first non-zero component of v (if existent) is $K!1$.

`Rotate(u, k)`

Given a vector u, return the vector obtained from u by rotating by k coordinate positions.

`Rotate(~u, k)`

Given a vector u, destructively rotate u by k coordinate positions.

`NumberOfRows(u)`

`Nrows(u)`

The number of rows in the vector u (1 of course; included for completeness).

`Support(u)`

A set of integers giving the positions of the non-zero components of the vector u.

`TensorProduct(u, v)`

The tensor (Kronecker) product of the vectors u and v. The resulting vector has degree equal to the product of the degrees of u and v.

`Trace(u, F)`

`Trace(u)`

Given a vector belonging to the space $K^{(n)}$, and a subfield F of K, return the vector obtained by replacing each component of u by its trace over the subfield F. If F is the prime field of K, it may be omitted.

`Weight(u)`

The number of non-zero components of the vector u.

Example H28E5

We illustrate the use of the arithmetic operators for module elements by applying them to elements of the 4-dimensional vector space over the field $\mathbf{Q}(w)$, where w is an 8-th root of unity.

```
> K<w> := CyclotomicField(8);
> V := VectorSpace(K, 4);
> x := V ! [ w, w^ 2, w^ 4, 0];
> y := V ! [1, w, w^ 2, w^ 4];
> x + y;
((1 + w) (w + w^2) (-1 + w^2) -1)
> -x;
((-w) (-w^2)         1         0)
> x - y;
((-1 + w) (-w + w^2) (-1 - w^2) 1)
> w * x;
(  (w^2) (w^3)  (-w)          0)
> y * w^ -4;
(       -1 (-w) (-w^2)         1)
> Normalize(x);
(         1   (w) (w^3)          0)
> InnerProduct(x, y);
(w - w^2 + w^3)
> z := V ! [1, 0, w, 0 ];
> z;
(       1        0 (w)        0)
> Support(z);
{ 1, 3 }
```

Example H28E6

We illustrate how one can define a non-trivial inner product on a space.

```
> Q := RationalField();
> F := SymmetricMatrix(Q, [1, 0,2, 0,0,3, 1,2,3,4]);
> F;
[1 0 0 1]
[0 2 0 2]
```

```
[0 0 3 3]
[1 2 3 4]
> V := VectorSpace(Q, 4, F);
> V;
Full Vector space of degree 4 over Rational Field
Inner Product Matrix:
[1 0 0 1]
[0 2 0 2]
[0 0 3 3]
[1 2 3 4]
> v := V![1,0,0,0];
> Norm(v);
1
> w := V![0,1,0,0];
> Norm(w);
2
> InnerProduct(v, w);
0
> z := V![0,0,0,1];
> Norm(z);
4
> InnerProduct(v, z);
1
> InnerProduct(w, z);
2
```

28.2.6 Indexing Vectors and Matrices

The indexing operations have a different meaning depending upon whether they are applied to a tuple space or a matrix space.

`u[i]`

`u[i, j]`

Given an vector u belonging to a K-vector space V, the result of this operation depends upon whether V is a tuple or matrix space.

If V is a subspace of $K^{(n)}$, and i, $1 \leq i \leq n$, is a positive integer, the i-th component of the vector u is returned (as an element of the field K).

If V is a subspace of $K^{(m \times n)}$, and i, $1 \leq i \leq m$, is a positive integer, $u[i]$ will return the i-th row of the matrix u (as an element of the vector space $K^{(n)}$). Similarly, if i and j, $1 \leq i \leq m$, $1 \leq j \leq n$, are positive integers, $u[i, j]$ will return the (i, j)-th component of the matrix u (as an element of K).

`u[i] := x`

`u[i] := x`

`u[i, j] := x`

Given an vector u belonging to a K-vector space V, and an element x of K, the result of this operation depends upon whether V is a tuple or matrix space.

If V is a subspace of $K^{(n)}$, and i, $1 \leq i \leq n$, is a positive integer, the i-th component of the vector u is redefined to be x.

If V is a subspace of $K^{(m \times n)}$ and $1 \leq i \leq m$ is a positive integer and x is an element of $K^{(n)}$, `u[i] := x` will redefine the i-th row of the matrix u to be the vector x, where x must be an element of $K^{(n)}$. Similarly, if $1 \leq i \leq m$, $1 \leq j \leq n$, are positive integers, `u[i, j] := x` will redefine the (i, j)-th component of the matrix u to be x, where x must be an element of K.

Example H28E7

We illustrate the use of the indexing operators for vector space elements by applying them to a 3-dimensional tuple space and a 2×3 matrix space over the field $\mathbf{Q}(w)$, where w is an 8-th root of unity.

```
> K<w> := CyclotomicField(8);
> V := VectorSpace(K, 3);
> u := V ! [ 1 + w, w^ 2, w^ 4];
> u;
((1 + w)     (w^2)          -1)
> u[3];
-1
> u[3] := 1 + w - w^7;
> u;
((1 + w) (w^2) (1 + w + w^3))
> // We now demonstrate indexing a matrix space
> W := KMatrixSpace(K, 2, 3);
> l := W ! [ 1 - w, 1 + w, 1 + w + w^2, 0, 1 - w^7, 1 - w^3 + w^6 ];
> l;
[(1 - w) (1 + w) (1 + w + w^2)]
[0 (1 + w^3) (1 - w^2 - w^3)]
> l[2];
(0 (1 + w^3) (1 - w^2 - w^3))
> l[2,2];
(1 + w^3)
> m := l[2];
> m;
(0 (1 + w^3) (1 - w^2 - w^3))
> l[2] := u;
> l;
[(1 - w) (1 + w) (1 + w + w^2)]
[(1 + w) (w^2) -1]
> l[2, 3] := 1 + w - w^7;
```

```
> l;
[(1 - w) (1 + w) (1 + w + w^2)]
[(1 + w) (w^2) (1 + w + w^3)]
```

28.3 Subspaces, Quotient Spaces and Homomorphisms

28.3.1 Construction of Subspaces

The conventions defining the presentations of subspaces and quotient spaces are as follows:

If V has been created using the function `VectorSpace` or `MatrixSpace`, then every subspace and quotient space of V is given in terms of a basis consisting of elements of V, i.e. by means of an embedded basis.

If V has been created using the function `RModule`, then every subspace and quotient space of V is given in terms of a reduced basis.

`sub< V | L >`

Given a K-vector space V, construct the subspace U generated by the elements of V specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of K defining an element of V;

(b) A set or sequence whose terms are elements of V;

(c) A subspace of V;

(d) A set or sequence whose terms are subspaces of V.

The generators stored for U consist of the vectors specified by terms L_i together with the stored generators for subspaces specified by terms of L_i. Repetitions of a vector and occurrences of the zero vector are removed (unless U is the trivial subspace).

The constructor returns the subspace U and the inclusion homomorphism $f : U \to V$. If V is of embedded type, the basis constructed for U consists of elements of V. If V is of standard type, a standard basis is constructed for U.

`Morphism(U, V)`

Assuming the vector space U has been created as a subspace of V, the function returns the matrix defining the embedding of U into V.

Example H28E8

The ternary Golay code is a six-dimensional subspace of the vector space $K^{(11)}$, where K is $\mathbf{F}_3$. This subspace is first constructed in the space constructed by the `VectorSpace` function.

```
> K11 := VectorSpace(FiniteField(3), 11);
> G3 := sub< K11  |
>     [1,0,0,0,0,0,1,1,1,1,1], [0,1,0,0,0,0,0,1,2,2,1],
>     [0,0,1,0,0,0,1,0,1,2,2], [0,0,0,1,0,0,2,1,0,1,2],
>     [0,0,0,0,1,0,2,2,1,0,1], [0,0,0,0,0,1,1,2,2,1,0] >;
> G3;
Vector space of degree 11, dimension 6 over GF(3)
Generators:
(1 0 0 0 0 0 1 1 1 1 1)
(0 1 0 0 0 0 0 1 2 2 1)
(0 0 1 0 0 0 1 0 1 2 2)
(0 0 0 1 0 0 2 1 0 1 2)
(0 0 0 0 1 0 2 2 1 0 1)
(0 0 0 0 0 1 1 2 2 1 0)
Echelonized basis:
(1 0 0 0 0 0 1 1 1 1 1)
(0 1 0 0 0 0 0 1 2 2 1)
(0 0 1 0 0 0 1 0 1 2 2)
(0 0 0 1 0 0 2 1 0 1 2)
(0 0 0 0 1 0 2 2 1 0 1)
(0 0 0 0 0 1 1 2 2 1 0)
```

Example H28E9

We now construct the ternary Golay code starting with the vector space constructed using the `RModule` function. In this case the subspace is presented on a reduced basis.

```
> K11 := RModule(FiniteField(3), 11);
> G3 := sub< K11 |
>     [1,0,0,0,0,0,1,1,1,1,1], [0,1,0,0,0,0,0,1,2,2,1],
>     [0,0,1,0,0,0,1,0,1,2,2], [0,0,0,1,0,0,2,1,0,1,2],
>     [0,0,0,0,1,0,2,2,1,0,1], [0,0,0,0,0,1,1,2,2,1,0] >;
> G3;
KModule G3 of dimension 6 with base ring GF(3)
> Basis(G3);
[
    G3: (1 0 0 0 0 0),
    G3: (0 1 0 0 0 0),
    G3: (0 0 1 0 0 0),
    G3: (0 0 0 1 0 0),
    G3: (0 0 0 0 1 0),
    G3: (0 0 0 0 0 1)
]
> f := Morphism(G3, K11);
```

```
> f;
[1 0 0 0 0 0 1 1 1 1 1]
[0 1 0 0 0 0 0 1 2 2 1]
[0 0 1 0 0 0 1 0 1 2 2]
[0 0 0 1 0 0 2 1 0 1 2]
[0 0 0 0 1 0 2 2 1 0 1]
[0 0 0 0 0 1 1 2 2 1 0]
```

28.3.2 Construction of Quotient Vector Spaces

`quo< V | L >`

Given a K-vector space V, construct the quotient vector space $W = V/U$, where U is the subspace generated by the elements of V specified by the list L. Each term L_i of the list L must be an expression defining an object of one of the following types:

(a) A sequence of n elements of K defining an element of V;

(b) A set or sequence whose terms are elements of V;

(c) A subspace of V;

(d) A set or sequence whose terms are subspaces of V.

The generators constructed for U consist of the elements specified by terms L_i together with the stored generators for subspaces specified by terms of L_i.

The constructor returns the quotient space W and the natural homomorphism $f : V \to W$.

`V / U`

Given a subspace U of the vector space V, construct the quotient space W of V by U. If r is defined to be $\dim(V) - \dim(U)$, then W is created as an r-dimensional vector space relative to the standard basis.

The constructor returns the quotient space W and the natural homomorphism $f : V \to W$.

Example H28E10

We construct the quotient of $K^{(11)}$ by the Golay code.

```
> K11 := VectorSpace(FiniteField(3), 11);
> Q3, f := quo< K11 |
>  [1,0,0,0,0,0,1,1,1,1,1], [0,1,0,0,0,0,0,1,2,2,1],
>  [0,0,1,0,0,0,1,0,1,2,2], [0,0,0,1,0,0,2,1,0,1,2],
>  [0,0,0,0,1,0,2,2,1,0,1], [0,0,0,0,0,1,1,2,2,1,0] >;
> Q3;
Full Vector space of degree 5 over GF(3)
> f;
Mapping from: ModTupFld: K11 to ModTupFld: Q3
```

Example H28E11

If we wished to construct this quotient of $K^{(11)}$ as a subspace of the original space, we could do so using the `Complement` function.

```
> K11 := VectorSpace(FiniteField(3), 11);
> S := sub< K11 |
>     [1,0,0,0,0,0,1,1,1,1,1], [0,1,0,0,0,0,0,1,2,2,1],
>     [0,0,1,0,0,0,1,0,1,2,2], [0,0,0,1,0,0,2,1,0,1,2],

```

Example H28E12

We construct a subspace and its quotient space in $\mathbf{Q}^{(3\times 4)}$.

```
> Q := RationalField();
> Q3 := VectorSpace(Q, 3);
> Q4 := VectorSpace(Q, 4);
> H34 := Hom(Q3, Q4);
> a := H34 ! [ 2, 0, 1, -1/2,  1, 0, 3/2, 4,  4/5, 6/7, 0, -1/3];
> b := H34 ! [ 1/2, -3, 0, 5,  1/3, 2, 4/5, 0,  5, -1, 5, 7];
> c := H34 ! [ -1, 4/9, 1, -4,  5, -5/6, -3/2, 0,  4/3, 7, 0, 7/9];
> d := H34 ! [ -3, 5, 1/3, -1/2,  2/3, 4, -2, 0,  0, 4, -1, 0];
> a, b, c, d;
[   2    0    1 -1/2]
[   1    0  3/2    4]
[ 4/5  6/7    0 -1/3]

[1/2  -3   0   5]
[1/3   2 4/5   0]
[  5  -1   5   7]

[  -1  4/9    1   -4]
[   5 -5/6 -3/2    0]
[ 4/3    7    0  7/9]

[  -3    5  1/3 -1/2]
[ 2/3    4   -2    0]
[   0    4   -1    0]
> U := sub< H34 | a, b, c, d >;
> U:Maximal;
```

```

28.4 Changing the Coefficient Field

The standard constructions described in section 31.5 for R-modules may be applied to vector spaces. In addition, we may extend or restrict the field of scalars, using the functions described here.

`ExtendField(V, L)`

Given a K-vector space V, with K a field and L an extension of K, construct the L-vector space $U = V \otimes_K L$. The function returns

(a) the vector space U; and

(b) the inclusion homomorphism $\phi : V \to U$.

`RestrictField(V, L)`

Given a K-vector space V, with K a field and L a subfield of K, construct the L-vector space U consisting of those vectors of V having all of their components lying in the subfield L. The function returns

(a) the vector space U; and

(b) the restriction homomorphism $\phi : V \to U$.

`VectorSpace(V, F)`

`KSpace(V, F)`

`KMatrixSpace(V, F)`

`KModule(V, F)`

Given an n-dimensional K-vector space V, and a subfield F of a finite field or cyclotomic field K such that K has degree m over F, construct a vector space U of dimension mn over the field F. The function returns

(a) the vector space U; and

(b) a mapping $\phi : V \to U$ such that a vector $(v_1, \ldots, v_i, \ldots, v_n)$ of V is mapped into the vector

$$(u_{11}, \ldots, u_{1n}, \ldots, u_{i1}, \ldots, u_{in}, \ldots, u_{n1}, \ldots u_{nn}),$$

where $(u_{i1}, \ldots, u_{in})$ is the field element v_i written as a vector over the subfield F.

28.5 Basic Operations

28.5.1 Accessing Vector Space Invariants

`V . i`

Given an vector space V and a positive integer i, return the i-th generating element of V.

`CoefficientField(V)`

`BaseField(V)`

Given a K-vector space V, return the field K.

`Degree(V)`

Given a K-vector space V which is a subspace of $K^{(n)}$, return n.

`Degree(u)`

Given an vector u belonging to a subspace of the vector space $K^{(n)}$, return n.

`Dimension(V)`

The dimension of the vector space V.

`Generators(V)`

The generators for the vector space V, returned as a set.

`NumberOfGenerators(M)`
`Ngens(M)`

The number of generators for the vector space V.

`OverDimension(V)`

Given a K-vector space V which is a subspace of $K^{(n)}$, return n.

`OverDimension(u)`

Given an vector u belonging to a subspace of the vector space $K^{(n)}$, return n.

`Generic(V)`

The generic vector space containing V, i.e. the full vector space in which V is naturally embedded.

`Parent(V)`

The power structure for the vector space V (the set consisting of all finite dimensional vector spaces).

28.5.2 Membership and Equality

`v in V`

Returns `true` if the element v lies in the vector space V, where v and V belong to a common space.

`v notin V`

Returns `true` if the element v does not lie in the vector space V, where v and V belong to a common space.

`U subset V`

Returns `true` if the K-vector space U is contained in the K-vector space V, where U and V are subspaces of some common vector space.

`U notsubset V`

Returns `true` if the K-vector space U is not contained in the K-vector space V, where U and V are subspaces of some common vector space.

`U eq V`

Returns `true` if the subspaces U and V are equal, where U and V belong to a common vector space.

`U ne V`

Returns `true` if the subspaces U and V are not equal, where U and V belong to a common vector space.

28.5.3 Operations on Subspaces

`U + V`

Sum of the subspaces U and V, where U and V must be subspaces of a common vector space.

`U meet V`

Intersection of the subspaces U and V, where U and V must be subspaces of a common vector space.

`U meet:= V`

Replace U with the intersection of the subspaces U and V, where U and V must be subspaces of a common vector space.

`&meet S`

Intersection of the subspaces of the set or sequence S, which must be subspaces of a common vector space.

`TensorProduct(U, V)`

The tensor (Kronecker) product of the vector spaces U and V, generated by all the tensor products of elements of U by elements of V. The resulting vector space has degree equal to the product of the degrees of U and V.

`Complement(V, U)`

Given a subspace U of the vector space V, construct a complement for U in V (a subspace of V).

`Transversal(V, U)`

Given a subspace U of the vector space V over a finite field, return a transversal for U in V as a set of vectors.

28.6 Reducing Vectors Relative to a Subspace

`ReduceVector(W, v)`

(Function.) Given a vector v from a tuple module V and a submodule W of V, return the reduction of v with respect to W (that is, the canonical representative of the coset $v + W$).

`ReduceVector(W, ~v)`

(Procedure.) Given a vector v from a tuple module V and a submodule W of V, replace v with its reduction of with respect to W (that is, the canonical representative of the coset $v + W$).

`DecomposeVector(U, v)`

Given a vector v from a tuple module V and a submodule U of V, return the unique u in U and w in the complement to U in $U+ < v >$ such that $v = u + w$.

28.7 Bases

This section is concerned with the construction of bases for vector spaces.

`VectorSpaceWithBasis(Q)`
`VectorSpaceWithBasis(a)`
`KSpaceWithBasis(Q)`
`KSpaceWithBasis(a)`
`KModuleWithBasis(Q)`

Create a vector space having as basis the terms of B (rows of a).

`Basis(V)`

The current basis for the vector space V, returned as a sequence of vectors.

`BasisElement(V, i)`

The i-th basis element for the vector space V.

`BasisMatrix(V)`

The current basis for the vector space V, returned as the rows of a matrix belonging to the matrix space $K^{(m\times n)}$, where m is the dimension of V and n is the over-dimension of V.

`Coordinates(V, v)`

Given a vector v belonging to the r-dimensional K-vector space V, with basis $v_1, \ldots, v_r$, return a sequence $[a_1, \ldots, a_r]$ of elements of K giving the coordinates of v relative to the V-basis: $v = a_1 * v_1 + \cdots + a_r * v_r$.

`Dimension(V)`

The dimension of the vector space V.

`ExtendBasis(Q, U)`

Given a sequence Q containing r linearly independent vectors belonging to the vector space U, extend the vectors of Q to a basis for U. The basis is returned in the form of a sequence T such that $T[i] = Q[i], i = 1, \ldots r$.

`ExtendBasis(U, V)`

Given an r-dimensional subspace U of the vector space V, return a basis for V in the form of a sequence T of elements such that the first r elements correspond to the given basis vectors for U.

`IsIndependent(S)`

Given a set S of elements belonging to the vector space V, return `true` if the elements of S are linearly independent.

`IsIndependent(Q)`

Given a sequence Q of elements belonging to the vector space V, return `true` if the terms of Q are linearly independent.

Example H28E13

These operations will be illustrated in the context of the subspace $G3$ of the 11-dimensional vector space over $\mathbf{F}_3$ defining the ternary Golay code.

```
> V11 := VectorSpace(FiniteField(3), 11);
> G3  := sub< V11 |  [1,0,0,0,0,0,1,1,1,1,1], [0,1,0,0,0,0,0,1,2,2,1],

```

28.8 Operations with Linear Transformations

Throughout this section, V is a subspace of $K^{(m)}$, W is a subspace of $K^{(n)}$ and a is a linear transformation belonging to $\mathrm{Hom}_K(V, W)$. See also the chapter on general matrices for many other functions applicable to such matrices (e.g., `EchelonForm`).

`v * a`

`a(v)`

Given an element v belonging to the vector space V, and an element a belonging to $\mathrm{Hom}_K(V, W)$, return the image of v under the linear transformation a as an element of the vector space W.

`a * b`

Given a matrix a belonging to $K^{(m\times n)}$ and a matrix b belonging to $K^{(n\times p)}$, for some integers m, n, p, form the product of a and b as an element of $K^{(m\times p)}$.

`Domain(a)`

The domain of the linear transformation a belonging to $\mathrm{Hom}_K(V, W)$, returned as a subspace of V.

`Codomain(a)`

The codomain of the linear transformation a belonging to $\mathrm{Hom}_K(V, W)$, returned as a subspace of W.

`Image(a)`

The image of the linear transformation a belonging to $\mathrm{Hom}_K(V, W)$, returned as a subspace of W.

`Rank(a)`

The dimension of the image of the linear transformation a, i.e., the rank of the matrix a.

`Kernel(a)`

`NullSpace(a)`

The kernel of the linear transformation a belonging to $\mathrm{Hom}_K(V, W)$, returned as a subspace of V.

`Cokernel(a)`

The cokernel of the linear transformation a belonging to $\mathrm{Hom}_K(V, W)$.

Example H28E14

We illustrate the map operations for matrix spaces in the following example:

```
> Q := RationalField();
> Q2 := VectorSpace(Q, 2);
> Q3 := VectorSpace(Q, 3);
> Q4 := VectorSpace(Q, 4);
> H23 := Hom(Q2, Q3);
> H34 := Hom(Q3, Q4);
> x := Q2 ! [ -1, 2 ];
> a := H23 ! [ 1/2, 3, 0,  2/3, 4/5, -1 ];
> a;
[1/2   3   0]

29 POLAR SPACES

Chapter 29
POLAR SPACES

29.1 Introduction

This chapter describes MAGMA functions for working with quadratic, bilinear and sesquilinear forms defined on vector spaces. The emphasis is on vector spaces defined over finite fields but in some instances the functions apply more widely. For quadratic forms defined on lattices see Chapter 32. For the interpretation of reflexive forms as algebras with involution see Chapter 87. General references for this material are [Bou07, Tay92].

29.2 Reflexive Forms

Let V be a vector space of dimension n over a field K. If σ is an automorphism of K, a σ-sesquilinear form on the vector space V over K is a map $\beta : V \times V \to K$ such that

$$\beta(u_1 + u_2, v) = \beta(u_1, v) + \beta(u_2, v),$$
$$\beta(u, v_1 + v_2) = \beta(u, v_1) + \beta(u, v_2)$$

and

$$\beta(au, bv) = a\sigma(b)\beta(u, v).$$

for all $u, u_1, u_2, v, v_1, v_2 \in V$ and all $a, b \in K$. If σ is the identity, the form is said to be *bilinear*.

A linear transformation g of V is an *isometry* if g preserves β; it is a *similarity* if it preserves β up to a non-zero scalar multiple.

A σ-sesquilinear form β is *reflexive* if for all $u, v \in V$, $\beta(u, v) = 0$ implies $\beta(v, u) = 0$. Any non-zero multiple of a reflexive form is again reflexive with the same group of isometries. By a theorem of Brauer [Bra36] (but sometimes referred to as the Birkhoff–von Neumann theorem), up to a non-zero scalar multiple, there are three types of *non-degenerate* reflexive forms:

Alternating. In this case σ is the identity, $\beta(u, u) = 0$ for all $u \in V$ and consequently $\beta(u, v) = -\beta(v, u)$ for all $u, v \in V$. The group of isometries is a *symplectic* group.

Symmetric. In this case σ is the identity and $\beta(u, v) = \beta(v, u)$ for all $u, v \in V$. If the characteristic of K is not two, the group of isometries is an *orthogonal* group. If the characteristic is two, the form is either alternating or pseudo-alternating (see below).

Hermitian. In this case σ is an automorphism of order two and $\beta(u, v) = \sigma\beta(v, u)$ for all $u, v \in V$. The group of isometries is a *unitary* group.

If V is a vector space V and if β is a reflexive form defined on V, the partially ordered set of totally isotropic subspaces with respect to β is often referred to as a *polar space*.

Similarly, there are polar spaces associated with quadratic forms (see Section 29.2.1). But throughout this chapter by polar space we shall simply mean a vector space furnished with either a reflexive σ-sesquilinear form or a quadratic form. See [Bue95, Chap. 2] for an account of polar spaces in a more general context.

Let K_0 be the fixed field of σ. Multiplying an alternating, symmetric or hermitian form by a non-zero element of K_0 leaves the type of the form unchanged.

However, multiplying an hermitian form by a non-zero element of K produces a sesquilinear form ξ and an element $\varepsilon \in K$ such that for all $u, v \in V$, $\xi(v, u) = \varepsilon\sigma\xi(u, v)$, where $\varepsilon\sigma(\varepsilon) = 1$. In this case ξ is said to be ε-hermitian.

Skew-hermitian. A reflexive σ-sesquilinear form is skew-hermitian if the order of σ is two and $\xi(v, u) = -\sigma\xi(v, u)$ for all $u, v \in V$. If β is hermitian and if $d \in K$ is chosen so that $d \neq \sigma(d)$, then $e = d - \sigma(d)$ satisfies $\sigma(e) = -e$. Thus $\xi(u, v) = e\beta(u, v)$ is skew-hermitian. The group of isometries of ξ coincides with the group of isometries of β and it is therefore a *unitary* group.

In the case of fields of characteristic two there is no distinction between hermitian and skew-hermitian forms and moreover, every alternating form is symmetric.

Pseudo-alternating. A symmetric form (in characteristic two) which is not alternating is said to be *pseudo-alternating*.

The three types of forms—alternating, symmetric and hermitian—correspond to the three types of classical groups of isometries: symplectic, orthogonal and unitary. But this is not quite the whole story because it does not include orthogonal groups over fields of characteristic two. In order to include these groups it is necessary to consider quadratic forms in addition to symmetric bilinear forms.

29.2.1 Quadratic Forms

If β is a bilinear form, a *quadratic form* with *polar form* β is a function $Q : V \to K$ such that

$$Q(av) = a^2 Q(v)$$

and

$$\beta(u, v) = Q(u + v) - Q(u) - Q(v)$$

for all $u, v \in V$ and all $a \in K$. We have $\beta(v, v) = 2Q(v)$ and therefore, if the characteristic of K is not two, β determines Q.

We extend the notion of polar space to include vector spaces V with an associated quadratic form Q. The pair (V, Q) is an orthogonal geometry and V is a *quadratic* space.

29.3 Inner Products

Every vector space V in MAGMA created via the `VectorSpace` intrinsic (or its synonym `KSpace`) has an associated bilinear form which is represented by a matrix and which can be accessed via `InnerProductMatrix(V)` or via the attribute `ip_form`. By default the inner product matrix is the identity. If the dimension of V is n, then any $n \times n$ matrix defined over the base field of V can serve as the inner product matrix by passing it to `VectorSpace` as an additional parameter.

If $e_1, e_2, \ldots, e_n$ is a basis for V, the matrix of the form β with respect to this basis is $J := \big(\beta(e_i, e_j)\big)$.

Example H29E1

```
> K := GF(11);
> J := Matrix(K,3,3,[1,2,3, 4,5,6, 7,8,9]);
> V := VectorSpace(K,3,J);
> InnerProductMatrix(V);
[ 1  2  3]
[ 4  5  6]
[ 7  8  9]
```

A vector space may also have an associated quadratic form. This can be assigned via the function `QuadraticSpace` described in Section 29.6.3 and, if assigned, it can be accessed as the return value of `QuadraticFormMatrix`.

In addition, in order to accommodate hermitian forms, a vector space of type `ModTupFld` has an attribute `Involution`. This attribute is intended to hold an automorphism (of order two) of the base field.

`DotProduct(u, v)`

If V is the generic space of the parent of u and v, let σ be the field automorphism `V‘Involution` if this attribute is assigned or the identity automorphism if `V‘Involution` is not assigned. If J is the inner product matrix of V, the expression `DotProduct(u,v)` evaluates to $uJ\sigma(v^{\mathrm{tr}})$. That is, it returns $\beta(u, v)$, where β is a bilinear or sesquilinear form on V.

`DotProductMatrix(W)`

The matrix of inner products of the vectors in the sequence W. The inner products are calculated using `DotProduct` and therefore take into account any field automorphism attached to the `Involution` attribute of the generic space of the universe of S.

`GramMatrix(V)`

If B is the basis matrix of V and if J is the inner product matrix, this function returns BJB^{tr}. In this case the `Involution` attribute is ignored.

`InnerProductMatrix(V)`

The inner product matrix attached to the generic space of V. This is the attribute `V‘ip_form`.

Example H29E2

This example illustrates the difference between `GramMatrix` and `InnerProductMatrix`. The function `GramMatrix` uses the echelonised basis of the subspace W. To obtain the matrix of inner products between a given list of vectors, use `DotProductMatrix`.

```
> K<a> := QuadraticField(-2);
> J := Matrix(K,3,3,[1,2,1, 2,1,0, 1,0,2]);
> V := VectorSpace(K,3,J);
> W := sub<V| [a,a,a], [1,2,3]>;
> InnerProductMatrix(W);
[1 2 1]
[2 1 0]
[1 0 2]
> GramMatrix(W);
[1 0]
[0 9]
> DotProductMatrix([W.1,W.2]);
[ -20 19*a]
[19*a   37]
```

Example H29E3

Continuing the previous example, the vector space V does not have the attribute `Involution` assigned and therefore `DotProduct` uses the *symmetric* bilinear form represented by the inner product matrix J. However, the field K has a well-defined operation of complex conjugation and so `InnerProduct` uses the *hermitian* form represented by J.

```
> u := W.1+W.2;
> DotProduct(u,u);
38*a + 17
> InnerProduct(u,u);
57
```

29.3.1 Orthogonality

If β is any bilinear or sesquilinear form, the vectors u and v are *orthogonal* if $\beta(u, v) = 0$. The *left orthogonal complement* of a subset X of V is the subspace

$$^{\perp}X := \{\, u \in V \mid \beta(u, x) = 0 \text{ for all } x \in X \,\}$$

and the *right orthogonal complement* of W is

$$X^{\perp} := \{\, u \in V \mid \beta(x, u) = 0 \text{ for all } x \in X \,\}.$$

If β is reflexive, then $^{\perp}X = X^{\perp}$.

`OrthogonalComplement(V, X : parameters)`

`Right` BoolElt *Default :* `false`

The default value is the left orthogonal complement of X in V. To obtain the right orthogonal complement set `Right` to `true`.

`Radical(V : parameters)`

`Right` BoolElt *Default :* `false`

The left radical of the inner product space V, namely $^{\perp}V$. To obtain the right radical set `Right` to `true`.

A bilinear or sesquilinear form β is *non-degenerate* if $\mathrm{rad}(V) = 0$, where V is the polar space of β.

`IsNondegenerate(V)`

Returns `true` if the determinant of the matrix of inner products of the basis vectors of V is non-zero, otherwise `false`. This function takes into account the field automorphism, if any, attached to the `Involution` attribute of the generic space of V.

If V is a quadratic space over a perfect field of characteristic 2, the restriction of the quadratic form Q to the radical is a semilinear functional (with respect to $x \mapsto x^2$) whose kernel is the *singular radical* of V. A quadratic space is *non-singular* if its singular radical is zero.

`SingularRadical(V)`

The kernel of the restriction of the quadratic form of the quadratic space V to the radical of V.

`IsNonsingular(V)`

Returns `true` if V is a non-singular quadratic space, otherwise `false`.

29.4 Isotropic and Singular Vectors and Subspaces

Let β be a reflexive bilinear or a sesquilinear form on the vector space V. A non-zero vector v is *isotropic* (with respect to β) if $\beta(v, v) = 0$. If Q is a quadratic form, a non-zero vector v is *singular* if $Q(v) = 0$.

`HasIsotropicVector(V)`

Determine whether the polar space V contains an isotropic vector; if it does, the second return value is a representative.

`HasSingularVector(V)`

Determine whether the quadratic space V contains a singular vector; if it does, the second return value is a representative.

An ordered pair of vectors (u, v) such that u and v are isotropic and $\beta(u, v) = 1$ is a *hyperbolic pair*. If V is a quadratic space, u and v are required to be singular.

`HyperbolicPair(V, u)`

Given a singular or isotropic vector u which is not in the radical, return a vector v such that (u, v) is a hyperbolic pair.

If V is the direct sum of subspaces U and W and if $\beta(u, w) = 0$ for all $u \in U$ and all $w \in W$, we write $V = U \perp W$.

A vector space V furnished with a reflexive form β has a direct sum decomposition $V = U \perp \mathrm{rad}(V)$, where U is any complement to $\mathrm{rad}(V)$ in V.

If V is a polar space, it has a *hyperbolic splitting*; namely, it is a direct sum

$$V = L_1 \perp L_2 \perp \cdots \perp L_m \perp W$$

where the L_i are 2-dimensional subspaces spanned by hyperbolic pairs and m is maximal. If the form defining the polar space is non-degenerate and not pseudo-alternating, then every isotropic (resp. singular) vector belongs to a hyperbolic pair and consequently W does not contain any isotropic (resp. singular) vectors. In this case the integer m is the *Witt index* of the form and W is called the *anisotropic component* of the splitting. A non-degenerate form on V is said to have *maximal Witt index* if $\dim V$ is $2m$ or $2m + 1$.

Example H29E4

The vector space of dimension 2 over $\mathbf{F}_2$ is pseudo-symplectic (the form is the identity matrix). It has three non-zero elements only one of which is isotropic. This confirms that not every isotropic vector in a non-degenerate pseudo-symplectic space belongs to a hyperbolic pair.

```
> V := VectorSpace(GF(2),2);
> IsPseudoSymplecticSpace(V);
true
> IsNondegenerate(V);
true
> { v : v in V | v ne V!0 and DotProduct(v,v) eq 0};
```

```
{
    (1 1)
}
```

`HyperbolicSplitting(V)`

A maximal list of pairwise orthogonal hyperbolic pairs together with a basis for the orthogonal complement of the subspace they span. This function requires the form to be non-degenerate and, except for symplectic spaces, the base ring of V must be a finite field.

Example H29E5

Find the hyperbolic splitting of a polar space defined by a symmetric bilinear form. In this example W is a non-degenerate subspace of the polar space V.

```
> K<a> := GF(7,2);
> J := Matrix(K,3,3,[1,2,1, 2,1,0, 1,0,2]);
> V := VectorSpace(K,3,J);
> W := sub<V| [a,a,a], [1,2,3]>;
> IsNondegenerate(W);
true
> HyperbolicSplitting(W);
<[
    [
        (a^20    1 a^39),
        (a^12    2    a)
    ]
], []>
```

Example H29E6

The polar space V of the previous example is degenerate and so `HyperbolicSplitting` cannot be applied directly. Instead, we first split off the radical.

```
> IsNondegenerate(V);
false
> R := Radical(V);
> H := (Dimension(R) eq 0) select V else
>   sub<V|[e : e in ExtendBasis(B,V) | e notin B] where B is Basis(R)>;
> HyperbolicSplitting(H);
<[
    [
        (   0 a^20    1),
        (   0 a^12    2)
    ]
], []>
```

A subspace W of a polar space V is *totally isotropic* if every non-zero vector of W is isotropic. If V is a quadratic space, W is *totally singular* if every non-zero vector of W is singular.

`IsTotallyIsotropic(V)`

Returns `true` if the polar space V is totally isotropic, otherwise `false`.

`IsTotallySingular(V)`

Returns `true` if the quadratic space V is totally singular, otherwise `false`.

Suppose that $V = L_1 \perp \cdots \perp L_m \perp W \perp \mathrm{rad}(V)$ where the L_i are 2-dimensional subspaces spanned by hyperbolic pairs (e_i, f_i) for $1 \leq i \leq m$. The subspaces $P = \langle e_1, \ldots, e_m \rangle$ and $N = \langle f_1, \ldots, f_m \rangle$ are totally isotropic and we call the 4-tuple $(\mathrm{rad}(V), P, N, W)$ a *Witt decomposition* of V. A polar space is *hyperbolic* if it is the direct sum of two totally isotropic (resp. totally singular) subspaces; in Bourbaki [Bou07, p. 66] the corresponding form is said to be *neutral*.

`WittDecomposition(V)`

The Witt decomposition of the space V.

`WittIndex(V)`

The Witt index of the polar space V; namely half the dimension of a maximal hyperbolic subspace.

`MaximalTotallyIsotropicSubspace(V)`

A representative maximal totally isotropic subspace of the polar space V.

`MaximalTotallySingularSubspace(V)`

A representative maximal totally singular subspace of the quadratic space V.

29.5 The Standard Forms

This section describes the "standard" alternating, hermitian, quadratic and symmetric forms defined on a finite dimensional vector space over a field. These are forms of maximal Witt index together with the quadratic forms of non-maximal Witt index over finite fields (see Section 29.4). Except for the orthogonal groups the standard forms are preserved by the MAGMA implementation of the classical groups over finite fields.

If J is the matrix of the form, then X preserves the form if $XJX^{\mathrm{tr}} = J$.

If β is a non-degenerate alternating form, then $\mathrm{rad}(V)$ and the anisotropic component of a hyperbolic splitting are zero. Thus the dimension of V must be even and V has a basis of mutually orthogonal hyperbolic pairs. In particular, up to equivalence, there is only one non-degenerate alternating form on V.

`StandardAlternatingForm(n,R)`

`StandardAlternatingForm(n,q)`

If $n = 2m$, this function returns the $n \times n$ matrix of a non-degenerate alternating form over the ring R (or the field of q elements) such that if e_1, e_2, ..., e_{2m} is the standard basis, then (e_1, e_{2m}), (e_2, e_{2m-1}), ..., (e_m, e_{m+1}) are mutually orthogonal hyperbolic pairs.

The group of isometries of this form is the symplectic group $\mathrm{Sp}(2m, R)$.

Example H29E7

Create a symplectic geometry with the standard alternating form and then check that every non-zero vector is isotropic.

```
> K := GF(5);
> J := StandardAlternatingForm(4,K);
> J;
[0 0 0 1]
[0 0 1 0]
[0 4 0 0]
[4 0 0 0]
> V := VectorSpace(K,4,J);
> forall{ v : v in V | DotProduct(v,v) eq 0 };
true
```

`StandardPseudoAlternatingForm(n,K)`

`StandardPseudoAlternatingForm(n,q)`

The matrix of the standard pseudo-alternating form of degree n over the field K (or the finite field of order q), which must have characteristic 2; that is, a symmetric form which is not alternating.

`StandardHermitianForm(n,K)`

`StandardHermitianForm(n,q)`

The first return value of this function is the $n \times n$ anti-diagonal matrix $(\delta_{i,n-i+1})$ over the field K (or the field of q^2 elements). If K is the finite field of q^2 elements, the second return value is the field involution $K \to K : x \mapsto x^q$. If K is a field which admits the operation of complex conjugation, the second return value is the field automorphism which sends each element to its complex conjugate.

If β is a non-degenerate hermitian form over a finite field, then $\mathrm{rad}(V)$ is zero and the dimension of the anisotropic component of a hyperbolic splitting is either 1 or 0.

In the finite field case, the group of isometries of this form is $\mathrm{GU}(n, q)$.

Suppose that β is the polar form of a quadratic form Q defined on the vector space V. A vector $v \in V$ is said to be *singular* if $Q(v) = 0$. A subspace W is *totally singular* is $Q(w) = 0$ for all $w \in W$. The *Witt index* of Q is the dimension of a maximal totally singular subspace. If the characteristic of the field is not 2 a subspace is totally singular if and only if it is totally isotropic with respect to β and hence in this case the Witt index of Q coincides with the Witt index of β.

`StandardQuadraticForm(n, K : parameters)`

`StandardQuadraticForm(n, q : parameters)`

`Minus`	BoolElt	*Default :* `false`
`Variant`	MonStgElt	*Default :* "Default"

An $n \times n$ upper triangular matrix representing a quadratic form over the field K (or the field of order q). The default option is to return a form of maximal Witt index, namely the upper triangular matrix whose non-zero entries are $\delta_{i,n-i+1}$, where $1 \leq i \leq (n+1)/2$.

If `Minus` is `true` and $n = 2m$, this function returns a form whose Witt index is $m - 1$. This option is available only for finite fields.

For historical reasons, over finite fields of odd characteristic, the (m, m) element in the quadratic form used by the orthogonal groups of odd degree is $1/4$.

If the K is a finite field and W is the anisotropic component of a hyperbolic splitting of a form of `Minus` type, then W has basis vectors e and f such that $Q(e) = \beta(e, f) = 1$ and $Q(f) = a$, where $x^2 + x + a$ is an irreducible polynomial in $F[x]$. This is the form returned by the `Default` option. If the characteristic of K is two, this is also returned by the `Revised` option. However, if the characteristic of K is odd, the `Revised` option returns a form corresponding to an orthonormal basis for W. The `Original` option returns the form preserved by `OldGOMinus(2*m,q)`.

Example H29E8

Construct a standard quadratic form of minus type.

```
> K<z> := GF(7,2);
```

```
> Q := StandardQuadraticForm(4,49 : Minus);
> Q;
[   0    0     0    1]
[   0    1     1    0]
[   0    0  z^23    0]
[   0    0     0    0]
> _<x> := PolynomialRing(K);
> a := Q[3,3];
> IsIrreducible(x^2+x+a);
true
```

Example H29E9

Compare the revised form with the standard form: the forms `Q` above and `QR` below have different entries in the central 2×2 block.

```
> QR := StandardQuadraticForm(4,49 : Minus, Variant := "Revised");
> QR;
[   0    0     0    1]
[   0    4     0    0]
[   0    0  z^11    0]
[   0    0     0    0]
```

`StandardSymmetricForm(n, K)`

`StandardSymmetricForm(n, q : parameters)`

`Minus`	BoolElt	*Default :* `false`
`Variant`	MonStgElt	*Default :* "Default"

In all casses this is $Q + Q^{\mathrm{tr}}$, where Q is the corresponding standard quadratic form, as defined above.

29.6 Constructing Polar Spaces

If J is an $n \times n$ matrix, the command `VectorSpace(K,n,J)` creates a vector space of dimension n over K with a bilinear form whose matrix is J.

The default form attached to every vector space in MAGMA is the symmetric form whose matrix is the identity matrix.

A vector space V is recognised as a polar space if any of the following conditions apply. (There is no check to ensure that the inner product matrix is is non-degenerate.)

1. There is a quadratic form attached to V.
2. There is a field involution attached to V and the inner product matrix of V is hermitian or skew-hermitian with respect to this involution.
3. The inner product matrix of V is symmetric or alternating.

Thus a vector space with a symmetric inner product matrix but no quadratic form attached is a polar space. If the characteristic of the field is 2 and the form is not alternating it is a pseudo-symplectic space, otherwise we shall call it an orthogonal space to distinguish it from quadratic spaces.

`IsPolarSpace(V)`

Check if the vector space V is a quadratic space or if the Gram matrix of V is a reflexive form.

`PolarSpaceType(V)`

The type of the polar space V, returned as a string.

Example H29E10

Create the standard vector space of dimension 4 over the rational field and check if it is a polar space.

```
> V := VectorSpace(Rationals(),4);
> IsPolarSpace(V);
true
> PolarSpaceType(V);
orthogonal space
```

29.6.1 Symplectic Spaces

`SymplecticSpace(J)`

The symplectic space of dimension n defined by the $n \times n$ matrix J. This function checks to ensure that J is alternating.

`IsSymplecticSpace(W)`

Returns `true` if the `Involution` attribute of the generic vector space W is not assigned and the space carries an alternating form, otherwise `false`.

Note that a quadratic space over a field of characteristic 2 satisfies these conditions and consequently this function will return `true` for these spaces.

`IsPseudoSymplecticSpace(W)`

Given a vector space W over a finite field, this intrinsic returns `true` if the base field has characteristic 2, the `Involution` attribute is not assigned to the generic space and the form is symmetric but not alternating, otherwise `false`.

29.6.2 Unitary Spaces

In order to accommodate hermitian forms it is necessary to assign a field automorphism of order two to the `Involution` attribute of the vector space.

Thus a unitary space is characterised as a vector space V whose ambient space, `Generic(V)`, has the attribute `Involution` and whose inner product matrix is either hermitian or skew hermitian.

`UnitarySpace(J, sigma)`

The n-dimensional unitary space over the base field K of J, where σ is an automorphism of K of order 2 and where J is an $n \times n$ matrix which is hermitian or skew-hermitian with respect to σ.

`IsUnitarySpace(W)`

Return `true` if the `Involution` attribute of the generic space of W is assigned and the form is either hermitian or skew-hermitian when restricted to W.

Example H29E11

Create a unitary geometry with the standard hermitian form and check that the given vector is isotropic. Note that the function `DotProduct` takes both the form and the field involution into account when calculating its values. For finite fields, the function `InnerProduct` *ignores* the field involution.

```
> K<z> := GF(25);
> J, sigma := StandardHermitianForm(5,K);
> J;
[   0    0    0    0    1]
[   0    0    0    1    0]
[   0    0    1    0    0]
```

```
[   0    1    0    0    0]
[   1    0    0    0    0]
> sigma(z);
z^5
> V := UnitarySpace(J,sigma);
> u := V![1,z,0,z^2,-1];
> DotProduct(u,u);
0
> InnerProduct(u,u);
z^20
```

`ConjugateTranspose(M, sigma)`

The transpose of the matrix $\sigma(M)$, where σ is an automorphism of the base field ofthe matrix M.

29.6.3 Quadratic Spaces

A vector space V with an attached quadratic form is called a *quadratic space*. The polar form of a quadratic space is the inner product matrix J of the space. If the characteristic of the field is not 2, the value of the quadratic form on a row vector v is $\frac{1}{2}v * J * v^{\mathrm{tr}}$.

`QuadraticSpace(Q)`

The quadratic space of dimension n defined by the quadratic form represented by an upper triangular $n \times n$ matrix Q. The inner product matrix of the space is $Q + Q^{\mathrm{tr}}$. If Q is not upper triangular, the space will be constructed but there is no guarantee that other functions in this package will return correct results.

`QuadraticSpace(f)`

The quadratic space of dimension n whose quadratic form is given by the quadratic polynomial f in n variables. If the variables are $x_1, \ldots, x_n$, then for $i \leq j$, the (i, j)-th entry of the matrix of the form is the coefficient of $x_i x_j$ in f.

`SymmetricToQuadraticForm(J)`

Provided the characteristic of the field is not two, this is the upper triangular matrix which represents the same quadratic form as the symmetric matrix J.

`QuadraticFormMatrix(V)`

The (upper triangular) matrix which represents the quadratic form of the quadratic space V.

`QuadraticNorm(v)`

The value $Q(v)$, where Q is the quadratic form attached to the generic space of the parent of the vector v.

`QuadraticFormPolynomial(V)`

The polynomial $\sum_{i \leq j} q_{ij} x_i x_j$, where $Q = (q_{ij})$ is the matrix of the quadratic form of the quadratic space V.

Example H29E12

The quadratic space defined by a polynomial.

```
> _<x,y,z> := PolynomialRing(Rationals(),3);
> f := x^2 + x*y +3*x*z - 2*y*z + y^2 +z^2;
> V := QuadraticSpace(f);
> PolarSpaceType(V);
quadratic space
> IsNonsingular(V);
true
> QuadraticFormMatrix(V);
[ 1  1  3]
[ 0  1 -2]
[ 0  0  1]
```

`OrthogonalSum(V, W)`

The orthogonal direct sum of the quadratic spaces V and W.

`TotallySingularComplement(V, U, W)`

Given totally singular subspaces U and W of the quadratic space V such that $U^\perp \cap W = 0$ this function returns a totally singular subspace X such that $V = X \oplus U^\perp$ and $W \subseteq X$.

`Discriminant(V)`

If V is a vector space over the finite field K and if J is the Gram matrix of V, the *discriminant* of V is the determinant Δ of J modulo squares. That is, the discriminant is 0 if Δ is a square in K, 1 if it is a non-square. The form J is required to be non-degenerate.

`ArfInvariant(V)`

The Arf invariant of the quadratic space V.

Currently this is available only for quadratic spaces of even dimension $2m$ over a finite field F of characteristic 2. In this case there are two possibilities: either the Witt index of the form is m and the Arf invariant is 0, or the Witt index is $m-1$ and the Arf invariant is 1.

`DicksonInvariant(V, f)`

The Dickson invariant of the isometry f of the quadratic space V is the rank (mod 2) of $1 - f$. If the polar form of Q is non-degenerate, the Dickson invariant defines a homomorphism from the orthogonal group $O(V)$ onto the additive group of order 2.

`SpinorNorm(V, f)`

The spinor norm of the isometry f of the quadratic space V. This is the discriminant of the Wall form (Section 29.8) of f.

`HyperbolicBasis(U, B, W)`

Given complementary totally singular subspaces U and W of a quadratic space and a basis B for U, return a sequence of pairwise orthogonal hyperbolic pairs whose second components form a basis for W.

`OrthogonalReflection(a)`

The reflection determined by a non-singular vector of a quadratic space.

`RootSequence(V, f)`

Given a matrix f representing an isometry of the quadratic space V, return a sequence of vectors such that the product of the corresponding orthogonal reflections is f. The empty sequence is returned if f is the identity matrix.

`ReflectionFactors(V, f)`

Given a matrix f representing an isometry of the quadratic space V, return a sequence of reflections whose product is f. The empty sequence corresponds to the identity matrix.

Given a quadratic space V defined by a quadratic form Q with polar form β and non-zero vectors $u, v \in V$ such that u is singular and $\beta(u, v) = 0$, the *Siegel transformation* (also called an Eichler transformation) is the isometry $\rho_{u,v}$ defined by

$$x\rho_{u,v} = x + \beta(x, v)u - \beta(x, u)v - Q(v)\beta(x, u)u.$$

`SiegelTransformation(u, v)`

The Siegel transformation defined by a singular vector u and a vector v orthogonal to u. The common parent of u and v must be a quadratic space.

Example H29E13

A group of isometries generated by Siegel transformations.

```
> Q := StandardQuadraticForm(4,3);
> V := QuadraticSpace(Q);
> u := V.1;
> QuadraticNorm(u);
0
> X := { v : v in V | DotProduct(u,v) eq 0 and QuadraticNorm(v) ne 0 };
> #X;
12
> H := sub< GL(V) | [SiegelTransformation(u,v) : v in X]>;
> #H;
9
```

29.7 Isometries and Similarities

If β is a bilinear or sesquilinear form on the vector space V, a linear transformation g of V is an *isometry* if g preserves β; it is a *similarity* if it preserves β up to a non-zero scalar multiple.

29.7.1 Isometries

`IsIsometry(U, V, f)`

Returns `true` if the map f is an isometry from U to V with respect to the attached forms.

`IsIsometry(f)`

Returns `true` if the map f is an isometry from its domain to its codomain.

`IsIsometry(V, g)`

Returns `true` if the matrix g is an isometry of V with respect to the attached form.

`IsIsometric(V, W)`

Determines whether the polar spaces V and W are isometric; if they are, an isometry is returned (as a map).

Example H29E14

A vector space is always equipped with a bilinear form and the default value is the identity matrix. However the "standard" symmetric form is $Q + Q^{\mathrm{tr}}$, where Q is the standard quadratic form. In the following example the polar spaces defined by these forms are similar but not isometric.

```
> F := GF(5);
> V1 := VectorSpace(F,5);
> PolarSpaceType(V1);
orthogonal space
> WittIndex(V1);
2
> J2 := StandardSymmetricForm(5,F);
> J2;
[0 0 0 0 1]
[0 0 0 1 0]
[0 0 2 0 0]
[0 1 0 0 0]
[1 0 0 0 0]
> V2 := VectorSpace(F,5,J2);
> IsIsometric(V1,V2);
false
> V3 := VectorSpace(F,5,2*J2);
> flag, f := IsIsometric(V1,V3); flag;
true
> IsIsometry(f);
true
```

If J is an $n \times n$ matrix which represents a bilinear form and if M is a non-singular $n \times n$ matrix, then J and MJM^{tr} are said to be *congruent* and they define isometric polar spaces.

Conversely, given bilinear forms J_1 and J_2 the following example shows how to use the `IsIsometric` function to determine whether J_1 and J_2 are congruent and if so how to find a matrix M such that $J_1 = MJ_2M^{\mathrm{tr}}$.

Example H29E15

Begin with alternating forms J_1 and J_2 over $\mathbf{F}_{25}$, construct the corresponding symplectic spaces and then use the isometry to define the matrix M.

```
> F<x> := GF(25);
> J1 := Matrix(F,4,4,[ 0, x^7, x^14, x^13, x^19, 0, x^8, x^5,
>   x^2, x^20, 0, x^17, x, x^17, x^5, 0 ]);
> J2 := Matrix(F,4,4,[ 0, x^17, 2, x^23, x^5, 0, x^15, x^5,
>   3, x^3, 0, 4, x^11, x^17, 1, 0 ]);
> V1 := SymplecticSpace(J1);
> V2 := SymplecticSpace(J2);
> flag, f := IsIsometric(V1,V2); assert flag;
```

```
> f;
Mapping from: ModTupFld: V1 to ModTupFld: V2 given by a rule
> M := Matrix(F,4,4,[f(V1.i) : i in [1..4]]);
> J1 eq M*J2*Transpose(M);
true
```

Example H29E16

Another way to obtain a matrix with the same effect as M is to use the function `TransformForm`.

```
> M1 := TransformForm(J1,"symplectic");
> M2 := TransformForm(J2,"symplectic");
> M_alt := M1*M2^-1;
> J1 eq M_alt*J2*Transpose(M_alt);
true
```

`CommonComplement(V, U, W)`

A common complement to the subspaces U and W in the vector space V. (The subspaces must have the same dimension.) This is used by the following function, which implements Witt's theorem.

`ExtendIsometry(V, U, f)`

An extension of the isometry $f : U \to V$ to an isometry $V \to V$, where U is a subspace of the polar space V.

This is an implementation of Witt's theorem on the extension of an isometry defined on a subspace of a symplectic, unitary or quadratic space. The isometry f must satisfy $f(U \cap \mathrm{rad}(V)) = f(U) \cap \mathrm{rad}(V)$.

If the characteristic is two and the form J of V is symmetric, then J must be alternating.

`IsometryGroup(V)`

The group of isometries of the polar space V. This includes degenerate polar spaces as well as polar spaces defined by a quadratic form over a field of characteristic two.

Given a reflexive form J, the function `IsometryGroup(J)` defined in Chapter 87 returns the isometry group of J. More generally, if S is a sequence of reflexive forms, the function `IsometryGroup(S)` returns the group of isometries of the system.

Example H29E17

We give an example of an isometry group of a degenerate quadratic space over a field of characteristic 2.

```
> F := GF(4);
> Q1 := StandardQuadraticForm(4,F : Minus);
> Q := DiagonalJoin(Q1,ZeroMatrix(F,2,2));
> V := QuadraticSpace(Q);
> G := IsometryGroup(V);

Example H29E18

The matrix M constructed in Example H29E15 can be used to conjugate the isometry group of J_1 to the isometry group of J_2.

```
> F<x> := GF(25);
> J1 := Matrix(F,4,4,[ 0, x^7, x^14, x^13, x^19, 0, x^8, x^5,
>   x^2, x^20, 0, x^17, x, x^17, x^5, 0 ]);
> J2 := Matrix(F,4,4,[ 0, x^17, 2, x^23, x^5, 0, x^15, x^5,
>   3, x^3, 0, 4, x^11, x^17, 1, 0 ]);
> V1 := SymplecticSpace(J1);
> V2 := SymplecticSpace(J2);
> flag, f := IsIsometric(V1,V2); assert flag;
> M := Matrix(F,4,4,[f(V1.i) : i in [1..4]]);
> G1 := IsometryGroup(V1);
> G2 := IsometryGroup(V2);
> M^-1*G1.1*M in G2;
true
> M^-1*G1.2*M in G2;
true
```

29.7.2 Similarities

`IsSimilarity(U, V, f)`

Returns `true` if the map f is a similarity from U to V with respect to the attached forms.

`IsSimilarity(f)`

Returns `true` if the map f is a similarity from its domain to its codomain.

`IsSimilarity(V, g)`

Returns `true` if the matrix g is a similarity of V with respect to the attached form.

`SimilarityGroup(V)`

The group of similarities of the polar space V. This includes degenerate polar spaces as well as polar spaces defined by a quadratic form over a field of characteristic two.

29.8 Wall Forms

Given an isometry f of a quadratic or symplectic space V with bilinear form β, the Wall form of f is the form θ defined on the image I of $1 - f$ by $\theta(u, v) = \beta(w, v)$, where $u = w(1 - f)$. In general, the Wall form is not reflexive.

`WallForm(V, f)`

The space of the Wall form of f and its embedding in V.

`WallIsometry(V, I, mu)`

The inverse of `WallForm`. This is an isometry corresponding to the embedding $\mu : I \to V$, where V is a quadratic or symplectic space.

`WallDecomposition(V, f)`

An isometry f of a quadratic or symplectic space V is *Wall-regular* if the restriction of $1 - f$ to the image of $1 - f$ is invertible. If f is any isometry of V this function returns a Wall-regular element f_r and a unipotent element f_u such that $f = f_r f_u = f_u f_r$.

`SemiOrthogonalBasis(V)`

If V is a vector space with a bilinear form β, a basis e_1, e_2, ..., e_n for V is semi-orthogonal if $\beta(e_i, e_j) = 0$ for $i < j$. This function returns a semi-orthogonal basis with respect to the non-degenerate, non-alternating form attached to V. If the base field is $\mathbf{F}_2$, the form should be symmetric.

29.9 Invariant Forms

Given a group G which acts on a vector space V over a finite field F, the space of all G-invariant bilinear forms is isomorphic to $\mathrm{Hom}_G(V, V^*)$, where V^* is the dual space of V. The isomorphism associates the form β to $\theta \in \mathrm{Hom}_G(V, V^*)$, where $\beta(u, v) = \langle v, u\theta \rangle$ and where $\langle v, \varphi \rangle$ denotes the action of φ on v. If $v_1, v_2, \ldots, v_n$ is a basis for V with dual basis $\omega_1, \omega_2, \ldots, \omega_n$, the matrix of θ with respect to these bases is $J = (\beta(e_i, e_j))$.

A linear transformation with matrix A preserves the form if and only if $AJA^{\mathrm{tr}} = J$.

If the characteristic of the field is not 2, then $J = \frac{1}{2}(J + J^{\mathrm{tr}}) + \frac{1}{2}(J - J^{\mathrm{tr}})$. Therefore, in this case, every G-invariant form is the sum of a G-invariant symmetric form and a G-invariant alternating form. If the characteristic of the field is 2, every alternating form is symmetric. Thus in this case the space of G-invariant alternating forms is a subspace of the space of G-invariant symmetric forms. If the G-module is irreducible these two spaces coincide.

`InvariantBilinearForms(G)`

Given a matrix group G this function returns two sequences: a basis for the space of G-invariant symmetric forms and a basis for the space of G-invariant alternating forms.

Example H29E19

In this example the group G is reducible but (up to a scalar multiple) there is a unique G-invariant bilinear form.

```
> F<x> := GF(25);
> G := MatrixGroup< 4, F |
>    [ 1, 0, 0, 0,  0, 1, 0, 0,  0, x^14, 1, 0,  0, 0, 0, 1 ],
>    [ 3, x^23, x^20, x^10,  2, 3, 0, x^13,  4, x^10, x^13, x^23,
>      x^5, x^11, x, x^17 ] >;
> IsIrreducible(G);
false
> InvariantBilinearForms(G);
[]
[
    [   0    0    0    1]
    [   0    0    1    0]
    [   0    4    0    0]
    [   4    0    0    0]
]
```

If G acts irreducibly on a vector space V of dimension n over a (finite) field F and if $\theta_0 : V \to V^*$ is a G-invariant isomorphism, then $D \to \mathrm{Hom}_G(V, V^*) : \theta \mapsto \theta\theta_0$ is an isomorphism of vector spaces, where $D = \mathrm{End}_G(V)$. The algebra D is a division ring and hence a field (since F is finite). Thus V becomes a vector space of dimension m over D, where $n = m|D : F|$ and G is isomorphic to a subgroup of $\mathrm{GL}(m, D)$.

Example H29E20

If G acts irreducibly on V, the spaces of symmetric and alternating G-invariant forms are isomorphic (as vector spaces) to subfields of $\mathrm{End}_G(V)$ and therefore their dimensions are either 0 or divide $\dim_F(V)$.

```
> F<a> := GF(25);
> G := MatrixGroup< 4, F |
>   [ a^10, a^21, a^4, 4,
>     a^16, 4, a^9, a^8,
>     a^20, 4, 4, a^13,
>     0, a^2, a^11, a ] >;
> IsIrreducible(G), #G;
true 626
> sym, alt := InvariantBilinearForms(G);
> #sym,#alt;
2 2
```

If the characteristic of the field is not two and if J is a symmetric bilinear form there is a unique upper triangular matrix Q such that $J = Q + Q^{\mathrm{tr}}$.

On the other hand, if the characteristic is two and J is alternating, the upper triangular matrices Q such that $J = Q + Q^{\mathrm{tr}}$ form an affine space of dimension $\dim V$.

Suppose that the characteristic is two. If G preserves a symmetric bilinear form which is not alternating, then G is reducible. Conversely, if G is irreducible and if J is the matrix of a symmetric form preserved by G, then the form must be alternating and there is a unique G-invariant quadratic form Q such that $J = Q + Q^{\mathrm{tr}}$.

`InvariantQuadraticForms(G)`

A basis for the space of quadratic forms preserved by the irreducible matrix group G.

Example H29E21

In the following example the quadratic forms which are invariant under the action of a cyclic group H of order 13 form a vector space of dimension 3 over $\mathbf{F}_4$.

```
> F<z> := GF(4);
> H := MatrixGroup<6,F |
>     [ z, 0, z^2, z, z, 1,
>       1, z, 0, z, z, z,
>       0, z^2, z, 1, z^2, z^2,
>       z, 1, z, 1, 1, 0,
>       1, z^2, z, z, 0, 1,
>       1, 0, 1, 0, z^2, 1 ] >;
>
> InvariantQuadraticForms(H);
[
    [  1   1   0   1   0   0]
    [  0   0   1 z^2 z^2   z]
```

```
    [  0   0   1   0 z^2   z]
    [  0   0   0   0   0   z]
    [  0   0   0   0 z^2   z]
    [  0   0   0   0   0 z^2],

    [  1   0   1 z^2   1   0]
    [  0   z   1   1   1   z]
    [  0   0   z   0   1   0]
    [  0   0   0 z^2 z^2 z^2]
    [  0   0   0   0 z^2   1]
    [  0   0   0   0   0   1],

    [  0   0   0   0   0   1]
    [  0   0   0   0   1   0]
    [  0   0   1   1   0   0]
    [  0   0   0   z   0   0]
    [  0   0   0   0   0   0]
    [  0   0   0   0   0   0]
]
```

Given a group G which acts on a vector space V over a finite field F with an automorphism $F \to F : a \mapsto \overline{a}$ of order 2, the space of G-invariant sesquilinear forms is isomorphic to the space of G-invariant semilinear maps from V to V^*; equivalently it is isomorphic to $\mathrm{Hom}_G(V, \overline{V}^*)$, where $\overline{V}^*$ is the semilinear dual of V, namely the space of all semilinear maps from V to F.

If $\theta \in \mathrm{Hom}_G(V, \overline{V}^*)$, the corresponding sesquilinear form β is defined by $\beta(u, v) = \langle v, u\theta \rangle$ where, as before, $\langle v, \varphi \rangle$ denotes the action of φ on v.

`SemilinearDual(M, mu)`

The semilinear dual of the G-module M with respect to the field automorphism `mu`.

`InvariantSesquilinearForms(G)`

A basis for the space of *hermitian* forms preserved by the matrix group G.

Example H29E22

Let F_0 be the fixed field of the involution. The set $\mathcal{H}$ of G-invariant hermitian forms is a vector space over F_0 and if the characteristic of F is not 2, then $\mathrm{Hom}_G(V, \overline{V}^*) \simeq \mathcal{H} \otimes_{F_0} F$.

```
> F<x> := GF(5,2);
> mu := hom< F->F | x :-> x^5 >;
> H := MatrixGroup< 5, F |
>    [ 0, x^3, 0, 1, x^9, x^8, 1, 0, x^11, x^7, x^20, x^16, 1,
>     x^11, x^3, x^21, 4, 1, x^3, x^23, x^4, x^3, x, x^3, 2 ] >;
> M := GModule(H);
> D := SemilinearDual(M,mu);
> E := AHom(M,D);
> Dimension(E);
```

```
5
> herm := InvariantSesquilinearForms(H);
> #herm;
5
```

Example H29E23

If an irreducible group preserves both a bilinear and a sesquilinear form then it is realisable over a subfield of its base field. Conversely, this observation can be used to construct an example:

```
> F<x> := GF(81);
> H := MatrixGroup< 4, F | [ChangeRing(g,F) : g in Generators(Sp(4,9))]>;
> InvariantBilinearForms(H);
[]
[
    [   0    0    0    1]
    [   0    0    1    0]
    [   0    2    0    0]
    [   2    0    0    0]
]
> InvariantSesquilinearForms(H);
[
    [   0    0    0 x^45]
    [   0    0 x^45    0]
    [   0  x^5    0    0]
    [ x^5    0    0    0]
]
```

`InvariantFormBases(G)`

This function returns four sequences: bases for the spaces of symmetric, alternating, hermitian and quadratic forms preserved by the matrix group G.

29.9.1 Semi-invariant Forms

Given a vector space V over a finite field F and a group G which acts on V, a bilinear form $\beta : V \times V \to F$ is *semi-invariant* if for all $g \in G$ there is a scalar $\lambda(g)$ such that $\beta(ug, vg) = \lambda(g)\beta(u, v)$ for all $u, v \in V$. The function $\lambda : G \to F^\times$ is a homomorphism and its kernel contains the derived group of G. The *twisted dual* V^*_λ of the G-module V is the dual space of V with G-action given by $\langle v, \varphi g\rangle = \lambda(g)\langle vg^{-1}, \varphi\rangle$; thus if A is the matrix of g acting on V the matrix of the action on V^*_λ with respect to the dual basis is $\lambda(g)A^{-\mathrm{tr}}$.

The space of all semi-invariant bilinear forms is isomorphic to $\mathrm{Hom}_G(V, V^*_\lambda)$. The isomorphism associates the form β to $\theta \in \mathrm{Hom}_G(V, V^*_\lambda)$, where $\beta(u, v) = \langle v, u\theta\rangle$.

If β is a bilinear form with matrix J, then the linear transformation g with matrix A preserves the form up to multiplication by $\lambda(g)$ if and only if $AJA^{\mathrm{tr}} = \lambda(g)J$

`TwistedDual(M, lambda)`

The twisted dual of the G-module M with respect to the linear character `lambda`.

`SemiInvariantBilinearForms(G)`

A sequence of triples $\langle L, S, A\rangle$ where L is a sequence of field elements (one for each generator) which define a homomorphism from the matrix group G to its base field and S and A are bases for the spaces of symmetric and alternating forms preserved by G (up to multiplication by scalars).

`SemiInvariantQuadraticForms(G)`

A sequence of pairs $\langle L, Q\rangle$ where L is a sequence of field elements (one for each generator) which define a homomorphism from the matrix group G to its base field and Q is a basis for the space of quadratic forms preserved by G (up to multiplication by scalars).

`TwistedSemilinearDual(M, lambda, mu)`

The twisted semilinear dual of the G-module M with respect to the linear character `lambda` and the field automorphism `mu`.

`SemiInvariantSesquilinearForms(G)`

A sequence of pairs $\langle L, H\rangle$ where L is a sequence of field elements (one for each generator) which define a homomorphism from the matrix group G to the field F_0, where the base field of G is a quadratic extension of F_0, and H is a basis for the space of hermitian forms preserved by G (up to multiplication by scalars).

Example H29E24

In this example H is a normal subgroup of the absolutely irreducible group N an H is irreducible but not absolutely irreducible.

```
> F<x> := GF(3,2);
> H := MatrixGroup<3,F|
>   [x^2,x^7,x^3, x,0,1, x^3,x^6,2],
>   [x^3, 0, 0, 0, x^3, 0, 0, 0, x^3 ] >;
> N := MatrixGroup<3,F|H.1,H.2,[x^5,x^5,2, 0,x^2,x^6, x^7,x^7,2]>;
> IsNormal(N,H);
true
> IsIrreducible(H), IsAbsolutelyIrreducible(H);
true false
> IsIrreducible(N), IsAbsolutelyIrreducible(N);
true true
> SemiInvariantSesquilinearForms(H);
[
    <[ 1, 2 ],
    [
        [  1   x   x]
        [x^3   0 x^3]
        [x^3   x   1],
```

```
        [  0 x^3   x]
        [  x   0 x^5]
        [x^3 x^7   0],

        [  0   0   1]
        [  0   1   0]
        [  1   0   0]
    ]>
]
> SemiInvariantSesquilinearForms(N);
[
    <[ 1, 2, 1 ],
    [
        [  0   0   1]
        [  0   1   0]
        [  1   0   0]
    ]>
]
```

PART V
LATTICES AND QUADRATIC FORMS

30 LATTICES

Chapter 30
LATTICES

30.1 Introduction

Lattices play an important role in various areas, e.g., representation theory, coding theory, geometry and algebraic number theory.

A lattice in MAGMA is a free $\mathbf{Z}$-module contained in $\mathbf{Q}^n$ or $\mathbf{R}^n$, together with a positive definite inner product having image in $\mathbf{Q}$ or $\mathbf{R}$. The information specifying a lattice is a basis, given by a sequence of elements in $\mathbf{Q}^n$ or $\mathbf{R}^n$, and a bilinear product $(\cdot, \cdot)$, given by $(v, w) = vMw^{tr}$ for a positive definite matrix M.

Central to the lattice machinery in MAGMA is a fast implementation of the *Lenstra-Lenstra-Lovász lattice reduction* algorithm [LLL82]. The Lenstra-Lenstra-Lovász algorithm (LLL for short) takes a basis of a lattice and returns a new basis of the lattice which is *LLL-reduced* which usually means that the vectors of the new basis have small norms. The MAGMA algorithm is based on both the floating-point LLL algorithm of Nguyen and Stehlé [NS09] and the exact integral algorithm as described by de Weger in [dW87], but includes many optimisations, with particular attention to different kinds of input matrices. The algorithm can operate on either a basis matrix or a Gram matrix and can be controlled by many parameters (selection of methods, LLL reduction constants, step and time limits, etc.).

For each lattice, a LLL-reduced basis for the lattice is computed and stored internally when necessary and subsequently used for many operations. This gives maximum efficiency for the operations, yet all the operations are presented using the external ("user") basis of the lattice. Lattices are thus a more efficient alternative to R-spaces where R is the integer ring $\mathbf{Z}$ since lattices use a LLL-reduced form of the basis matrix extensively instead of the Hermite form of a basis matrix used by R-spaces which may have very large entries.

Another important component of the lattice machinery is a very efficient algorithm for enumerating all vectors of a lattice with norms in a given range. This algorithm is used for computing the minimum, the shortest vectors, vectors up to a chosen length, and vectors close to or closest to a given vector (possibly) outside a lattice.

Several interesting lattices are directly accessible inside MAGMA using standard constructions (e.g., root lattices and preimages of linear codes). Additionally, an interface has been provided to convert lattices in the database of G. Nebe and N.J.A. Sloane [NS01a] into MAGMA format.

30.2 Presentation of Lattices

A lattice in MAGMA is a free **Z**-module of rank m inside $\mathbf{Z}^n$, $\mathbf{Q}^n$, or $\mathbf{R}^n$, where $m \leq n$. We call m the rank or dimension of the lattice and n its degree. A lattice with $m = n$ is called a *full* lattice. There are two pieces of information which completely determine a lattice L: the basis matrix B and the inner product matrix M. M is always a positive definite matrix (i.e., a matrix M such that $vMv^{tr} > 0$ for all non-zero vectors $v \in \mathbf{R}^n$).

All other information associated with a lattice L is derived from B and M. For example, the inner product $(\cdot, \cdot)$ for L is given by $(v, w) = vMw^{tr}$ and thus the Gram matrix F for L giving the inner products of the basis vectors is BMB^{tr}.

Lattices differ from R-spaces in that a lattice is always a **Z**-module even if entries of some elements of the lattice are not integers. For R-spaces the base ring R affects the module structure but for lattices the "base ring" R is just defined to be the smallest ring over which the basis and inner product matrices can be represented. MAGMA basically has two kinds of lattices: *exact* lattices for which all of the entries of B and M (and thus F) lie in either **Z** or **Q**, and *non-exact* lattices for which all of the entries of B and M (and thus F) lie in a particular approximate real field **R**.

For exact lattices, the "base ring" R may be **Z** or **Q** as mentioned above so that elements are represented over R, but otherwise there is nothing in the lattice which distinguishes between the **Z** and **Q** cases. When exact lattices are printed, the basis matrix B is presented uniquely as an integral matrix divided by a minimal positive integral denominator. The inner product matrix M is presented similarly. This tends to be a more natural presentation which reflects the **Z**-module structure. Another useful feature of this presentation is that the inner product can be efficiently defined to be the identity matrix divided by an appropriate integral scale factor. In this way, the basis can be kept rational while still obtaining an integral primitive Gram matrix (a matrix with integral entries which are coprime), thus avoiding the need for rescaling the basis by an irrational square root. This method is followed in the construction of special lattices provided within MAGMA.

For non-exact lattices, the basis matrix B is simply presented as it is represented over the ring R which is an approximate real field. Some operations applicable for exact lattices are not possible for non-exact lattices. Thus if in the description of a function below it is said that the function can only be applied to an exact lattice it means that the function cannot be applied to a lattice over an approximate real field.

Two lattices are said to be *compatible* if their inner product matrices are equal. Many operations on lattices assume that their arguments are compatible. Intuitively, two lattices and their elements are not comparable if their inner product matrices are different.

Associated with a lattice L is its coordinate lattice L' which has the standard basis (i.e., its basis matrix is the identity matrix) but has the same Gram matrix as L. Some operations, e.g., automorphism group, always work with the coordinates of elements of the lattice, so it is necessary to move to the coordinate lattice.

The category of lattices is `Lat`.

30.3 Creation of Lattices

Lattices can be created in elementary ways whereby the basis matrix or a generating matrix and possibly also the inner product matrix are specified. MAGMA also provides functions for creating lattices from linear codes or algebraic number fields and for creating some special lattices.

30.3.1 Elementary Creation of Lattices

This subsection describes the elementary ways of creating lattices by supplying the basis or the Gram matrix.

There are two ways of specifying the basis of a lattice at creation. First, a generating matrix can be specified whose rows need not be independent; the matrix is reduced to a LLL-reduced form and zero rows are removed to yield a basis matrix. Secondly, a basis matrix (with independent rows) can be specified; this matrix is used for the basis matrix without any changes being made to it. As well as the basis, a particular inner product can also be specified by a symmetric positive definite matrix. By default (when a particular inner product matrix is not given), the inner product is taken to be the standard Euclidean product.

Instead of giving the basis one can also define a lattice by its Gram matrix F which prescribes the inner products of the basis vectors. The basis is taken to be the standard basis and the inner product matrix is taken as F so that the Gram matrix for the lattice is also F.

```
Lattice(X, M)
```

```
Lattice(n, Q, M)
```

```
Lattice(S, M)
```

`CheckPositive` BOOLELT *Default :* `true`

Construct the lattice L specified by the given generating matrix and with inner product given by the $n \times n$ matrix M. The generating matrix can be specified by an $r \times n$ matrix X, an integer n with a sequence Q of ring elements of length rn (interpreted as a $r \times n$ matrix), or an R-space S of dimension r and degree n. In each case, the generating matrix need not have independent rows (though it always will in the R-space case). The matrix is reduced to a LLL-reduced form and zero rows are removed to yield a basis matrix B of rank m (so $m \leq r$). The lattice L is then constructed to have rank m, degree n, basis matrix B and inner product matrix M. By default MAGMA checks that M is positive definite but by setting `CheckPositive := false` this check will be suppressed. (Unpredictable behaviour will follow if unchecked incorrect input is given.)

```
Lattice(X)
```

```
Lattice(n, Q)
```

```
Lattice(S)
```

Construct the lattice L specified by the given generating matrix and with standard Euclidean inner product. The generating matrix can be specified by an $r \times n$ matrix X, an integer n with a sequence Q of ring elements of length rn (interpreted as a $r \times n$ matrix), or an R-space S of dimension r and degree n. In each case, the generating matrix need not have independent rows (though it always will in the R-space case). The matrix is reduced to a LLL-reduced form and zero rows are removed to yield a basis matrix B of rank m (so $m \leq r$). The lattice L is then constructed to have rank m, degree n, basis matrix B and standard Euclidean inner product.

`LatticeWithBasis(B, M)`

`LatticeWithBasis(n, Q, M)`

`LatticeWithBasis(S, M)`

`CheckIndependent`	BoolElt	*Default :* `true`
`CheckPositive`	BoolElt	*Default :* `true`

Construct the lattice L with the specified $m \times n$ basis matrix and with inner product given by the $n \times n$ matrix M. The basis matrix B can be specified by an $m \times n$ matrix B, an integer n with a sequence Q of ring elements of length mn (interpreted as an $m \times n$ matrix B), or an R-space S of dimension m and degree n (whose basis matrix is taken to be B). The rows of B must be independent (i.e., form a basis). The lattice L is then constructed to have rank m, degree n, basis matrix B and inner product matrix M. (Note that the basis matrix B is *not* reduced to a LLL-reduced form as in the `Lattice` function.) By default Magma checks that the rows of the matrix B specifying the basis are independent but by setting `CheckIndependent := false` this check will be suppressed. By default Magma also checks that M is positive definite but by setting `CheckPositive := false` this check will be suppressed. (Unpredictable behaviour will follow if unchecked incorrect input is given.)

`LatticeWithBasis(B)`

`LatticeWithBasis(n, Q)`

`LatticeWithBasis(S)`

`CheckIndependent`	BoolElt	*Default :* `true`

Construct the lattice L with the specified $m \times n$ basis matrix and with standard Euclidean inner product. The basis matrix B can be specified by an $m \times n$ matrix B, an integer n with a sequence Q of ring elements of length mn (interpreted as an $m \times n$ matrix B), or an R-space S of dimension m and degree n (whose basis matrix is taken to be B). The rows of B must be independent (i.e., form a basis). The lattice L is then constructed to have rank m, degree n, basis matrix B and standard Euclidean product. (Note that the basis matrix B is *not* reduced to a LLL-reduced form as in the `Lattice` function.) By default Magma checks that the rows of the matrix B specifying the basis are independent but by setting `CheckIndependent`

`:= false` this check will be suppressed. (Unpredictable behaviour will follow if unchecked incorrect input is given.)

`LatticeWithGram(F)`

`LatticeWithGram(n, Q)`

`CheckPositive` BOOLELT *Default :* `true`

Construct a lattice with the given Gram matrix. The Gram matrix F can be specified as a symmetric $n \times n$ matrix F, or an integer n and a sequence Q of ring elements of length n^2 or $\binom{n+1}{2}$. In the latter case, a sequence of length n^2 is regarded as an $n \times n$ matrix and a sequence of length $\binom{n+1}{2}$ as a lower triangular matrix determining a symmetric matrix F.

This function constructs the lattice L of degree n having the standard basis and inner product matrix F, therefore having Gram matrix F as well. By default MAGMA checks that F is positive definite but by setting `CheckPositive := false` this check will be suppressed. (Unpredictable behaviour will follow if unchecked incorrect input is given.)

`StandardLattice(n)`

Create the standard lattice $\mathbf{Z}^n$ with standard Euclidean inner product.

`CoordinateLattice(L)`

Constructs the lattice with the same Gram matrix as the lattice L, but with basis equal to the canonical basis of the free module of Rank(L) over the base ring of L. The identification of basis elements thus determines an isometry of lattices.

`ScaledLattice(L,n)`

Constructs the coordinate lattice with Gram matrix equal to that of the lattice L scaled by the integer or rational n. The identification of basis elements thus determines an similitude of lattices.

Example H30E1

We create the lattice in $\mathbf{Z}^3$ of degree 3 and rank 2 generated by the vectors $(1, 2, 3)$ and $(3, 2, 1)$ in four different ways. The first two (identical) lattices are represented by LLL-reduced bases since the `Lattice` function is used to create them, while the latter two (identical) lattices remain represented by the original basis since the `LatticeWithBasis` function is used to create them.

```
> B := RMatrixSpace(IntegerRing(), 2, 3) ! [1,2,3, 3,2,1];
> B;
[1 2 3]
[3 2 1]
> L1 := Lattice(B);
> L1;
Lattice of rank 2 and degree 3
Basis:
( 2  0 -2)
```

```
( 1  2  3)
> L2 := Lattice(3, [1,2,3, 3,2,1]);
> L2 eq L1;
true
> L3 := LatticeWithBasis(B);
> L3;
Lattice of rank 2 and degree 3
Basis:
(1 2 3)
(3 2 1)
> L4 := LatticeWithBasis(3, [1,2,3, 3,2,1]);
> L4 eq L3, L1 eq L3;
true true
```

We next create a 3×3 positive definite matrix M and create the lattice L with basis the same as above but also with inner product matrix M. We note the Gram matrix of the lattice which equals BMB^{tr} where B is the basis matrix.

```
> B := RMatrixSpace(IntegerRing(), 2, 3) ! [1,2,3, 3,2,1];
> M := MatrixRing(IntegerRing(), 3) ! [3,-1,1, -1,3,1, 1,1,3];
> M;
[ 3 -1  1]
[-1  3  1]
[ 1  1  3]
> IsPositiveDefinite(M);
true
> L := LatticeWithBasis(B, M);
> L;
Lattice of rank 2 and degree 3
Basis:
(1 2 3)
(3 2 1)
Inner Product Matrix:
[ 3 -1  1]
[-1  3  1]
[ 1  1  3]
> GramMatrix(L);
[56 40]
[40 40]
```

Finally, we create a lattice C with the same Gram matrix as the last lattice, but with standard basis. To do this we use the `LatticeWithGram` function. This lattice C is the *coordinate* lattice of L: it has the same Gram matrix as L but is not compatible with L since its inner product matrix is different to that of L.

```
> F := MatrixRing(IntegerRing(), 2) ! [56,40, 40,40];
> C := LatticeWithGram(F);
> C;
Standard Lattice of rank 2 and degree 2
Inner Product Matrix:
```

```
[56 40]
[40 40]
> GramMatrix(C);
[56 40]
[40 40]
> C eq CoordinateLattice(L);
true
> GramMatrix(C) eq GramMatrix(L);
true
>  C eq L;
Runtime error in 'eq': Arguments are not compatible
```

30.3.2 Lattices from Linear Codes

This subsection presents some standard constructions (known as constructions 'A' and 'B') to obtain lattices from linear codes. In some cases the structural invariants of these lattices (e.g., minimum and kissing number, hence the centre density) can be deduced from invariants of the codes; in general one still gets estimates for the invariants of the lattices.

`Lattice(C, "A")`

Let C be a linear code of length n over a prime field $K := \mathbf{F}_p$. Construct the lattice $L \subseteq \mathbf{Z}^n$ which is the full preimage of C under the natural epimorphism from $\mathbf{Z}^n$ onto K^n.

`Lattice(C, "B")`

Let C be a linear code of length n over a prime field $K := \mathbf{F}_p$ such that all code words have coordinate sum 0. Construct the lattice $L \subseteq \mathbf{Z}^n$ which consists of all vectors reducing modulo p to a code word in C and whose coordinate sum is 0 modulo p^2. The inner product matrix is set to the appropriate scalar matrix so that the Gram matrix is integral and primitive (its entries are coprime).

Example H30E2

The 16-dimensional Barnes-Wall lattice Λ_{16} can be constructed from the first order Reed-Muller code of length 16 using construction 'B'. Note that the inner product matrix is the identity matrix divided by 2 so that the Gram matrix is integral and primitive.

```
> C := ReedMullerCode(1, 4);
> C: Minimal;
[16, 5, 8] Reed-Muller Code (r = 1, m = 4) over GF(2)
> L := Lattice(C, "B");
> L;
Lattice of rank 16 and degree 16
Basis:
(1 0 0 1 0 1 1 0 0 1 1 0 1 0 0 1)
(0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1)
```

```
(0 0 1 1 0 0 1 1 0 0 1 1 0 0 1 1)
(0 0 0 2 0 0 0 0 0 0 0 0 0 0 0 2)
(0 0 0 0 1 1 1 1 0 0 0 0 1 1 1 1)
(0 0 0 0 0 2 0 0 0 0 0 0 0 0 0 2)
(0 0 0 0 0 0 2 0 0 0 0 0 0 0 0 2)
(0 0 0 0 0 0 0 2 0 0 0 0 0 0 0 2)
(0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1)
(0 0 0 0 0 0 0 0 0 2 0 0 0 0 0 2)
(0 0 0 0 0 0 0 0 0 0 2 0 0 0 0 2)
(0 0 0 0 0 0 0 0 0 0 0 2 0 0 0 2)
(0 0 0 0 0 0 0 0 0 0 0 0 2 0 0 2)
(0 0 0 0 0 0 0 0 0 0 0 0 0 2 0 2)
(0 0 0 0 0 0 0 0 0 0 0 0 0 0 2 2)
(0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 4)
Inner Product denominator: 2
```

30.3.3 Lattices from Algebraic Number Fields

Let K be an algebraic number field of degree n over $\mathbf{Q}$. Then K has n embeddings into the complex numbers, denoted by $\sigma_1, \ldots, \sigma_n$. By convention the first s of these are embeddings into the real numbers and the last $2t$ are pairs of complex embeddings such that $\sigma_{s+t+i} = \overline{\sigma_{s+i}}$ for $1 \le i \le t$. The T_2-norm $K \to \mathbf{R} : \alpha \mapsto \sum_{i=1}^{n} |\sigma_i(\alpha)|^2$ defines a positive definite norm on K in which an order or ideal is a positive definite lattice. We restrict to the r real embeddings and the first s complex embeddings to obtain an embedding of a rank n order or ideal $\mathbf{R}^s \times \mathbf{C}^s = \mathbf{R}^n$. By rescaling the complex coordinates by $\sqrt{2}$, we recover the T_2-norm of the element as its Euclidean norm under the embedding in $\mathbf{R}^n$. This embedding, given by

$$\alpha \mapsto \Big(\sigma_1(\alpha), \ldots, \sigma_s(\alpha), \sqrt{2}\,\mathrm{Re}(\sigma_{s+1}(\alpha)), \sqrt{2}\,\mathrm{Im}(\sigma_{s+1}(\alpha)), \ldots, \sqrt{2}\,\mathrm{Im}(\sigma_{s+t}(\alpha))\Big)\,,$$

is called the *Minkowski map* on K.

`MinkowskiLattice(O)`

`Lattice(O)`

Given an order O in a number field of degree n, create the lattice L in $\mathbf{R}^n$ generated by the images of the basis of O under the Minkowski map, followed by the isomorphism $O \to L$.

`MinkowskiLattice(I)`

`Lattice(I)`

Given an ideal I of an order O in a number field of degree n, create the lattice in $\mathbf{R}^n$ generated by the images of the basis of I under the Minkowski map, followed by the isomorphism $O \to L$.

`MinkowskiSpace(K)`

Construct the real inner product space V defined with respect to the inner product matrix of the T_2-norm on the number field K, followed by the Minkowski map $K \to V$.

Example H30E3

In this example we create the lattice corresponding to the equation order of the number field $\mathbf{Q}(\sqrt[3]{15})$. For comparison we apply the Minkowski map to the elements of the basis for the order.

```
> P<x> := PolynomialRing(Integers());
> R := EquationOrder(NumberField(x^3-15));
> w := R![0,1,0];
> L, f := MinkowskiLattice(R);
> L;
Lattice of rank 3 and degree 3 over Real Field
Basis:
Lattice of rank 3 and degree 3 over Real field of precision 30
Basis:
(1.0000000000000000000000000000 1.4142135623730950488016887242l
    0.0000000000000000000000000000)
(2.4662120743304701014916113231 5 -1.7438752816032172007962969421 6
    3.0204805898002556568833586998 8)
(6.0822019955734001848984449977 4 -4.3007662756163029791484373981 2
    -7.4491457008462102763572729513 9)
> B := Basis(R);
> f(B[2]);
> f(B[2]);
(2.4662120743304701014916113231 5 -1.7438752816032172007962969421 6
    3.0204805898002556568833586998 8)
```

Similarly, we create the lattice defined by the ideal generated by $w^2 + 1$, and verify the that the T_2-norm, given by `Length` on the number field, agrees with the norm of the lattice image.

```
> I := ideal< R | w^2+1 >;
> L, f := Lattice(I);
> B := Basis(I);
> [ Length(B[k]) : k in [1..3] ];
[ 113.97954334487115456712250954195650692309680189826241920804543

30.3.4 Special Lattices

This subsection presents functions to construct some special lattices, namely root lattices, laminated lattices and Kappa-lattices.

A much wider variety of lattices can be found in a database provided by G. Nebe and N.J.A. Sloane at the web-site [NS01a]. These lattices can easily be made accessible to MAGMA by a conversion script also available at this web-site. The database currently contains (at least):

- The root lattices A_n and their duals for $1 \leq n \leq 24$
- The root lattices D_n and their duals for $1 \leq n \leq 24$
- The root lattices E_n and their duals for $6 \leq n \leq 8$
- The laminated lattices Λ_n for $1 \leq n \leq 24$ including the 16-dimensional Barnes-Wall lattice Λ_{16} and the Leech lattice Λ_{24}
- The Kappa-lattices K_n and their duals for $7 \leq n \leq 13$ including the Coxeter-Todd lattice K_{12}
- The perfect lattices up to dimension 7
- The 3-dimensional Bravais lattices
- Various interesting lattices in dimensions 20, 24, 28, 32, 40, 80, 105 including, e.g., some of the densest known lattices in dimension 32.

`Lattice(X, n)`

Given a family name X as a string which is one of `"A"`, `"B"`, `"C"`, `"D"`, `"E"`, `"F"`, `"G"`, `"Kappa"` or `"Lambda"`, together with an integer n, construct a lattice subject to the following specifications:

`A`: The root lattice A_n which is the zero-sum lattice in $\mathbf{Q}^{n+1}$.

`B`: $n \geq 2$: The root lattice B_n which is the standard lattice of dimension n.

`C`: $n \geq 3$: The root lattice C_n which is the even sublattice of $\mathbf{Z}^n$ and is equal to D_n.

`D`: $n \geq 3$: The root lattice D_n which is the even sublattice of $\mathbf{Z}^n$, also called the checkerboard lattice.

`E`: $6 \leq n \leq 8$: The root lattice E_n, also called Gosset lattice.

`F`: $n = 4$: The root lattice F_4 which is equal to D_4.

`G`: $n = 2$: The root lattice G_2 which is equal to A_2.

`Kappa`: $1 \leq n \leq 13$: The Kappa-lattice K_n. For $n = 12$ this is the Coxeter-Todd lattice.

`Lambda`: $1 \leq n \leq 31$: The laminated lattice Λ_n. For $n = 16$ this is the Barnes-Wall lattice, for $n = 24$ the Leech lattice.

To avoid irrational entries, each lattice is presented with inner product matrix taken to be the identity matrix divided by a suitable scale factor so that the Gram matrix is integral and primitive (its entries are coprime).

30.4 Lattice Elements

The following functions allow basic operations on elements of lattices. The elements of lattices are simply (row) vectors, just as for R-spaces. Most of the operations for R-space elements are also applicable to lattice elements.

30.4.1 Creation of Lattice Elements

`L . i`

Return the i-th basis element of the current basis of the lattice L.

`L ! Q`

`elt< L | Q >`

Given a lattice L of degree n and a sequence Q of length n, create the lattice element with the corresponding sequence elements as entries. The sequence must consist of elements coercible into the base ring of L. The resulting vector must lie within L.

`CoordinatesToElement(L, C)`

`Coordelt(L, C)`

Given a lattice L of rank m and a sequence or vector $C = [c_1, \ldots, c_m]$ of length m of *integers*, create the lattice element $c_1 \cdot b_1 + \ldots + c_m \cdot b_m$, where $[b_1, \ldots, b_m]$ is the basis of L.

`L ! 0`

`Zero(L)`

Return the zero element of the lattice L.

30.4.2 Operations on Lattice Elements

`-v`

Given an element v in a lattice L, return its negation $-v$ in L.

`v + w`

Given elements v and w in a lattice L, return the sum $v + w$ in L.

`v - w`

Given elements v and w in a lattice L, return the difference $v - w$ in L.

`v * s`
`s * v`

Given an element v in a lattice L and a scalar s of the ring S, return the product $s \cdot v$ (scalar multiplication of v by s). If s is an integer, the resulting vector will lie in L; otherwise the resulting vector will lie in the R-space of the appropriate degree whose coefficient ring is the parent S of s.

`v / s`

Given an element v in a lattice L and a scalar s of the ring S, return the product $(1/s) \cdot v$ (scalar multiplication of v by $1/s$). The resulting vector will always lie in the R-space of the appropriate degree whose coefficient ring is the field of fractions of the parent S of s.

`v div d`

Given an element v in a lattice L and an *integer* d, return the vector $(1/d) \cdot v$ (scalar multiplication of v by $1/d$) as an element of L if the scaled vector lies in L. If the scaled vector does not lie in L, an error ensues. Note that this is different from v/d.

`v +:= w`

(Assignment statement.) Replace lattice element v by the sum $v + w$.

`v -:= w`

(Assignment statement.) Replace lattice element v by the difference $v - w$.

`v *:= n`

(Assignment statement.) Replace lattice element v by the scalar product $n \cdot v$, where n is an integer.

`v * T`

Given an element v in a lattice L of degree n, return the result of multiplying v from the right by the $n \times n$ matrix T. The matrix T may be any matrix which is n by n and over the base ring of L. The resulting product must lie in the lattice L.

`InnerProduct(v, w)`
`(v, w)`

Given elements v and w of a lattice L, return their inner product (v, w) with respect to the inner product of L. This is vMw^{tr} where M is the inner product matrix of L.

`Norm(v)`

Given an element v of a lattice L, return its norm (v, v) with respect to the inner product of L. This is vMv^{tr} where M is the inner product matrix of L. Note that in the case of a lattice with standard Euclidean inner product this is the square of the usual Euclidean length.

`Length(v, K)`

`Length(v)`

Given an element v of a lattice L, return its length $\sqrt{(v,v)}$ with respect to the inner product of L as an element of the real field K. This is $\sqrt{vMv^{tr}}$ where M is the inner product matrix of L. The argument for the real field K may be omitted, in which case K is taken to be the current default real field. In the case of a lattice with standard Euclidean inner product this is the usual Euclidean length.

`Support(v)`

Given an element v of a lattice L, return its support, i.e., the numbers of the columns at which v has non-zero entries.

30.4.3 Predicates and Boolean Operations

`v in L`

Given an element v of a lattice which is compatible with the lattice L, return `true` if and only if v is in L.

`v eq w`

Given elements v and w of a lattice L, return `true` if and only if lattice elements v and w of lattice L are equal.

`v ne w`

Given elements v and w of a lattice L, return `false` if and only if lattice elements v and w of lattice L are equal.

`IsZero(v)`

Given an element v of a lattice L, return `true` if and only if v is the zero element L.

30.4.4 Access Operations

`ElementToSequence(v)`

`Eltseq(v)`

Given an element v of a lattice L of degree n, return the sequence of entries of v of length n.

`Coordinates(v)`

Given an element v of a lattice L having $\mathbf{Z}$-basis $[b_1, \ldots, b_m]$, return a sequence $[c_1, \ldots, c_m]$ of elements of $\mathbf{Z}$ giving the (unique) coordinates of v relative to the $\mathbf{Z}$-basis, so that $v = c_1 \cdot b_1 + \ldots + c_m \cdot b_m$.

`Coordinates(L, v)`

Given a lattice L of degree n having $\mathbf{Z}$-basis $[b_1, \ldots, b_m]$, together with an element v of a lattice L' (also of degree n), return a sequence $[c_1, \ldots, c_m]$ of elements of $\mathbf{Z}$ giving the (unique) coordinates of v relative to the $\mathbf{Z}$-basis of L, so that $v = c_1 \cdot b_1 + \ldots + c_m \cdot b_m$.

`CoordinateVector(v)`

Given an element v of a lattice L having $\mathbf{Z}$-basis $[b_1, \ldots, b_m]$, return the vector $c = (c_1, \ldots, c_m)$ of the coordinate lattice C of L (see the function `CoordinateLattice`) giving the (unique) coordinates of v relative to the $\mathbf{Z}$-basis, so that $v = c_1 \cdot b_1 + \ldots + c_m \cdot b_m$.

`CoordinateVector(L, v)`

Given a lattice L of degree n having $\mathbf{Z}$-basis $[b_1, \ldots, b_m]$, together with an element v of a lattice L' (also of degree n), return the vector $c = (c_1, \ldots, c_m)$ of the coordinate lattice C of L (see the function `CoordinateLattice`) giving the (unique) coordinates of v relative to the $\mathbf{Z}$-basis of L, so that $v = c_1 \cdot b_1 + \ldots + c_m \cdot b_m$.

Example H30E4

This example demonstrates simple uses of the operations on lattice elements.

```
> L := LatticeWithBasis(3, [1,0,0, 1,2,3, 3,6,2]);
> L;
Lattice of rank 3 and degree 3
Basis:
(1 0 0)
(1 2 3)
(3 6 2)
> Coordelt(L, [1, 2, 1]);
( 6 10  8)
> v := L.2;
> w := L ! [2, 4, 6];
> Eltseq(v);
[ 1, 2, 3 ]
> Coordinates(w);
[ 0, 2, 0 ]
> Coordelt(L, [1, 1, 1]);
(5 8 5)
> Norm(v);
14
> InnerProduct(v, w);
28
> A := MatrixRing(Integers(), 3);
> X := A ! [0,-1,0, 1,0,0, 0,1,2];
> X;
[ 0 -1  0]
```

```
[ 1  0  0]
[ 0  1  2]
> u := L.1 + L.3;
> Determinant(X);
2
> Norm(u);
56
> u * X;
( 6 -2  4)
> Norm(u * X);
56
```

30.5 Properties of Lattices

The following functions provide access to the elementary attributes and properties of lattices. Other attributes and invariants of a lattice, e.g., successive minimum, kissing number, and theta series are described in subsequent sections.

30.5.1 Associated Structures

`AmbientSpace(L)`

The ambient rational or real vector space in which the lattice L embeds, followed by the embedding map.

`CoordinateSpace(L)`

The ambient vector space of the coordinate lattice, i.e., the vector space of dimension equal to the rank of the lattice L, with inner product matrix equal to the Gram matrix of L. The embedding map is returned as the second return value.

`Category(L)`

`Type(L)`

Returns the category `Lat` of lattices.

30.5.2 Attributes of Lattices

`Dimension(L)`

`Rank(L)`

Return the rank of the lattice L, which equals the number of basis elements in L. Note that the rank of the lattice may be smaller than its degree n, which is the dimension of the real space $\mathbf{R}^n$ in which L is defined.

`Degree(L)`

Return the degree of the lattice L, which is the dimension n of the real space $\mathbf{R}^n$ in which L is defined.

`Degree(v)`

Return the degree of the lattice element v, which the degree of the lattice to which it belongs.

`Content(L)`

Given an exact lattice L, return the largest rational number c such that $(u, v) \in c\mathbf{Z}$ for all $u, v \in L$.

`Level(L)`

Given an integral lattice L, return the smallest integer k such that $k(v, v) \in 2\mathbf{Z}$ for all v in the dual of L.

`Determinant(L)`

Returns the determinant of the lattice L, which is defined to be the determinant of the Gram matrix F of L. For a full rank lattice the square root of `Determinant(L)` is the volume of a fundamental parallelotope of the lattice.

`GramMatrix(L)`

Return the Gram matrix for the lattice L of rank m, which is the $m \times m$ matrix $F = BMB^{tr}$, where B is the basis matrix of L and M is the inner product matrix of L. Thus the (i, j)-th entry of F equals the inner product of the basis vectors b_i and b_j of L.

`GramMatrix(X)`

Given a matrix X, return XX^{tr}. Note that this function will take half the time as would be taken for the invocation `X*Transpose(X)` since the symmetry of the result is taken advantage of.

`InnerProductMatrix(L)`

The inner product matrix M of the lattice L, which is an $n \times n$ matrix, where n is the degree of L. If L has the standard Euclidean product, M is the identity matrix.

`Basis(L)`

Return the basis of the lattice L as a sequence $[b_1, \ldots, b_m]$ of elements of L.

`BasisMatrix(L)`

Return the $m \times n$ matrix having the basis elements of L as rows, where m is the rank and n the degree of L. The coefficient ring of the matrix is the same as the base ring of L.

`BasisDenominator(L)`

Given an exact lattice L, return the common denominator of the entries of the current basis of L.

`QuadraticForm(L)`

The quadratic form of the lattice L as a multivariate polynomial.

30.5.3 Predicates and Booleans on Lattices

`L eq M`

Given lattices L and M, return `true` if and only if the lattices have the same basis matrix and inner product matrix.

`L ne M`

The logical negation of `eq`.

`L subset M`

Return `true` if and only if L is a sublattice of M, i.e., both L and M are lattices, and L is a subset of M.

`IsExact(L)`

Return `true` if and only if L is an exact lattice, i.e., the coefficient ring of L is $\mathbf{Z}$ or $\mathbf{Q}$ and $(v, w) \in \mathbf{Q}$ for all $v, w \in L$.

`IsIntegral(L)`

Return `true` if and only if L is an integral lattice, i.e., if and only if $(v, w) \in \mathbf{Z}$ for all $v, w \in L$.

`IsEven(L)`

Return `true` if and only if L is an even lattice, i.e., if and only if L is integral and $(v, v) \in 2\mathbf{Z}$ for all $v \in L$.

30.5.4 Base Ring and Base Change

`BaseRing(L)`

`CoefficientRing(L)`

Return the base ring of the lattice L, which is the ring over which the elements of L are represented. Note that lattices are always **Z**-modules even if the base ring is not **Z**; the base ring R is just defined to be the smallest ring over which the basis and inner product matrices can be represented. See the section on presentation of lattices at the beginning of the chapter for further discussion.

`CoordinateRing(L)`

Return the ring of coordinate coefficients for the lattice L. This currently will always return the integer ring **Z**.

`ChangeRing(L, S)`

`BaseChange(L, S)`

`BaseExtend(L, S)`

Given a lattice L, return the lattice L' obtained from coercing the entries of the basis and of the matrix for the inner product into the ring S, together with the homomorphism from L to L'. This will result in an error if any of the entries is not coercible into S. This function is only really useful for moving between real fields of varying precision (it is unnecessary and ineffectual to change a lattice from **Z** to **Q**; see the section on presentation of lattices).

30.6 Construction of New Lattices

30.6.1 Sub- and Superlattices and Quotients

`sub< L | S >`

Given a lattice L and a list S, construct the sublattice L' of L generated by the elements specified by the list S. Each term S_i of the list S must be an expression defining an object of one of the following types:

(a) an element of L or coercible into L,

(b) a set or sequence of elements coercible into L,

(c) a sublattice of L,

(d) a set or sequence of sublattices of L.

The constructor returns the sublattice L' and the inclusion homomorphism from L' into L.

`ext< L | S >`

Given a lattice L lying inside $V = \mathbf{R}^n$ and a list S, construct the superlattice L' of L generated by L together with the elements specified by the list S. Each term S_i of the list S must be an expression defining an object of one of the following types:

(a) an element of V or coercible into V,

(b) a set or sequence of elements coercible into V,

(c) a sublattice of V,

(d) a set or sequence of sublattices of V.

The constructor returns the superlattice L' and the inclusion homomorphism from L into L'.

`T * L`

Given a lattice L of rank m and an $l \times m$ integer matrix, construct the sublattice of L defined by the transformation matrix T, i.e., the lattice generated by the rows of the matrix obtained by multiplying the basis matrix of L from the left by T. The resulting lattice will have rank less than or equal to l.

`s * L`
`L * s`

Given a lattice L and a scalar s, construct the sublattice or superlattice of L obtained by multiplying the basis matrix of L by the scalar s.

`L / s`

Given a lattice L and a scalar s, construct the sublattice or superlattice of L obtained by multiplying the basis matrix of L by the scalar $1/s$.

`quo< L | S >`

Given a lattice L and a list S, construct the quotient L/L', where L' is the sublattice of L generated by the elements of the list S. The elements of S must be the same as for the `sub<>` constructor. The quotient $Q := L/L'$ is constructed as an abelian group. As a second value the function returns the natural epimorphism $L \to Q$.

`L / S`

Given two lattices L and S such that S is a sublattice of L, construct the quotient $Q := L/S$ as an abelian group. As a second value the function returns the natural epimorphism $L \to Q$.

`Index(L, S)`

Given a lattice L and a sublattice S of L, return the index of S in L. This is the cardinality of the quotient L/S. If the index is infinite, zero is returned.

Example H30E5

We demonstrate simple uses of the `sub-`, `ext-` and `quo`-constructors.

```
> L := LatticeWithBasis(4, [1,2,3,4, 0,1,1,1, 0,1,3,5]);
> L;
Lattice of rank 3 and degree 4
Basis:
(1 2 3 4)
(0 1 1 1)
(0 1 3 5)
> E := ext<L | [1,0,0,0]>;
> E;
Lattice of rank 3 and degree 4
Basis:
( 1  0  0  0)
( 0  1  0 -1)
( 0  1  1  1)
> Index(E, L);
2
> Q, f := quo<E | L>;
> Q;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*Q.1 = 0
> f(E.1);
Q.1
```

30.6.2 Standard Constructions of New Lattices

The functions in this section enable one to construct new lattices from old ones using standard operations. Note that the functions will preserve the basis matrices of their arguments if possible (e.g., `DirectSum`), but if this is not possible the basis of the resulting lattice will be LLL-reduced (e.g., +, `meet`).

`Dual(L)`

`Rescale` BoolElt *Default :* `true`

Let L be a lattice in $\mathbf{R}^n$ and let $V := \mathbf{R} \otimes_{\mathbf{Z}} L$ be the real vector space generated by L. Then the dual lattice $L^{\#}$ of L is defined by $L^{\#} := \{v \in V | (v, l) \in \mathbf{Z}\ \forall l \in L\}$. For an integral lattice L one always has $L \subseteq L^{\#}$. This function returns a rescaled version L' of the dual $L^{\#}$ by default so that the basis of L' is LLL-reduced and L' is an integral lattice and its Gram matrix is primitive (its entries are coprime). By setting the parameter `Rescale` to `false`, the rescaling can be suppressed and the proper dual lattice is returned.

`PartialDual(L, n)`

`Rescale` BoolElt *Default :* `true`

Given an integral lattice L and a positive integer n that divides the exponent e of the `DualQuotient` group of L, this function computes the nth partial dual of L. This is defined by pulling back $(e/n) \cdot g$ for generators g of the `DualQuotient` and intersecting with the lattice itself.

`DualBasisLattice(L)`

Let L be a lattice in $\mathbf{R}^n$ and let $V := \mathbf{R} \otimes_{\mathbf{Z}} L$ be the real vector space generated by L, then $L^{\#} := \{v \in V | (v, l) \in \mathbf{Z}\ \forall l \in L\}$ is the dual lattice of L. Let B be the basis matrix of L, M the inner product matrix of L, and F the Gram matrix of L. This function returns the dual $L^{\#}$ as the lattice with basis matrix $F^{-1}B$ and inner product matrix M (so that its Gram matrix is F^{-1}).

`DualQuotient(L)`

Given an integral lattice L, construct the dual quotient Q of L, which is defined to be the finite abelian group $L^{\#}/L$ of order `Determinant(L)`, where $L^{\#}$ is the unscaled dual lattice of L (the lattice returned by `Dual` with the `Rescale` parameter set to `false`). This function returns three values:

(a) The dual quotient Q.

(b) The unscaled dual lattice $L^{\#}$.

(c) The natural epimorphism $\phi : L^{\#} \to Q$ whose kernel is L.

`EvenSublattice(L)`

Given an integral lattice L, construct its maximal even sublattice together with the natural embedding into L.

Example H30E6

```
> L := Lattice(LatticeDatabase(), 541);
> Dimension(L);
29
> IsEven(L);
true
> IsEven(Dual(L));
false;
> G := DualQuotient(L);
> Exponent(G);
8
> Factorization(Determinant(L));
[ <2, 31> ]
> PartialDual(L,1) eq L;
true
> Factorization(Determinant(PartialDual(L, 2)));
```

```
[ <2, 54> ]
> Factorization(Determinant(PartialDual(L, 4)));
[ <2, 73> ]
> Factorization(Determinant(PartialDual(L, 8)));
[ <2, 56> ]
> Factorization(Determinant(Dual(L)));
[ <2, 56> ]
```

`L + M`

Given compatible lattices L and M, construct the lattice generated by their union.

`L meet M`

Given compatible lattices L and M, construct their intersection $L \cap M$.

`DirectSum(L, M)`

`OrthogonalSum(L, M)`

Given lattices L and M, construct their orthogonal sum which is their direct sum with inner product being the orthogonal sum of the inner products of L and M.

`OrthogonalDecomposition(L)`

Given a lattice L, construct the sequence of indecomposable orthogonal summands composing L. Additional bilinear forms can be given in F. In this case the decomposition will be orthogonal wrt. these forms as well.

`OrthogonalDecomposition(F)`

`Optimize` BoolElt *Default :* `false`

Given a sequence of bilinear forms F, where the first form is positive definite, returns the basis matrices $B_1, \ldots, B_s$ of the indecomposable orthogonal summands of the standard lattice $\mathbf{Z}^n$ wrt. the forms in F. The second return value is a list of s sequences. The i-th sequence contains the forms of F wrt. to basis described by B_i. If `Optimize` is set, then the basis matrices will be LLL reduced wrt. the first form in F.

`TensorProduct(L, M)`

Given two lattices L and M, construct their tensor product with inner product given by the Kronecker product of the matrices defining the inner products of L and M.

`ExteriorSquare(L)`

Given a lattice L, construct its exterior square, generated by the skew tensors in $L \otimes L$. The inner product is inherited from the inner product of the tensor square of the vector space containing L and the exterior square lattice lies inside the tensor square of the lattice.

`SymmetricSquare(L)`

Given a lattice L, construct its symmetric square, generated by the symmetric tensors in $L \otimes L$. The inner product is inherited from the inner product of the tensor square of the vector space containing L and the symmetric square lattice lies inside the tensor square of the lattice.

`PureLattice(L)`

Given a lattice L of degree n with integral or rational entries, return the pure lattice $P = (\mathbf{Q} \otimes L) \cap \mathbf{Z}^n$ of L. The pure lattice P generates the same subspace in $\mathbf{Q}^n$ over $\mathbf{Q}$ that L does but the elementary divisors of its basis matrix are trivial.

`IntegralBasisLattice(L)`

Given an exact lattice L, return the lattice obtained from L by multiplying the basis by the smallest positive scalar S so that the resulting basis is integral, and S.

30.7 Reduction of Matrices and Lattices

The functions in this section perform reduction of lattice bases. For each reduction algorithm there are three functions: a function which takes a basis matrix, a function which takes a Gram matrix and a function which takes a lattice.

30.7.1 LLL Reduction

The Lenstra-Lenstra-Lovász algorithm [LLL82] was first described in 1982 and was immediately used by the authors to provide a polynomial-time algorithm for factoring integer polynomials, for solving simultaneous diophantine equations and for solving the integer programming problem. It very quickly received much attention and in the last 25 years has found an incredible range of applications, in such areas as computer algebra, cryptography, optimisation, algorithmic number theory, group theory, etc. However, the original LLL algorithm is mainly of theoretical interest, since, although it has polynomial time complexity, it remains quite slow in practice. Rather, floating-point variants are used, where the underlying Gram-Schmidt orthogonalisation is performed with floating-point arithmetic instead of rational arithmetic (which produces huge numerators and denominators). Most of these floating-point variants are heuristic, but here we use the provable Nguyen-Stehlé algorithm [NS09] (see also [Ste09] for more details about the implementation).

Let $\delta \in (1/4, 1]$ and $\eta \in [1/2, \sqrt{\delta})$. An ordered set of d linearly independent vectors $b_1, b_2, \ldots, b_d \in \mathbf{R}^n$ is said to be (δ, η)-LLL-reduced if the two following conditions are satisfied:

(a) For any $i > j$, we have $|\mu_{i,j}| \leq \eta$,

(b) For any $i < d$, we have $\delta \|b_i^*\|^2 \leq \|b_{i+1}^* + \mu_{i+1,i} b_{i+1}^*\|^2$,

where $\mu_{i,j} = (b_i, b_j^*)/\|b_j^*\|^2$ and b_i^* is the i-th vector of the Gram-Schmidt orthogonalisation of $(b_1, b_2, \ldots, b_d)$. LLL-reduction classically refers to the case where $\eta = 1/2$ and $\delta = 3/4$ since it was the choice of parameters originally made in [LLL82], but the closer that η

and δ are to $1/2$ and 1, respectively, the more reduced the lattice basis should be. In the classical LLL algorithm, the polynomial-time complexity is guaranteed as long as $\delta < 1$, whereas the floating-point LLL additionally requires that $\eta > 1/2$.

A (δ, η)-LLL-reduced basis $(b_1, b_2, \ldots, b_d)$ of a lattice L has the following useful properties:

(a) $\|b_1\| \leq \left(\delta - \eta^2\right)^{-(d-1)/4} (\det L)^{1/d}$,

(b) $\|b_1\| \leq (\delta - \eta^2)^{-(d-1)/2} \min_{b \in L \setminus \{0\}} \|b\|$,

(c) $\prod_{i=1}^{d} \|b_i\| \leq (\delta - \eta^2)^{-d(d-1)/4} (\det L)$,

(d) For any $j < i$, $\|b_j^*\| \leq (\delta - \eta^2)^{(j-i)/2} \|b_i^*\|$.

The default Magma parameters are $\delta = 0.75$ and $\eta = 0.501$, so that $(\delta - \eta^2)^{-1/4} < 1.190$ and $(\delta - \eta^2)^{-1/2} < 1.416$. The four previous bounds can be reached, but in practice one usually obtains better bases. It is possible to obtain lattice bases satisfying these four conditions without being LLL-reduced, by using the so-called Siegel condition [Akh02]; this useful variant, though available, is not the default one.

Internally, the LLL routine may use up to eight different LLL variants, one of them being de Weger's exact integer method [dW87], and the seven others relying upon diverse kinds of floating-point arithmetic. All but one of these variants are heuristic and implement diverse ideas from [SE94], Victor Shoup's NTL [Sho] and [NS06]. The heuristic variants possibly loop forever, but when that happens it is hopefully detected and a more reliable variant is used. For a given input, the LLL routine tries to find out which variant should be the fastest, and may eventually call other variants before the end of the execution: either because it deems that the current variant loops forever or that a faster variant could be used with the thus-far reduced basis. This machinery remains unknown to the user (except when the LLL verbose mode is activated) and makes the Magma LLL routine the fastest currently available, with the additional advantage of being fairly reliable.

The floating-point variants essentially differ on the two following points:

(a) whether or not the matrix basis computations are performed with the help of a complete knowledge of the Gram matrix of the vectors (the matrix of the pairwise inner products),

(b) the underlying floating-point arithmetic.

In theory, to get a provable variant, one needs the Gram matrix and arbitrary precision floating-point numbers (as provided by the MPFR-based [Pro] Magma real numbers). In practice, to get an efficient variant, it is not desirable not to maintain the exact knowledge of the Gram matrix (maintaining the Gram matrix represents asymptotically a large constant fraction of the total computational cost), while it is desirable to use the machine processor floating-point arithmetic (for instance, C doubles). Three of the seven variants use the Gram matrix, while the four others do not. In each group (either the three or the remaining four), one variant relies on arbitrary precision floating-point arithmetic, another on C doubles and another on what we call doubles with extended exponent. These last variants are important because they are almost as fast as the variants based on C doubles, and can be used for much wider families of inputs: when the initial basis is made of integers larger than approximately 500 bits, overflows can occur with the C doubles. To be

precise, a "double with extended exponent" is a C double with a C integer, the last one being the extended exponent. So far, we have described six variants. The seventh does not rely on the Gram matrix and is based on an idea similar to "doubles with extended exponents". The difference is that for a given vector of dimension n, instead of having n pairs of doubles and integers, one has n doubles and only one integer: the extended exponent is "factorised". This variant is quite often the one to use in practice, because it is reasonably efficient and not too unreliable.

Important warning. By default, the `LLL` routine is entirely reliable. This implies the default provable variant can be *much* slower than the heuristic one. By setting `Proof` to `false`, a significant run-time improvement can be gained without taking much risk: even in that case, the `LLL` routine remains more reliable than any other implementation based on floating-point arithmetic. For any application where guaranteed LLL-reduction is not needed, we recommend setting `Proof` to `false`.

Recommended usage. The formal description of the function `LLL` below explains all the parameters in detail, but we first note here some common situations which arise. The desired variant of LLL is often not the default one. Since the LLL algorithm is used in many different contexts and with different output requirements, it seems impossible to define a natural default variant, and so using the LLL routine efficiently often requires some tuning. Here we consider three main-stream situations.

- It may be desired to obtain the main LLL inequalities (see the introduction of this subsection), without paying much attention to the δ and η reduction parameters. In this case one should activate the `Fast` parameter, possibly with the verbose mode to know afterwards which parameters have been used.
- It may be desired to have the main LLL inequalities for a given pair of parameters (δ, η). In this case one should set the parameters `Delta` and `Eta` to the desired values, and set `SwappingCondition` to `"Siegel"`.
- It may be desired to compute a very well LLL-reduced basis. In this case one should set `Delta` to 0.9999, `Eta` to 0.5001, and possibly also activate the `DeepInsertion` option.

In any case, if you want to be absolutely sure of the quality of the output, you need to keep the `Proof` option activated.

Example H30E7

This example is meant to show the differences between the three main recommended usages above. Assume that we are interested in the lattice generated by the rows of the matrix B defined as follows.

```
> R:=RealField(5);
> B:=RMatrixSpace(IntegerRing(), 50, 51) ! 0;
> for i := 1 to 50 do B[i][1] := RandomBits(10000); end for;
> for i := 1 to 50 do B[i][i+1] := 1; end for;
```

The matrix B is made of 100 vectors of length 101. Each entry of the first column is approximately 10000 bits long. Suppose first that we use the default variant.

```
> time C:=LLL(B:Proof:=false);
```

```
Time: 11.300
> R!(Norm (C[1]));
5.1959E121
```

The output basis is $(0.75, 0.501)$-reduced. Suppose now that we only wanted to have a basis that satisfies the main LLL properties with $\delta = 0.75$ and $\eta = 0.501$. Then we could have used the Siegel swapping condition.

```
> time C:=LLL(B:Proof:=false, SwapCondition:="Siegel");
Time: 10.740
> R!(Norm (C[1]));
6.6311E122
```

Notice that the quality of the output is quite often worse with the Siegel condition than with the Lovász condition, but the main LLL properties are satisfied anyway. Suppose now that we want a very well reduced basis. Then we fix δ and η close to 1 and 0.5 respectively.

```
> time C:=LLL(B:Proof:=false, Delta:=0.9999, Eta:=0.5001);
Time: 19.220
> R!(Norm (C[1]));
1.8056E121
```

This is of course more expensive, but the first output vector is significantly shorter. Finally, suppose that we only wanted to "shorten" the entries of the input basis, very efficiently and without any particular preference for the reduction factors δ and η. Then we could have used the `Fast` option, that tries to choose such parameters in order to optimize the running-time.

```
> time C:=LLL(B:Proof:=false, Fast:=1);
Time: 8.500
> R!(Norm (C[1]));
6.2746E121
```

By activating the verbose mode, one can know for which parameters the output basis is reduced.

```
> SetVerbose ("LLL", 1);
> C:=LLL(B:Proof:=false, Fast:=1);
[...]
The output basis is (0.830,0.670)-reduced
```

`LLL(X)`

`Al`	MonStgElt	*Default :* "*New*"
`Proof`	BoolElt	*Default :* `true`
`Method`	MonStgElt	*Default :* "*FP*"
`Delta`	RngElt	*Default :* 0.75
`Eta`	RngElt	*Default :* 0.501
`InitialSort`	BoolElt	*Default :* `false`
`FinalSort`	BoolElt	*Default :* `false`

`StepLimit`	RngIntElt	*Default :* 0
`TimeLimit`	RngElt	*Default :* 0.0
`NormLimit`	RngIntElt	*Default :*
`UseGram`	BoolElt	*Default :* `false`
`DeepInsertions`	BoolElt	*Default :* `false`
`EarlyReduction`	BoolElt	*Default :* `false`
`SwapCondition`	MonStgElt	*Default :* "*Lovasz*"
`Fast`	RngIntElt	*Default :* 0
`Weight`	SeqEnum	*Default :* $[0, \ldots, 0]$

Given a matrix X belonging to the matrix module $S = \mathrm{Hom}_R(M, N)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, compute a matrix Y whose non-zero rows are a LLL-reduced basis for the **Z**-lattice spanned by the rows of X (which need not be **Z**-linearly independent). The LLL function returns three values:

(a) A LLL-reduced matrix Y in S whose rows span the same lattice (**Z**-module) as that spanned by the rows of X.

(b) A unimodular matrix T in the matrix ring over **Z** whose degree is the number of rows of X such that $TX = Y$;

(c) The rank of X.

Note that the returned transformation matrix T is *always* over the ring of integers **Z**, even if R is not **Z**.

The input matrix X does not need to have linearly independent rows: this function performs a floating-point variant of what is usually known as the MLLL algorithm of M. Pohst [Poh87]. By default the rows of the returned matrix Y are sorted so that all the zero rows are at the bottom. The non-zero vectors are sorted so that they form a LLL-reduced basis (except when `FinalSort` is `true`; see below).

A detailed description of the parameters now follows. See the discussion and the example above this function for recommended parameters for common cases.

By default, the `Proof` option is set to `true`. It means that the result is guaranteed. It is possible, and usually faster, to switch off this option: it will perform the same calculations, without checking that the output is indeed reduced by using the L^2 algorithm. For the vast majority of cases, we recommend setting `Proof` to `false`.

By default the δ and η constants used in the LLL conditions are set respectively to 0.75 and 0.501 (except when `Method` is `"Integral"`, see below). The closer δ and η are to 1 and 0.5, respectively, the shorter the output basis will be. In the original description of the LLL algorithm, δ is 0.75 and η is 0.5. Making δ and η vary can have a significant influence on the running time. If `Method` is `"Integral"`, then by default η is set to 0.5 and δ to 0.99. With this value of `Method`, the parameter δ can be chosen arbitrarily in $(0.25, 1]$, but when δ is 1, the running time

may increase dramatically. If `Method` is not `"Integral"`, then δ may be chosen arbitrarily in $(0.25, 1)$, and η may be chosen arbitrarily in $(0.5, \sqrt{\delta})$. Notice that the parameters δ and η used internally will be slightly larger and smaller than the given ones, respectively, to take floating-point inaccuracies into account and to ensure that the output basis will indeed be reduced for the expected parameters. In all cases, the output basis will be (δ, η)-LLL reduced.

For matrices over $\mathbf{Z}$ or $\mathbf{Q}$, there are two main methods for handling the Gram-Schmidt orthogonalisation variables used in the algorithm: the Nguyen-Stehlé floating-point method (called L^2) and the exact integral method described by de Weger in [dW87]. The Nguyen-Stehlé algorithm is implemented as described in the article, along with a few faster heuristic variants. When `Method` is `"FP"`, these faster variants will be tried first, and when they are considered as misbehaving, they will be followed by the proved variant automatically. When `Method` is `"L2"`, the provable L^2 algorithm is used directly. Finally, when `Method` is `"Integral"`, the De Weger integral method is used. In this case, the `DeepInsertions`, `EarlyReduction`, `Siegel SwapCondition`, `NormLimit`, `Fast` and `Weight` options are unavailable (the code is older and has not been updated for these). Furthermore, the default value for `Eta` is then 0.5. The default `FP` method is nearly always *very* much faster than the other two methods.

By default, it is possible (though it happens very infrequently) that the returned basis is not of the expected quality. In order to be sure that the output is indeed correct, `Method` can be set to either `"Integral"` or `"L2"`.

The parameter `InitialSort` specifies whether the vectors should be sorted by length before the LLL reduction. When `FinalSort` is `true`, the vectors are sorted by increasing length (and alphabetical order in case of equality) after the LLL reduction (this parameter was called `Sort` before V2.13). The resulting vectors may therefore not be strictly LLL-reduced, because of the permutation of the rows.

The parameter `UseGram` specifies that for the floating-point methods (`L2` and `FP`) the computation should be performed by computing the Gram matrix F, using the `LLLGram` algorithm below, and by updating the basis matrix correspondingly. MAGMA will automatically do this internally for the floating-point method if it deems that it is more efficient to do so, so this parameter just allows one to stipulate that this method should or should not be used. For the integral method, using the Gram matrix never improves the computation, so the value of this parameter is simply ignored in this case.

Setting the parameter `StepLimit` to a positive integer s will cause the function to terminate after s steps of the main loop. Setting the parameter `TimeLimit` to a positive real number t will cause the function to terminate after the algorithm has been executed for t seconds (process user) time. Similarly, setting the parameter `NormLimit` to a non-negative integer N will cause the algorithm to terminate after a vector of norm less or equal to N has been found. In such cases, the current reduced basis is returned, together with the appropriate transformation matrix and an upper bound for the rank of the matrix. Nothing precise can then be said exactly about the reduced basis (it will not be LLL-reduced in general of course) but will at least

be reduced to a certain extent.

When the value of the parameter `DeepInsertions` is `true`, Schnorr-Euchner's deep insertion algorithm is used [SE94]. It usually provides better bases, but can take significantly more time. In practice, one may first LLL-reduce the basis and then use the deep insertion algorithm on the computed basis.

When the parameter `EarlyReduction` is `true` and when any of the two floating-point methods are used, some early reduction steps are inserted inside the execution of the LLL algorithm. This sometimes makes the entries of the basis smaller very quickly. It occurs in particular for lattice bases built from minimal polynomial or integer relation detection problems. The speed-up is sometimes dramatic, especially if the reduction in length makes it possible to use C integers for the basis matrix (instead of multiprecision integers) or C doubles for the floating-point calculations (instead of multiprecision floating-point numbers or doubles with additional exponent).

The parameter `SwapCondition` can be set either to `"Lovasz"` (default) or to `"Siegel"`. When its value is `"Lovasz"`, the classical Lovász swapping condition is used, whereas otherwise the so-called *Siegel* condition is used. The Lovász condition tests whether the inequality $\|b_i^* + \mu_{i,i-1} b_{i-1}^*\|^2 \geq \delta \|b_{i-1}^*\|^2$ is satisfied or not, whereas in the Siegel case the inequality $\|b_i^*\|^2 \geq (\delta - \eta^2)\|b_{i-1}^*\|^2$ is used (see [Akh02] for more details). In the Siegel case, the execution may be significantly faster. Though the output basis may not be LLL-reduced, the classical LLL inequalities (see the introduction of this subsection) will be fulfilled.

When the option `Fast` is set to 1 or 2, all the other parameters may be changed internally to end the execution as fast as possible. Even if the other parameters are not set to the default values, they may be ignored. This includes the parameters `Delta`, `Eta` and `SwapCondition`, so that the output basis may not be LLL-reduced. However, if the verbose mode is activated, the chosen values of these parameters will be printed, so that the classical LLL inequalities (see the introduction of this subsection) may be used afterwards. When `Fast` is set to 2, the chosen parameters are such that the classical LLL inequalities will be at least as strong as for the default parameters `Delta` and`Eta`.

If `Weight` is the list of integers $[x_1, \ldots, x_n]$ (where n is the degree of the lattice), then the LLL algorithm uses a weighted Euclidean inner product: the inner product of the vectors $(v_1, v_2, \ldots, v_n)$ and $(w_1, w_2, \ldots, w_n)$ is defined to be $\sum_{i=1}^{n} \left(v_i \cdot w_i \cdot 2^{2x_i}\right)$.

By default, the `Al` parameter is set to `New`. If it is set to `Old`, then the former MAGMA LLL is used (prior to V2.13); notice that in this case, the execution is not guaranteed to finish and that the output basis may not be reduced for the given LLL parameters. This variant is not maintained anymore.

Note 1: If the input basis has many zero entries, then try to place them in the last columns; this will slightly improve the running time.
Note 2: If the elementary divisors of the input matrix are fairly small, relative to the size of the matrix and the size of its entries, then it may be very much quicker

to reduce the matrix to Hermite form first (using the function `HermiteForm`) and then to LLL-reduce this matrix. This case can arise: for example, when one has a "very messy" matrix for which it is known that the lattice described by it has a relatively short basis.
Note 3: Sometimes, the `EarlyReduction` variant can significantly decrease the running time.

`BasisReduction(X)`

`BasisReduction(X)`

This is a shortcut for `LLL(X:Proof:=false)`.

`LLLGram(F)`

`Isotropic` BoolElt *Default :* `false`

Given a symmetric matrix F belonging to the the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, so that $F = XX^{tr}$ for some matrix X over the real field, compute a matrix G which is the Gram matrix corresponding to a LLL-reduced form of the matrix X. The rows of the corresponding generator matrix X need not be **Z**-linearly independent in which case F will be singular. This function returns three values:

(a) A LLL-reduced Gram matrix G in S of the Gram matrix F;

(b) A unimodular matrix T in the matrix ring over **Z** whose degree is the number of rows of F such that $G = TFT^{tr}$.

(c) The rank of F (which equals the dimension of the lattice generated by X).

The options available are the same as for the `LLL` routine, except of course the `UseGram` option that has no sense here. The `Weight` parameter should not be used either. The routine can be used with any symmetric matrix (possibly not definite nor positive): Simon's indefinite LLL variant (which puts absolute values on the Lovász condition) is used (see [Sim05]).

When the option `Isotropic` is true, some attempt to deal with isotropic vectors is made. (This is only relevant when working on an indefinite Gram matrix). In particular, if the determinant is squarefree, hyperbolic planes are split off iteratively.

`LLLBasisMatrix(L)`

Given a lattice L with basis matrix B, return *the LLL basis matrix* B' of L, together with the transformation matrix T such that $B' = TB$. The LLL basis matrix B' is simply defined to be a LLL-reduced form of B; it is stored in L when computed and subsequently used internally by many lattice functions. The LLL basis matrix will be created automatically internally as needed with $\delta = 0.999$ by default (note that this is different from the usual default of 0.75); by the use of parameters to this function one can ensure that the LLL basis matrix is created in a way which is different to the default. The parameters (not listed here again) are the same as for the function `LLL` (q.v.), except that the limit parameters are illegal.

`LLLGramMatrix(L)`

Given a lattice L with Gram matrix F, return the *LLL Gram matrix* F' of L, together with the transformation matrix T such that $F' = TFT^{tr}$. F' is simply defined to be $B'(B')^{tr}$, where B' is the LLL basis matrix of L—see the function `LLLBasisMatrix`. The parameters (not listed here again) are the same as for the function `LLL` (q.v.), except that the limit parameters are illegal.

`LLL(L)`

Given a lattice L with basis matrix B, return a new lattice L' with basis matrix B' and a transformation matrix T so that L' is equal to L but B' is LLL-reduced and $B' = TB$. Note that the inner product used in the LLL computation is that given by the inner product matrix of L (so, for example, the resulting basis may not be LLL-reduced with respect to the standard Euclidean norm). The LLL basis matrix of L is used, so calling this function with argument L is completely equivalent (ignoring the second return value) to the invocation `LatticeWithBasis(LLLBasisMatrix(L), InnerProductMatrix(L))`. The parameters (not listed here again) are the same as for the function `LLL` (q.v.), except that the limit parameters are illegal. The `BasisReduction` shortcut to turn off the `Proof` option is also available.

`BasisReduction(L)`

This is a shortcut for `LLL(L:Proof:=false)`.

`SetVerbose("LLL", v)`

(Procedure.) Set the verbose printing level for the LLL algorithm to be v. Currently the legal values for v are `true`, `false`, 0, 1, 2 and 3 (`false` is the same as 0, and `true` is the same as 1). The three non-zero levels notify when the maximum LLL-reduced rank of the LLL algorithm increases, level 2 also prints the norms of the reduced vectors at such points, and level 3 additionally gives some current status information every 15 seconds.

Example H30E8

We demonstrate how the LLL algorithm can be used to find very good multipliers for the extended GCD of a sequence of integers. Given a sequence $Q = [x_1, \ldots, x_n]$ of integers we wish to find the GCD g of Q and integers m_i for $1 \leq i \leq m$ such that $g = m_1 \cdot x_1 + \ldots + m_n \cdot x_m$.
For this example we set Q to a sequence of $n = 10$ integers of varying bit lengths (to make the problem a bit harder).

```
> Q := [ 67015143, 248934363018, 109210, 25590011055, 74631449,
>        10230248, 709487, 68965012139, 972065, 864972271 ];
> n := #Q;
> n;
10
```

We next choose a scale factor S large enough and then create the $n \times (n+1)$ matrix $X = [I_n|C]$ where C is the column vector whose i-th entry is $S \cdot Q[i]$.

```
> S := 100;
```

```
> X := RMatrixSpace(IntegerRing(), n, n + 1) ! 0;
> for i := 1 to n do X[i][i + 1] := 1; end for;
> for i := 1 to n do X[i][1] := S * Q[i]; end for;
> X;
[6701514300     1 0 0 0 0 0 0 0 0 0]
[24893436301800 0 1 0 0 0 0 0 0 0 0]
[10921000       0 0 1 0 0 0 0 0 0 0]
[2559001105500  0 0 0 1 0 0 0 0 0 0]
[7463144900     0 0 0 0 1 0 0 0 0 0]
[1023024800     0 0 0 0 0 1 0 0 0 0]
[70948700       0 0 0 0 0 0 1 0 0 0]
[6896501213900  0 0 0 0 0 0 0 1 0 0]
[97206500       0 0 0 0 0 0 0 0 1 0]
[86497227100    0 0 0 0 0 0 0 0 0 1]
```

Finally, we compute a LLL-reduced form L of X.

```
> L := LLL(X);
> L;
[   0    0    1    0  -15   -6    3    1    2   -3   -3]
[   0   -3    5   -3  -11   -1    0    8  -14    4    3]
[   0   -5   -2    2   -2   14    8   -6    8    1   -4]
[   0    6    1   -3  -10   -3  -14    5    0    8    8]
[   0   -1   -2    0   -2  -13    8    6    8   10   -2]
[   0   -9   -3  -11    5    7   -1    1    9  -11   -2]
[   0   16    0    3    3    9   -3    0   -1   -4  -11]
[   0   -6    1  -16    4   -1    6   -6   -5    7   -7]
[   0    9   -3  -10    7   -3    1   -7    8    0   18]
[-100   -3   -1   13   -1   -4    2    3    4    5   -1]
```

Notice that the large weighting on the first column forces the LLL algorithm to produce as many vectors as possible at the top of the matrix with a zero entry in the first column (since such vectors will have shorter norms than any vector with a non-zero entry in the first column). Thus the GCD of the entries in Q is the entry in the bottom left corner of L divided by S, viz. 1. The last n entries of the last row of L gives a sequence of multipliers M for the extended GCD algorithm. Also, taking the last n entries of each of the first $n-1$ rows of L gives independent null-relations for the entries of Q (i.e., the kernel of the corresponding column matrix). We check that M gives a correct sequence of multipliers.

```
> M := Eltseq(L[10])[2 .. n+1]; M;
[ 3, 1, -13, 1, 4, -2, -3, -4, -5, 1 ]
> &+[Q[i]*M[i]: i in [1 .. n]];
-1
```

30.7.2 Pair Reduction

`PairReduce(X)`

Given a matrix X belonging to the the matrix module $S = \mathrm{Hom}_R(M, N)$ or the matrix algebra $S = M_n(R)$, where R is $\mathbf{Z}$ or $\mathbf{Q}$, compute a matrix Y whose rows form a pairwise reduced basis for the $\mathbf{Z}$-lattice spanned by the rows of X. Being pairwise reduced (i.e., $2|(v, w)| \leq \min(\|v\|, \|w\|)$ for all pairs of basis vectors) is a much simpler criterion than being LLL-reduced, but often yields sufficiently good results very quickly. It can also be used as a preprocessing for LLL or in alternation with LLL to obtain better bases. The rows of X need not be Z-linearly independent. This function returns two values:

(a) The pairwise reduced matrix Y row-equivalent to X as a matrix in S;

(b) A unimodular matrix T in the matrix ring over $\mathbf{Z}$ whose degree is the number of rows of X such that $TX = Y$.

`PairReduceGram(F)`

`Check` BoolElt *Default :* `false`

Given a symmetric positive semidefinite matrix F belonging to the the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is $\mathbf{Z}$ or $\mathbf{Q}$, so that $F = XX^{tr}$ for some matrix X over the real field, compute a matrix G which is the Gram matrix corresponding to a pairwise reduced form of the matrix X. The rows of the corresponding matrix X need not be Z-linearly independent. This function returns two values:

(a) The pairwise reduced Gram matrix G of F as a matrix in S;

(b) A unimodular matrix T in the matrix ring over $\mathbf{Z}$ whose degree is the number of rows of F which gives the corresponding transformation: $G = TFT^{tr}$.

The matrix F must be a symmetric positive semidefinite matrix; if it is not the results are unpredictable. By default, Magma does not check this since it may be expensive in higher dimensions and in many applications will be known a priori. The checking can be invoked by setting `Check := true`.

`PairReduce(L)`

Given a lattice L with basis matrix B, return a new lattice L' with basis matrix B' and a transformation matrix T so that L' is equal to L but B' is pairwise reduced and $B' = TB$. Note that the inner product used in the pairwise reduction computation is that given by the inner product matrix of L (so, for example, the resulting basis may not be pairwise reduced with respect to the standard Euclidean norm).

30.7.3 Seysen Reduction

`Seysen(X)`

Given a matrix X belonging to the the matrix module $S = \mathrm{Hom}_R(M, N)$ or the matrix algebra $S = M_n(R)$, where R is $\mathbf{Z}$ or $\mathbf{Q}$, compute a matrix Y whose rows form a Seysen-reduced basis for the $\mathbf{Z}$-lattice spanned by the rows of X. The rows of X need not be Z-linearly independent. The Seysen-reduced matrix Y is such that the entries of the corresponding Gram matrix $G = YY^{tr}$ and its inverse G^{-1} are simultaneously reduced. This function returns two values:

(a) The Seysen-reduced matrix Y corresponding to X as a matrix in S;

(b) A unimodular matrix T in the matrix ring over $\mathbf{Z}$ whose degree is the number of rows of X such that $TX = Y$.

`SeysenGram(F)`

`Check` BoolElt *Default :* `false`

Given a symmetric positive semidefinite matrix F belonging to the the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is $\mathbf{Z}$ or $\mathbf{Q}$, so that $F = XX^{tr}$ for some matrix X over the real field, compute a matrix G which is the Gram matrix corresponding to a Seysen-reduced form of the matrix X. The rows of the corresponding matrix X need not be Z-linearly independent. The Seysen-reduced Gram matrix G is such that the entries of G and its inverse G^{-1} are simultaneously reduced. This function returns two values:

(a) The Seysen-reduced Gram matrix G of F as a matrix in S;

(b) A unimodular matrix T in the matrix ring over $\mathbf{Z}$ whose degree is the number of rows of F which gives the corresponding transformation: $G = TFT^{tr}$.

The matrix F must be a symmetric positive semidefinite matrix; if it is not the results are unpredictable. By default, Magma does not check this since it may be expensive in higher dimensions and in many applications will be known a priori. The checking can be invoked by setting `Check := true`.

`Seysen(L)`

Given a lattice L with basis matrix B, return a new lattice L' with basis matrix B' and a transformation matrix T so that L' is equal to L but B' is Seysen-reduced and $B' = TB$. Note that the inner product used in the Seysen-reduction computation is that given by the inner product matrix of L (so, for example, the resulting basis may not be Seysen-reduced with respect to the standard Euclidean norm). The effect of the reduction is that the basis of L' and the dual basis of L' will be simultaneously reduced.

Example H30E9

We demonstrate how the function `Seysen` can be used on the Gram matrix of the Leech lattice to obtain a gram matrix S for the lattice so that both S and S^{-1} are simultaneously reduced. Note that all three reduction methods yield a basis of vectors of minimal length, but the Seysen reduction also has a dual basis of vectors of norm 4. This is of interest in representation theory, for example, as the entries of the inverse of the Gram matrix control the size of the entries in a representation on the lattice.

```
> F := GramMatrix(Lattice("Lambda", 24));
> [ F[i][i] : i in [1..24] ];
[ 8, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
> [ (F^-1)[i][i] : i in [1..24] ];
[ 72, 8, 12, 8, 10, 4, 4, 8, 8, 4, 4, 8, 4, 4, 4, 4, 4, 4, 4, 4, 8, 4, 4, 8 ]
> L := LLLGram(F);
> P := PairReduceGram(F);
> S := SeysenGram(F);
> [ L[i][i] : i in [1..24] ];
[ 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
> [ P[i][i] : i in [1..24] ];
[ 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
> [ S[i][i] : i in [1..24] ];
[ 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
> [ (L^-1)[i][i] : i in [1..24] ];
[ 6, 4, 8, 4, 32, 4, 4, 8, 18, 4, 4, 8, 8, 8, 12, 4, 6, 4, 20, 4, 8, 4, 14, 4 ]
> [ (P^-1)[i][i] : i in [1..24] ];
[ 72, 40, 12, 8, 10, 4, 4, 8, 8, 4, 4, 8, 4, 4, 4, 4, 4, 4, 4, 4, 8, 4, 4, 8 ]
> [ (S^-1)[i][i] : i in [1..24] ];
[ 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4 ]
```

30.7.4 HKZ Reduction

An ordered set of d linearly independent vectors $b_1, b_2, \ldots, b_d \in \mathbf{R}^n$ is said to be Hermite-Korkine-Zolotarev-reduced (HKZ-reduced for short) if the three following conditions are satisfied:

(a) For any $i > j$, we have $|\mu_{i,j}| \leq 0.501$,

(b) The vector b_1 is a shortest non-zero vector in the lattice spanned by $b_1, b_2, \ldots, b_d$,

(c) The vectors $b_2 - \mu_{2,1}b_1, \ldots, b_d - \mu_{d,1}b_1$ are themselves HKZ-reduced,

where $\mu_{i,j} = (b_i, b_j^*)/\|b_j^*\|^2$ and b_i^* is the i-th vector of the Gram-Schmidt orthogonalisation of $(b_1, b_2, \ldots, b_d)$.

`HKZ(X)`

`Proof`	BoolElt	*Default :* `true`
`Unique`	BoolElt	*Default :* `false`
`Prune`	SeqEnum	*Default :* $[\ldots, [1.0, \ldots, 1.0], \ldots]$

Given a matrix X over a subring of the real field, compute a matrix Y whose non-zero rows are an HKZ-reduced basis for the **Z**-lattice spanned by the rows of X (which need not be **Z**-linearly independent). The HKZ function returns an HKZ-reduced matrix Y whose rows span the same lattice (**Z**-module) as that spanned by the rows of X, and a unimodular matrix T in the matrix ring over **Z** whose degree is the number of rows of X such that $TX = Y$.

Although the implementation relies on floating-point arithmetic, the result can be guaranteed to be correct. By default, the `Proof` option is set to `true`, thus guaranteeing the output. The run-time might be improved by switching off this option.

A given lattice may have many HKZ-reduced bases. If the `Unique` option is turned on, a uniquely determined HKZ-reduced basis is computed. This basis is chosen so that: for any $i > j$, we have $\mu_{i,j} \in [-1/2, 1/2)$; for any i, the first non-zero coordinate of the vector b_i^* is positive; and for any i, the vector b_i^* is the shortest among possible vectors for the lexicographical order.

The implementation solves the Shortest Vector Problem for lattices of dimensions 1 to d, where d is the number of rows of the input matrix X. The latter instances of the Shortest Vector Problem are solved with the same enumeration algorithm as is used for computing the minimum of a lattice, which can be expressed as a search within a large tree. The i-th table of the `Prune` optional parameter is used to prune the i-dimensional enumeration. The default value is:

$[[1.0 : j \texttt{ in } [1..i]] : i \texttt{ in } [1..\texttt{NumberOfRows}(X)]]$.

See the introduction of Section 30.8 for more details on the `Prune` option.

`HKZGram(F)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[\ldots, [1.0, \ldots, 1.0], \ldots]$

Given a symmetric positive semidefinite matrix F over a subring of the real field so that $F = XX^{tr}$ for some matrix X over the real field, compute a matrix G which is the Gram matrix corresponding to an HKZ-reduced form of the matrix X. The function returns the HKZ-reduced Gram matrix G of F, and a unimodular matrix T in the matrix ring over **Z** whose degree is the number of rows of F which gives the corresponding transformation: $G = TFT^{tr}$.

HKZ(L)

Proof	BoolElt	*Default :* true
Prune	SeqEnum	*Default :* $[\ldots, [1.0, \ldots, 1.0], \ldots]$

Given a lattice L with basis matrix B, return a new lattice L' with basis matrix B' and a transformation matrix T so that L' is equal to L but B' is HKZ-reduced and $B' = TB$.

SetVerbose("HKZ", v)

(Procedure.) Set the verbose printing level for the HKZ algorithm to be v. Currently the legal values for v are true, false, 0 and 1 (false is the same as 0, and true is the same as 1). More information on the progress of the computation can be obtained by setting the "Enum" verbose on.

GaussReduce(X)

GaussReduceGram(F)

GaussReduce(L)

Restrictions of the HKZ functions to lattices of rank 2.

Example H30E10

HKZ-reduced bases are much harder to compute than LLL-reduced bases, but provide a significantly more powerful representation of the spanned lattice. For example, computing all short lattice vectors is more efficient if one starts from an HKZ-reduced basis.

```
> d:=60;
> B:=RMatrixSpace(IntegerRing(), d, d)!0;
> for i:=1 to d do for j:=1 to d do B[i][j]:=Random(100*d); end for; end for;
> time C1 := LLL(B);
Time: 0.020
> time C2 := HKZ(B);
Time: 1.380
> m := Norm(C2[1]);
> time _:=ShortVectors(Lattice(C1), 11/10*m);
Time: 1.750
> time _:=ShortVectors(Lattice(C2), 11/10*m);
Time: 0.850
> time _:=ShortVectors(Lattice(C1), 3/2*m);
Time: 73.800
> time _:=ShortVectors(Lattice(C2), 3/2*m);
Time: 32.220
```

30.7.5 Recovering a Short Basis from Short Lattice Vectors

`ReconstructLatticeBasis(S, B)`

Given a basis S of a finite index sublattice of the lattice L spanned by the rows of the integral matrix B, return a matrix C whose rows span L and are not much longer than those of S. Specifically, the algorithm described in Lemma 7.1 of [MG02] is implemented, and the rows of the output matrix satisfy the following properties:

(a) For any i, $\|c_i\| \leq i^{1/2}\|s_i\|$,

(b) For any i, $\|c_i^*\| \leq \|s_i^*\|$,

where c_i^* (respectively s_i^*) denotes the i-th vector of the Gram-Schmidt orthogonalisation of $(c_1, c_2, \ldots, c_d)$ (respectively $(s_1, s_2, \ldots, s_d)$) .

30.8 Minima and Element Enumeration

The functions in this section are all based on one algorithm which enumerates all vectors of a lattice in a specified hyperball [FP83, Kan83, SE94]. As the underlying computational problems (the Shortest and Closest Lattice Vector Problems) are hard [Ajt98, vEB81], the general application of this algorithm is restricted to lattices of moderate dimension (up to 50 or 60). However, some tasks like finding a couple of short vectors or finding the minimum of a lattice without symmetry may still be feasible in higher dimensions. The function `EnumerationCost` provides an estimate of the cost of running the enumeration algorithm on a specified input. This allows to know beforehand if the computation is likely to terminate within a reasonable amount of time.

For each function which enumerates short vectors of a lattice L, there is a corresponding function which enumerates vectors of L which are close to a given vector w (which usually lies outside L). Note that if one wishes to enumerate short vectors of the coset $L+w$ of the lattice L, where w is any vector of degree compatible with L, one can simply enumerate vectors $v \in L$ close to $-w$ and then just take the vectors $v + w$ for each v as the short vectors of the coset.

The enumeration routine underlying all the functions described below relies on floating-point approximations. However, it can be run in a rigorous way in some cases, see [PS08]. By default, the outputs of the functions `Minimum`, `PackingRadius`, `HermiteNumber`, `CentreDensity`, `Density`, `KissingNumber`, `ShortestVectors`, `ShortestVectorsMatrix`, `ShortVectors`, `ShortVectorsMatrix` and `ThetaSeries` are guaranteed to be correct. This correctness guarantee can be turned off by setting the optional parameter `Proof` to `false`. However, this comes virtually for free, the additional computations being most often negligible. In the present version of Magma, the outputs of all other functions are only likely to be correct.

The enumeration algorithm from [FP83, Kan83, SE94] can be interpreted as a search within a large tree. This can be extremely time-consuming. Schnorr, Euchner and Hörner [SE94, SH95] introduced techniques to prune the latter tree: the correct output might be missed, but the execution of the algorithm is likely to terminate faster. A new pruning strategy is available for the functions `Minimum`, `PackingRadius`, `HermiteNumber`,

`CentreDensity`, `Density`, `KissingNumber`, `ShortestVectors`, `ShortestVectorsMatrix`, `ShortVectors`, `ShortVectorsMatrix` and `ThetaSeries`. Naturally, if the pruning strategy is used, the result cannot be guaranteed to be correct anymore. Let $(b_1, b_2, \ldots, b_d)$ be a basis of a lattice L, let $(b_1^*, b_2^*, \ldots, b_d^*)$ denote its Gram-Schmidt orthogonalisation, and let $\mu_{i,j} = (b_i, b_j^*)/\|b_j^*\|^2$ for $i \geq j$. Suppose we are interested in finding all vectors in L of norm $\leq u$. The enumeration algorithm considers the equations:

$$\| \sum_{j=i}^{d} \left(\sum_{k=j}^{d} \mu_{k,j} x_k \right) b_j^* \|^2 \leq u, \text{ for } i = d, d-1, \ldots, 1,$$

where the x_k's are integers. If the `Prune` optional parameter is set to $[p_1, \ldots, p_d]$, then the equations above will be replaced by:

$$\| \sum_{j=i}^{d} \left(\sum_{k=j}^{d} \mu_{k,j} x_k \right) b_j^* \|^2 \leq p_i u, \text{ for } i = d, d-1, \ldots, 1.$$

The p_i's must belong to the interval $[0, 1]$. For a given input $((b_1, \ldots, b_d), u)$ to the enumeration procedure, it is possible to heuristically estimate both the running-time gain and the probability of missing a solution. See Subsection 30.8.6 for more details.

30.8.1 Minimum, Density and Kissing Number

The functions in this subsection compute invariants of a lattice which are all related to its minimum. See [JC98] for background about minimum, density and kissing numbers.

`Minimum(L)`

`Min(L)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the minimum of the lattice L, i.e., the minimal norm of a non-zero vector in the lattice. Note that this is in general a hard problem and may be very time consuming. See also the attributes section below for how to assert the minimum of a lattice.

`PackingRadius(L)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

The packing radius is half the square root of the minimum of the non-zero lattice L.

`HermiteConstant(n)`

Return the n-th Hermite constant raised to the power of n. The exact value is provided if $n \leq 8$ or $n = 24$, and otherwise an upper bound is returned. The n-th Hermite constant is defined as the maximum of `Min`(L)/`Determinant`(L) over all n-dimensional lattices L.

`HermiteNumber(L)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the Hermite number of the non-zero lattice L, i.e., $\texttt{Min}(L)/\texttt{Determinant}(L)$.

`CentreDensity(L)`
`CenterDensity(L)`
`CentreDensity(L, K)`
`CenterDensity(L, K)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

The center density of the lattice L, as an element of the real field K. This is defined to be the square root of $(\texttt{Min}(L)/4)^{\texttt{Rank(L)}}/\texttt{Determinant(L)}$. The argument for the real field K may be omitted, in which case K is taken to be the current default real field.

The product of the centre density by the volume of a sphere of radius 1 in n-dimensional space gives the density of the lattice-centered sphere packing of L, called the density of the lattice.

`Density(L)`
`Density(L, K)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

The density of the lattice L, as an element of the real field K, i.e., the density of the lattice-centered sphere packing. If the argument for the real field K is omitted, the field K is taken to be the default real field.

`KissingNumber(L)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the kissing number of the lattice L, which equals the number of vectors of minimal non-zero norm (twice the length of the sequence returned by `ShortestVectors(L)` since that returns only normalized vectors). This is the maximum number of nonoverlapping spheres of diameter `Minimum(L)` with centres at lattice points which touch a fixed sphere of the same diameter with centre at a lattice point.

Example H30E11

We create the Leech lattice Λ_{24} and compute its minimum (4), density, and kissing number (196560). Note that the computation of the minimum is very fast since the lattice is even and at least one basis element has norm 4; one has only to prove that there are no vectors of norm 2.

```
> L := Lattice("Lambda", 24);
> IsEven(L), Norm(L.2);
true 4
> time Minimum(L);
4
Time: 0.020
> Density(L);
0.0019295743094039230479033455 6369
> time KissingNumber(L);
196560
Time: 0.180
```

30.8.2 Shortest and Closest Vectors

`ShortestVectors(L)`

`Max`	RngIntElt	*Default :* ∞
`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the shortest non-zero vectors of the lattice L, i.e., the vectors $v \in L$ such that (v, v) is minimal, as a sorted sequence Q. The vectors are computed up to sign (so only one of v and $-v$ appears in Q) and normalized so that the first non-zero entry in each vector is positive, and Q is sorted with respect to lexicographic order. By default, all the (normalized) vectors are computed; the optional parameter `Max` allows the user to specify the maximal number of computed vectors. Note that unless the minimum of the lattice is already known, it has to be computed by this function, which may be very time consuming.

`ShortestVectorsMatrix(L)`

`Max`	RngIntElt	*Default :* ∞
`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the shortest non-zero vectors of the lattice L as the rows of a matrix. This is more efficient or convenient for some applications than forming the sequence of vectors. Note that the matrix will lie in the appropriate matrix space and the inner product for L will not be related to the rows of the matrix (which will lie in the appropriate R-space). By default, all the (normalized) vectors are computed; the optional parameter `Max` allows the user to specify the maximal number of computed vectors.

`ClosestVectors(L, w)`

`Max` RngIntElt *Default :* ∞

Return the vectors of the lattice L which are closest to the vector w, together with the minimal squared distance d. w may be any element of a lattice of degree n or an R-space of degree n compatible with L, where n is the degree of L. The closest vectors are those vectors $v \in L$ such that the squared distance $(v - w, v - w)$ between v and w (and thus the distance between v and w) is minimal; this minimal squared distance is the second return value d. The vectors are returned as a sequence Q, sorted with respect to lexicographic order. Note that the closest vectors are *not* symmetrical with respect to sign (while the shortest vectors are) so the returned closest vectors are not normalized. By default, all the closest vectors are computed; the optional parameter `Max` allows the user to specify the maximal number of computed vectors.

`ClosestVectorsMatrix(L, w)`

`Max` RngIntElt *Default :* ∞

Return the vectors of the lattice L which are closest to the vector w as a matrix, together with the squared distance d. w may be any element of a lattice of degree n or an R-space of degree n compatible with L, where n is the degree of L. Note that the matrix will lie in the appropriate matrix space and the inner product for L will not be related to the rows of the matrix (which will lie in the appropriate R-space). The vectors are returned as sequence Q, sorted with respect to lexicographic order. Note that the closest vectors are *not* symmetrical with respect to sign (while the shortest vectors are) so the returned closest vectors are not normalized. By default, all the closest vectors are computed; the optional parameter `Max` allows the user to specify the maximal number of computed vectors.

Example H30E12

We create the Gosset lattice $L = E_8$ and find the shortest vectors of L. There are 120 normalized vectors so the kissing number is 240, and the minimum is 2.

```
> L := Lattice("E", 8);
> S := ShortestVectors(L);
> #S;
120
> KissingNumber(L);
240
> { Norm(v): v in S };
{ 2 }
> Minimum(L);
2
```

We note that the rank of the space generated by the shortest vectors is 8 so that the successive minima of L are $[2, 2, 2, 2, 2, 2, 2, 2]$ (see the function `SuccessiveMinima` below).

```
> Rank(ShortestVectorsMatrix(L));
```

```
8
```

We next find the vectors in L which are closest to a certain vector in the Q-span of L. The vector is an actual hole of L and the square of its distance from L is $8/9$.

```
> w := RSpace(RationalField(), 8) !
>   [ -1/6, 1/6, -1/2, -1/6, 1/6, -1/2, 1/6, -1/2 ];
> C, d := ClosestVectors(L, w);
> C;
[
    (-1/2 -1/2 -1/2 -1/2  1/2 -1/2  1/2 -1/2),
    (-1/2  1/2 -1/2 -1/2 -1/2 -1/2  1/2 -1/2),
    (-1/2  1/2 -1/2 -1/2  1/2 -1/2 -1/2 -1/2),
    (-1/2  1/2 -1/2  1/2  1/2 -1/2  1/2 -1/2),
    ( 1/2  1/2 -1/2 -1/2  1/2 -1/2  1/2 -1/2),
    ( 0  0 -1  0  0 -1  0  0),
    ( 0  0 -1  0  0  0  0 -1),
    ( 0  0  0  0  0 -1  0 -1),
    (0 0 0 0 0 0 0 0)
]
> d;
8/9
> { Norm(v): v in C };
{ 0, 2 }
```

We verify that the squared distance of the vectors in C from w is $8/9$.

```
> { Norm(v - w): v in C };
{ 8/9 }
```

We finally notice that these closest vectors are in fact amongst the shortest vectors of the lattice (together with the zero vector).

```
> Set(C) subset (Set(S) join {-v: v in S} join { L!0 });
true
```

30.8.3 Short and Close Vectors

`ShortVectors(L, u)`

`ShortVectors(L, l, u)`

`Max`	RngIntElt	*Default :* ∞
`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Return the vectors of the lattice L with norm within the prescribed range, together with their norms, as a sorted sequence Q. The sequence Q contains tuples of the form $< v, r >$ where v is a vector and r its norm. Either one positive number u can be given, specifying the range $(0, u]$, or a pair l, u of positive numbers, specifying the

range $[l, u]$. The vectors are computed up to sign (so only one of v and $-v$ appears in Q) and normalized so that the first non-zero entry in each vector is positive, and Q is sorted with respect to first the norms and then the lexicographic order for the vectors. By default, all the (normalized) vectors with norm in the prescribed range are computed. The optional parameter `Max` allows the user to specify the maximal number of computed vectors.

`ShortVectorsMatrix(L, u)`

`ShortVectorsMatrix(L, l, u)`

`Max`	RngIntElt	*Default :* ∞
`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

This is very similar to `ShortVectors`, but returns the vectors of the lattice L with norm within the prescribed range as the rows of a matrix S rather than as a sequence of tuples. This is more efficient or convenient for some applications than forming the sequence. By default, all the (normalized) vectors with norm in the prescribed range are computed. The optional parameter `Max` allows the user to specify the maximal number of computed vectors. Note that the matrix will lie in the appropriate matrix space and the inner product for L will not be related to the rows of the matrix (which will lie in the appropriate R-space).

`CloseVectors(L, w, u)`

`CloseVectors(L, w, l, u)`

`Max`	RngIntElt	*Default :* ∞

Return the vectors of the lattice L whose squared distance from the vector w is within the prescribed range, together with their squared distances, as a sorted sequence Q. The returned sequence Q contains tuples of the form $< v, d >$ where v is a vector from L and $d = (v - w, v - w)$ is its squared distance from w. w may be any element of a lattice of degree n or an R-space of degree n compatible with L, where n is the degree of L. Either one positive number u can be given, specifying the range $(0, u]$, or a pair l, u of positive numbers, specifying the range $[l, u]$. Note that close vectors are *not* symmetrical with respect to sign (while short vectors are) so the returned close vectors are not normalized. Q is sorted with respect to first the squared distances and then the lexicographic order for the vectors. By default, all the vectors with squared distance in the prescribed range are computed. The optional parameter `Max` allows the user to specify the maximal number of computed vectors.

`CloseVectorsMatrix(L, w, u)`

`CloseVectorsMatrix(L, w, l, u)`

`Max` RngIntElt *Default :* ∞

This is very similar to `CloseVectors`, but returns the vectors of the lattice L whose squared distance from the vector w is within the prescribed range as the rows of a matrix C rather than as a sequence of tuples. This is more efficient or convenient for some applications than forming the sequence. w may be any element of a lattice of degree n or an R-space of degree n compatible with L, where n is the degree of L. By default, all the close vectors are computed. The optional parameter `Max` allows the user to specify the maximal number of computed vectors. Note that the matrix will lie in the appropriate matrix space and the inner product for L will not be related to the rows of the matrix (which will lie in the appropriate R-space).

Example H30E13

Let $Q = [a_1, \ldots, a_n]$ be a sequence of (not necessarily distinct) positive integers and let s be a positive integer. We wish to find all solutions to the equation $\sum_{i=1}^{n} x_i a_i = s$ with $x_i \in \{0, 1\}$. This is known as the *Knapsack* problem. The following lattice-based solution is due to Schnorr and Euchner (op. cit., at the beginning of this chapter). To solve the problem, we create the lattice L of rank $n + 1$ and degree $n + 2$ with the following basis:

$$\begin{aligned} b_1 &= (2, 0, \ldots, 0, na_1, 0) \\ b_2 &= (0, 2, \ldots, 0, na_2, 0) \\ &\vdots \\ b_n &= (0, 0, \ldots, 2, na_n, 0) \\ b_{n+1} &= (1, 1, \ldots, 1, ns, 1). \end{aligned}$$

Then every vector $v = (v_1, \ldots, v_{n+2}) \in L$ such that the norm of v is $n + 1$ and

$$v_1, \ldots, v_n, v_{n+2} \in \{\pm 1\}, v_{n+1} = 0,$$

yields the solution $x_i = |v_i - v_{n+2}|/2$ for $i = 1, \ldots, n$ to the original equation.

We first write a function `KnapsackLattice` which, given the sequence Q and sum s, creates a matrix X representing the above basis and returns the lattice generated by the rows of X. Note that the `Lattice` creation function will automatically LLL-reduce the matrix X as it creates the lattice.

```
> function KnapsackLattice(Q, s)
>     n := #Q;
>     X := RMatrixSpace(IntegerRing(), n + 1, n + 2) ! 0;
>     for i := 1 to n do
>         X[i][i] := 2;
>         X[i][n + 1] := n * Q[i];
>         X[n + 1][i] := 1;
```

```
>     end for;
>     X[n + 1][n + 1] := n * s;
>     X[n + 1][n + 2] := 1;
>     return Lattice(X);
> end function;
```

We next write a function `Solutions` which uses the function `ShortVectors` to enumerate all vectors of the lattice L having norm exactly $n + 1$ and thus to find all solutions to the Knapsack problem associated with L. (Note that the minimum of the lattice may be less than $n + 1$.) The function returns each solution as a sequence of indices for Q.

```
> function KnapsackSolutions(L)
>     n := Rank(L) - 1;
>     M := n + 1;
>     S := ShortVectors(L, M, M);
>     return [
>         [i: i in [1 .. n] | v[i] ne v[n + 2]]: t in S |
>             forall{i: i in [1 .. n] cat [n + 2] | Abs(v[i]) eq 1} and
>                 v[n + 1] eq 0 where v is t[1]
>     ];
> end function;
```

We now apply our functions to a sequence Q of 12 integers each less than 1000 and the sum 2676. There are actually 4 solutions. We verify that each gives the original sum.

```
> Q := [ 52, 218, 755, 221, 574, 593, 172, 771, 183, 810, 437, 137 ];
> s := 2676;
> L := KnapsackLattice(Q, s);
> L;
Lattice of rank 13 and degree 14
Determinant: 1846735827632128
Basis:
( 0  0  0  0 -2  0  0  0  0  0  2  2  0  0)
( 1  1 -1 -1 -1  1 -1 -1 -1  1  1  1  0  1)
( 1 -1 -1 -1 -1  1  1 -1  1  1  1 -1  0  1)
( 1  1  1  1 -3  1  1 -1 -1  1 -1 -1  0  1)
( 1 -1 -3  1  1 -1 -1  1 -1  1  1  1  0  1)
( 2  2  0  0  0 -2  2  2 -2  0 -2  0  0  0)
( 3 -1  1  1 -1  1 -1 -1 -1 -1  1  1  0  1)
( 1 -1  1  1  1  1  3 -1 -1 -1 -1  1  0 -1)
(-1 -1 -1 -1  1  1  1  1 -1 -1 -1  1  0  1)
( 2  0  0  2  0  2  0  0  0  0 -2  0  0 -2)
(-1 -1 -1  1  1 -1 -1  1 -1  1  1 -3  0 -1)
(-1 -1  1 -1 -1  1 -1 -1 -1  3 -1  1  0 -3)
( 0 -2  0  0  2  0 -2  0 -2  0  0  0 12  0)
> S := KnapsackSolutions(L);
> S;
[
    [ 2, 3, 4, 5, 8, 12 ],
    [ 3, 4, 5, 7, 8, 9 ],
```

```
    [ 3, 4, 7, 8, 9, 11, 12 ],
    [ 1, 2, 3, 4, 9, 10, 11 ]
]
> [&+[Q[i]: i in s]: s in S];
[ 2676, 2676, 2676, 2676 ]
```

Finally, we apply our method to a larger example. We let Q be a sequence consisting of 50 random integers in the range $[1, 2^{1000}]$. We let I be a random subset of $\{1 \dots 50\}$ and let s be the sum of the elements of Q indexed by I. We then solve the Knapsack problem with input (Q, s) and this time obtain I as the only answer.

```
> b := 1000;
> n := 50;
> SetSeed(1);
> Q := [Random(1, 2^b): i in [1 .. n]];
> I := { };
> while #I lt n div 2 do
>     Include(~I, Random(1, n));
> end while;
> I := Sort(Setseq(I)); I;
[ 1, 3, 4, 7, 10, 11, 13, 14, 18, 20, 22, 23, 26, 28, 29, 34, 35, 37, 40, 41,
42, 45, 48, 49, 50 ]
> s := &+[Q[i]: i in I]; Ilog2(s);
1003
> time L := KnapsackLattice(Q, s);
Time: 0.570
> [Ilog2(Norm(b)): b in Basis(L)];
[ 5, 46, 46, 45, 47, 47, 46, 46, 46, 46, 46, 46, 46, 45, 47, 46, 46, 46, 46,
47,46, 46, 45, 46, 46, 46, 46, 46, 46, 46, 46, 46, 46, 46, 46, 46, 45, 46, 46,
45, 45, 46, 46, 46, 46, 46, 45, 46, 46, 46, 46, 46 ]
> time KnapsackSolutions(L);
[
    [ 1, 3, 4, 7, 10, 11, 13, 14, 18, 20, 22, 23, 26, 28, 29, 34, 35, 37, 40,
    41, 42, 45, 48, 49, 50 ]
]
Time: 0.040
```

Example H30E14

In this example we demonstrate how short vectors of lattices can be used to split homogeneous components of integral representations. We first define an integral matrix group of degree 8. The group is isomorphic to A_5 and the representation contains the 4-dimensional irreducible representation of A_5 with multiplicity 2.

```
> G := MatrixGroup< 8, Integers() |
>   [ -673,  -291,  -225,  -316,   250,   -32,    70,  -100,
>      252,   274,   349,   272,  -156,   -94,  -296,   218,
>     2532,  1159,   609,  5164, -1450,  -181,   188,   742,
>     -551,   163,   629, -1763,   285,  -162,  -873,   219,
```

```
>    -2701,  -492,   411, -3182,  1062,  -397, -1195,   151,
>    -5018, -1112,  1044,-12958,  2898,  -153, -2870,  -454,
>     2581,    90, -1490,  8197, -1553,   261,  2556,  -149,
>    -3495, -2776, -3218, -2776,  1773,   652,  2459, -1910],
>   [ 2615,  1314,  1633,   400,  -950, -1000, -2480,  1049,
>      161,   159,   347,  -657,     2,  -385,  -889,   230,
>    -2445, -1062, -1147,   269,   744,  1075,  2441,  -795,
>     1591,   925,  1454, -1851,  -350, -1525, -3498,   982,
>    10655,  5587,  7476, -1751, -3514, -5575,-13389,  4873,
>     6271,  3253,  4653, -6126, -1390, -5274,-11904,  3219,
>    -3058, -1749, -2860,  5627,   392,  3730,  8322, -2009,
>     4875,  1851,  1170,  5989, -2239,   625,  1031,   692] >;
> Order(G);
60
```

Since the group is small enough we can generate elements in the endomorphism ring by averaging over the group elements.

```
> M := MatrixRing(Integers(), 8);
> e := [ &+[ M!g * MatrixUnit(M, i, i) * M!(g^-1) : g in G ] : i in [1..4] ];
> E := sub<M | e>;
> Dimension(E);
4
```

We now transform E into a lattice of dimension 4 and degree 64 and rescale the basis vectors so that they have lengths of the same order of magnitude.

```
> L := Lattice(64, &cat[ Eltseq(b) : b in Basis(E) ]);
> LL := sub<L | [ Round( Norm(L.4)/Norm(L.i) ) * L.i : i in [1..4] ]>;
> Minimum(LL);
910870284600
> SV := ShortVectors(LL, 100*Minimum(LL));
> #SV;
46
> Sing := [ X : v in SV | Determinant(X) eq 0 where X is M!Eltseq(v[1]) ];
> #Sing;
3
```

We thus have found three singular elements amongst the 46 shortest vectors and use the kernel of the first of these to get the representation on a subspace of dimension 4.

```
> ker := LLL( KernelMatrix(Sing[1]) );
> ker;
[ 10   0  -9   5  -2   0   5  -4]
[ -3  -4   1 -16   3   5   4  -3]
[ -8 -11 -10  -1   4   0   6  -5]
[-13   3   4  10   1   5   8   2]
> H := MatrixGroup<4, Integers() | [Solution(ker, ker*g) : g in Generators(G)]>;
> H;
MatrixGroup(4, Integer Ring)
Generators:
```

```
    [ 1  0  0  0]
    [-3 -2 -4 -5]
    [-2 -3 -3 -4]
    [ 2  3  4  5]
    [-1 -1 -1 -1]
    [ 2  1  2  2]

30.8.4 Short and Close Vector Processes

`ShortVectorsProcess(L, u)`

`ShortVectorsProcess(L, l, u)`

Given a lattice L and a range, create a corresponding short vectors lattice enumeration process P. This process provides the environment for enumerating each vector $v \in L$ with norm within the range. Either a positive number u can be given, specifying the range $(0, u]$, or a pair l, u of positive numbers, specifying the range $[l, u]$. Successive calls to `NextVector` (see below) will result in the enumeration of the vectors.

`CloseVectorsProcess(L, w, u)`

`CloseVectorsProcess(L, w, l, u)`

Given a lattice L, a vector w and a range, create a corresponding close vectors lattice enumeration process P. This process provides the environment for enumerating each vector $v \in L$ such its squared distance $(v - w, v - w)$ from w is within the range. w may be any element of a lattice of degree n or an R-space of degree n compatible with L, where n is the degree of L. Either a positive number u can be given, specifying the range $(0, u]$, or a pair l, u of positive numbers, specifying the range $[l, u]$. Successive calls to `NextVector` (see below) will result in the enumeration of the vectors.

`NextVector(P)`

Given a lattice enumeration process P as created by `ShortVectorsProcess` or `CloseVectorsProcess`, return the next element found in the enumeration.

If the process is for short vectors, the next short vector of the specified region of the lattice is returned together with its norm, or the zero vector together with -1, indicating that the enumeration process has been completed. The vectors are computed up to sign (so that only one of v and $-v$ will be enumerated) and normalized so that the first non-zero entry in each vector is positive.

If the process is for the vectors close to w, the next close vector v whose squared distance $d = (v - w, v - w)$ from w is in the specified range is returned together with

d, or the zero vector together with -1, indicating that the enumeration process has been completed. The close vectors are *not* symmetrical with respect to sign (while short vectors are) so the returned close vectors are not normalized. Note also that to test for completion the second return value should be tested for equality with -1 (or, preferably, the next function `IsEmpty` should be used) since the zero vector could be a valid close vector.

Note that the order of the vectors returned by this function in each case is arbitrary, unlike the previous functions where the resulting sequence or matrix is sorted.

`IsEmpty(P)`

Given a lattice enumeration process P, return whether the process P has found all short or close vectors.

30.8.5 Successive Minima and Theta Series

`SuccessiveMinima(L)`

`SuccessiveMinima(L, k)`

Return the first k successive minima of lattice L, or all of the m successive minima of L if k is omitted, where m is the rank of L. The first k successive minima $M_1, \ldots, M_k$ of a lattice L are defined by the property that $M_1, \ldots, M_k$ are minimal such that there exist linearly independent vectors $l_1, \ldots, l_k$ in L with $(l_i, l_i) = M_i$ for $1 \leq i \leq k$. The function returns a sequence containing the minima M_i and a sequence containing the vectors l_i. The lattice L must be an exact lattice (over $\mathbf{Z}$ or $\mathbf{Q}$). Note that the minima are unique but the vectors are not.

`ThetaSeries(L, n)`

`Proof`	BoolElt	*Default :* `true`
`Prune`	SeqEnum	*Default :* $[1.0, \ldots, 1.0]$

Given an integral lattice L and a small positive integer n, return the Theta series $\Theta_L(q)$ of L as a formal power series in q to precision n (i.e., up to and including the coefficient of q^n). The coefficient of q^k in $\Theta_L(q)$ is defined to be the number of vectors of norm k in L. Note that this function needs to enumerate all vectors of L having norm up to and including n, so its application is restricted to lattices where the number of these vectors is reasonably small. The lattice L must be an exact lattice (over $\mathbf{Z}$ or $\mathbf{Q}$). Note that the angle bracket notation should be used to assign a name to the indeterminate for the returned Theta series (e.g., `T<q> := ThetaSeries(L);`).

Example H30E15

We show how a lattice enumeration process can be used to compute the Theta series of a lattice. We write a simple function `Theta` which takes a lattice L and precision n and returns the Theta series of L up to the term q^n just as in the function `ThetaSeries`. The function assumes that the

lattice L is integral. We simply loop over the non-zero vectors of norm up to n and count the number of vectors for each norm.

```
> function Theta(L, n)
>     Z := IntegerRing();
>     P := ShortVectorsProcess(L, n);
>     C := [1] cat [0: i in [1 .. n]];
>     while not IsEmpty(P) do
>         v, norm := NextVector(P);
>         C[Z!norm + 1] +:= 2;
>     end while;
>     return PowerSeriesRing(IntegerRing()) ! C;
> end function;
```

We now compute the Theta series up to norm 10 of the Gosset lattice E_8 using the function `Theta`. We compare this MAGMA-language version with the builtin function `ThetaSeries` (which is much faster of course because of the lack of interpreter overhead etc.).

```
> L := Lattice("E", 8);
> time T<q> := Theta(L, 10);
Time: 0.050
> T;
1 + 240*q^2 + 2160*q^4 + 6720*q^6 + 17520*q^8 + 30240*q^10
> time TT<r> := ThetaSeries(L, 10);
Time: 0.000
> TT;
1 + 240*q^2 + 2160*q^4 + 6720*q^6 + 17520*q^8 + 30240*q^10 + O(q^11)
```

`ThetaSeriesIntegral(L, n)`

`Proof`	BOOLELT	*Default :* `true`
`Prune`	SEQENUM	*Default :* $[1.0, \ldots, 1.0]$

Restriction of `ThetaSeries` to integral lattices.

30.8.6 Lattice Enumeration Utilities

`SetVerbose("Enum", v)`

(Procedure.) Set the verbose printing level for the lattice enumeration algorithm to be v. Currently the legal values for v are `true`, `false`, 0, and 1 (`false` is the same as 0, and `true` is the same as 1). When the verbose level is non-zero, some information about the current status of the enumeration algorithm is printed out every 15 seconds. This concerns the functions `Minimum`, `CentreDensity`, `CenterDensity`, `Density`, `KissingNumber`, `ShortestVectors`, `ShortestVectorsMatrix`, `ShortVectors`, `ShortVectorsMatrix` and `ThetaSeries`.

`EnumerationCost(L)`

`EnumerationCost(L, u)`

`Prune` SeqEnum *Default :* $[1.0, \ldots, 1.0]$

Estimate the number of nodes in the tree to be visited during the execution of the enumeration algorithm, for the lattice L and an hyperball of squared radius u. If u is not provided, an upper bound to the lattice minimum is used. Since the cost per tree node is relatively constant, this function can be used to obtain a heuristic estimate of the running-time of the enumeration algorithm. Note that in some cases the enumeration may run faster than expected, because the tree to be visited may be shrunk during the execution, as described in [SE94]. Contrary to the enumeration itself, this function runs in time polynomial in the input bit-size (if the value of the `Prune` optional parameter is the default one). It relies on the Gaussian heuristic, which consists in estimating the number of integral points within an n-dimensional body by its volume (see [HS07] for more details).

If the `Prune` parameter is set to $[p_1, \ldots, p_d]$, then `EnumerationCost` estimates the cost of the tree pruned with the strategy described in the introduction of the present section, with pruning coefficients $p_1, \ldots, p_d$. Although the enumeration itself is likely to terminate faster, the estimation of the cost may be significantly more time-consuming.

`EnumerationCostArray(L)`

`EnumerationCostArray(L, u)`

`Prune` SeqEnum *Default :* $[1.0, \ldots, 1.0]$

Estimate the number of nodes in each layer of the tree to be visited during the execution of the enumeration algorithm, for the lattice L and an hyperball of squared radius u. If u is not provided, an upper bound to the lattice minimum is used.

Example H30E16

The algorithm that enumerates short lattice vectors may be very time-consuming. The `EnumerationCost` and `EnumerationCostArray` functions allow one to estimate the running-time on a given enumeration instantiation, before actually running the algorithm. If the running-time estimate is too high, then it is unlikely that the execution will terminate within a reasonable amount of time. A good strategy then consists in reducing the input lattice basis further. If the running-time estimate remains too high, then pruning the enumeration tree should be considered. Both the running-time gain and the "probability" of missing a solution can be estimated.

```
> B:=RMatrixSpace(IntegerRing(), 50, 51) ! 0;
> for i := 1 to 50 do B[i][1] := RandomBits(1000); end for;
> for i := 1 to 50 do B[i][i+1] := 1; end for;
> B := LLL(B);
> EnumerationCost (Lattice(B));
4.06E18
```

The value above is an estimate of the number of nodes in the enumeration tree that corresponds to the computation of the shortest non-zero vectors in the lattice spanned by the rows of B. This

is much too high to have a chance to terminate. Reducing B further allows us to compute these shortest non-zero vectors.

```
> B:=LLL(B:Delta:=0.999);
> EnumerationCost(Lattice(B));
1.03E13
> B:=LLL(B:Delta:=0.999, DeepInsertions);
> EnumerationCost(Lattice(B));
7.43E7
> time _:=ShortestVectors(Lattice(B));
3.660
```

In larger dimensions, reducing the lattice further may not prove sufficient to make the enumeration reasonably tractable. Then pruning the enumeration tree can be considered.

```
>  B:=RMatrixSpace(IntegerRing(), 65, 66) ! 0;
>  for i := 1 to 65 do B[i][1] := RandomBits(1000); end for;
>  for i := 1 to 65 do B[i][i+1] := 1; end for;
>  B := LLL(B:Delta:=0.999);
>  B := LLL(B:Delta:=0.999, DeepInsertions);
>  EnumerationCost(Lattice(B));
2.77E12
> p:=[1.0: i in [1..65]];
> for i:=10 to 55 do p[i] := (100-i)/90.; end for;
> for i:=56 to 65 do p[i]:=0.5; end for;
> EnumerationCost(Lattice(B):Prune:=p);
1.75E10
> time _:=ShortestVectors(Lattice(B):Prune:=p);
Time: 422.120
```

Assuming that the number of visited tree nodes per time unit remains roughly constant, the execution would have taken around 18 hours without pruning. It is possible to estimate the likeliness of not missing the optimal solution, by looking at the first coefficient returned by `EnumerationCostArray`. Assuming the Gaussian heuristic, this is the ratio between the first coefficients of `EnumerationCostArray` with and without the pruning table.

```
>  t1:= EnumerationCostArray(Lattice(B):Prune:=p)[1];
>  t2:= EnumerationCostArray(Lattice(B))[1];
>  t1/t2;
0.992
```

Experimentally, it seems that pruning coefficients that decrease linearly (except for the first and last indices) provide good trade-offs between efficiency gain and success likeliness.

30.9 Theta Series as Modular Forms

The theta series of an integral lattice L is (the q-expansion of) a modular form whose weight is half the dimension of the lattice, and whose level and nebentypus are determined by the quotient $L^{\#}/L$. The space of forms with given weight, level and character is finite dimensional, which means the theta series is uniquely characterised as an element of that space from knowledge of finitely many of its coefficients.

The routine described below carries this out explicitly: given an integral lattice, it returns an element of a MAGMA space of modular forms, Moreover this is done with the least possible effort spent determining coefficients via lattice enumeration. Several ideas are used here, the most important of which is that linear constraints can be obtained from knowing coefficients of the theta series of L *and* of its partial dual lattices; in practice, one needs a certain number of coefficients in total, and the `EnumerationCost` functionality is useful for balancing how many to compute for each of the duals.

We say L is *q-modular* if it is isomorphic to its qth partial dual L_q. Knowledge that modularities exist is of some use in the algorithm, because q-modularity clearly implies that L and L_q have the same theta series.

Normalisation of theta series: We use a normalisation that is most natural in this context, in order that the theta series is a modular form on $\Gamma_0(N)$ with the level N as small as possible. In this section, the theta series of an even integral lattice L will mean $\Sigma_{v\in L} q^{1/2|v|^2}$, while the theta series of an odd integral lattice L will mean $\Sigma_{v\in L} q^{|v|^2}$, where $q = e^{2i\pi z}$.

`ThetaSeriesModularFormSpace(L)`

Given an integral lattice L, this returns the space of modular forms which contains the theta series of L. Note: the theta series is normalised as described above.

`ThetaSeriesModularForm(L)`

`KnownTheta`	RNGSERPOWELT	*Default :*
`KnownDualThetas`	SEQENUM[TUP]	*Default :*
`KnownModularities`	SET[RNGINTELT]	*Default :*
`ComputeModularities`	SET[RNGINTELT]	*Default :*

Given an integral lattice L, this returns the theta series of L as a modular form in the appropriate space: more precisely, in `ThetaSeriesModularFormSpace(L)`. Note: the theta series is normalised as described above.

If some coefficients of the theta series of L are already known, this information may be specified by setting the optional argument `KnownTheta` to be a power series f, indicating that L has theta series equal to f up to the precision of f.

More generally, if coefficients are known for any partial dual lattices, these may be specified by setting `KnownDualThetas`. This argument must be a sequence of tuples of the form $< q, f_q >$, indicating that the qth partial dual L_q has theta series equal to f_q up to the precision of f_q.

If L is known to possess modularities, the optional argument `KnownModularities` may be set equal to any set of integers q such that L is q-modular (as defined above).

In addition, `ComputeModularities` may be specified to control whether the function checks for q-modularities (for possible q, that are not listed as `KnownModularities`); its value may be a boolean, or a set of integers.

30.10 Voronoi Cells, Holes and Covering Radius

The functions in this section compute the Voronoi cell of a lattice around the origin and associated information. Note that the computation of the Voronoi cell is of truly exponential complexity and is therefore the use of these functions is restricted to small dimensions (up to about 10). See [JC98] for the relevant definitions.

A lattice to which any of these functions are applied must be an exact lattice (over **Z** or **Q**).

`VoronoiCell(L)`

Return the Voronoi cell of the lattice L around the origin which is the convex polytope consisting of all the points closer to the origin than to any other lattice point of L. This function returns three values:

(a) A sequence V of vectors which are the vertices of the Voronoi cell.

(b) A set E of pairs, where each pair $\{i, j\}$ represents an edge connecting $V[i]$ and $V[j]$.

(c) A sequence P of vectors defining the relevant hyperplanes. A vector p corresponds to the hyperplane given by $(x, p) = \mathrm{Norm}(p)/2$.

`VoronoiGraph(L)`

Return a graph having the vertices and edges of the Voronoi cell of the lattice L as vertices and edges, respectively.

`Holes(L)`

Return a sequence of vectors which are the holes of the lattice L. The holes are defined to be the vertices of the Voronoi cell around the origin. Note that this involves computing the Voronoi cell of L around the origin.

`DeepHoles(L)`

Return a sequence of vectors which are the deep holes of the lattice L. The deep holes are defined to be the holes of maximum norm and are points of maximum distance to all lattice points. Note that this involves computing the Voronoi cell of L around the origin.

`CoveringRadius(L)`

Return the squared covering radius of the lattice L, which is the norm of the deep holes of L. Note that this involves computing the Voronoi cell of L around the origin.

`VoronoiRelevantVectors(L)`

Return the Voronoi relevant hyperplanes (as a set of vectors) of the Voronoi cell of L around the origin. Note that this is the same as the third return value of the `VoronoiCell` intrinsic. However, it is usually much faster since it does not compute the Voronoi cell of L. The algorithm employed is [AEVZ02, Section C].

Example H30E17

We compute the Voronoi cell of a perfect lattice of dimension 6.

```
> L := LatticeWithGram(6, [4, 1,4, 2,2,4, 2,2,1,4, 2,2,1,1,4, 2,2,2,2,2,4]);
> L;
Standard Lattice of rank 6 and degree 6
Inner Product Matrix:
[4 1 2 2 2 2]
[1 4 2 2 2 2]
[2 2 4 1 1 2]
[2 2 1 4 1 2]
[2 2 1 1 4 2]
[2 2 2 2 2 4]
> time V, E, P := VoronoiCell(L);
Time: 1.740
> #Holes(L), #DeepHoles(L), CoveringRadius(L);
782 28 5/2
```

The Voronoi cell has 782 vertices, but only 28 of these are of maximal norm 5/2 and therefore deep holes. We now compute the norms and cardinalities for the shallow holes.

```
> M := MatrixRing(Rationals(), 6) ! InnerProductMatrix(L);
> N := [ (v*M, v) : v in V ];
> norms := Sort(Setseq(Set(N))); norms;
[ 17/9, 2, 37/18, 20/9, 7/3, 5/2 ]
> card := [ #[ x : x in N | x eq n ] : n in norms ]; card;
[ 126, 16, 288, 180, 144, 28 ]
```

So there are 126 holes of norm 17/9, 16 holes of norm 2, etc. We now investigate the Voronoi cell as a polyhedron.

```
> #V, #E, #P;
782 4074 104
> { Norm(L!p) : p in P };
{ 4, 6 }
> #ShortVectors(L, 6);
52
```

The polyhedron which is the convex closure of the holes has 782 vertices, 4074 edges and 104 faces. The faces are defined by vectors of length up to 6 and all such vectors are relevant (since there are only 104). We finally look at the graph defined by the vertices and edges of the Voronoi cell.

```
> G := VoronoiGraph(L);
```

```
> IsConnected(G);
true
> Diameter(G);
8
> Maxdeg(G);
20 ( -1   0 1/2 1/2 1/2   0)
> v := RSpace(Rationals(), 6) ! [ -1, 0, 1/2, 1/2, 1/2, 0 ]; (v*M, v);
5/2
```

The graph is (of course) connected, its diameter is 8 and the vertices of maximal degree 20 are exactly the deep holes.

30.11 Orthogonalization

The functions in this section perform orthogonalization and orthonormalization of lattice bases over the field of fractions of the base ring. Note that this yields a basis orthogonalization of the space in which a lattice embeds; in contrast `OrthogonalDecomposition` returns a decomposition into orthogonal components over the base ring. Basis orthogonalization is equivalent to diagonalization of the inner product matrix of a space.

`Orthogonalize(M)`

Given a basis matrix M over a subring R of the real field, compute a matrix N which is row-equivalent over to M over the field of fractions K of R, but whose rows are orthogonal (i.e., NN^{tr} is a diagonal matrix). This function returns three values:

(a) An orthogonalized matrix N in row-equivalent to X over K;

(b) An invertible matrix T in the matrix ring over K whose degree is the number of rows of M such that $TM = N$;

(c) The rank of M.

`Diagonalization(F)`

`OrthogonalizeGram(F)`

Given a symmetric $n\times$n matrix F over R, where R is a subring of the real field, compute a *diagonal* matrix G such that $G = TFT^{tr}$ for some invertible matrix T over K, where K is the field of fractions of R. F need not have rank n. This function returns three values:

(a) A diagonal matrix G defined over R;

(b) An invertible $n\times$n matrix T over K such that $G = TFT^{tr}$;

(c) The rank of F.

`Orthogonalize(L)`

For a lattice L, return a new lattice having the same Gram matrix as L but embedded in an ambient space with diagonal inner product matrix.

`Orthonormalize(M, K)`
`Cholesky(M, K)`
`Orthonormalize(M)`
`Cholesky(M)`

For a symmetric, positive definite matrix M, and a real field K, return a lower triangular matrix T over K such that $M = TT^{tr}$. The algorithm must take square roots so the result is returned as a matrix over the real field K. If the real field K is omitted, K is taken to be the default real field. Note that this function takes a Gram matrix M, *not* a basis matrix as in the previous functions.

`Orthonormalize(L, K)`
`Cholesky(L, K)`
`Orthonormalize(L)`
`Cholesky(L)`

Given a lattice L with Gram matrix F, together with a real field K, return a new lattice over K which has the same Gram matrix F as L but has the standard Euclidean inner product. (This will involve taking square roots so that is why the result must be over a real field.) The argument for the real field K may be omitted, in which case K is taken to be the current default real field. This function is equivalent to the invocation `LatticeWithBasis(Orthonormalize(GramMatrix(L), K))`. It is sometimes more convenient to work with the resulting lattice since it has the standard Euclidean inner product.

Example H30E18

As an example for a lattice with non-trivial basis and inner product matrices we choose the dual lattice of the 12-dimensional Coxeter-Todd lattice. We compute the inner products of all pairs of shortest vectors and notice that this gets faster after changing to an isomorphic lattice with weighted standard Euclidean inner product.

```
> L := Dual(CoordinateLattice(Lattice("Kappa", 12)));
> SL := ShortestVectors(L);
> SL := SL cat [ -v : v in SL ]; #SL;
756
> time { (v,w) : v,w in SL };
{ -4, -2, -1, 0, 1, 2, 4 }
Time: 7.120
> M := Orthogonalize(L);
> SM := ShortestVectors(M);
> SM := SM cat [ -v : v in SM ]; #SM;
756
> time { (v,w) : v,w in SM };
{ -4, -2, -1, 0, 1, 2, 4 }
```

```
Time: 1.300
```

30.12 Testing Matrices for Definiteness

The functions in this section test matrices for positive definiteness, etc. They may applied to any symmetric matrix over a real subring (i.e., **Z**, **Q**, or a real field). Each function works by calling the function `OrthogonalizeGram` on its argument and then determining whether the resulting diagonal matrix has the appropriate form.

`IsPositiveDefinite(F)`

Given a symmetric matrix F belonging to the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, return whether F is positive definite, i.e., whether $vFv^{tr} > 0$ for all non-zero vectors $v \in \mathbf{R}^n$.

`IsPositiveSemiDefinite(F)`

Given a symmetric matrix F belonging to the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, return whether F is positive semi-definite, i.e., whether $vFv^{tr} \geq 0$ for all non-zero vectors $v \in \mathbf{R}^n$.

`IsNegativeDefinite(F)`

Given a symmetric matrix F belonging to the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, return whether F is negative definite, i.e., whether $vFv^{tr} < 0$ for all non-zero vectors $v \in \mathbf{R}^n$.

`IsNegativeSemiDefinite(F)`

Given a symmetric matrix F belonging to the matrix module $S = \mathrm{Hom}_R(M, M)$ or the matrix algebra $S = M_n(R)$, where R is a subring of the real field, return whether F is negative semi-definite, i.e., whether $vFv^{tr} \leq 0$ for all non-zero vectors $v \in \mathbf{R}^n$.

30.13 Genera and Spinor Genera

The genus of an exact lattice has a distinct type `SymGen` which holds a representative lattice, and the local data defining the genus. Each genus consists of 2^n spinor genera, for some integer n, typically 1. The spinor genera share the same type `SymGen`. Unlike the genus, the spinor genus is not determined solely by the local data of the genus, so the cached representative is necessary to define the spinor class.

Equality testing of genera is fast, since this requires only a comparison of the canonical local information. It is also possible to enumerate representatives of all equivalences classes in a genus or spinor genus. This is done by a process of exploration of the p-neighbour graph, for an appropriate prime p. The neighbouring functions can be applied to individual lattices to find p-neighbours or the closure under the p-neighbour process. Functions for computing and comparing the local p-adic equivalence classes of lattices, mediated by the type `SymGenLoc`.

30.13.1 Genus Constructions

`Genus(L)`
`Genus(G)`

Given an exact lattice L or a spinor genus G this function returns the genus of L. If given a genus the function returns G itself.

`SpinorGenus(L)`

Given an exact lattice L, returns the spinor genus of L.

`SpinorGenera(G)`

Given a genus G, returns the sequence of spinor genera. If G is a spinor genus, then this function returns the sequence consisting of G itself.

30.13.2 Invariants of Genera and Spinor Genera

`Representative(G)`

Returns a representative lattice for the genus symbol G.

`IsSpinorGenus(G)`

Returns `true` if and only if G is a spinor genus. This is the negation of `IsGenus(G)`.

`IsGenus(G)`

Returns `true` if and only if G is a genus. This is the negation of `IsSpinorGenus(G)`.

`Determinant(G)`

Returns the determinant of the genus symbol G.

`LocalGenera(G)`

Returns the sequence of p-adic genera of the genus symbol G.

`Representative(G)`

Returns a representative lattice for the genus symbol G.

`G1 eq G2`

Given two genus symbols, return `true` if and only if they represent the same genus. This computation is fast for genera, but currently for spinor genera invokes a call to `Representatives`.

`#G`

The number of isometry classes in the genus or spinor genus G.

Enumeration of isometry classes is done by an explicit call to `Representatives`, so that `#G` is an expensive computation.

`SpinorCharacters(G)`

Return the spinor characters of the genus symbol G as a sequence of Dirichlet characters whose kernels intersect exactly in the group of automorphous numbers. Consult Conway and Sloane [JC98] for precise definitions and significance of the spinor kernel and automorphous numbers.

`SpinorGenerators(G)`

Return the spinor generators of the genus symbol G as a sequence of primes which generate the group of spinor norms. The primes generate a group dual to that generated by the spinor characters.

`AutomorphousClasses(L,p)`

`AutomorphousClasses(G,p)`

A set of integer representatives of the p-adic square classes in the image of the spinor norm of the lattice L (respectively the genus symbol G).

`IsSpinorNorm(G,p)`

Returns `true` if and only if p is coprime to 2 and the determinant, and p is the norm of an element of the spinor kernel of G.

30.13.3 Invariants of p-adic Genera

`Prime(G)`

Return the prime p for which G represents the p-adic genus.

`Representative(G)`

Returns a canonical representative lattice of the p-adic genus G, with Gram matrix in Jordan form. For odd p the Jordan form is diagonalized.

`Determinant(G)`

This function returns a canonical p-adic representative of the determinant of the p-adic genus G. The determinant is well-defined only up to squares.

`Dimension(G)`

Return the dimension of the p-adic genus G.

`G1 eq G2`

Given local genus symbols $G1$ and $G2$, return `true` if and only if they have the same prime and the same canonical Jordan form.

30.13.4 Neighbour Relations and Graphs

`Neighbour(L, v, p)`

`Neighbor(L, v, p)`

Let L be an integral lattice, p a prime which does not divide Determinant(L) and v a vector in $L \setminus pL$ with $(v, v) \in p^2\mathbf{Z}$. The p-neighbour of L with respect to v is the lattice generated by L_v and $p^{-1}v$, where $L_v := \{x \in L | (x, v) \in p\mathbf{Z}\}$.

See [Kne57] for the original definition and [SP91] for a generalization of the neighbouring method.

`Neighbours(L, p)`

`Neighbors(L, p)`

For an integral lattice L and prime p, returns the sequence of p-neighbours of L.

`NeighbourClosure(L, p)`

`NeighborClosure(L, p)`

`Bound` RngIntElt *Default :* 2^{32}

For an integral lattice L and prime p, returns the sequence of lattices obtained by transitive closure of the p-neighbours of L.

Note that neighbours with respect to two vectors v_1, v_2 whose images in L/pL lie in the same projective orbit of Aut(L) on L/pL are isometric. Therefore only projective orbit representatives of the action of Aut(L) on L/pL are used. The large number of orbits restricts the complexity of this algorithm, hence the function gives an error if $p^{\mathrm{Rank}(L)}$ is greater than `Bound`, by default set to 2^{32}.

`GenusRepresentatives(L)`

`SpinorRepresentatives(L)`

`Representatives(G)`

`Bound`	RngIntElt	*Default :* 2^{32}
`Depth`	RngIntElt	*Default :*

For an exact lattice L with genus or spinor genus G, this function enumerates the isometry classes in G by constructing the p-neighbour closure (up to isometry). This construction used using an appropriate prime or primes p not dividing the determinant of L. For the genus, sufficiently many primes p are chosen to generate the full image, modulo the spinor kernel, of each character defining the spinor kernel. The parameters are exactly as for the `NeighbourClosure` function.

`AdjacencyMatrix(G,p)`

For a genus or spinor genus G, this function determines the adjacency matrix of the p-neighbour graph on the representative classes for G. The integer p must be prime, and if G is a spinor genus, then an error ensues if p is not an automorphous number for G.

Example H30E19

We construct the root lattice E_8 (the unique even unimodular lattice of dimension 8) as a 2-neighbour of the 8-dimensional standard lattice.

```
> Z8 := StandardLattice(8);
> v := Z8 ! [1,1,1,1,1,1,1,1];
> E8 := Neighbour(Z8, v, 2);
> E8;
Lattice of rank 8 and degree 8
Basis:
( 2  0  0  0  0  0  0  2)
( 2  0  0  0  0  0  0 -2)
( 1  1 -1  1  1 -1  1  1)
( 1  1 -1 -1 -1 -1 -1 -1)
( 1 -1 -1 -1 -1 -1  1 -1)
( 0  0  2  0  0  0  0  2)
( 0  0  0  0  2  0  0  2)
( 0  0  0  0  0  2  0  2)
Basis denominator: 2
```

The so-obtained lattice is in fact identical to the one returned by the standard construction.

```
> L := Lattice("E", 8);
> L;
Lattice of rank 8 and degree 8
Basis:
( 4  0  0  0  0  0  0  0)
```

```
(-2  2  0  0  0  0  0  0)
( 0 -2  2  0  0  0  0  0)
( 0  0 -2  2  0  0  0  0)
( 0  0  0 -2  2  0  0  0)
( 0  0  0  0 -2  2  0  0)
( 0  0  0  0  0 -2  2  0)
( 1  1  1  1  1  1  1  1)
Basis Denominator: 2
> E8 eq L;
true
```

Example H30E20

In this example we enumerate representatives for the genus of the Coxeter-Todd lattice, performing the major steps manually. The whole computation can be done simply by calling the `GenusRepresentatives` function but the example illustrates how the function actually works.

We use a combination of the automorphism group, isometry and neighbouring functions. The idea is that the neighbouring graph spans the full genus which therefore can be computed by successively generating neighbours and checking them for isometry with already known ones. The automorphism group comes into play, since neighbours with respect to vectors in the same projective orbit under the automorphism group are isometric.

```
> L := CoordinateLattice(Lattice("Kappa", 12));
> G := AutomorphismGroup(L);
> G2 := ChangeRing(G, GF(2));
> O := LineOrbits(G2);
> [ Norm(L!Rep(o).1) : o in O ];
[ 4, 8, 10 ]
```

Hence only the first and second orbits give rise to a 2-neighbour. To obtain an even neighbour, the second vector has to be adjusted by an element of $2 * L$ such that it has norm divisible by 8.

```
> v1 := L ! Rep(O[1]).1;
> v1 +:= 2 * Rep({ u : u in Basis(L) | (v1,u) mod 2 eq 1 });
> v2 := L ! Rep(O[2]).1;
> Norm(v1), Norm(v2);
16 8
> L1 := Neighbour(L, v1, 2);
> L2 := Neighbour(L, v2, 2);
> bool := IsIsometric(L, L1); bool;
true
> bool := IsIsometric(L, L2); bool;
false
```

So we obtain only one non-isometric even neighbour of L. To obtain the full genus we can now proceed with $L2$ in the same way, and do this with the following function `EvenGenus`. Note that this function is simply one component of the function `GenusRepresentatives`.

```
> function EvenGenus(L)
```

```
>      // Start with the lattice L
>      Lambda := [ CoordinateLattice(LLL(L)) ];
>      cand := 1;
>      while cand le #Lambda do
>          L := Lambda[cand];
>          G := ChangeRing( AutomorphismGroup(L), GF(2) );
>          // Get the projective orbits on L/2L
>          O := LineOrbits(G);
>          for o in O do
>              v := L ! Rep(o).1;
>              if Norm(v) mod 4 eq 0 then
>                  // Adjust the vector such that its norm is divisible by 8
>                  if not Norm(v) mod 8 eq 0 then
>                      v +:= 2 * Rep({ u : u in Basis(L) | (v,u) mod 2 eq 1 });
>                  end if;
>                  N := LLL(Neighbour(L, v, 2));
>                  new := true;
>                  for i in [1..#Lambda] do
>                      if IsIsometric(Lambda[i], N) then
>                          new := false;
>                          break i;
>                      end if;
>                  end for;
>                  if new then
>                      Append(~Lambda, CoordinateLattice(N));
>                  end if;
>              end if;
>          end for;
>          cand +:= 1;
>      end while;
>      return Lambda;
> end function;
>
> time Lambda := EvenGenus(L);
Time: 9.300
> #Lambda;
10
> [ Minimum(L) : L in Lambda ];
[ 4, 2, 2, 2, 2, 2, 2, 2, 2, 2 ]
> &+[ 1/#AutomorphismGroup(L) : L in Lambda ];
4649359/4213820620800
```

We see that the genus consists of 10 classes of lattices where only the Coxeter-Todd lattice has minimum 4 and get the mass of the genus as 4649359/4213820620800.

30.14 Attributes of Lattices

This section lists various attributes of lattices which can be examined and set by the user. This allows low-level control of information stored in lattices. Note that when an attribute is set, only minimal testing can be done on the value so if an incorrect value is set, unpredictable results may occur. Note also that if an attribute is not set, referring to it in an expression (using the ‘ operator) will *not* trigger the calculation of it (while intrinsic functions do); rather an error will ensue. Use the `assigned` operator to test whether an attribute is set.

`L‘Minimum`

The attribute for the minimum of a rational or integer lattice L. If the attribute `L‘Minimum` is examined, either the minimum is known so it is returned or an error results. If the attribute `L‘Minimum` is set by assignment, it must be a positive number equal to the minimum of the lattice. MAGMA will not check that this is correct since that may be very time-consuming. If the attribute is already set, the new value must be the same as the old value.

`L‘MinimumBound`

The attribute for an upper bound to the minimum of a rational or integer lattice L. If the attribute `L‘MinimumBound` is examined, either an upper bound to the minimum is known so it is returned or an error results. If the attribute `L‘MinimumBound` is set by assignment, it must be a positive number greater than or equal to the minimum of the lattice. MAGMA will not check that this is correct since that may be very time-consuming. If the attribute is already set, the new value must be the same as or smaller than the old value.

30.15 Database of Lattices

MAGMA includes a database containing most of the lattices explicitly presented in the Catalogue of Lattices maintained by Neil J.A. Sloane and Gabriele Nebe [NS01b].

Many standard lattices included in the Sloane & Nebe catalogue are not in the database as they may be obtained by applying MAGMA's standard lattice creation functions. Also omitted from the database are a small number of catalogued lattices defined over rings other than $\mathbf{Z}$ or $\mathbf{Q}$.

The information available for any given lattice in the catalogue varies considerably. A similar variety is found in the Magma database version, although some data (generally either easily computable or rarely available in the catalogue) is omitted.

Where the Magma database does retain data, it is not altered from the data in the catalogue. Thus the caveat which comes with that catalogue remains relevant: “Warning! Not all the entries have been checked!”

A second version of the Lattice Database has been made available with Version 2.16 of MAGMA. It adds a few more lattices, contains more information about automorphism groups, and adds Θ-series as attributes. Furthermore, it removes some duplicates. The user should be warned that the numbering of lattices (and naming in some cases) differs

between the two versions. The newer version, however, does not contain information about any Hermitian structure at the current time.

The entries of the database can be accessed in three ways:

(i) the i-th entry of the database can be requested;

(ii) the i-th entry of a particular dimension d can be specified;

(iii) the desired entry can be denoted by its name N. This name is specified exactly as in the catalogue, including all punctuation and whitespace. In the rare event that two or more entries share a single name, particular entries may be distinguished by supplying an integer i in addition to N, to denote the i-th entry with name N.

30.15.1 Creating the Database

`LatticeDatabase()`

This function returns a database object which contains information about the database.

30.15.2 Database Information

This section gives the functions that enable the user to find out what is in the database.

`#D`

`NumberOfLattices(D)`

Returns the number of lattices stored in the database.

`LargestDimension(D)`

Returns the largest dimension of any lattice in the database.

`NumberOfLattices(D, d)`

Returns the number of lattices of dimension d stored in the database.

`NumberOfLattices(D, N)`

Returns the number of lattices named N stored in the database.

`LatticeName(D, i)`

Return the name and dimension of the i-th entry of the database D.

`LatticeName(D, d, i)`

Return the name and dimension of the i-th entry of dimension d of the database D.

`LatticeName(D, N)`

Return the name and dimension of the first entry of the database with name N.

`LatticeName(D, N, i)`

Return the name and dimension of the i-th entry of the database with name N.

Example H30E21

We find out the names of the database entries.

```
> D := LatticeDatabase();
> NumberOfLattices(D);
700
```

The database contains 700 lattices. We get the set of all names in the database.

```
> names := {LatticeName(D,i): i in [1..#D]};
> #names;
673;
> Random(names);
S4(5):2
> NumberOfLattices(D, "S4(5):2");
1
```

There are 673 names, so 27 repeated names in the database, but only one with name "S4(5):2".

30.15.3 Accessing the Database

The following functions retrieve lattice information from the database.

`Lattice(D, i: parameters)`

`Lattice(D, d, i: parameters)`

`Lattice(D, N: parameters)`

`Lattice(D, N, i: parameters)`

`TrustAutomorphismGroup`

BOOL *Default :* `true`

Returns the i-th entry (of dimension d or name N) from the database D as a lattice L.

If the `TrustAutomorphismGroup` parameter is assigned `false`, then any data which claims to be the automorphism group will not be stored in L.

`LatticeData(D, i)`

`LatticeData(D, d, i)`

`LatticeData(D, N)`

`LatticeData(D, N, i)`

Returns a record which contains all the information about the i-th lattice stored in the database D (of dimension d or name N). The automorphism group is returned separately from the lattice and not stored in it.

Example H30E22

We look up a lattice in the database. There are 19 lattices of dimension 6 in the database. We get the 10th.

```
> D := LatticeDatabase();
> NumberOfLattices(D, 6);
19
> L := Lattice(D, 6, 10);
> L;
Standard Lattice of rank 6 and degree 6
Minimum: 4
Inner Product Matrix:
[4 1 2 2 2 2]
[1 4 2 2 2 2]
[2 2 4 1 2 2]
[2 2 1 4 2 2]
[2 2 2 2 4 1]
[2 2 2 2 1 4]
```

There may be more information stored than just what is returned by the `Lattice` function. We get the record containing all the stored lattice data.

```
> R := LatticeData(D, 6, 10);
> Format(R);
recformat<name, dim, lattice, minimum, kissing_number,
is_integral, is_even, is_unimodular, is_unimodular_hermitian,
modularity, group_names, group, group_order,
hermitian_group_names, hermitian_group, hermitian_group_order,
hermitian_structure>
```

This lists all possible fields in the record. They may or may not be assigned for any particular lattice.

```
> R`lattice eq L;
true
> R`name;
A6,1
> assigned R`kissing_number;
true
> R`kissing_number;
42
> assigned R`group;
false
> A := AutomorphismGroup(L);
> A : Minimal;
MatrixGroup(6, Integer Ring) of order 96 = 2^5 * 3
```

The result of the `Lattice` call is equal to the `lattice` field of the data record. The kissing number was stored, but the automorphism group wasn't. We computed the group (as a matrix group over the integers) and found it has order 96.

30.15.4 Hermitian Lattices

There are a few facilities for computing with Hermitian lattices over an imaginary quadratic field or a quaternion algebra. However, these functions apply to a Gram matrix, and not a lattice *per se*. The main application is for automorphism groups that preserve a structure.

`HermitianTranspose(M)`

Given a matrix over an imaginary quadratic field or a quaternion algebra, return the conjugate transpose.

`ExpandBasis(M)`

Given a matrix over an imaginary quadratic field or a quaternion algebra, expand it to a basis over the rationals.

`HermitianAutomorphismGroup(M)`
`QuaternionicAutomorphismGroup(M)`

Given a conjugate symmetric Gram matrix, compute the automorphism group.

Various functions for matrix groups over associative algebras are available here, such as `CharacterTable` and `IsConjugate` which simply use a re-writing over the rationals, and `InvariantForms` which after using `GHom` needs to restrict to elements fixed by the quaterionic structure. Finally, there is `QuaternionicGModule` which will split a G-module over a quaternionic structure.

`InvariantForms(G)`

Given a matrix group over an associative algebra or an imaginary quadratic field, return a basis for the forms fixed by it.

`QuaternionicGModule(M, I, J)`

Given a G-module M and I and J in the endomorphism algebra that anti-commute and whose squares are scalars, write G over the quaternionic structure given by I and J.

`MooreDeterminant(M)`

Given a conjugate-symmetric matrix over a quaternion algebra, compute the Moore determinant. This is the "normal" determinant, which is well-defined here because all the diagonal elements are rational, and thus there is no ambiguity between left/right division.

Example H30E23

We construct the Coxeter-Todd lattice over $Q_{3,\infty}$ starting with the group $SU(3,3)$.

```
> G := SU(3, 3);
> chi := CharacterTable(G)[2];
> M := GModule(chi,Integers());
> E := EndomorphismAlgebra (M);
> while true do r:=&+[Random([-2..2])*E.i : i in [1..4]];
>                if r^2 eq -1 then break; end if; end while;
> while true do s:=&+[Random([-2..2])*E.i : i in [1..4]];
>                if s^2 eq -3 and r*s eq -s*r then break; end if; end while;
> MM := QuaternionicGModule(M, r, s);
> Discriminant(BaseRing(MM));
3
> MG := MatrixGroup(MM);
> IF := InvariantForms(MG); IF;
[
    [1 -1/2*i + 1/6*k 1/3*k]
    [1/2*i - 1/6*k 1 -1/3*j]
    [-1/3*k 1/3*j 1]
]
> assert IsIsomorphic(G, MG);
```

Example H30E24

We compute the quaternionic automorphism group for the Leech lattice.

```
> A<i,j,k> := QuaternionAlgebra<Rationals()|-1,-1>;
> v := [];
> v[1] := [2+2*i,0,0,0,0,0]; /* from Wilson's paper */
> v[2] := [2,2,0,0,0,0];
> v[3] := [0,2,2,0,0,0];
> v[4] := [i+j+k,1,1,1,1,1];
> v[5] := [0,0,1+k,1+j,1+j,1+k];
> v[6] := [0,1+j,1+j,1+k,0,1+k];
> V := [Vector(x) : x in v];
> W := [Vector([Conjugate(x) : x in Eltseq(v)]): v in V];
> M6 := Matrix(6,6,[(V[i],W[j])/2 : i,j in [1..6]]); /* 6-dim over A */
> time Q := QuaternionicAutomorphismGroup(M6);
> assert #Q eq 503193600;
```

The same can be done for the Coxeter-Todd lattice.

```
> A<i,j,k> := QuaternionAlgebra<Rationals()|-1,-3>;
> a := (1+i+j+k)/2;
> M3 := Matrix(3,3,[2,a,-1, Conjugate(a),2,a, -1,Conjugate(a),2]);
> time Q := QuaternionicAutomorphismGroup(M3);
```

```
> assert #Q eq 12096;
```

One can also compute the automorphism group over the Eisenstein field, using `InvariantForms` on the realisation of this group as `ShephardTodd(34)`.

```
> G := ShephardTodd(34);
> IF := InvariantForms(G); // scaled Coxeter-Todd over Q(sqrt(-3))
> A := HermitianAutomorphismGroup(IF[1]);
> assert IsIsomorphic(A,G);
```

31 LATTICES WITH GROUP ACTION

Chapter 31
LATTICES WITH GROUP ACTION

31.1 Introduction

In MAGMA, a G-lattice L is a lattice upon which a finite integral matrix group G acts by right multiplication. MAGMA allows various computations with lattices associated with finite integral matrix groups by use of G-lattices.

The computation of the automorphism group of a lattice (i.e. the largest matrix group that acts on the lattice) and the testing of lattices for isometry is performed within MAGMA by a search designed by Bill Unger, which is based on the Plesken-Souvignier backtrack algorithm [PS97], together with ordered partition methods. Optionally, this may be combined with orthogonal decomposition code of Gabi Nebe.

If G is a finite integral matrix group, then MAGMA uses Plesken's centering algorithm ([Ple74]) to construct all G-invariant sublattices of a given G-lattice L. The lattice of G-invariant sublattices of L can be explored much like the lattice of submodules over finite fields.

31.2 Automorphism Group and Isometry Testing

The functions in this section compute the automorphism group of a lattice and test lattices for isometry. Currently the lattices to which these functions are applied must be exact (over **Z** or **Q**).

`AutomorphismGroup(L)`

`Stabilizer`	RNGINTELT	*Default :* 0
`BacherDepth`	RNGINTELT	*Default :* −1
`Generators`	[GRPMATELT]	*Default :*
`NaturalAction`	BOOL	*Default :* `false`
`Decomposition`	BOOL	*Default :* `false`
`Vectors`	MTRX	*Default :*

This function computes the automorphism group G of a lattice L which is defined to be the group of those automorphisms of the **Z**-module underlying L which preserve the inner product of L. L must be an exact lattice (over **Z** or **Q**). The group G is returned as an integral matrix group of degree m acting on the *coordinate* vectors of L by multiplication where m is the rank of L. The coordinate vectors of L are the elements of the coordinate lattice C of L which has the same Gram matrix as L, but standard basis of degree m (C can be created using the function `CoordinateLattice`). G does not act on the elements of L, since there is no natural

matrix action of the automorphism group on L in the case that the rank of L is less than its degree. However, if the rank of L equals its degree, then the parameter `NaturalAction` may be set to `true`, in which case the resulting group has the natural action on the basis vectors (not the coordinate vectors); note that in this case the resulting matrix group will have (non-integral) rational entries in general, even though the image under the group of an integral basis vector will always be integral.

The algorithm uses a backtrack search to find images of the basis vectors. A vector is a possible image if it has the correct inner product with the images chosen so far. Additional invariants which have to be respected by automorphisms are used by default and are usually sufficient for satisfactory performance. For difficult examples the parameters described below allow to consider further invariants which are more sophisticated and harder to compute, but often find dead ends in the backtrack at an early stage.

The algorithm computes and stores a set of short vectors in the lattice that spans the lattice and is guaranteed closed under the action of the automorphism group. This restricts its general application, as for high dimensional lattices the number of vectors of minimal length may be too large to work with. However, the function can of course be applied to lattices in higher dimensions with a reasonable number of short vectors.

Setting the parameter `Stabilizer := i` will cause the function to compute only the point stabilizer of i basis vectors. These will in general not be the first i basis vectors, as the function chooses the basis to speed up the computation.

The parameter `Depth` is retained for compatibility with previous versions of MAGMA(which used Souvignier's AUTO program) but it is now ignored. The improved backtrack search achieved by using ordered partition methods has made the `Depth` concept unnecessary.

In some hard examples one may want to use Bacher polynomials, which are a combinatorial invariant that usually separates the orbits of the automorphism group on the short vectors. However, these are expensive to calculate and should only be used if one suspects that the automorphism group has many orbits on the short vectors. The parameter `BacherDepth` specifies to which depth the Bacher polynomials may used and should usually be chosen to be 1, since even small automorphism groups will have only very few (most likely 1) orbits on the vectors having correct scalar product with the first image. Setting `BacherDepth` to zero forbids the use of Bacher polynomial invariant. Setting it to anything else allows the algorithm to use this invariant at level 1. Bacher polynomials are computed by counting pairs of vectors having a certain scalar product with other vectors. This scalar product is by default chosen to be half the norm of the vector, since this will usually be the value which occurs least frequent.

In some situations one may already know a subgroup of the full automorphism group, either by the construction of the lattice or an earlier stabilizer computation. This subgroup can be made available by setting `Generators := Q`, where Q is a set or sequence containing the generators of the subgroup.

Since V2.13, the algorithm has had the ability to first attempt to compute an orthogonal decomposition of L by considering the sublattices spanned by the set of shortest vectors, and if there is a non-trivial decomposition the automorphism group is computed via an algorithm of G. Nebe which computes the automorphism groups for the components and combines these. This decomposition method can be invoked by setting `Decomposition` to `true`.

When decomposition is suppressed, it is possible to supply the backtrack algorithm with the set of vectors to be used as domain for the search. To do this set the parameter `Vectors` to be a matrix so that the rows of the matrix give the lattice elements to be used. (Only one of a vector and its negative should be given.) To guarantee correctness of the result, the rows of the matrix should satisfy two conditions:

The rows, together with their negations, must be closed under the action of the full automorphism group, and

The sublattice of L generated by the rows of the matrix must equal L.

These conditions are not checked by the code, and it is up to the user of this parameter to ensure the correctness of their input. For example, the function `ShortVectorsMatrix` returns a matrix which satisfies the first condition. If the first condition is not satisfied, there are no guarantees about what will happen. The second condition may be violated and still give a useful result. In particular, if the sublattice generated by the vectors given has finite index in the full lattice, then the final result will be the correct automorphism group. The problem is that the backtrack search may not be particularly efficient. This may still be better than working with a very large set of vectors satisfying the second condition.

`AutomorphismGroup(L, F)`

`Stabilizer`	RngIntElt	*Default :* 0
`BacherDepth`	RngIntElt	*Default :* 0
`Generators`	[GrpMatElt]	*Default :*
`Vectors`	Mtrx	*Default :*

This function computes the subgroup of the automorphism group of the lattice L which fixes also the forms given in the set or sequence F. The matrices in F are not required to be positive definite or even symmetric. This is for example useful to compute automorphism groups of lattices over algebraic number fields. The parameters are as above.

`AutomorphismGroup(F)`

`Stabilizer`	RngIntElt	*Default :* 0
`BacherDepth`	RngIntElt	*Default :* 0
`Generators`	[GrpMatElt]	*Default :*

This function computes the matrix group fixing all forms given as matrices in the sequence F. The first form in F must be symmetric and positive definite, while the

others are arbitrary. The call of this function is equivalent to `AutomorphismGroup( LatticeWithGram(F[1]), [ F[i] : i in [2..#F] ] )`. This function can be used to compute the Bravais group of a matrix group G which is defined to be the full automorphism group of the forms fixed by G. The parameters are as above.

Example H31E1

In this example we compute the automorphism group of the root lattice E_8 and manually transform the action on the coordinates into an action on the lattice vectors. Note that this exactly the same as using the `NaturalAction` parameter for the function `AutomorphismGroup`.

```
> L := Lattice("E", 8);
> G := AutomorphismGroup(L);
> #G; FactoredOrder(G);
696729600
[ <2, 14>, <3, 5>, <5, 2>, <7, 1> ]
> M := MatrixRing(Rationals(), 8);
> B := BasisMatrix(L);
> A := MatrixGroup<8, Rationals() | [B^-1 * M!G.i * B : i in [1 .. Ngens(G)]]>;
> A;
MatrixGroup(8, Rational Field)
Generators:
    [   0    0 -1/2  1/2 -1/2  1/2    0    0]
    [   0    0  1/2  1/2  1/2  1/2    0    0]
    [   0    0 -1/2  1/2  1/2 -1/2    0    0]
    [-1/2  1/2    0    0    0    0 -1/2  1/2]
    [   0    0 -1/2 -1/2  1/2  1/2    0    0]
    [-1/2 -1/2    0    0    0    0 -1/2 -1/2]
    [-1/2 -1/2    0    0    0    0  1/2  1/2]
    [ 1/2 -1/2    0    0    0    0 -1/2  1/2]

    [ 1/4  1/4  1/4 -1/4 -3/4 -1/4 -1/4 -1/4]
    [-1/4 -1/4  3/4  1/4 -1/4  1/4  1/4  1/4]
    [-1/4 -1/4 -1/4  1/4 -1/4  1/4  1/4 -3/4]
    [-1/4 -1/4 -1/4  1/4 -1/4  1/4 -3/4  1/4]
    [ 1/4 -3/4  1/4 -1/4  1/4 -1/4 -1/4 -1/4]
    [ 3/4 -1/4 -1/4  1/4 -1/4  1/4  1/4  1/4]
    [-1/4 -1/4 -1/4  1/4 -1/4 -3/4  1/4  1/4]
    [-1/4 -1/4 -1/4 -3/4 -1/4  1/4  1/4  1/4]

    [1 0 0 0 0 0 0 0]
    [0 1 0 0 0 0 0 0]
    [0 0 1 0 0 0 0 0]
    [0 0 0 1 0 0 0 0]
    [0 0 0 0 1 0 0 0]
    [0 0 0 0 0 1 0 0]
    [0 0 0 0 0 0 0 1]
    [0 0 0 0 0 0 1 0]
```

```
> [ #Orbit(A, b) : b in Basis(L) ];
[ 2160, 240, 240, 240, 240, 240, 240, 240 ]
> AutomorphismGroup(L: NaturalAction) eq A;
true
```

Example H31E2

In this example we demonstrate how stabilizers can be used to obtain a big subgroup of the full automorphism group fairly quickly.

```
> L := Lattice("Kappa", 13);
> LL, T := PairReduce(L);
> time G2 := AutomorphismGroup(L : Stabilizer := 2);
Time: 0.030
> #G2;
48
> time GG2 := AutomorphismGroup(LL : Stabilizer := 2);
Time: 0.020
> #GG2;
48
> Z := IntegerRing();
> H := MatrixGroup< 13, Z | G2, [ T^-1*g*T : g in Generators(GG2) ] >;
> #H;
311040
> MatrixRing(Z, 13) ! -1 in H;
false
```

The pair reduction yields a different basis for the same lattice and both 2-point stabilizers have order 48. After transforming the automorphisms of LL back to automorphisms of L, the two stabilizers generate a group of reasonable size which still can be enlarged by an index of 2 by adding $-I$. We thus obtain a group of order 622080 which turns out to be the full automorphism group of the lattice L.

```
> time G := AutomorphismGroup(L);
Time: 0.020
> #G;
622080
```

Example H31E3

```
> L := Lattice("Lambda", 19);
> time G := AutomorphismGroup(L);
Time: 0.300
> #G;
23592960
> DS := DerivedSeries(G);
> [ #DS[i]/#DS[i+1] : i in [1..#DS-1] ];
[ 4, 3, 4 ]
```

```
> [ IsElementaryAbelian(DS[i]/DS[i+1]) : i in [1..#DS-1] ];
[ true, true, true ]
> H := DS[#DS];
> C := Core(G, Sylow(H, 2));
> Q := H/C; #Q, IsSimple(Q);
60 true
> LS := LowerCentralSeries(C);
> [ #LS[i]/#LS[i+1] : i in [1..#LS-1] ];
[ 256, 16, 2 ]
```

Hence, $G := \mathrm{Aut}(\Lambda_{19})$ has a series of normal subgroups with factors $2^2, 3, 2^2, A_5, 2^8, 2^4, 2$.

IsIsometric(L, M)

IsIsomorphic(L, M)

BacherDepth	RngIntElt	*Default :* 0
LeftGenerators	[GrpMatElt]	*Default :*
RightGenerators	[GrpMatElt]	*Default :*
LeftVectors	Mtrx	*Default :*
RightVectors	Mtrx	*Default :*

This function determines whether the lattices L and M are isometric. The method is a backtrack search analogous to the one used to compute the automorphism group of a lattice. If the lattices are isometric, the function returns a transformation matrix T as a second return value such that $F_2 = TF_1T^{tr}$, where F_1 and F_2 are the Gram matrices of L and M, respectively.

For isometric lattices the cost of finding an isometry is roughly the cost of finding one automorphism of the lattice. Again, the computation may be sped up by using the additional invariants described for the automorphism group computation.

In many applications one will check whether a lattice is isometric to one for which the automorphism group is already known. In this situation the automorphism group of the second lattice can be made available by setting `RightGenerators := Q`, where Q is a set or sequence containing the generators of the group. Note however, that for isometric lattices this may slow down the computation, since generators for stabilizers have to be recomputed. Similarly, generators for an automorphism group of the first lattice may be supplied as `LeftGenerators`.

Corresponding to the `Vectors` parameter for automorphism group calculation, the parameters `LeftVectors` and `RightVectors` allow the user to. As above, left refers to the first lattice, right to the second. Either both of these parameters can be set, or neither, an error results if just one is set. The restrictions on what constitutes correct values for these parameters are as for the `Vectors` parameter above. For correct isometry testing, the vectors given must be such that any isometry will map the left vectors into the union of the right vectors and their negatives. These conditions are not checked in the code, they are the responsibility of the user.

IsIsometric(L, F_1, M, F_2)

IsIsomorphic(L, F_1, M, F_2)

IsIsometric(L, M)

IsIsomorphic(L, M)

BacherDepth	RngIntElt	*Default :* 0
LeftGenerators	[GrpMatElt]	*Default :*
RightGenerators	[GrpMatElt]	*Default :*
LeftVectors	Mtrx	*Default :*
RightVectors	Mtrx	*Default :*

This function determines whether the lattices L and M are isometric with an isometry respecting also additional bilinear forms given by the sequences of Gram matrices F_1 and F_2. The return values and parameters are as above.

IsIsometric(F_1, F_2)

IsIsomorphic(F_1, F_2)

BacherDepth	RngIntElt	*Default :* 0
LeftGenerators	[GrpMatElt]	*Default :*
RightGenerators	[GrpMatElt]	*Default :*
LeftVectors	Mtrx	*Default :*
RightVectors	Mtrx	*Default :*

For two sequences of F_1 and F_2 of Gram matrices, determine whether a simultaneous isometry exists, i.e., a matrix T such that $TF_1[i]T^{tr} = F_2[i]$ for i in $[1..\#F_1]$. The first form in both sequences must be positive definite. The return values and parameters are as above.

Example H31E4

We construct the 16-dimensional Barnes-Wall lattice in two different ways and show that the so-obtained lattices are isometric.

```
> L := Lattice("Lambda", 16);
> LL := Lattice(ReedMullerCode(1, 4), "B");
> time bool, T := IsIsometric(L, LL : Depth := 4);
Time: 2.029
> bool;
true
> T * GramMatrix(L) * Transpose(T) eq GramMatrix(LL);
true
```

We can also show that L is a 2-modular lattice (i.e., isometric to its rescaled dual).

```
> IsIsometric(L, Dual(L));
true
```

```
[ 0  1  1 -1  1 -1  0  0 -1  1 -1  0  0  0  0  0]
[-2 -3 -4  1 -2  3 -1 -2  0  1 -1 -1  1  1  1 -1]
[-1 -1 -1  1  0 -1  0 -1  0  2 -1 -1  1  1  1 -1]
[ 0  1  1 -1  1  0  0  0 -1  0  0  0  0  0  0  0]
[ 0 -1 -2  0 -1  2 -1 -1  0  1 -1  0  1  0  0  0]
[ 1  2  2  0  2 -3  0  0 -2  4 -2 -1  1  1 -1 -1]
[-1 -1 -2  0  0  1  0 -1  0  0  0 -1  1  1  1 -1]
[ 1  2  3 -1  2 -3  1  1 -1  0  0  0  0  0 -1  1]
[ 0  1  1  0  2 -3  0 -1 -2  4 -2 -2  1  1  1 -1]
[ 0 -1 -2  0 -2  3 -1  0  1 -1  0  1  0  0 -1  0]
[ 0  0  1  1  0 -1  1  1  1 -1  0  1  0  0 -1  0]
[ 0 -1 -1  1 -2  2 -1  0  1  0  0  1  0 -1 -1  0]
[ 0  0  0  0  0  0  0  1  1 -1  0  1  0  0 -1  0]
[ 0 -1 -2  0 -2  3  0  0  1 -2  0  1  1  0 -2  1]
[ 0  1  1 -1  1 -1  0  0 -1  1  0 -1  0  0  1  0]
[ 0  0 -1 -1  0  1  0 -1 -1  1 -1 -1  1  1  0  0]
```

31.2.1 Automorphism Group and Isometry Testing over $\mathbf{F}_q[t]$

Let q be some power of an odd prime. A bilinear form b over $\mathbf{F}_q[t]$ is said to be definte if the corresponding quadratic form is anisotropic over the completion of $\mathbf{F}_q(t)$ at the infinite place $(1/t)$.

The functions in this section compute automorphism groups and isometries of definite bilinear forms over $\mathbf{F}_q[t]$.

`DominantDiagonalForm(X)`

`Canonical`	Bool	*Default :* `false`
`ExtensionField`	FldFin	*Default :*

Let X be a symmetric $n \times n$-matrix of rank n over a polynomial ring $K[t]$ where K denotes a field of characteristic different from 2. The function returns a symmetric matrix G and some $T \in \mathrm{GL}(n, K[t])$ such that $G = TXT^{tr}$ has dominant diagonal. I.e. the degrees of the diagonal entries of G are ascending and the degree of a non-diagonal entry is less than the degrees of the corresponding diagonal entries (see [Ger03]).

If K is a finite field and X represents a definite form and `Canonical` is set to `true`, then the form G will be unique and the third return value will be the automorphism group of G i.e. the stabilizer of G in $\mathrm{GL}(n, K[t])$. The algorithm employed is [Kir12]. Note however, the uniqueness depends on some internal choices being made. Thus the fourth return value is a finite field E which must be given as the optional argument `ExtensionField` in subsequent runs over K to ensure that results are compatible (c.f. the following example). In particular, the defining polynomial and the primitive element of E are important for the uniqueness.

Example H31E5

We test whether two definite forms over $\mathbf{F}_q[t]$ are isometric.

```
> R<t> := PolynomialRing( GF(5) );
> X1:= SymmetricMatrix([ t^3, t+1, 2*t^2+2*t+2 ] );
> X2:= SymmetricMatrix([ t^3, t^4+2*t+2, t^5+2*t^2+2*t+3 ]);
> G1, T1, Aut, E:= DominantDiagonalForm(X1 : Canonical);
> T1 * X1 * Transpose(T1) eq G1;
true
> GG:= [ Matrix(g) : g in Generators(Aut) ];
> forall{g : g in GG | g * G1 * Transpose(g) eq G1 };
true
```

So the form G_1 is invariant under Aut. Now we reduce the second form X_2. To be able to compare the results, we have to provide the field E from above.

```
> G2, T2 := DominantDiagonalForm(X2 : Canonical, ExtensionField:= E);
> G1 eq G2;
true
```

Thus the two forms X_1 and X_2 are isometric and $T_1^{-1}T_2$ is an isometry.

`AutomorphismGroup(G)`

`ExtensionField` FldFin *Default :*

Computes the automorphism group of the definite bilinear form given by the symmetric matrix G over $\mathbf{F}_q[t]$.

The second return value is a finite field as explained in `DominantDiagonalForm` above. It may be supplied for later calls over the same ground field $\mathbf{F}_q$ via the optional argument `ExtensionField` to safe some time if q is large. The correctness of the algorithm does not depend on it.

`IsIsometric(G1, G2)`

`ExtensionField` FldFin *Default :*

Tests whether two definite bilinear forms over $\mathbf{F}_q[t]$ are isometric. If so, the second return value is a matrix $T \in \mathrm{GL}(n, q)$ such that $TG1T^{tr} = G2$.

The third return value is a finite field as explained in `DominantDiagonalForm` above. It may be supplied for later calls over the same ground field $\mathbf{F}_q$ via the optional argument `ExtensionField` to safe some time if q is large. The correctness of the algorithm does not depend on it.

`ShortestVectors(G)`

Returns a sequence Q which contains the shortest non-zero vectors with respect to a given definite bilinear form G over $\mathbf{F}_q[t]$ where q is odd. The sequence Q contains tuples $< v, r >$ where v is a shortest vector and r denotes its norm with respect to G.

`ShortVectors(G, B)`

Let G be a definite bilinear form of rank n over $\mathbf{F}_q[t]$ for some odd q. The function returns a sequence Q which contains all vectors in $\mathbf{F}_q[t]^n$ whose norm with respect to G is at most B. The sequence Q contains tuples $< v, r >$ where v is such a short vector and r denotes its norm with respect to G.

31.3 Lattices from Matrix Groups

In MAGMA a G-lattice L is a lattice upon which a finite integral matrix group G acts by right multiplication.

Each G-lattice L has references to both the original ("natural") group G which acts on the standard lattice in which L is embedded and also the reduced group of L which is the reduced representation of G on the basis of L.

31.3.1 Creation of G-Lattices

The following functions create G-lattices. Note that the group G must be a finite integral matrix group.

`Lattice(G)`

Given a finite integral matrix group G, return the standard G-lattice (with standard basis and rank equal to the degree of G).

`LatticeWithBasis(G, B)`

Given a finite integral matrix group G and a non-singular matrix B whose row space is invariant under G (i.e., $Bg = T_g B$ for each $g \in G$ where T_g is a unimodular integral matrix depending on g), return the G-lattice with basis matrix B. (The number of columns of B must equal the degree of G; G acts naturally on the lattice spanned by B.)

`LatticeWithBasis(G, B, M)`

Given a finite integral matrix group G, a non-singular matrix B whose row space is invariant under G (i.e., $Bg = T_g B$ for all $g \in G$ where T_g is a unimodular integral matrix depending on g) and a positive definite matrix M invariant under G (i.e., $gMg^{tr} = M$ for all $g \in G$) return the G-lattice with basis matrix B and inner product matrix M. (The number of columns of B must equal the degree of G and both the number of rows and the number of columns of M must equal the degree of G; G acts naturally on the lattice spanned by B and fixes the Gram matrix of the lattice).

`LatticeWithGram(G, F)`

Given a finite integral matrix group G and a positive definite matrix F invariant under G (i.e., $gFg^{tr} = F$ for all $g \in G$) return the G-lattice with standard basis and inner product matrix F (and thus Gram matrix F). (Both the number of rows and the number of columns of M must equal the degree of G; G fixes the Gram matrix of the returned lattice).

31.3.2 Operations on G-Lattices

The following functions provide basic operations on G-lattices.

`IsGLattice(L)`

Given a lattice L, return whether L is a G-lattice (i.e., there is a group associated with L).

`Group(L)`

Given a G-lattice L, return the matrix group of the (reduced) action of G on L. The resulting group thus acts on the coordinate lattice of L (like the automorphism group).

`NumberOfActionGenerators(L)`

`Nagens(L)`

Given a G-lattice L, return the number of generators of G.

`ActionGenerator(L, i)`

Given a G-lattice L, return the i-th generator of the (reduced) action of G on L. This is the reduced action of the i-th generator of the original group G (which may be the identity matrix).

`NaturalGroup(L)`

Given a G-lattice L, return the matrix group of the (natural) action of G on L. The resulting group thus acts on L naturally.

`NaturalActionGenerator(L, i)`

Given a G-lattice L, return the i-th generator of the natural action of G on L. This is simply the i-th generator of the original group G.

31.3.3 Invariant Forms

The functions in this section compute invariant forms for G-lattices.

`InvariantForms(L)`

For a G-lattice L, return a basis for the space of invariant bilinear forms for G (represented by their Gram matrices) as a sequence of matrices. The first entry of the sequence is a positive definite symmetric form for G.

`InvariantForms(L, n)`

For a G-lattice L, return a sequence consisting of $n \geq 0$ invariant bilinear forms for G.

`SymmetricForms(L)`

For a G-lattice L, return a basis for the space of symmetric invariant bilinear forms for G. The first entry of the sequence is a positive definite symmetric form of G.

`SymmetricForms(L, n)`

For a G-lattice L, return a sequence of $n \geq 0$ independent symmetric invariant bilinear forms for G. The first entry of the first sequence (if $n > 0$) is a positive definite symmetric form for G.

`AntisymmetricForms(L)`

For a G-lattice L, return a basis for the space of antisymmetric invariant bilinear forms for G.

`AntisymmetricForms(L, n)`

For a G-lattice L, return a sequence of $n \geq 0$ independent antisymmetric invariant bilinear forms for G.

`NumberOfInvariantForms(L)`

For a G-lattice L, return the dimension of the space of (symmetric and antisymmetric) invariant bilinear forms for G. The algorithm uses a modular method which is always correct and is faster than the actual computation of the forms.

`NumberOfSymmetricForms(L)`

For a G-lattice L, return the dimension of the space of symmetric invariant bilinear forms for G.

`NumberOfAntisymmetricForms(L)`

For a G-lattice L, return the dimension of the space of antisymmetric invariant bilinear forms for G.

`PositiveDefiniteForm(L)`

For a G-lattice L, return a positive definite symmetric form for G. This is a positive definite matrix F such that $gFg^{tr} = F$ for all $g \in G$.

31.3.4 Endomorphisms

The functions in this subsection compute endomorphisms of G-lattices. This is done by approximating the averaging operator over the group and applying it to random elements.

`EndomorphismRing(L)`

For a G-lattice L, return the endomorphism ring of L as a matrix algebra over $\mathbf{Q}$.

`Endomorphisms(L, n)`

For a G-lattice L, return a sequence containing n independent endomorphisms of L as elements of the corresponding matrix algebra over $\mathbf{Q}$. n must be in the range $[0..d]$, where d is the dimension of the endomorphism ring of L. This function may be useful in situations where the full endomorphism algebra is not required, e.g., to split a reducible lattice.

`DimensionOfEndomorphismRing(L)`

Return the dimension of the endomorphism algebra of the G-lattice L by a modular method (which always yields a correct answer).

`CentreOfEndomorphismRing(L)`

For a G-lattice L, return the centre of the endomorphism ring of L as a matrix algebra over $\mathbf{Q}$.

This function can be used to split a reducible lattice into its homogeneous components.

`CentralEndomorphisms(L, n)`

For a G-lattice L, return a sequence containing n independent central endomorphisms of L as elements of the corresponding matrix algebra over $\mathbf{Q}$. n must be in the range $[0..d]$, where d is the dimension of the centre of the endomorphism ring of L.

`DimensionOfCentreOfEndomorphismRing(L)`

Return the dimension of the centre of the endomorphism algebra of the G-lattice L by a modular method (which always yields a correct answer).

31.3.5 G-invariant Sublattices

The functions in this section compute G-invariant sublattices of a given G-lattice L.

For a fixed prime p, the algorithm constructs the maximal G-invariant sublattices of L as kernels of $\mathbf{F}_pG$-epimorphisms $L/pL \to S$ for some simple $\mathbf{F}_pG$-module S as described in [Ple74].

Iterating this process yields all G-invariant sublattices of L whose index in L is a p-power. Finally, intersecting lattices of coprime index yields all sublattices of L.

`Sublattices(G, Q)`

`Sublattices(L, Q)`

`Limit`	RngIntElt	*Default :* ∞
`Levels`	RngIntElt	*Default :* ∞
`Projections`	[Mtrx]	*Default :* []

Given either

(a) an integral matrix group G with natural lattice $L = \mathbf{Z}^n$

(b) a sequence G of integral matrices generating a $\mathbf{Z}$-order in $\mathbf{Q}^{n\times n}$ with natural lattice $L = \mathbf{Z}^n$

(c) a G-lattice L in $\mathbf{Q}^n$.

together with a set or sequence Q of primes, compute the G-invariant sublattices of L (as a sequence) which are not contained in pL for any $p \in Q$ and whose index in L is a product of elements of Q.

This set of G-invariant sublattices of L is finite if and only if $\mathbf{Q}_p \otimes L$ is irreducible as a $\mathbf{Q}_p G$-module for all $p \in Q$.

Setting the parameter `Limit := n` will terminate the computation after n sublattices have been found.

Setting the parameter `Levels := n` will only compute sublattices M such that L/M has at most n composition factors.

The optional parameter `Projections` can be a sequence of n by n matrices that describe projections on $\mathbf{Q}^n$ that map L to itself. In this case, MAGMA will only compute those sublattices of L which have the same images under the projections as L does.

The second return value indicates whether the returned sequence contains all such sublattices or not.

`Sublattices(G, p)`

`Sublattices(L, p)`

`Limit`	RNGINTELT	*Default :* ∞
`Levels`	RNGINTELT	*Default :* ∞
`Projections`	[MTRX]	*Default :* []

The same as the above where the set Q consists only of the given ptime p.

`Sublattices(G)`

`Sublattices(L)`

`Limit`	RNGINTELT	*Default :* ∞
`Levels`	RNGINTELT	*Default :* ∞
`Projections`	[MTRX]	*Default :* []

For an integral matrix group G or a G-lattice L this intrinsic equals the one above with Q taken to be the prime divisors of the order of G.

`SublatticeClasses(G)`

`MaximalOrders`	BOOLELT	*Default :* `false`

For an integral matrix group G returns representatives for the isomorphism classes of G-invariant lattices (i.e. the orbits under the unit group of the endomorphism ring E of G).

If `MaximalOrders` is set to `true`, only sublattice classes which are invariant under some maximal order of E are considered.

Currently the function requires E to be a field.

Example H31E6

We construct sublattices of the standard G-lattice where G is an absolutely irreducible degree-8 integral matrix representation of the group $\mathrm{GL}(2,3) \times \mathrm{S}_3$.

We first define the group G.

```
> G := MatrixGroup<8, IntegerRing() |
>    [-1,  0,  0,  0,  0,  0,  0,  0,
>      0,  0, -1,  0,  0,  0,  0,  0,
>      0,  0,  0,  1,  0,  0,  0,  0,
>      0,  1,  0,  0,  0,  0,  0,  0,
>     -1,  0,  0,  0,  1,  0,  0,  0,
>      0,  0, -1,  0,  0,  0,  1,  0,
>      0,  0,  0,  1,  0,  0,  0, -1,
>      0,  1,  0,  0,  0, -1,  0,  0],
>
>    [ 0,  0,  0,  0,  0,  0,  0,  1,
>      0,  0,  0,  0,  0,  0,  1,  0,
>      0,  0,  0,  0, -1,  0,  0,  0,
>      0,  0,  0,  0,  0,  1,  0,  0,
>      0,  0,  0, -1,  0,  0,  0,  1,
>      0,  0, -1,  0,  0,  0,  1,  0,
>      1,  0,  0,  0, -1,  0,  0,  0,
>      0, -1,  0,  0,  0,  1,  0,  0]>;
```

We next compute the unique positive definite form F fixed by G.

```
> time F := PositiveDefiniteForm(G);
Time: 0.050
> F;
[2 0 0 0 1 0 0 0]
[0 2 0 0 0 1 0 0]
[0 0 2 0 0 0 1 0]
[0 0 0 2 0 0 0 1]
[1 0 0 0 2 0 0 0]
[0 1 0 0 0 2 0 0]
[0 0 1 0 0 0 2 0]
[0 0 0 1 0 0 0 2]
```

We now compute all sublattices of the standard G-lattice.

```
> time Sub := Sublattices(G);
Time: 0.370
> #Sub;
18
```

For each sublattice we compute the invariant positive definite form for the group given by the action of G on the sublattice.

```
> PrimitiveMatrix := func<X |
>     P ! ((ChangeRing(P, RationalField()) ! X) / GCD(Eltseq(X)))
```

```
>         where P is Parent(X)>;
> FF := [PrimitiveMatrix(B * F * Transpose(B))
>             where B is BasisMatrix(L): L in Sub];
```

We next create the sequence of all the lattices whose Gram matrices are given by the (LLL-reduced) forms.

```
> Sub := [LatticeWithGram(LLLGram(F)) : F in FF];
> #Sub;
18
```

We now compute representatives for the **Z**-isomorphism classes of the sequence of lattices.

```
> Rep := [];
> for L in Sub do
>     if forall{LL: LL in Rep | not IsIsometric(L, LL)} then
>         Append(~Rep, L);
>     end if;
> end for;
> #Rep;
4
```

Thus there are 4 non-isomorphic sublattices. We note the size of the automorphism group, the determinant, the minimum and the kissing number of each lattice. (In fact, the automorphism groups of these 4 lattices happen to be maximal finite subgroups of $\mathrm{GL}(8, \mathbf{Q})$ and all have $\mathrm{GL}(2,3) \times \mathrm{S}_3$ as a common irreducible subgroup.)

```
> time A := [AutomorphismGroup(L) : L in Rep];
Time: 0.240
> [#G: G in A];
[ 497664, 6912, 696729600, 2654208 ]
> [Determinant(L): L in Rep];
[ 81, 1296, 1, 16 ]
> [Minimum(L): L in Rep];
[ 2, 4, 2, 2 ]
> [KissingNumber(L): L in Rep];
[ 24, 72, 240, 48 ]
```

Finally, we note that each lattice is isomorphic to a standard construction based on root lattices.

```
> l := IsIsometric(Rep[1],
>        TensorProduct(Lattice("A", 2), StandardLattice(4))); l;
true
> l := IsIsometric(Rep[2],
>        TensorProduct(Lattice("A", 2), Lattice("F", 4))); l;
true
> l := IsIsometric(Rep[3], Lattice("E", 8)); l;
true
> l := IsIsometric(Rep[4],
>        TensorProduct(Lattice("F", 4), StandardLattice(2))); l;
```

Example H31E7

This example illustrates the optional argument `Projections`.

```
> G := MatrixGroup<4, IntegerRing() |
> [ -1, 0, 1, 0, 0, -1, 1, -3, -1, 0, 0, 0, 0, 0, 0, 1 ],
> [ -1, 0, 0, 0, -3, 2, 0, 3, 0, 0, -1, 0, 1, -1, 0, -1 ] >;
> E := EndomorphismRing(G);
> I := CentralIdempotents(ChangeRing(E, RationalField())); I;
[
    [ 0  0  0  0]
    [-1  1  0  0]
    [ 0  0  0  0]
    [ 0  0  0  1],
    [1 0 0 0]
    [1 0 0 0]
    [0 0 1 0]
    [0 0 0 0]
]
```

Since the central idempotents are all integral, they map the standard lattice $\mathbf{Z}^n$ to itself. Even though this group G fixes infinitely many sublattices of Z^n (even up to scalar multiples), there can only be finitely many which have the same images under the central idempotents as $\mathbf{Z}^n$.

```
> S := Sublattices(G : Projections:= I); #S;
3
```

So in this case there are only three such lattices. To check that the lattices do project correctly, we can use

```
> I := [ Matrix(Integers(), i) : i in I ];
> Images := [ [Image(BasisMatrix(s) * i) : i in I] : s in S ];
> #Set(Images) eq 1;
true
```

31.3.6 Lattice of Sublattices

MAGMA can construct the lattice V of all G-invariant sublattices of the standard lattice $L = \mathbf{Z}^n$. Various properties of the lattice V may then be examined. MAGMA only stores the primitive sublattices of L, i.e. those sublattices that are not contained in kL for some $k > 1$.

In general, G fixes infinitely many primitive lattices. Thus one has to limit the number of sublattices to be constructed just as in the `Sublattice` intrinsic. In this case, all operations on V like coercions, intersections, sums etc. assume that the result of the operation is again is a scalar multiple of some element stored in V.

The lattice V has type `LatLat` and elements of V have type `LatLatElt` and are numbered from 1 to n where n is the number of primitive sublattices of L that have been constructed in the beginning.

31.3.6.1 Creating the lattice of sublattices

`SublatticeLattice(G, Q)`

`Limit`	RngIntElt	*Default :* ∞
`Levels`	RngIntElt	*Default :* ∞
`Projections`	[Mtrx]	*Default :* []

Given either an integral matrix group G of degree n or a sequence G of integral matrices generating a $\mathbf{Z}$-order in $\mathbf{Q}^{n\times n}$ together with a set or sequence Q of primes, compute the G-invariant sublattices of $\mathbf{Z}^n$ (as a sequence) which are not contained in $p\mathbf{Z}^n$ for any $p \in Q$ and whose index in $\mathbf{Z}^n$ is a product of elements of Q.

The second return value indicates whether all G-invariant lattices have been constructed.

The optional parameters are the same as for the `Sublattices` intrinsic.

`SublatticeLattice(G, p)`

`Limit`	RngIntElt	*Default :* ∞
`Levels`	RngIntElt	*Default :* ∞
`Projections`	[Mtrx]	*Default :* []

Same as above where the set Q consists only of the given prime p.

`SublatticeLattice(G)`

`Limit`	RngIntElt	*Default :* ∞
`Levels`	RngIntElt	*Default :* ∞
`Projections`	[Mtrx]	*Default :* []

Same as above where the set Q is taken to be set of prime divisors of the order of the group G.

Example H31E8

This example shows how to create a lattice of sublattices.

```
> G:= sub< GL(2, Integers()) | [0,1,-1,0] >;
> V:= SublatticeLattice(G); V;
Lattice of 2 sublattices
```

31.3.6.2 Operations on the Lattice of Sublattices

In the following, V is a lattice of G-invariant lattices for some group or **Z**-order G and Q denotes the set of primes that where used to create V.

`#V`

The number of (primitive) lattices stored in V.

`V ! i`

The i-th element of the lattice V with respect to the internal labeling.

`V ! M`

Given a (basis matrix of some) G-invariant lattice M, create the element of the lattice V corresponding to M.

`NumberOfLevels( V )`

The number of different levels (layers) stored in V. Note that levels are counted starting from 0.

`Level(V, i)`

The primitive lattices stored at the i-th level (layer). Note that levels are counted starting from 0.

`Levels(v)`

The i-th entry of the result is a sequence of the primitive lattice elements lying on the $i-1$-th level.

`Primes(V)`

The primes that where used to create V.

`Constituents(V)`

A sequence containing the constituents (simple $\mathbf{F}_pG$ - modules) that where used during the construction of the G-lattices in V.

`IntegerRing() ! e`

The integer corresponding to lattice element e.

`e + f`

The sum of the lattice elements e and f.

`e meet f`

The intersection of the lattice elements e and f.

`e eq f`

Tests whether e and f are equal.

`MaximalSublattices(e)`

The sequence S of maximal sublattices of e having index p for some $p \in Q$. The second return value is a list C of integers such that $S[i]/e$ is isomorphic to the $C[i]$-th constituent of V. The ordering of the constituents is the same as in the `Constituents` intrinsic.

`MinimalSuperlattices(e)`

The sequence S of minimal superlattices of e in which e has index p for some $p \in Q$. The second return value is a list C of integers such that $e/S[i]$ is isomorphic to the $C[i]$-th constituent of V. The ordering of the constituents is the same as in the `Constituents` intrinsic.

`Lattice(e)`

The G-lattice corresponding to e.

`BasisMatrix(e)`

`Morphism(e)`

The basis matrix of the G-lattice corresponding to e.

Example H31E9

Let G be the automorphism group of the root lattice A_5. Since G is absolutely irreducible, it fixes only finitely many lattices up to scalars. We explore them.

```
> G:= AutomorphismGroup(Lattice("A", 5));
> FactoredOrder(G);
[ <2, 5>, <3, 2>, <5, 1> ]
> #SublatticeLattice(G, 5);
1
```

Hence there are no primitive sublattices between L and $5L$. Hence it suffices to check only the lattices at 2 and 3 the two remaining prime divisors of the order of G.

```
> V:= SublatticeLattice(G, {2,3}); #V;
4
> M:= MaximalSublattices(V ! 1); M;
[
    sublattice number 2,
    sublattice number 3
]
> V ! 2 meet V ! 3;
sublattice number 4
```

Moreover, the second and third lattice are (up to rescaling) dual to each other with respect to some G-invariant form.

```
> F:= PositiveDefiniteForm(G);
> L:= Dual(Lattice(BasisMatrix(V ! 2), F) : Rescale:= false);
> V ! L;
```

```
sublattice number 3 times 1/6
```

In particular, every G-invariant lattice can be constructed from lattice number 2 by taking scalar multiples, duals, sums and intersections. For example the standard lattice can be written as:

```
> (V ! 2) + (V ! (6*L));
sublattice number 1
```

Example H31E10

Let G be the 8-dimensional (faithful) rational representation of $\mathrm{SL}(2,7)$. Its endomorphism ring E is isomorphic to $\mathbf{Q}(\sqrt{-7})$. We find all G-invariant lattices of G that are invariant under the maximal order M of E up to multiplication with elements in E. After this is done, we quickly obtain all finite subgroups of $\mathrm{GL}(8,\mathbf{Q})$ (up to conjugacy) that include a normal subgroup conjugate to G.
To shorten the example, we choose G such that the standard lattice L is already invariant under M.

```
> SetSeed(1);
> G:= MatrixGroup<8, IntegerRing() |
>    [ 0, 1, 0, 0, 0, 0, -1, 0, -1, 0, 0, 0, 0, 0, -1, 1,
>      0, 0, 0, 1, 0, 0, -1, 0, 0, 0, -1, 0, 0, 0, -1, 1,
>      0, 0, 0, 0, 0, 1, -1, 0, 0, 0, 0, 0, -1, 0, -1, 1,
>      0, 0, 0, 0, 0, 0, -1, 1, 0, 0, 0, 0, 0, 0, -2, 1 ],
>    [ 0, -1, 0, 0, 0, 0, 0, 1, 0, 0, 1, 0, 0, 0, 0, 0,
>     -1, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, -1, 1,
>      0, 0, 0, -1, 0, 0, 0, 1, 0, 0, 0, 0, 0, 1, 0, 0,
>      0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1 ] >; #G;
336
> E:= EndomorphismRing(G);
> M:= MaximalOrder(ChangeRing(E, RationalField()));
> ok, M:= CanChangeUniverse(Basis(M), MatrixRing(Integers(), 8)); ok;
true
```

So L is M-invariant. The lattices at the primes 3 and 7 are multiples of L as we can see as follows:

```
> w7:= IntegralMatrix(E.2 - Trace(E.2)/8);
> w7 div:= GCD( Eltseq(w7) );                    // a square root of 7
> V:= SublatticeLattice([ Matrix(G.i) : i in [1..Ngens(G)] ] cat M, [3,7]); #V;
2
> V ! w7;
sublattice number 2
```

So it remains to check the lattices at 2. The two prime ideals in M over 2 are generated by `p` and `q` where

```
> p:= 1 - (w7+1) div 2;
> q:= (w7+1) div 2;
> Gens:= [ Matrix(G.i) : i in [1..Ngens(G)] ];
> V:= SublatticeLattice(Gens cat M, 2: Levels:= 3);
> Levels(V);
```

```
[
    [
        sublattice number 1
    ],
    [
        sublattice number 2,
        sublattice number 3
    ],
    [
        sublattice number 4,
        sublattice number 5,
        sublattice number 6
    ],
    [
        sublattice number 7,
        sublattice number 8,
        sublattice number 9,
        sublattice number 10
    ]
]
> [ V | BasisMatrix(V ! i)*x : i in [1..3], x in [p,q] ];
[
    sublattice number 4,
    sublattice number 7,
    sublattice number 8,
    sublattice number 6,
    sublattice number 9,
    sublattice number 10
]
```

So the lattice numbers $1, 2, 3$ and 5 represent the orbits of the action of E on the set of all MG-invariant lattices. Moreover, every matrix group N normalizing G acts on the MG-invariant lattices and (up to conjugacy) thus fixes one of these four lattices. If it fixes L, it also fixes $V!2 + V!3 = V!5$ and vice versa. Similarly, it fixes $V!2$ if and only if it fixes $V!3$.

```
> F:= PositiveDefiniteForm(G);
> N1:= Normalizer(AutomorphismGroup(LatticeWithGram(F)), G); #N1;
672
> A:= AutomorphismGroup(Lattice(BasisMatrix(V ! 2), F) : NaturalAction);
> N2:= Normalizer(A, ChangeRing(G, Rationals())); #N2;
336
```

So `N1` (which is isomorphic to $2.L(2,7):2$) is up to conjugacy the only proper finite extension of G in $\mathrm{GL}(8, \mathbf{Q})$.

32 QUADRATIC FORMS

Chapter 32
QUADRATIC FORMS

32.1 Introduction

This chapter describes miscellaneous functionality for fairly general quadratic forms. The main feature currently here is an implementation of Simon's algorithm for finding isotropic subspaces of integral forms.

In MAGMA, quadratic forms are generally represented either as multivariate polynomials, or as symmetric matrices.

32.2 Constructions and Conversions

`SymmetricMatrix(f)`

Given a multivariate polynomial that is homogeneous of degree 2, this returns a symmetric matrix representing the same quadratic form.

`GramMatrix(L)`

The symmetric matrix giving the quadratic form on the lattice L.

`QuadraticForm(L)`

The quadratic form associated to the lattice L, as a multivariate polynomial.

`QuadraticForm(M)`

The quadratic form for a symmetric matrix M, as a multivariate polynomial.

32.3 Local Invariants

These commands calculate the standard invariants that characterize a quadratic form over the rationals. Definitions of the invariants may be found in Conway-Sloane [JC98], Chapter 15, Section 5.1.

```
pSignature(f,p)
pSignature(M,p)
pSignature(L,p)
```

The p-signature of the specified quadratic form over the rationals, where p is a prime number or -1 (designating the real place).

For odd primes p, this is defined by diagonalizing the form, and adding p-parts of these entries to 4 times the number of anti-squares (mod p) amongst these entries. The term "anti-square" modulo p denotes something that has: odd valuation at p; and the prime-to-p part, called u, has Kronecker symbol $(\frac{u}{p}) = -1$.

At $p = 2$ it is the sum of the odd parts of the diagonalized entries plus 4 times the number of anti-squares. In either case, the final answer is really only defined modulo 8 (this is so that p-signatures are invariant under rational equivalence).

At the real place, it is the difference between the number of positive and negative eigenvalues (the terminology here can be murky).

```
Oddity(f)
Oddity(L)
Oddity(M)
```

This returns the 2-signature of the given quadratic form over the rationals.

```
pExcess(f, p)
pExcess(M, p)
pExcess(L, p)
```

The p-excess of the specified quadratic form over the rationals, where p is a prime number or -1 (designating the real place). The p-excess is the difference between the p-signature and dimension for odd primes (including -1), and is the negation of this for $p = 2$. The sum of p-excesses over all primes should be 0 modulo 8.

```
WittInvariant(f, p)
WittInvariant(M, p)
WittInvariant(L, p)
HasseMinkowskiInvariant(f, p)
HasseMinkowskiInvariant(M, p)
HasseMinkowskiInvariant(L, p)
```

Calculates the Witt invariant (sometimes called the Hasse-Minkowski invariant) over $\mathbf{Q}_p$ of the given quadratic form. Again the form must be defined over either the rationals or the integers. The result is returned as something in the set $\{-1, +1\}$. One definition of this invariant is to diagonalize the form and then take the product (in our multiplicative notation) of the Hilbert symbols of the $\binom{n}{2}$ pairs of distinct nonzero diagonal entries, as in §5.3 of Chapter 15 of Conway-Sloane [JC98], which is what is implemented here. Another method would be to use a comparison of p-excesses with the standard form (also in Conway-Sloane). Starting with a p-adic input could lead to precision problems at the diagonalization step, and so is not allowed. Can also be called via `HasseMinkowskiInvariant`.

`WittInvariants(f)`
`WittInvariants(M)`
`WittInvariants(L)`
`HasseMinkowskiInvariants(f)`
`HasseMinkowskiInvariants(M)`
`HasseMinkowskiInvariants(L)`

Compute `WittInvariant(f,p)` for all bad primes p, and return the result of a sequence of tuples, each entry given by $\langle p, W_p(f)\rangle$. The set of bad primes includes the real place, the prime $p = 2$, and all primes that divide either the numerator or the denominator of the determinant of symmetric matrix associated to f. Can also be called via `HasseMinkowskiInvariants`.

32.4 Isotropic Subspaces

`IsotropicSubspace(f)`
`IsotropicSubspace(M)`

This returns an isotropic subspace for the given quadratic form (which must be either integral or rational), which may be given either as a multivariate polynomial f or as a symmetric matrix M. The subspace returned is in many cases guaranteed to be a maximal totally isotropic subspace. More precisely (assuming that the form is nonsingular), upon writing (r, s) for the signature of f with $r \geq s$, the dimension of the space returned is at least $\min(r, s + 2) - 2$, which is maximum possible when $s \leq r + 2$. Since version 2.18, an improvement to the original algorithm has been appended, which typically (subject to a solvability criterion for a 4-dimensional subspace) enlarges the dimension of space by 1 when $r + s$ is even and $s \leq r + 2$.

The algorithm used is due to Simon (see [Sim05]), and uses on the Bosma-Stevenhagen algorithm for the 2-part of the class groups of a quadratic field (see [BS96]). There is no corresponding intrinsic for a lattice: since the associated form is definite, there are no isotropic vectors.

Example H32E1

```
> v :=  [ 6, -2, -7, 5, -2, -10, -3, 5, -7, -3, 10, -8, 5, 5, -8, 0 ];
> M := Matrix(4, 4, v); M;
[  6  -2  -7   5]
[ -2 -10  -3   5]
[ -7  -3  10  -8]
[  5   5  -8   0]
> Determinant(M); Factorization(Determinant(M));
1936
[ <2, 4>, <11, 2> ]
> WittInvariant(M, 2);
-1
> WittInvariant(M, 11);
1
> D := Diagonalization(M); D; // signature (2,2)
[     6      0      0      0]
[     0    -96      0      0]
[     0      0     18      0]
[     0      0      0 -34848]
> pSignature(M, -1); // should be the difference of 2 and 2
0
> n := Degree(Parent(M));
> Q := Rationals();
> E := [ Q ! D[i][i] : i in [1..n]];
> &*[ &*[ HilbertSymbol(E[i], E[j], 2) : i in [j+1..n]] : j in [1..n-1]];
-1
> &*[ &*[ HilbertSymbol(E[i], E[j], 11) : i in [j+1..n]] : j in [1..n-1]];
1
> IsotropicSubspace(M);
RSpace of degree 4, dimension 2 over Integer Ring
Generators:
( 3 -3  0  4)
( 4 -4  0 -2)
Echelonized basis:

33 BINARY QUADRATIC FORMS

Chapter 33
BINARY QUADRATIC FORMS

33.1 Introduction

A binary quadratic form is an integral form $ax^2+bxy+cy^2$ which is represented in MAGMA by a tuple $\langle a, b, c\rangle$. Binary quadratic forms play an central role in the ideal theory of quadratic fields, the classical theory of complex multiplication, and the theory of modular forms. Algorithms for binary quadratic forms provide efficient means of computing in the ideal class group of orders in a quadratic field. By using the explicit relation of definite quadratic forms with lattices with nontrivial endomorphism ring in the complex plane, one can apply modular and elliptic functions to forms, and exploit the analytic theory of complex multiplication.

The structures of quadratic forms of a given discriminant D correspond to ordered bases of ideals in an order in a quadratic number field, defined up to scaling by the rationals. A form is primitive if the coefficients a, b, and c are coprime. For negative discriminants the primitive reduced forms in this structure are in bijection with the class group of projective or invertible ideals. For positive discriminants, the reduced orbits of forms are used for this purpose. MAGMA holds efficient algorithms for composition, enumeration of reduced forms, class group computations, and discrete logarithms. A significant novel feature is the treatment of nonfundamental discriminants, corresponding to nonmaximal orders, and the collections of homomorphisms between different class groups coming from the inclusions of these orders.

The functionality for binary quadratic forms is rounded out with various functions for applying modular and elliptic functions to forms, and for class polynomials associated to class groups of definite forms.

33.2 Creation Functions

33.2.1 Creation of Structures

For any integer D congruent to 0 or 1 modulo 4, it is possible to create the parent structure of binary quadratic forms of discriminant D.

```
BinaryQuadraticForms(D)
```

```
QuadraticForms(D)
```

Create the structure of integral binary quadratic forms of discriminant D.

33.2.2 Creation of Forms

Binary quadratic forms may be created by coercing a triple $[a, b, c]$ of integer coefficients into the parent structure of forms of discriminant $D = b^2 - 4ac$. Other constructors are provided for constructing the group identity, prime forms, or allowing the omission of third element c of the sequence.

```
Identity(Q)
```

```
Q ! 1
```

Create the principal form in the structure Q of binary quadratic forms of discriminant D. The principal form is either $X^2 - D/4Y^2$ if $D \bmod 4$ is 0 and $X^2 + XY + (D-1)/4Y^2$ if it is 1. The principal form is a reduced form representing the identity element of the class group of Q.

```
Q ! [a, b, c]
```

```
elt< Q | a, b, c >
```

```
elt< Q | a, b >
```

Returns the binary quadratic form $aX^2 + bXY + cY^2$ in the magma of forms Q of discriminant D. Here c is determined by the solution of the equality $D = b^2 - 4ac$; if no integer c exists satisfying this, an error will occur.

```
PrimeForm(Q, p)
```

If p is a split prime or a ramified prime not dividing the conductor of the magma of quadratic forms Q, returns a quadratic form $pX^2 + bXY + cY^2$ in Q.

33.3 Basic Invariants

Structures of binary quadratic forms are defined in terms of a discriminant, and membership in a structure determined by this invariant. To aid in the construction of forms, additional elementary functions are provided to test integer inputs to determine if they define valid discriminants of quadratic forms.

```
Discriminant(f)
```

The discriminant $b^2 - 4ac$ of a quadratic form $f = aX^2 + bXY + cY^2$.

```
Discriminant(Q)
```

The discriminant of the quadratic forms belonging to the magma of quadratic forms Q.

```
IsDiscriminant(D)
```

Return `true` if the integer D is the discriminant of some quadratic form; `false` otherwise.

`FundamentalDiscriminant(D)`

The fundamental discriminant corresponding to the integer D.

`IsFundamental(D)`

`IsFundamentalDiscriminant(D)`

Return `true` if D is an integer other than 0 or 1 congruent to 0 or 1 modulo 4, which is not of the form $m^2 D_K$ for $m > 1$ and any other such integer D_K.

`Conductor(Q)`

The conductor of quadratic forms whose discriminant is that of the magma of quadratic forms Q.

33.4 Operations on Forms

33.4.1 Arithmetic

`Conjugate(f)`

Given a form $f = ax^2 + bxy + cy^2$, returns the conjugate form $ax^2 - bxy + cy^2$.

`f * g`

`Composition(f, g)`

`Al`	MonStgElt	*Default :* "*Gauss*"
`Reduction`	BoolElt	*Default :* `false`

Returns the composition of two binary quadratic forms f and g. The operator `'*'` returns a reduced representative of the product using a fast composition algorithm of Shanks. In contrast, the default for `Composition` is `Reduction := false`, so that one can work in the group of forms, rather in the set of class group representatives. The function `Composition` takes a further parameter `Al` which specifies whether the algorithm of Gauss or Shanks, set to `"Gauss"` by default. The algorithm of Shanks performs partial intermediate reductions, so the combination `Reduction := false` and `Al := "Shanks"` are incompatible and returns a runtime error.

`f ^ n`

`Power(f, n)`

`Al`	MonStgElt	*Default :* "*Gauss*"
`Reduction`	BoolElt	*Default :* `false`

Returns the n-th power of a form f. The operator `'^'` returns a reduced representative, using the fast composition algorithm of Shanks. In contrast, the default for `Power` is `Reduction := false`, so that one can work in the group of forms rather than in the class group. The function `Power` takes the further parameter `Al` in order to specify whether the algorithm of Gauss or Shanks is used, set to `"Gauss"` by default. The algorithm of Shanks performs partial intermediate reductions, so

the combination `Reduction := false` and `Al := "Shanks"` are incompatible and returns a runtime error.

`Reduction(f)`
`ReducedForm(f)`

Returns a reduced quadratic form equivalent to f, and the transformation matrix.

`ReductionStep(f)`

Returns the result of applying one reduction step to the quadratic form f.

`ReductionOrbit(f)`

The cycle of reduced forms equivalent to f (and each other) where f has positive discriminant.

`Order(f)`

For a binary quadratic form f, returns its order as an element of the class group $Cl(Q)$ where Q is the parent of f.

33.4.2 Attribute Access

The coefficient sequence can be accessed as a sequence of integers, providing the inverse operation to the forms coercion constructor.

`f[i]`

The i-th coefficient of f, where $1 \leq i \leq 3$.

`Eltseq(f)`
`ElementToSequence(f)`

The sequence $[a, b, c]$ where f is the form $ax^2 + bxy + cy^2$.

33.4.3 Boolean Operations

Several boolean operators apply to quadratic forms.

`f in Q`

Return `true` if and only if f is in Q, that is f and Q have the same discriminant.

`f eq g`

Return `true` if the quadratic form f and g are equal and `false` otherwise.

`IsIdentity(f)`

Return `true` if and only if f is the principal form in its parent structure.

`IsReduced(f)`

Return `true` if the quadratic form f is reduced; `false` otherwise.

`IsEquivalent(f, g)`

Return `true` if the quadratic forms f and g reduce to the same form and `false` otherwise. If `true` and the discriminant is negative, then the transformation matrix is also returned. An error is returned if the forms are not of the same discriminant.

33.4.4 Related Structures

In addition to the Parent and Category structures of binary quadratic forms of discriminant D, the quadratic forms map to the ideals of a fixed order or discriminant D in a quadratic number field.

`Parent(f)`

`Category(Q)`

`QuadraticOrder(Q)`

Given a structure of quadratic forms of discriminant D, returns the associated order of discriminant D in a quadratic field.

`Ideal(f)`

Given a quadratic form $f = ax^2 + bxy + cy^2$, returns the ideal $(a, (-b + \sqrt{D})/2)$ in the quadratic order $\mathbf{Z}[(t + \sqrt{D})/2]$, where t equals 0 or 1.

33.5 Class Group

`ReducedForms(Q)`

Given the structure of quadratic forms of negative discriminant D, returns the sequence of all primitive reduced forms of discriminant D.

`ReducedOrbits(Q)`

Given the structure of quadratic forms of positive discriminant D, returns the sequence of all reduced orbits of primitive forms of discriminant D, as an indexed set.

`ClassNumber(Q: parameters)`

`ClassNumber(D: parameters)`

`Al`	MonStgElt	*Default :* "*Automatic*"
`FactorBasisBound`	FldReElt	*Default :* 0.1
`ProofBound`	FldReElt	*Default :* 6
`ExtraRelations`	RngIntElt	*Default :* 1

The class number of binary quadratic forms Q of discriminant D. The parameter `Al` may be supplied to select the method used to calculate the class number. The possible values are `"ReducedForms"` (enumerating all reduced forms), `"Shanks"`

(using a Shanks-based algorithm in the class group), "Sieve" or "NoSieve". The default is to use reduced form enumeration for small discriminants, the Shanks algorithm for the middle range, a class group index-calculus for large discriminants and the sieve method described in [Jac99] for very large discriminants.

The remaining parameters apply to the index-calculus computations only; for details about the parameters FactorBasisBound, ProofBound and ExtraRelations see the description of ClassGroup.

ClassGroup(Q: *parameters*)

FactorBasisBound	FldReElt	*Default :* 0.1
ProofBound	FldReElt	*Default :* 6
ExtraRelations	RngIntElt	*Default :* 1
Al	MonStgElt	*Default :* "*Automatic*"

The class group of the binary quadratic forms Q of discriminant D. The function also returns a map from the abelian group to the structure of quadratic forms.

Depending on the size of D, either a Shanks-based method is used ([Tes98a, BJT97]) an index calculus variant ([CDO93, HM89, Coh93]) or a sieving method. The parameters FactorBasisBound, ProofBound and ExtraRelations apply to the index calculus method only. This method performs in two steps: In the first step a factor basis containing prime forms of norm $< B_1$ is build. Next, one looks for generators for the full lattice of relations between the forms in the factor basis. The determinant of this lattice will be the class number and the Smith-form of the relation matrix gives the structure of the class group. Once the matrix is of full rank, the algorithm will look for ExtraRelations more relations to potentially decrease the discriminant.

In the second stage, for all prime forms of norm $< B_2$ it is verified that they are in the class group generated by the forms of the first step. The bounds are chosen to be $B_1 :=$ FactorBasisBound$\cdot \log^2 |D|$ and $B_2 :=$ ProofBound$\cdot \log^2 |D|$, so the result is correct under the assumption of GRH.

The final result is then checked against the Euler product over the first 30.000 primes. If the quotient becomes to large, a warning is issued. In this case one should increase the ExtraRelations parameter.

If the parameter Al is set to "Sieve" (regardless of the size of D) or D is larger than 10^{20} then the sieving method described in [Jac99] which uses the multiple polynomial quadratic sieve (MPQS) will be used. This is currently only proven under GRH. If the parameter Al is set to "NoSieve" then the sieving method will not be used regardless of the size of D.

ClassGroupStructure(Q: *parameters*)

The structure of the class group of the binary quadratic forms Q of discriminant D returned as a sequence of integers giving the abelian invariants.

For details about the parameters Al, FactorBasisBound, ProofBound and Extra Relations, see ClassGroup.

`AmbiguousForms(Q)`

Enumerates the ambiguous forms of negative discriminant D, where D is the discriminant of the magma of binary quadratic forms Q.

`TwoTorsionSubgroup(Q)`

The subgroup of 2–torsion elements of in the class group of Q.

Example H33E1

We give an example of some computations in the class group of a magma of quadratic forms. Elements in the class group are not really represented by single reduced forms but by cycles of equivalent reduced forms.

```
> Q<z> := QuadraticField(7537543);                        // arbitrary choice
> Q := QuadraticForms(Discriminant(Q));
> C, m := ClassGroup(Q);
> C;
Abelian Group isomorphic to Z/2 + Z/76
Defined on 2 generators
Relations:
    76*C.1 = 0
    2*C.2 = 0
>                                    // get the generators as quadratic forms:
> f := m(C.1);
> g := m(C.2);
> h := g^2;
> g, h;
<-1038,4894,1493> <-887,4340,3189>
> c := [];                      // create the cycle of forms equivalent to g^2:
> repeat
>     h := ReductionStep(h);
>     Append(~c, h);
> until h eq g^2;
> P := Parent(g);
> Identity(P) in c;
true                 // this proves that the second class has order dividing 2
> for d in Divisors(76) do
>     c := [];
>     h := f^d;
>     repeat h := ReductionStep(h); Append(~c, h);
>     until h eq f^d;
>     d, Identity(P) in c, #c;
> end for;
1 false 16
2 false 14
4 false 12                           // the cycle lengths vary
19 false 18
38 false 16
```

```
76 true 14                          // so the true order of this class is 76
```

33.6 Class Group Coercions

The class group of a nonmaximal quadratic order R of discriminant $m^2 D_K$, are related to the class group of the maximal order O_K of fundamental discriminant D_K by an exact sequence.

$$1 \to \frac{(O_K/mO_K)^*}{O_K^*\,(\mathbf{Z}/m\mathbf{Z})^*} \to Cl(O) \to Cl(O_K) \to 1$$

Similar maps exist between quadratic orders O_1 and O_2 in a field K, with conductors m_1 and m_2, respectively, such that $m_1 \mid m_2$. The corresponding maps on quadratic forms are implemented on quadratic forms. The homomorphism is returned as a map object, or can be called directly via the coercion operator.

`FundamentalQuotient(Q)`

The quotient homomorphism from the class group of Q to the class group of fundamental discriminant.

`QuotientMap(Q1, Q2)`

Given two structures of quadratic forms Q_1 and Q_2, such that the discriminant of Q_2 equals a square times the discriminant of Q_1, the quotient homomorphism from Q_1 to Q_2 is returned as a map object.

`Q ! f`

The `!` operator applies the quotient homomorphism for automatic coercion of forms f of discriminant $m^2 D$ into the structure Q of forms of discriminant D.

33.7 Discrete Logarithms

`Log(b, x)`

The discrete logarithm of binary quadratic form x with respect to base b, or -1 if MAGMA can that determine no solution exists. This function exists only for negative discriminant forms. Computation is done via the Pohlig-Hellman algorithm along with a collision search subroutine (a variant of Pollard's rho method). If the user is unsure whether a solution exists, it is safest to use `Log` with a time limit (see below) to prevent an infinite loop in the collision search.

`Log(b, x, t)`

Searches for up to t seconds for the discrete logarithm of binary quadratic form x with respect to base b. This function exists only for negative discriminant forms. If Magma is able to determine no solution exists, then -1 will be returned. If no solution is found within the given time frame, then -2 will be returned. Computation is done via the Pohlig-Hellman algorithm along with a collision search subroutine (a variant of Pollard's rho method).

33.8 Elliptic and Modular Invariants

Binary quadratic forms of negative discriminant describe positive definite lattices in the complex plane, with integral-valued inner product. As such, it is possible to apply modular and elliptic functions to the form, interpreting this as an element of the upper half plane.

`Lattice(f)`

Given a binary quadratic form $f = ax^2 + bxy + cy^2$ of negative discriminant, returns the rank two lattice of f having Gram matrix

$$\begin{pmatrix} a & b/2 \\ b/2 & c \end{pmatrix}.$$

Note that the lattice L is the half-integral lattice such that integral representations $f(x, y) = n$ are in bijection with vectors (x, y) of norm n, which will be a rational number.

`GramMatrix(f)`

Returns the Gram matrix of the binary quadratic form f, which need not be of negative discriminant. The matrix will be half-integral and defined over the rationals.

`ThetaSeries(f, n)`

The integral theta series of the binary quadratic form f to precision n.

`RepresentationNumber(f, n)`

The nth representation number of the form f of negative discriminant.

`jInvariant(f)`

For a binary quadratic form $f = ax^2 + bxy + cy^2$ with negative discriminant, return the j–invariant of f, equal to the j–invariant of $\tau = (-b + \sqrt{b^2 - 4ac})/2a$.

`Eisenstein(k, f)`

Given a positive even integer $k = 2n$ and a binary quadratic form $f = ax^2 + bxy + cy^2$, return the value of the Eisenstein series $E_k(L)$ at the complex lattice $L = \langle a, (-b + \sqrt{b^2 - 4ac})/2 \rangle$.

`WeierstrassSeries(z, f)`

Given a complex power series z with positive valuation and a binary quadratic form $f = ax^2 + bxy + cy^2$, returns the q–expansion of the Weierstrass $\wp$-function at the complex lattice $L = \langle a, (-b + \sqrt{b^2 - 4ac})/2 \rangle$.

Example H33E2

```
> Q := QuadraticForms(-163);
> f := PrimeForm(Q,41);
> CC<i> := ComplexField();
> PC<z> := LaurentSeriesRing(CC);
> x := WeierstrassSeries(z,f);
> y := -Derivative(x)/2;
> A := -Eisenstein(4,f)/48;
> B := Eisenstein(6,f)/864;
> Evaluate(y^2 - (x^3 + A*x + B),1/2);
1.384608660824596881000000000 E-26 - 1.305091481190174818000000000 E-26*i
```

33.9 Class Invariants

`HilbertClassPolynomial(D)`

Given a negative discriminant D, returns the Hilbert class polynomial, defined as the minimal polynomial of $j(\tau)$, where $\mathbf{Z}[\tau]$ is an imaginary quadratic order of discriminant D.

`WeberClassPolynomial(D)`

Given a negative discriminant D congruent to 1 modulo 8, returns the Weber class polynomial, defined as the minimal polynomial of $f(\tau)$, where $\mathbf{Z}[\tau]$ is an imaginary quadratic order of discriminant D and f is a particular normalized Weber function generating the same class field as $j(\tau)$. A root $f(\tau)$ of the Weber class polynomial is an integral unit generating the ring class field related to the corresponding root $j(\tau)$ of the Hilbert class polynomial by the expression

$$j(\tau) = \frac{(f(\tau)^{24} - 16)^3}{f(\tau)^{24}},$$

where $\mathrm{GCD}(D, 3) = 1$, and

$$j(\tau) = \frac{(f(\tau)^{8} - 16)^3}{f(\tau)^{8}},$$

if 3 divides D. For further details, consult Yui and Zagier [YZ97].

33.10 Matrix Action on Forms

A matrix in $\mathrm{SL}(2, \mathbf{Z})$ acts on the right on quadratic forms by the rule

$$f(x, y) \begin{pmatrix} r & s \\ t & u \end{pmatrix} = f(rx + sy, tx + uy),$$

which is provided in MAGMA by the operator $*$.

`f * M`

The action of $\mathrm{SL}(2, \mathbf{Z})$ on forms.

PART VI
GLOBAL ARITHMETIC FIELDS

34 NUMBER FIELDS

Chapter 34
NUMBER FIELDS

34.1 Introduction

The number field module in MAGMA is based on the Kant/Kash system (Kant-V4) [KAN97], [KAN00], developed by the group of M. Pohst in Berlin.

This chapter deals only with the basic operations possible with number fields (objects of type `FldNum`) and their elements `FldNumElt`. Apart from material covered here, there is a wealth of other functions implemented and documented in detail in chapters dealing with

* Cyclotomic fields, Chapter 36
* Quadratic fields, Chapter 35
* Orders in number fields, including ideal theory, Chapter 37
* Galois Theory, Chapter 38
* Class Field Theory, Chapter 39

Furthermore, a lot of functionality of number fields is also shared by function fields of transcendence degree 1 (Chapters 42, 41) and functionality is imported from other areas, in particular, finite fields and polynomial rings.

Number fields in MAGMA are finite extensions of the field $\mathbf{Q}$ of rational numbers or of another number field. Number fields of the first kind, ie. number fields that are created as extensions of $\mathbf{Q}$ are referred to as absolute fields, while extensions of number fields are called relative fields.

Number fields support extended types (Section 1.14), they can be indexed by the type of the coefficient ring: `FldNum[FldRat]` refers to an absolute extension over $\mathbf{Q}$, while `FldNum[FldNum]` refers to a relative extension.

Formally, in MAGMA, an object K of type `FldNum` is an algebraic extension of finite degree over a number field k or $\mathbf{Q}$. It should be thought of as constructed as a quotient ring of a univariate polynomial ring over the base field modulo some irreducible polynomial: $K = k[t]/(f(t)k[t])$ Or, the field may be constructed as a multivariate quotient: $K = k[s_1, \ldots, s_n]/(f_1(s_1), \ldots, f_n(s_n))$ where all the polynomials are univariate. However, a slightly different representation is used internally.

An important consequence of this representation as a quotient of a polynomial ring is that one cannot distinguish between e.g. $\mathbf{Q}[2^{(1/3)}]$ and $\mathbf{Q}[\zeta_3 2^{(1/3)}]$ – both of them are generated using a root of $t^3 - 2$. Therefore every non trivial extension generates a **new** object – even if the same polynomial is used repeatedly, except when the user explicitly tells MAGMA to check whether the polynomial has been used before. This also implies that number fields are not automatically embedded into $\mathbf{C}$ the field of complex numbers, in contrast to both quadratic and cyclotomic fields that are. Using `Conjugates` or the language of places in section 34.8 all embeddings into $\mathbf{C}$ or $\mathbf{R}$ can be found and used.

It is important to remember that **Q** is **not** a number field. However, it is possible to create an extension of degree 1 over **Q** that is a number field using, for example

Example H34E1

```
> K := ext<Rationals()|Polynomial([0,1]):DoLinearExtension>;
```

One has to distinguish between number fields with a (known) primitive element α`:= K.1` which is a zero of f and number fields where no primitive element is known. In this case α_i`:= K.i` will be a zero of f_i.

Number fields always have a 'power' basis, i.e. a basis containing only powers of the zero(s) of the defining polynomial(s) and product of those powers. This allows for example to define homomorphisms from number fields by specifying images of the generators only.

An absolute extension is always an extension of **Q**. An arbitrary number field K can always be converted into an isomorphic extension of **Q** using a constructive variant of the primitive element theorem, `AbsoluteField`. Similarly, a number field defined by multiple polynomials can be converted into a field defined by a single polynomial using `SimpleExtension`.

Likewise, if a subfield k of K is known, an isomorphic field as an extension of k can be computed.

The most important facts about the different representations are the following:

* Arithmetic is fastest in absolute simple extensions. Thus, if one wants to do lots of basic arithmetic with the elements the transformation to an absolute representation is advisable. However, typically the operations are fastest when the elements are "small" in size.
* Invariants (like `Degree`, `Discriminant`, `Norm`, `Trace` etc.) are always relative to the current representation.
* Conversions of fields tend to be time consuming thus should be avoided if possible. However, once the different field representations are computed, the conversion of elements is not too time consuming.
* Some operations and invariants can (currently) only be done for absolute representations. Essentially, these are computations involving subfields and class and unit group computations.

Number fields support only arithmetic with their elements and the computation of some invariants (`GaloisGroup`, `Subfields`, `AutomorphismGroup`). Although invariants like the class group can be computed for `FldNum`s this is only a shortcut for the corresponding computations for the maximal orders so e.g. `ClassGroup(K)` is expanded to `ClassGroup(MaximalOrder(K))`.

34.2 Creation Functions

The following describes how number fields may be created. It also shows some ways of creating elements of these rings and homomorphisms from these rings into an arbitrary ring.

34.2.1 Creation of Number Fields

Algebraic Number Fields can be created in a various ways, most of which involve polynomials. The fields can be created as absolute extensions, i.e. an extension of **Q** by one or more irreducible polynomial(s), or as a relative extension which is an extension of an algebraic field by one or more polynomial(s) irreducible over that field.

`NumberField(f)`

`Check`	BoolElt	*Default :* `true`
`DoLinearExtension`	BoolElt	*Default :* `false`
`Global`	BoolElt	*Default :* `false`

Given an irreducible polynomial f of degree $n \geq 1$ over $K = \mathbf{Q}$ or some number field K, create the number field $L = K(\alpha)$ obtained by adjoining a root α of f to K.

The polynomial f is allowed to have either integer coefficients, coefficients in an order of K, coefficients from the rational field or some algebraic field K. The field K will be referred to as `CoefficientField`. If the polynomial is defined over a field and the coefficients have denominators greater than 1, an equivalent polynomial $df(x)$ is used to define L, where d is the least common multiple of the denominators of the coefficients of f.

If the optional parameter `Check` is set to `false` then the polynomial is not checked for irreducibility. This is useful when building relative extensions where factoring can be time consuming.

If `DoLinearExtension` is `true` and the degree of f is 1 a trivial extension is returned. This is an object of type `FldNum` but of degree 1. Otherwise (or by default), the coefficient field of f is returned. (This is important in situations where the number of extensions matters.) Furthermore, a degree 1 extension of **Q** is a field isomorphic to **Q**, but regarded by Magma as a number field (while **Q** itself is not, since `FldRat` is not a subtype of `FldNum`). This then supports all of the number field functions (including for instance fractional ideals) while the `Rationals()` do not. On the other hand, arithmetic will be slower.

If `Global` is `true`, then Magma checks if this polynomial is the defining polynomial of some other field created using `Global := true`. In this case, the old field will be returned.

The angle bracket notation may be used to assign the root α to an identifier e.g. `L<y> := NumberField(f)` where y will be a root of f.

`RationalsAsNumberField()`

`QNF()`

This creates a number field isomorphic to **Q**. It is equivalent to `NumberField(x-1 : DoLinearExtension)`, where x is `PolynomialRing(Rationals()).1`.

The result is a field isomorphic to **Q**, but regarded by MAGMA as a number field (while **Q** itself is not, since `FldRat` is not a subtype of `FldNum`). It therefore supports all of the number field functions, while the `Rationals()` do not. On the other hand, arithmetic will be slower.

Coercion can be used to convert to and from the `Rationals()`.

`NumberField(s)`

`Check`	BOOLELT	*Default :* `true`
`DoLinearExtension`	BOOLELT	*Default :* `false`
`Abs`	BOOLELT	*Default :* `false`

Let K be a possibly trivial algebraic extension of **Q**. K will be referred to as the `CoefficientField`.

Given a sequence s of nonconstant polynomials $s_1, \ldots, s_m$, that are irreducible over K, create the number field $L = K(\alpha_1, \ldots, \alpha_m)$ obtained by adjoining a root α_i of each s_i to K. The polynomials s_i are allowed to have coefficients in an order of K (or **Z**) or in K or a suitable field of fractions, but if in the latter cases denominators occur in the coefficients of s_i, an integral polynomial is used instead of s_i, as in the case of the definition of a number field by a single polynomial.

If $m > 1$ and `Abs` is `false`, a tower of extension fields

$$L_0 = K \subset L_1 = K(\alpha_m) \subset L_2 = K(\alpha_{m-1}, \alpha_m) \subset \cdots \subset L_m = K(\alpha_1, \ldots, \alpha_m) = L$$

is created, and L is a relative extension by s_1 over its ground field $L_{m-1} = K(\alpha_2, \ldots, \alpha_m)$. Thus, this construction has the same effect as m applications of the `ext` constructor. The angle bracket notation may be used to assign the m generators α_i to identifiers: `L<a`$_1$`, ..., a`$_m$`> := NumberField([ s`$_1$`, ..., s`$_m$ `]);` thus the first generator a_1, which corresponds to `L.1`, generates L over its ground field.

Note that it is important to ensure that in each of the above steps the polynomial s_i is irreducible over L_{i-1}; by default MAGMA will check that this is the case. If the optional parameter `Check` is set to `false` then this checking will not be done.

If the optional parameter `Abs` is changed to `true`, then a non-simple extension will be returned. This is a extension of the coefficient field of the f_i but such that the base field of L will be K. The ith generator will be a root of the ith polynomial in this case, but all of the generators will have L as parent. In this case, a sparse representation of number field elements will be used (based on multivariate polynomial rings). As a consequence, costs for arithmetic operations will (mainly) depend on the number of non-zero coefficients of the elements involved rather than the field

degree. This allows to define and work in fields of degree $< 10^6$. However, for general elements this representation is slower than the dense (default) representation.

If the optional parameter `DoLinearExtension` is set to `true`, linear polynomials will not be removed from the list.

```
ext<  F | s1, ..., sn  >
```

```
ext< F | s >
```

`Check`	BoolElt	*Default :* `true`
`Global`	BoolElt	*Default :* `false`
`Abs`	BoolElt	*Default :* `false`
`DoLinearExtension`	BoolElt	*Default :* `false`

Construct the number field defined by extending the number field F by the polynomials s_i or the polynomials in the sequence s. Similar as for `NumberField(S)` described above, F may be $\mathbf{Q}$. A tower of fields similar to that of `NumberField` is created and the same restrictions as for that function apply to the polynomials that can be used in the constructor.

Example H34E2

To create the number field $\mathbf{Q}(\alpha)$, where α is a zero of the integer polynomial $x^4 - 420x^2 + 40000$, one may proceed as follows:

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> Degree(K);
> K;
Number Field with defining polynomial x^4 - 420*x^2 + 40000 over the Rational
Field
> y^4 - 420*y^2;
-40000
```

By assigning the generating element to y, we can from here on specify elements in the field as polynomials in y. The elements will always be printed as polynomials in $\mathbf{Q}[y]/f$:

```
> z := y^5/11;
> z;
1/11*(420*y^3 - 40000*y)
```

K can be further extended by the use of either `ext` or `NumberField`.

```
> R<y> := PolynomialRing(K);
> f := y^2 + y + 1;
> L := ext<K | f>;
> L;
Number Field with defining polynomial y^2 + y + 1 over K
```

This is equivalent to

```
> KL := NumberField([x^2 + x + 1, x^4 - 420*x^2 + 40000]);
```

```
> KL;
Number Field with defining polynomial $.1^2 + $.1 + 1 over its ground field
```

but different to

```
> LK := NumberField([x^4 - 420*x^2 + 40000, x^2 + x + 1]);
> LK;
Number Field with defining polynomial $.1^4 - 420*$.1^2 + 40000 over its ground
field
```

To illustrate the use of `Global`:

```
> K1 := NumberField(x^3-2 : Global);
> K2 := NumberField(x^3-2 : Global);
> L1 := NumberField(x^3-2);
> L2 := NumberField(x^3-2);
> K1 eq K2;
true
> K1 eq L1;
false
> L1 eq L2;
false;
> K1!K2.1;
K1.1;
>  K2!K1.1;
K1.1
>> L1!L2.1;
     ^
Runtime error in '!': Arguments are not compatible
LHS: FldNum
RHS: FldNumElt
```

A typical application of `DoLinearExtension` is as follows. To construct a Kummer extension of degree p, one has to start with a field containing the p-th roots of unity. In most situation this will be a field extension of degree $p-1$, but what happens if ζ_p is already in the base field?

```
> AdjoinRoot := function(K, p: DoLinearExtension := false)
>   f := CyclotomicPolynomial(p);
>   f := Polynomial(K, f);
>   f := Factorisation(f)[1][1];
>   return ext<K|f : DoLinearExtension := DoLinearExtension>;
> end function;
> K := NumberField(x^2+x+1);
> E1 := AdjoinRoot(K, 3);
> E1;
Number Field with defining polynomial x^2 + x + 1 over the
Rational Field
> E2 := AdjoinRoot(K, 3 : DoLinearExtension);
> E2;
Number Field with defining polynomial ext<K|>.1 - K.1 over
K
```

```
> Norm(E1.1);
1
> Norm(E2.1);
K.1
> Norm($1);
1
```

`RadicalExtension(F, d, a)`

`Check`	BoolElt	*Default :* `true`

Let F be a number field. Let a be an integral element of F chosen such that a is not an n-th power for any n dividing d. Returns the number field obtained by adjoining the d-th root of a to F.

`SplittingField(F)`

`Abs`	BoolElt	*Default :* `true`
`Opt`	BoolElt	*Default :* `true`

Given a number field F, return the splitting field of its defining polynomial. The roots of the defining polynomial in the splitting field are also returned.

If `Abs` is `true`, the resulting field will be an absolute extension, otherwise a tower is returned.

If `Opt` is `true`, an attempt of using `OptimizedRepresentation` is done. If successful, the resulting field will have a much nicer representation. On the other hand, computing the intermediate maximal orders can be extremely time consuming.

`SplittingField(f)`

Given an irreducible polynomial f over $\mathbf{Z}$, return its splitting field.

`SplittingField(L)`

`Abs`	BoolElt	*Default :* `false`
`Opt`	BoolElt	*Default :* `false`

Given a sequence L of polynomials over a number field or the rational numbers, compute a common splitting field, ie. a field K such that every polynomial in L splits into linear factors over K. The roots of the polynomials are returned as the second return value.

If the optional parameter `Abs` is `true`, then a primitive element for the splitting field is computed and the field returned will be generated by this primitive element over $\mathbf{Q}$. If in addition `Opt` is also `true`, then an optimized representation of K is computed as well.

`sub< F | e1, ..., en >`

Given a number field F with coefficient field G and n elements $e_i \in F$, return the number field $H = G(e_1, \ldots, e_n)$ generated by the e_i (over G), as well as the embedding homomorphism from H to F.

`MergeFields(F, L)`

`CompositeFields(F, L)`

Let F and L be absolute number fields. Returns a sequence of fields $[M_1, \ldots, M_r]$ such that each field M_i contains both a root of the generating polynomial of F and a root of the generating polynomial of L.

In detail: Suppose that F is the smaller field (wrt. the degree). As a first step we factorise the defining polynomial of L over F. For each factor obtained, an extension of F is constructed and then transformed into an absolute extension. The sequence of extension fields is returned to the user.

`Compositum(K, L)`

For absolute number fields K and L, at least one of which must be normal, find a smallest common over field. Note that in contrast to `CompositeFields` above the result here is essentially unique since one field was normal.

`quo< FldNum : R | f >`

`Check` BoolElt *Default :* `true`

Given a ring of polynomials R in one variable over a number field K, create the number field $K(\alpha)$ obtained by adjoining a root α of f to K. Here the coefficient ring K of R is allowed to be the rational field $\mathbf{Q}$. The polynomial f is allowed to have coefficients in K, but if coefficients occur in f which require denominator greater than 1 when expressed on the basis of K, the polynomial will be replaced by an equivalent one requiring no such denominators: $\tilde{f}(x) = df(x)$, where d is a common denominator. The parameter `Check` determines whether the polynomial is checked for irreducibility.

The angle bracket notation may be used to assign the root α to an identifier: `K<y> := quo< FldNum : R | f >`.

If the category `FldNum` is not specified, `quo< R | f >` creates the quotient ring R/f as a generic ring (not as a number field), in which only elementary arithmetic is possible.

Example H34E3

To illustrate the use of `CompositeFields` we will use this function to compute the normal closure of $\mathbf{Q}(\alpha)$ where α is a zero of the integer polynomial $x^3 - 2$:

```
> K := RadicalExtension(Rationals(), 3, 2);
> l := CompositeFields(K, K);
> l;
[
```

```
    Number Field with defining polynomial $.1^3 - 2 over the Rational
    Field,
    Number Field with defining polynomial $.1^6 + 108 over the Rational
    Field
]
```

The second element of l corresponds to the smallest field L_2 containing two distinct roots of x^3-2. Since the degree of K is 3, L_2 is the splitting field of f and therefore the normal closure of K.

`OptimizedRepresentation(F)`

`OptimisedRepresentation(F)`

Given a number field F with ground field $\mathbf{Q}$, this function will attempt to find an isomorphic field L with a better defining polynomial than the one used to define F. If such a polynomial is found then L is returned; otherwise F will be returned. For more details, please refer to `OptimizedRepresentation`.

Example H34E4

Some results of `OptimizedRepresentation` are shown.

```
> R<x> := PolynomialRing(Rationals());
> K := NumberField(x^4-420*x^2+40000);
> L := OptimizedRepresentation(K);
> L ne K;
true
> L;
Number Field with defining polynomial x^4 - 4*x^3 -
    17*x^2 + 42*x + 59 over the Rational Field
> L eq OptimizedRepresentation(L);
```

34.2.2 Maximal Orders

The maximal order $\mathcal{O}_K$ is the ring of integers of an algebraic field consisting of all integral elements of the field; that is, elements which are roots of monic integer polynomials. It may also be called the number ring of a number field. It is arguably the single most important invariant of a number field, in fact in number theory when one talks about units, ideals, etc. of number fields, it is typically implied that the maximal order is the underlying ring.

Maximal orders and orders in general are explained in detail in the chapter 37, here we only give a very brief overview.

There are a number of algorithms which MAGMA uses whilst computing maximal orders. The main ones are the Round–2 and the Round–4 methods ([Coh93, Bai96, Poh93, PZ89] for absolute extensions and [Coh00, Fri97, Pau01b] for relative extensions).

`MaximalOrder(F)`
`IntegerRing(F)`
`Integers(F)`
`RingOfIntegers(F)`

`Al`	MonStgElt	*Default :* "*Auto*"
Verbose	`MaximalOrder`	*Maximum :* 5

Create the ring of integers of the algebraic number field F. An integral basis for F can be found as the basis of the maximal order.

For information on the parameters, see Section 37.2.3.

34.2.3 Creation of Elements

Since number fields are though of as quotients of (multivariate) polynomial rings, elements in those fields are represented as (multivariate) polynomials in the generator(s) of the field.

`F ! a`
`elt< F | a >`

Coerce a into the number field F. Here a may be an integer or a rational field element, or an element from a subfield of F, or from an order in such or any other field related to F through chains of subfields, optimised representation, absolute fields, etc.

`F ! [`a_0`, `a_1`, ..., `a_{m-1}`]`
`elt< F | [ `a_0`, `a_1`, ..., `a_{m-1}` ] >`
`elt< F | `a_0`, `a_1`, ..., `a_{m-1}` >`

Given the number field, F of degree m over its ground field G and a sequence $[a_0, \ldots, a_{m-1}]$ of elements of G, construct the element $a_0\alpha_0 + a_1\alpha_1 + \cdots a_{m-1}\alpha_{m-1}$ of F where the α_i are the basis elements of F. In case F was generated by a root of a single polynomial, we will always have $\alpha_i = \mathbf{F}.\mathbf{1}^i$. If F was defined using multiple polynomials and the `Abs` parameter, the basis will consist of products of powers of the generators.

`Random(F, m)`

A random element of the number field F. The maximal size of the coefficients is determined by the integer m.

Example H34E5

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^4-420*x^2+40000);
> y^6;
136400*y^2 - 16800000
```

```
> K![-16800000, 0, 136400, 0];
136400*y^2 - 16800000
> K := NumberField([x^3-2, x^2-5]:Abs);
> Basis(K);
[
    1,
    K.1,
    K.1^2,
    K.2,
    K.1*K.2,
    K.1^2*K.2
]
> K![1,2,3,4,5,6];
6*K.1^2*K.2 + 3*K.1^2 + 5*K.1*K.2 + 2*K.1 + 4*K.2 + 1
```

One(K)	Identity(K)
Zero(K)	Representative(K)

34.2.4 Creation of Homomorphisms

To specify homomorphisms from number fields, it is necessary to specify the image of the generating elements, and possible to specify a map on the coefficient field.

hom< F -> R | r >
hom< F -> R | h, r >
hom< F -> R | r >
hom< F -> R | h, r >

Given an algebraic number field F, defined as an extension of the coefficient field G, as well as some ring R, build the homomorphism ϕ obtained by sending the defining primitive element α of F to the element $r \in R$.

In case the field F was defined using multiple polynomials, instead of an image for the primitive element, one has to give images for each of the generators.

It is possible (if $G = \mathbf{Q}$) and sometimes necessary (if $G \neq \mathbf{Q}$) to specify a homomorphism ϕ on F by specifying its action on G by providing a homomorphism h with G as its domain and R its codomain together with the image of α. If R does not cover G then the homomorphism h from G into R is necessary to ensure that the ground field can be mapped into R.

Example H34E6

We show a way to embed the field $\mathbf{Q}(\sqrt{2})$ in $\mathbf{Q}(\sqrt{2}+\sqrt{3})$. The application of the homomorphism suggests how the image could have been chosen.

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^2-2);
> KL<w> := NumberField(x^4-10*x^2+1);
> H := hom< K -> KL | (9*w-w^3)/2 >;
> H(y);
1/2*(-w^3 + 9*w)
> H(y)^2;
2
```

34.3 Structure Operations

In the lists below K always denotes a number field.

34.3.1 General Functions

Number fields form the MAGMA category FldNum. The notional power structures exist as parents of algebraic fields with no operations are allowed.

`Category(K)` `Type(K)` `ExtendedType(K)` `Parent(K)`

`AssignNames(~K, s)`

Procedure to change the names of the generating elements in the number field K to the contents of the sequence of strings s.

The i-th sequence element will be the name used for the generator of the $(i-1)$-st subfield down from K as determined by the creation of K, the first element being used as the name for the generator of K. In the case where K is defined by more than one polynomial as an absolute extension, the ith sequence element will be the name used for the root of the ith polynomial used in the creation of K.

This procedure only changes the names used in printing the elements of K. It does *not* assign to any identifiers the value of a generator in K; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies K, it is necessary to have a reference ~K to K in the call to this function.

`Name(K, i)`

`K . i`

Given a number field K, return the element which has the i-th name attached to it, that is, the generator of the $(i-1)$-st subfield down from K as determined by the creation of K. Here i must be in the range $1 \leq i \leq m$, where m is the number of polynomials used in creating K. If K was created using multiple polynomials as an absolute extension, K.i will be a root of the ith polynomial used in creating K.

34.3.2 Related Structures

Each number field has other structures related to it in various ways.

`GroundField(F)`
`BaseField(F)`
`CoefficientField(F)`
`CoefficientRing(F)`

Given a number field F, return the number field over which F was defined. For an absolute number field F, the function returns the rational field $\mathbf{Q}$.

`AbsoluteField(F)`

Given a number field F, this returns an isomorphic number field L defined as an absolute extension (i.e. over $\mathbf{Q}$). (For algorithm, see [Tra76])

`SimpleExtension(F)`

Given a number field F or an order O, this returns an isomorphic field L defined as an absolute simple extension. (For algorithm, see [Tra76])

`RelativeField(F, L)`

Given number fields L and F such that MAGMA knows that F is a subfield of L, return an isomorphic number field M defined as an extension over F.

Example H34E7

It is often desirable to build up a number field by adjoining several algebraic numbers to $\mathbf{Q}$. The following function returns a number field that is the composite field of two given number fields K and L, provided that $K \cap L = \mathbf{Q}$; if K and L have a common subfield larger than $\mathbf{Q}$ the function returns a field with the property that it contains a subfield isomorphic to K as well as a subfield isomorphic to L.

```
> R<x> := PolynomialRing(Integers());
> Composite := function( K, L )
>     T<y> := PolynomialRing( K );
>     f := T!DefiningPolynomial( L );
>     ff := Factorization(f);
>     LKM := NumberField(ff[1][1]);
>     return AbsoluteField(LKM);
> end function;
```

To create, for example, the field $\mathbf{Q}(\sqrt{2}, \sqrt{3}, \sqrt{5})$, the above function should be applied twice:

```
> K := NumberField(x^2-3);
> L := NumberField(x^2-2);
> M := NumberField(x^2-5);
> KL := Composite(K, L);
> S<s> := PolynomialRing(BaseField(KL));
> KLM<w> := Composite(KL, M);
```

```
> KLM;
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

Note, that the same field may be constructed with just one call to NumberField followed by AbsoluteField:

```
> KLM2 := AbsoluteField(NumberField([x^2-3, x^2-2, x^2-5]));
> KLM2;
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

or by

```
> AbsoluteField(ext<Rationals() | [x^2-3, x^2-2, x^2-5]>);
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

In general, however, the resulting polynomials of KLM and $KLM2$ will differ. To see the difference between SimpleExtension and AbsoluteField, we will create KLM2 again:

```
> KLM3 := NumberField([x^2-3, x^2-2, x^2-5]: Abs);
> AbsoluteField(KLM3);
Number Field with defining polynomials [ x^2 - 3, x^2 - 2,
    x^2 - 5] over the Rational Field
> SimpleExtension(KLM3);
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

PrimeRing(F) PrimeField(F)

Centre(F)

Embed(F, L, a)

Install the embedding of a simple number field F in L where the image of the primitive element of F is the element a of L. This embedding will be used in coercing from F into L.

Embed(F, L, a)

Install the embedding of the non-simple number field F in L where the image of the generating elements of F are in the sequence a of elements of L. This embedding will be used in coercing from F into L.

EmbeddingMap(F, L)

Returns the embedding map of the number field F in L if an embedding is known.

Example H34E8

MAGMA does not recognize two independently created number fields as equal since more than one embedding of a field in a larger field may be possible. To coerce between them, it is convenient to be able to embed them in each other.

```
> k := NumberField(x^2-2);
> l := NumberField(x^2-2);
>  l!k.1;
>> l!k.1;
    ^
Runtime error in '!': Arguments are not compatible
LHS: FldNum
RHS: FldNumElt
> l eq k;
false
> Embed(k, l, l.1);
> l!k.1;
l.1
> Embed(l, k, k.1);
> k!l.1;
k.1
```

`Embed` is useful in specifying the embedding of a field in a larger field.

```
> l<a> := NumberField(x^3-2);
> L<b> := NumberField(x^6+108);
> Root(L!2, 3);
1/18*b^4
> Embed(l, L, $1);
> L!l.1;
1/18*b^4
```

Another embedding would be

```
> Roots(PolynomialRing(L)!DefiningPolynomial(l));
[
    <1/36*(-b^4 - 18*b), 1>,
    <1/36*(-b^4 + 18*b), 1>,
    <1/18*b^4, 1>
]
> Embed(l, L, $1[1][1]);
> L!l.1;
1/36*(-b^4 - 18*b)
```

`MinkowskiSpace(F)`

The Minkowski vector space V of the absolute number field F as a real vector space, with inner product given by the T_2-norm (`Length`) on F, and by the embedding $F \to V$.

```
Completion(K, P)
comp< K|P >
```

Precision RngIntElt *Default :* 20

For an absolute extension K of $\mathbf{Q}$, compute the completion at a prime ideal P which must be either a prime ideal of the maximal order or unramified. The result will be a local field or ring with relative precision `Precision`.

The returned map is the canonical injection into the completion. It allows pointwise inverse operations.

```
Completion(K, P)
```

Precision RngIntElt *Default :* 20

For an absolute extension K over $\mathbf{Q}$ and a (finite) place P, compute the completion at P. The precision and the map are as described for `Completion`.

34.3.3 Representing Fields as Vector Spaces

It is possible to express a number field as a vector space of any subfield using the intrinsics below. Such a construction also allows one to find properties of elements over these subfields.

```
Algebra(K, J)
Algebra(K, J, S)
```

Returns the associative structure constant algebra which is isomorphic to the number field K as an algebra over J. Also returns the isomorphism from K to the algebra mapping w^i to the $i+1$st unit vector of the algebra where w is a primitive element of K.

If a sequence S is given it is taken to be a basis of K over J and the isomorphism will map the ith element of S to the ith unit vector of the algebra.

```
VectorSpace(K, J)
KSpace(K, J)
VectorSpace(K, J, S)
KSpace(K, J, S)
```

The vector space isomorphic to the number field K as a vector space over J and the isomorphism from K to the vector space. The isomorphism maps w^i to the $i+1$st unit vector of the vector space where w is a primitive element of K.

If S is given, the isomorphism will map the ith element of S to the ith unit vector of the vector space.

Example H34E9

We use the `Algebra` of a relative number field to obtain the minimal polynomial of an element over a subfield which is not in its coefficient field tower.

```
> K := NumberField([x^2 - 2, x^2 - 3, x^2 - 7]);
> J := AbsoluteField(NumberField([x^2 - 2, x^2 - 7]));
> A, m := Algebra(K, J);
> A;
Associative Algebra of dimension 2 with base ring J
> m;
Mapping from: RngOrd: K to AlgAss: A
> m(K.1);
(1/10*(J.1^3 - 13*J.1)                        0)
> m(K.1^2);
(2 0)
> m(K.2);
(1/470*(83*J.1^3 + 125*J.1^2 - 1419*J.1 - 1735) 1/940*(-24*J.1^3 - 5*J.1^2 +
    382*J.1 + 295))
> m(K.2^2);
(3 0)
> m(K.3);
(1/10*(-J.1^3 + 23*J.1)                         0)
> m(K.3^2);
(7 0)
> A.1 @@ m;
1
> A.2 @@ m;
(($.1 - 1)*$.1 - $.1 - 1)*K.1 + ($.1 + 1)*$.1 + $.1 + 1
>

34.3.4 Invariants

Some information describing a number field can be retrieved.

`Characteristic(F)`

`Degree(F)`

Given a number field F, return the degree $[F : G]$ of F over its ground field G.

`AbsoluteDegree(F)`

Given a number field F, return the absolute degree of F over $\mathbf{Q}$.

`Discriminant(F)`

Given an extension F of $\mathbf{Q}$, return the discriminant of F. This discriminant is defined to be the discriminant of the defining polynomial, **not** as the discriminant of the maximal order.

The discriminant in a relative extension F is the ideal in the base ring generated by the discriminant of the defining polynomial.

`AbsoluteDiscriminant(K)`

Given a number field K, return the absolute value of the discriminant of K regarded as an extension of $\mathbf{Q}$.

`Regulator(K)`

Given a number field K, return the regulator of K as a real number. Note that this will trigger the computation of the maximal order and its unit group if they are not known yet. This only works in an absolute extension.

`RegulatorLowerBound(K)`

Given a number field K, return a lower bound on the regulator of O or K. This only works in an absolute extension.

`Signature(F)`

Given an absolute number field F, returns two integers, one being the number of real embeddings, the other the number of pairs of complex embeddings of F.

`UnitRank(K)`

The unit rank of the number field K (one less than the number of real embeddings plus number of pairs of complex embeddings).

`DefiningPolynomial(F)`

Given a number field F, the polynomial defining F as an extension of its ground field G is returned.

For non simple extensions, this will return a list of polynomials.

`Zeroes(F, n)`

Given an absolute number field F, and an integer n, return the zeroes of the defining polynomial of F with a precision of exactly n decimal digits. The function returns a sequence of length the degree of F; all of the real zeroes appear before the complex zeroes.

Example H34E10

The information provided by `Zeros` and `DefiningPolynomial` is illustrated below.

```
> L := NumberField(x^6+108);
> DefiningPolynomial(L);
x^6 + 108
> Zeros(L, 30);
[ 1.889881574842309747150815910899999999994 +

```

34.3.5 Basis Representation

The basis of a number field can be expressed using elements from any compatible ring.

`Basis(F)`

`Basis(F, R)`

Return the current basis for the number field F over its ground ring as a sequence of elements of F or as a sequence of elements of R.

`IntegralBasis(F)`

`IntegralBasis(F, R)`

An integral basis for the algebraic number field F is returned as a sequence of elements of F or R if given. This is the same as the basis for the maximal order. Note that the maximal order will be determined (and stored) if necessary.

Example H34E11

The following illustrates how a basis can look different when expressed in a different ring.

```
> f := x^5 + 5*x^4 - 75*x^3 + 250*x^2 + 65625;
> N := NumberField(f);
> N;
Number Field with defining polynomial x^5 + 5*x^4 - 75*x^3 + 250*x^2 + 65625
over the Rational Field
> Basis(N);
[
    1,
    N.1,
    N.1^2,
    N.1^3,
    N.1^4
]
> IntegralBasis(N);
[
    1,
    1/5*N.1,
    1/25*N.1^2,
    1/125*N.1^3,
    1/625*N.1^4
]
> IntegralBasis(N, MaximalOrder(N));
[
    [1, 0, 0, 0, 0],
    [0, 1, 0, 0, 0],
    [0, 0, 1, 0, 0],
    [0, 0, 0, 1, 0],
    [0, 0, 0, 0, 1]
```

```
]
```

`AbsoluteBasis(K)`

Returns an absolute basis for the number field K, i.e. a basis for K as a $\mathbf{Q}$ vector space. The basis will consist of the products of the basis elements of the intermediate fields. The expansion is done depth-first.

Example H34E12

We continue our example of a field of degree 4.
The functions `Basis` and `IntegralBasis` both return a sequence of elements, that can be accessed using the operators for enumerated sequences. Note that if, as in our example, O is the maximal order of K, both functions produce the same output:

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> O := MaximalOrder(K);
> I := IntegralBasis(K);
> B := Basis(O);
> I, B;
[
    1,
    1/2*y,
    1/40*(y^2 + 10*y),
    1/800*(y^3 + 180*y + 400)
]
[
    0.1,
    0.2,
    0.3,
    0.4
]
> Basis(O, K);
[
    1,
    1/2*y,
    1/40*(y^2 + 10*y),
    1/800*(y^3 + 180*y + 400)
]
```

34.3.6 Ring Predicates

Number fields can be tested for having several properties that may hold for general rings.

`F eq L`

Returns `true` if and only if the number fields F and L are indentical.

No two number fields which have been created independently of each other will be considered equal since it is possible that they can be embedded into a larger field in more than one way.

`IsCommutative(R)` `IsUnitary(R)` `IsFinite(R)`
`IsOrdered(R)` `IsField(R)`
`IsNumberField(R)` `IsAlgebraicField(R)`

`IsEuclideanDomain(F)`

This is not a check for euclidean number fields. This function will always return `true`, as all number fields are euclidean domains.

`IsSimple(F)`

Checks if the number field F is defined as a simple extension over the base ring.

`IsPID(F)` `IsUFD(F)`

`IsPrincipalIdealRing(F)`

Always `true` for number fields.

`IsDomain(R)`
`F ne L` `K subset L`

`HasComplexConjugate(K)`

This function returns `true` if there is an automorphism in the number field K that acts like complex conjugation.

`ComplexConjugate(x)`

For an element x of a number field K where `HasComplexConjugate` returns `true` (in particular this includes totally real fields, cyclotomic and quadratic fields and CM-extensions), the conjugate of x is returned.

34.3.7 Field Predicates

Here all the predicates that are specific to number fields are listed.

`IsIsomorphic(F, L)`

Given two number fields F and L, this returns `true` as well as an isomorphism $F \to L$, if F and L are isomorphic, and it returns `false` otherwise.

`IsSubfield(F, L)`

Given two number fields F and L, this returns `true` as well as an embedding $F \hookrightarrow L$, if F is a subfield of L, and it returns `false` otherwise.

`IsNormal(F)`

Returns `true` if and only if the number field F is a normal extension. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois group computation.

`IsAbelian(F)`

Returns `true` if and only if the number field F is a normal extension with abelian Galois group. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois Group computation.

`IsCyclic(F)`

Returns `true` if and only if the number field F is a normal extension with cyclic Galois group. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois and automorphism group.

`IsAbsoluteField(K)`

Returns `true` iff the number field K is a constructed as an absolute extension of $\mathbf{Q}$.

34.4 Element Operations

34.4.1 Parent and Category

`Parent(a)` `Category(a)` `Type(a)` `ExtendedType(a)`

34.4.2 Arithmetic

The table below lists the generic arithmetic functions on number field elements. Note that automatic coercion ensures that the binary operations `+`, `-`, `*`, and `/` may be applied to an element of a number field and an element of one of its orders; the result will be a number field element.

`+ a` `- a`

`a + b` `a - b` `a * b` `a / b` `a ^ k`

`Sqrt(a)`

Returns the square root of the number field element a if it exists in the field containing a.

`Root(a, n)`

Returns the n-th root of the number field element a if it exists in the field containing a.

`IsSquare(a)`

Return `true` if the number field element a is a kth power, (respectively square) and the root if so.

`Denominator(a)`

Returns the denominator of the number field element a, that is the least common multiple of the denominators of the coefficients of a.

`Numerator(a)`

Returns the numerator of the number field element a, that is the element multiplied by its denominator.

`Qround(E, M)`

`ContFrac` BoolElt *Default :* `true`

Finds an approximation of the number field element E where the denominator is bounded by the integer M. If `ContFrac` is `true`, the approximation is computed by applying the continued fraction algorithm to the coefficients of E viewed over Q.

34.4.3 Equality and Membership

Elements may also be tested for whether they lie in an ideal of an order. See Section 37.9.5.

`a eq b` `a ne b`

`a in F`

34.4.4 Predicates on Elements

In addition to the generic predicates `IsMinusOne`, `IsZero` and `IsOne`, the predicates `IsIntegral` and `IsPrimitive` are defined on elements of number fields.

`IsIntegral(a)`

Returns `true` if the element a of a number field F is contained in the ring of integers of F, `false` otherwise. We use the minimal polynomial to determine the answer, which means that the calculation of the maximal order is *not* triggered if it is not known yet. A denominator d such that $d * a$ is integral is also returned on request.

`IsPrimitive(a)`

Returns `true` if the element a of the number field F generates F over its coefficient field.

`IsTotallyPositive(a)`

Returnes `true` iff all real embeddings of the number field element a are positive. For elements in absolute fields this is equivalent to all real conjugates being positive.

`IsZero(a)` `IsOne(a)`
`IsMinusOne(a)` `IsUnit(a)`
`IsNilpotent(a)` `IsIdempotent(a)`
`IsZeroDivisor(a)` `IsRegular(a)`
`IsIrreducible(a)` `IsPrime(a)`

34.4.5 Finding Special Elements

Generators of fields can be retrieved.

`K . 1`

Return the image α of x in $G[x]/f$ where f is the first defining polynomial of the number field K and G is the base field of K.

In case of simple extensions this will be a primitive element.

`PrimitiveElement(K)`

Returns a primitive element for the simple number field K, that is an element whose minimal polynomial has the same degree as the field. For a simple number field K this is $K.1$, while for non-simple fields a random element with this property is returned.

`Generators(K)`

The set of generators of the number field K over its coefficient field, that is a set containing a root of each defining polynomial is returned.

`GeneratorsOverBaseRing(K)`

A set of generators of the number field K over $\mathbf{Q}$.

`GeneratorsSequence(K)`

The sequence of generators of the number field K over its coefficient field, that is a sequence containing a root of each defining polynomial is returned.

`GeneratorsSequenceOverBaseRing(K)`

A sequence of generators of the number field K over $\mathbf{Q}$.

`Generators(K, k)`

A sequence of generators of the number field K over k is returned. That is a sequence containing a root of each defining polynomial for K and its subfield down to the level of k is returned.

34.4.6 Real and Complex Valued Functions

The functions here return (sequences of) real or complex numbers. The precision of these numbers is governed by the appropriate or field's internal precision. See Section 37.3 for more information.

`AbsoluteValues(a)`

Return a sequence of length $r_1 + r_2$ of the real absolute values of the conjugates of the number field element a. The first r_1 values are the absolute values of the real embeddings of the element, the next r_2 are the lengths of the complex embeddings with their weight factors. That is, if the real conjugates of a are w_i, for $1 \leq i \leq r_1$, and the complex conjugates of a are $x_i \pm iy_i$ (for $1 \leq i \leq r_2$), then `AbsoluteValues` returns $[|w_1|, \ldots, |w_{r_1}|, \sqrt{\frac{x_{r_1+1}^2+y_{r_1+1}^2}{2}}, \ldots \sqrt{\frac{x_{r_1+r_2}^2+y_{r_1+r_2}^2}{2}}]$.

`AbsoluteLogarithmicHeight(a)`

Let P be the minimal polynomial of the number field element a over $\mathbf{Z}$, with leading coefficient a_0 and roots $\alpha_1, \ldots, \alpha_n$. Then the absolute logarithmic height is defined to be

$$h(\alpha) = \frac{1}{n} \log(a_0 \prod_{j=1}^{n} \max(1, |\alpha_j|)).$$

`Conjugates(a)`

The real and complex conjugates of the given algebraic number a, as a sequence of n complex numbers. The r_1 real conjugates appear first, and are followed by r_2 pairs of complex conjugates. The field should be an absolute extension. The ordering of the conjugates is consistent for elements of the same field (or even for elements of different fields that have the same defining polynomial).

`Conjugate(a, k)`

Equivalent to `Conjugates(a)[k]`.

`Conjugate(a, l)`

Let $l := [l_1, \ldots, l_n]$ be a sequence of positive integers and assume that the number field K, the parent of a is given as a tower with n steps, $\mathbf{Q} \subseteq K_1 \subseteq \ldots \subseteq K_n = K$. This function computes the image of a in $\mathbf{C}$ or $\mathbf{R}$ under the embedding determined by l, that is under embedding obtained by extending the l_1 embedding of K_1 to K_2, then extending the l_2nd of those embeddings to K_3 and so on.

`Length(a)`

Return the T_2-norm of the number field element a, which is a real number. This equals the sum of the (complex) norms of the conjugates of a.

`Logs(a)`

Return the sequence of length $r_1 + r_2$ of logarithms of the absolute values of the conjugates of a number field element $a \neq 0$.

`CoefficientHeight(E)`

Computes the coefficient height of the number field element E, that is for an element of an absolute field it returns the maximum of the denominator and the largest coefficient wrt. to the basis of the parent. For elements in relative extensions, it returns the maximal coefficient height of all the coefficients wrt. the basis of the parent.

This function indicates in some way the difficulty of operations involving this element.

`CoefficientLength(E)`

Computes the coefficient length of the number field element E, that is for an element of an absolute field it returns the sum of the denominator and the absolute values of all coefficients wrt. to the basis of the parent. For elements in relative extensions, it returns the sum of the coefficient length of all the coefficients wrt. the basis of the parent.

This function gives an indication on the amount of memory occupied by this element.

34.4.7 Norm, Trace, and Minimal Polynomial

The norm, trace and minimal polynomial of number field elements can be calculated both with respect to the coefficient ring and to **Z** or **Q**.

`Norm(a)`

`Norm(a, R)`

The relative norm $\mathrm{N}_{\mathrm{L/F}}(\mathrm{a})$ over F of the element a of the number field L where F is the field over which L is defined as an extension. If R is given the norm is calculated over R. In this case, R must occur as a coefficient ring somewhere in the tower under L.

`AbsoluteNorm(a)`

`NormAbs(a)`

The absolute norm $\mathrm{N}_{\mathrm{L}/\mathbf{Q}}(\mathrm{a})$ over **Q** of the element a of the number field L.

`Trace(a)`

`Trace(a, R)`

The relative trace $\mathrm{Tr}_{L/F}(a)$ over F of the element a of the number field L where F is the field over which L is defined as an extension. If R is given the trace is computed over R. In this case, R must occur as a coefficient ring somewhere in the tower under L.

`AbsoluteTrace(a)`

`TraceAbs(a)`

The absolute trace $\mathrm{Tr}_{L/\mathbf{Q}}(a)$ over **Q** of the element a of the number field L.

`CharacteristicPolynomial(a)`

`CharacteristicPolynomial(a, R)`

Given an element a from a number field L, returns the characteristic polynomial of the element over R if given or the subfield F otherwise where F is the field over which L is defined as an extension.

`AbsoluteCharacteristicPolynomial(a)`

Given an element a from a number field, this function returns the characteristic polynomial of a over **Q**.

`MinimalPolynomial(a)`

`MinimalPolynomial(a, R)`

Given an element a from a number field L, returns the minimal polynomial of the element over R if given otherwise the subfield F where F is the field over which L is defined as an extension.

`AbsoluteMinimalPolynomial(a)`

Given an element a from a number field, this function returns the minimal polynomial of the element as a polynomial over $\mathbf{Q}$.

`RepresentationMatrix(a)`

`RepresentationMatrix(a, R)`

Return the representation matrix of the number field element a, that is, the matrix which represents the linear map wrt to the field basis, given by multiplication by a. The ith row of the representation matrix gives the coefficients of aw_i with respect to the basis $w_1, \ldots, w_n$.

If R is given the matrix is over R and with respect to the basis of the order or field over R.

`AbsoluteRepresentationMatrix(a)`

Return the representation matrix of the number field element a relative to the $\mathbf{Q}$-basis of the field constructed using products of the basis elements, where a is an element of the relative number field L.

Let $L_i := \sum L_{i-1}\omega_{i,j}$, $L := L_n$ and $L_0 := \mathbf{Q}$. Then the representation matrix is computed with respect to the $\mathbf{Q}$-basis $(\prod_j \omega_{i_j,j})_{i\in I}$ consisting of products of basis elements of the different levels.

Example H34E13

We create the norm, trace, minimal polynomial and representation matrix of the element $\alpha/2$ in the quartic field $\mathbf{Q}(\alpha)$.

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^4-420*x^2+40000);
> z := y/2;
> Norm(z), Trace(z);
2500 0
> MinimalPolynomial(z);
ext<Q|>.1^4 - 105*ext<Q|>.1^2 + 2500
> RepresentationMatrix(z);
[     0    1/2      0      0]
[     0      0    1/2      0]
[     0      0      0    1/2]
[-20000      0    210      0]
```

The awkwardness of the printing of the minimal polynomial above can be overcome by providing a parent for the polynomial, keeping in mind that it is a univariate polynomial over the rationals:

```
> P<t> := PolynomialRing(RationalField());
> MinimalPolynomial(z);
t^4 - 105*t^2 + 2500
```

34.4.8 Other Functions

Elements can be represented by sequences and have a product representation.

`Eltseq(a)`

For an element a of a number field F, a sequence of coefficients of length degree of F with respect to the basis is returned.

`Eltseq(E, k)`

For an algebraic number $E \in K$ and a ring k which occurs somewhere in the defining tower for K, return the list of coefficients of E over k, that is, apply `Eltseq` to E and to its coefficients until the list is over k.

`Flat(e)`

The coefficients of the number field element e wrt. to the canonical Q basis for its field. This is performed by iterating `Eltseq` until the coefficients are rational numbers. The coefficients obtained match the coefficients wrt. to `AbsoluteBasis`.

`a[i]`

The coefficient of the ith basis element in the number field element a.

`ProductRepresentation(a)`

Return sequences P and E such that the product of elements in P to the corresponding exponents in E is the algebraic number a.

`ProductRepresentation(P, E)`

`PowerProduct(P, E)`

Return the number field element a of the universe of the sequence P such that a is the product of elements of P to the corresponding exponents in the sequence E.

34.5 Class and Unit Groups

This section briefly describes the functions available to compute in and with the ideal and unit group of the number field, that is with the corresponding group in the maximal order. For more details and an idea of the algorithms involved, see Sections 37.6 and 37.7.

All functions mentioned in this section support the verbose flag `ClassGroup` up to a maximum value of 5.

Ideals in MAGMA are discussed in Section 37.9.

`ClassGroup(K: parameters)`

`Bound`	RngIntElt	*Default :* MinkowskiBound
`Proof`	MonStgElt	*Default :* "*Full*"
`Enum`	BoolElt	*Default :* `true`
`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`ClassGroup`	*Maximum :* 5

The group of ideal classes for the ring of integers O of the number field K is returned as an abelian group, together with a map from this abstract group to O. The map admits inverses and can therefore be used to compute "discrete logarithms" for the class group.

With the default values for the optional parameters the Minkowski bound is used and the last step of the algorithm verifies correctness, hence a fully proven result is returned.

If `Bound` is set to some positive integer M, M is used instead of the Minkowski bound. The validity of the result still depends on the `"Proof"` parameter.

If `Proof := "GRH"`, everything remains as in the default case except that a bound based on the GRH is used to replace the Minkowski bound. This bound may be enlarged setting the "Bound" parameter accordingly. The result will hence be correct under the GRH.

If `Proof := "Bound"`, the computation stops if an independent set of relations between the prime ideals below the chosen bound is found. The relations may not be maximal.

If `Proof := "Subgroup"`, a maximal subset of the relations is constructed. In terms of the result, this means that the group returned will be a subgroup of the class group (i.e. the list of prime ideals considered may be to small).

If `Proof := "Full"` (the default) a guaranteed result is computed. This is equivalent to `Bound := MinkowskiBound(K)` and `Proof := "Subgroup"`.

If only `Bound` is given, the `Proof` defaults to `"Subgroup"`.

Finally, giving `Proof := "Current"` is the same as repeating the last call to `ClassGroup()`, but without the need to explicitly restate the value of `Proof` or `Bound`. If there was no prior call to `ClassGroup`, a fully proven computation will be carried out.

If `Enum := false`, then instead of enumerating short elements to get relations, Magma will use random linear combinations of a reduced basis instead. For "small" fields this will typically slow down the computations, but for large fields it is sometimes not possible to find any point using enumeration so that this is necessary for "large" fields. Unfortunately, there is no known criterion to decide beforehand if a field is "large" or "small".

If `Al` is set to `"Sieve"` (regardless of the size of the discriminant) or the discriminant of K is greater than 10^{30} then the sieving method described in [Bia] (or [Jac99] for quadratic fields) will be used. If `Al` is set to `"NoSieve"` then the sieving method will not be used regardless of the size of the discriminant.

`ConditionalClassGroup(K)`

The class group of the number field K assuming the generalized Riemann hypothesis.

`ClassNumber(K: parameters)`

`Bound`	RngIntElt	*Default :* MinkowskiBound
`Proof`	MonStgElt	*Default :* "*Full*"
`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`ClassGroup`	*Maximum :* 5

Return the class number of the ring of integers O of a number field K. The options for the parameters are the same as for `ClassGroup`.

`BachBound(K)`

An integral upper bound for norms of generators of the ideal class group for the number field K assuming the generalized Riemann hypothesis.

`MinkowskiBound(K)`

An unconditional integral upper bound for norms of the generators of the ideal class group for the number field K.

`UnitGroup(K)`

`MultiplicativeGroup(K)`

`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`UnitGroup`	*Maximum :* 6

Given a number field K, this function returns an (abstract) abelian group U, as well as a bijection m between U and the units of the maximal order. The unit group consists of the torsion subgroup, generated by the image `m(U.1)` and a free part, generated in O by the images `m(U.i)` for $2 \leq i \leq r_1 + r_2$.

The parameter `Al` can be used to specify an algorithm. It should be one of `"Automatic"`, (default, a choice will be made for the user) `"ClassGroup"`, `"Dirichlet"`, `"Mixed"` (the best known Dirichlet method), `"Relation"` or `"Short"` (which is a variation of `"Mixed"`). In the case of real quadratic fields, a continued fraction algorithm is available, `"ContFrac"`.

`TorsionUnitGroup(K)`

The torsion subgroup of the unit group of the number field K, i.e. its maximal order. The torsion subgroup is returned as an abelian group T, together with a map m from the group to the order O. The torsion subgroup will be cyclic, and is generated by `m(T.1)`.

`UnitRank(K)`

Return the unit rank of the ring of integers O of a number field K.

Example H34E14

In our field defined by $x^4 - 420 * x^2 + 40000$, we obtain the class and unit groups as follows.

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> C := ClassGroup(K);
> C;
Abelian Group of order 1
> U := UnitGroup(K);
> U;
Abelian Group isomorphic to Z/2 + Z + Z + Z
Defined on 4 generators
Relations:
      2*U.1 = 0
> T := TorsionUnitGroup(K);
> T;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*T.1 = 0
```

34.6 Galois Theory

`GaloisGroup(K)`

`Subfields(K)`

`AutomorphismGroup(K)`

See Sections 38.2, 38.3 and 38.1.

34.7 Solving Norm Equations

MAGMA can solve norm, Thue, index form and unit equations. In this section, we will only dicuss norm equations, other types of Diophantine equations are discussed in 37.8.

Norm equations in the context of number fields occur in many applications. While MAGMA contains efficient algorithms to solve norm equations it is important to understand the difference between the various types of norm equations that occur. Given some element θ in a number field k together with a finite extension K/k, there are two different types of norm equations attached to this data:

- Diophantine norm equations, that is norm equations where a solution $x \in K$ is restricted to a particular order (or any additive subgroup), and
- field theoretic norm equations where any element in $x \in K$ with $N(x) = \theta$ is a solution.

While in the first case the number of *different* (up to equivalence) solutions is finite, no such restriction holds in the field case. On the other hand, the field case often allows to prove the existence or non-existence of solutions quickly, while no efficient tests exist for the Diophantine case. So it is not surprising that different methods are applied for the different cases.

`NormEquation(F, m)`

`Primes`	ESEQ OF PRIME IDEALS	*Default :* []
`Nice`	BOOLELT	*Default :* `true`

Given a number field F and an element m of the base field of F, this function returns a boolean indicating whether an element $\alpha \in F$ exists such that $\mathrm{N}_{\mathrm{F/L}}(\alpha)$, the norm of α with respect to the base field L of F equals m, and if so, a sequence of length 1 of solutions α.

The field theoretic norm equations are all solved using S-units. Before discussing some details, we outline the method.

- Determine a set S of prime ideals. We try to obtain a solution as a S-unit for this set S.
- Compute a basis for the S-units
- Compute the action of the norm-map
- Obtain a solution as a preimage.

In general, no effective method is known for the first step. If the field is relative normal however, it is known that is S generates the class group of F and if m is a S-unit, then S is large enough (*suitable* in ([Coh00, 7.5]) [Fie97, Sim02, Gar80]. Thus to find S we have to compute the class group of F. If a (conditional) class group is already known, it is used, otherwise an *unconditional* class group is computed. The initial set S consists of all prime ideals occurring in the decomposition of $m\mathbf{Z}_F$. Note that this step includes the factorisation of m and thus can take a long time is m is large.

Next, we determine a basis for the S-unit group and the action of the norm on it. This give the norm map as a map on the S-unit group as an abstract abelian group.

Finally, the right hand side m is represented as an element of the S-unit group and a solution is then obtained as a preimage under the norm map.

If `Nice` is true, then MAGMA attempts to find a smaller solution by applying a LLL reduction to the original solution.

If `Primes` is give it must contain a list of prime ideals of L. Together with the primes dividing m it is used to form the set S bypassing the computation of an unconditional class group in this step. If L is not normal this can be used to guarantee that S is large enough. Note that the class group computation is still performed when the S-units are computed. Since the correctness of the S-unit group (we need only p-maximality for all primes dividing the (relative) degree of L) can be verified independently of the correctness of the class group, this can be used to derive provable results in cases where the class group cannot be computed unconditionally.

By default, the `MaximalOrder(L)` is used to compute the class group. If the attribute `NeqOrder` is set on L it must contain a maximal order of L. If present, this order will be used for all the subsequent computations.

`NormEquation(m, N)`

`Raw`	BOOLELT	*Default :* `false`
`Primes`	ESEQ OF PRIME IDEALS	*Default :* []

Let N be a map on the multiplicative group of some number field. Formally N may also be defined on the maximal order of the field. This intrinsic tries to find a pre-image for the element m under N.

This function works by realising N as a endomorphism of S-units for a suitable set S.

If N is a relative norm and if L is (absolutely) normal then the set S as computed for the field theoretic norm equation is guaranteed to be large enough to find a solution if it exists. Note: this condition is not checked.

If `Primes` is given it will be supplemented by the primes dividing m and then used as the set S.

If `Raw` is given, the solution is returned as an unevaluated power product. See the example for details.

The main use of this function is for Galois theoretical constructions where the subfields are defined as fields fixed by certain automorphisms. In this situation the norm function can be realised as the product over the fixed group. It is therefore not necessary to compute a (very messy) relative representation of the field.

`SimNEQ(K, e, f)`

`S`	[RNGORDIDL]	*Default :* `false`
`HasSolution`	BOOLELT	*Default :* `false`

For a number field K and subfield elements $e \in k_1$ and $f \in k_2$, try to find a solution to the simultaneous norm equations $N_{K/k_1}(x) = e$ and $N_{K/k_2}(x) = f$. The algorithm proceeds by first guessing a likely set S of prime ideals that will support

a solution - it is exists. Initially S will contain all ramified primes in K, the support of e and f and enough primes to generate the class group of K. In case K is normal over Q this set is large enough to support a solution if there is a solution at all. For arbitrary fields that is most likely not the case. However, if `S` is passed in as a parameter then the set used internally will contain at least this set. If `HasSolution` is `true`, MAGMA will add primes to S until a solution has been found. This is useful in situations where for some theoretical reason it is known that there has to be a solution.

Example H34E15

We try to solve $N(x) = 3$ in some relative extension: (Note that since the larger field is a quadratic extension, the second call tells us that there is no integral element with norm 3)

```
> x := PolynomialRing(Integers()).1;
> K := NumberField([x^2-229, x^2-2]);
> NormEquation(K, 3);
true [
  1/3*K.1 - 16/3
]
```

Next we solve the same equation but come from a different angle, we will define the norm map as an element of the group ring and, instead of explicitly computing a relative extension, work instead with the implicit fixed field.

```
> F := AbsoluteField(K);
> t := F!K.2;
> t^2;
2
> A, _, mA := AutomorphismGroup(F);
> S := sub<A | [ x : x in A | mA(x)(t) eq t]>;
> N := map<F -> F | x:-> &* [ mA(y)(x) : y in S]>;
> NormEquation(3, N);
true [
  -5/1*$.1 + 2/3*$.3
]
```

Finally, to show the effect of `Raw`:

```
> f, s, base := NormEquation(3, N:Raw);
> s;
[
  ( 0  1 -1  1 -1  0  2 -1 -1 -1 -1  2  0  0)
]
> z := PowerProduct(base, s[1]);
> z;
-5/1*$.1 + 2/3*$.3
> N(z);
3
```

34.8 Places and Divisors

A place of a number field K, an object of type `PlcNumElt`, is a class of absolute values (valuations) that induce the same topology on the field. By a famous theorem of Ostrowski, places of number fields are either finite, in which case they are in a one-to-one correspondence with the on-zero prime ideals of the maximal order, or infinite. The infinite places are identified with the embedding of K into $\mathbf{R}$ or with pairs of embeddings into $\mathbf{C}$.

The group of divisors is formally the free group generated by the finite places and the $\mathbf{R}$-vectorspace generated by the infinite ones. Divisors are of type `DivNumElt`. Places have formal parent of type `PlcNum`, while divisors belong to `DivNum`.

34.8.1 Creation of Structures

`Places(K)`

`DivisorGroup(K)`

The set of places of the number field K and the group of divisors of K respectively.

34.8.2 Operations on Structures

`d1 eq d2` `p1 eq p2`

`NumberField(P)`

`NumberField(D)`

The number field for which P is the set of places or D is the group of divisors.

34.8.3 Creation of Elements

`Place(I)`

The place corresponding to prime ideal I.

`Decomposition(K, p)`

`Decomposition(K, I)`

A sequence of tuples of places and multiplicities. When a finite prime (integer) p is given, the places and multiplicities correspond to the decomposition of p in the maximal order of K. When the infinite prime is given, a sequence of all infinite places is returned.

`Decomposition(K, p)`

For a number field K and a place p of the coefficient field of K, compute all places (and their multiplicity) that extend p. For finite places this is equivalent to the decomposition of the underlying prime ideal. The sequence returned will contain the places of K extending p and their ramification index.

For an infinite place p, this function will compute all extensions of p in K. In this case, the integer returned in the second component of the tuples will be 1 if p is complex or if p is real and extends to a real place and 2 otherwise.

`Decomposition(m, p)`

`Decomposition(m, p)`

For an extension K/k of number fields (where k can be Q as well), given by the embedding map $m : k \to K$, decompose the place p of k in the larger field. In case $k = Q$, the place is given as either a prime number or zero to indicate the infinite place. The sequence returned contains pairs where the first component is a place above p via m and the second is the ramification index.

`InfinitePlaces(K)`

A sequence containing all the infinite places of the number field K is returned.

`Divisor(pl)`

The divisor $1 * pl$ for a place pl.

`Divisor(I)`

The divisor which is the linear combination of the places corresponding to the factorization of the ideal I and the exponents of that factorization.

`Divisor(x)`

The principal divisor xO where O is the maximal order of the underlying number field of which x is an element. In particular, this computes a finite divisor.

`RealPlaces(K)`

For a number field K a sequence containing all real (infinite) places is computed. For an absolute field this are precisely the embeddings into R coming from the real roots of the defining polynomial.

34.8.4 Arithmetic with Places and Divisors

Divisors and places can be added, negated, subtracted and multiplied and divided by integers.

`d1 + d2` `- d` `d1 - d2` `d * k` `d div k`

34.8.5 Other Functions for Places and Divisors

`Valuation(a, p)`

The valuation of the element a of a number field at the place p.

`Valuation(I, p)`

The valuation of the ideal I at the finite place p.

`Support(D)`

The support of the divisor D as a sequence of places and a sequence of the corresponding exponents.

`Ideal(D)`

The ideal corresponding to the finite part of the divisor D.

`Evaluate(x, p)`

The evaluation of the number field element x in the residue class field of the place p, i.e. for a finite place p this corresponds to the image under the residue class field map for the underlying prime ideal. For infinite places, this returns the corresponding conjugate, ie. a real or complex number.

`RealEmbeddings(a)`

The sequence of real embeddings of the algebraic number a is computed, i.e. a is evaluated at all real places of the number field.

`RealSigns(a)`

A sequence containing ± 1 depending on whether the evaluation of the number field element a at the corresponding real place is positive or negative.

`IsReal(p)`

For an infinite place p, returns `true` if the corresponding embedding is real, i.e. if `Evaluate` at p will give real results.

`IsComplex(p)`

For an infinite place p, return `true` if the corresponding embedding is complex, i.e. if `Evaluate` at p will generally yield complex results.

`IsFinite(p)`

For a place p of a number field, return if the place is finite, i.e. if it corresponds to a prime ideal.

`IsInfinite(p)`

For a place p of a number field return if the place is infinite, ie. if it corresponds to an embedding of the number field into the real or complex numbers. If the place is infinite, the index of the embedding it corresponds to is returned as well.

`Extends(P, p)`

For two places P of K and p of k where K is an extension of k, check whether P extends p. For finite places, this is equivalent to checking if the prime ideal corresponding to P dives, in the maximal order of K the prime ideal of p. For infinite places `true` implies that for elements of k, evaluation at P and p will give identical results.

`InertiaDegree(P)`

`Degree(P)`

For a place P of a number field, return the inertia degree of P. That is for a finite place, return the degree of the residue class field over it's prime field, for infinite places it is always 1.

`Degree(D)`

For a divisor D of a number field, the degree is the weighted sum of the degrees of the supporting places, the weights being the multiplicities.

`NumberField(P)`

`NumberField(D)`

For a place P or divisor D of a number field, return the underlying number field.

`ResidueClassField(P)`

For a place P of a number field, compute the residue class field of P. For a finite place this will be a finite field, namely the residue class field of the underlying prime ideal. For an infinite place, the residue class field will be the field of real or complex numbers.

`UniformizingElement(P)`

For a finite place P of a number field, return an element of valuation 1. This will be the uniformizing element of the underlying prime ideal as well.

`LocalDegree(P)`

The degree of the completion at the place P, i.e. the product of the inertia degree times the ramification index.

`RamificationIndex(P)`

The ramification index of the place P. For infinite real places this is 1 and 2 for complex places.

`DecompositionGroup(P)`

For a place P of a normal number field, return the decomposition group as a subgroup of the (abstract) automorphism group.

34.9 Characters

There is an ability to use characters on number fields, similar to Dirichlet characters over the integers. These are implemented via `DirichletGroup` on number field elements, and `HeckeCharacterGroup` on ideals. The former is the dual of the `RayResidueRing` of an ideal, and the latter is the dual of the `RayClassGroup` of an ideal. Arithmetic on groups can be done multiplicatively, and the characters can be evaluated at suitable field elements and ideals. The `sub` constructor, along with `+` and `meet` for subgroups on the same modulus, should also work.

The associated types are `GrpDrchNF` and `GrpDrchNFElt`, `GrpHecke` and `GrpHeckeElt`. The number field must be an absolute extension of the rationals.

34.9.1 Creation Functions

`DirichletGroup(I)`

`DirichletGroup(I, oo)`

Given an ideal I of the integer ring of the number field K and a set of real places of K, the intrinsic `DirichletGroup` will return the dual group to the `RayResidueRing` of the specified information.

`HeckeCharacterGroup(I)`

`HeckeCharacterGroup(I, oo)`

Given an ideal I of the integer ring of the number field K and a set of real places of K, the intrinsic `HeckeCharacterGroup` will return the dual group to the `RayClassGroup` of the specified information.

`UnitTrivialSubgroup(G)`

Given a group of Dirichlet characters, return the subgroup that is trivial on the image of the field units in the residue ring.

`TotallyUnitTrivialSubgroup(G)`

Given a group of Dirichlet characters, return the subgroup that is totally trivial on the image of the field units in the residue ring. That is, it is trivial at each place individually.

34.9.2 Functions on Groups and Group Elements

`Modulus(G)`

`Modulus(G)`

`Modulus(chi)`

`Modulus(chi)`

Returns the modulus ideal and a (possibly empty) sequence of real places.

```
Order(chi)
Order(psi)
```

Returns the order of a Dirichlet or Hecke character.

```
Random(G)
Random(G)
```

Returns a random element of a Dirichlet or Hecke group.

```
Domain(G)
Domain(G)
```

Returns the number field that is the domain for the Dirichlet character.

```
Domain(G)
Domain(G)
```

Returns the set of ideals that is the domain for the Hecke character.

```
Decomposition(chi)
```

Returns a list of characters of prime power modulus (and real places) whose product (after extension to the original `DirichletGroup`) is the given Dirichlet character.

```
Conductor(chi)
Conductor(psi)
```

The product of the moduli of the all nontrivial characters in the decomposition of the given Dirichlet character, given as an ideal and a set of real places. Similarly with Hecke characters, where, in fact, one takes the `DirichletRestriction` of the Hecke character, and decomposes this.

```
AssociatedPrimitiveCharacter(chi)
AssociatedPrimitiveCharacter(psi)
```

The primitive Dirichlet character associated to the one that is given, which can be obtained by multiplying all the nontrivial characters in the decomposition. Similarly with Hecke characters, for which this decomposes the `DirichletRestriction` to finds its underlying primitive part, and then takes the `HeckeLift` of this.

```
Restrict(chi, D)
Restrict(psi, H)
Restrict(chi, I)
Restrict(psi, I)
Restrict(chi, I, oo)
Restrict(psi, I, oo)
Restrict(G, D)
Restrict(G, H)
Restrict(G, I)
Restrict(G, I)
Restrict(G, I, oo)
Restrict(G, I, oo)
```

Given a Dirichlet character modulo an ideal I and a Dirichlet character group modulo J for which $I \subseteq J$ (including behavior at real places when specified) with the character trivial on $(J/I)^\star$, this returns the restricted character on J. Similarly with Hecke characters, and with an ideal (with possible real places) at the second argument. Also with a group of characters as the first argument.

```
TargetRestriction(G, C)
TargetRestriction(H, C)
```

Given a group of Dirichlet or Hecke characters and a cyclotomic field, return the subgroup of characters whose image is contained in the cyclotomic field.

```
SetTargetRing(~chi, e)
SetTargetRing(~psi, e)
```

Given a Dirichlet or Hecke character and a suitable root of unity, modify the character to take values according to this root unity. The ring element must be a root of unity, and its order must be a multiple of the order of the character. Writing $m = \mathrm{ord}(\chi)$, if the character previously had $\chi(u) = \zeta_m^v$, it will now have $\chi(u) = (e^q)^v$ where q is $\mathrm{ord}(e)/m$.

```
Extend(chi, D)
Extend(psi, H)
Extend(chi, I)
Extend(psi, I)
Extend(chi, I, oo)
Extend(psi, I, oo)
```

```
Extend(G, D)
Extend(G, H)
Extend(G, I)
Extend(G, I)
Extend(G, I, oo)
Extend(G, I, oo)
```

Given a Dirichlet character modulo I and a Dirichlet character group modulo J for which $J \subseteq I$ (again possibly including the real places), this function returns the induced character on J, that is, the one that is trivial on $(I/J)^\star$. A second return value corresponds to a kernel. Similarly with Hecke characters, and with an ideal (with possible real places) at the second argument. Also with a group of characters as the first argument.

34.9.3 Predicates on Group Elements

```
IsTrivial(chi)
IsTrivial(psi)
```

Returns whether the given character corresponds to the trivial element in the character group.

```
IsTrivialOnUnits(chi)
```

Returns whether a Dirichlet character is trivial on the units of the number field; this determines whether the character can lift to a Hecke character on the ideals.

```
IsOdd(chi)
```

Returns whether a Dirichlet character χ has $\chi(-1) = -1$.

```
IsEven(chi)
```

Returns whether a Dirichlet character χ has $\chi(-1) = +1$.

```
IsTotallyEven(chi)
```

Returns whether a Dirichlet character χ has $\chi_p(-1) = +1$ for each χ_p in its decomposition.

```
IsPrimitive(chi)
IsPrimitive(psi)
```

Returns whether a Dirichlet character is primitive, that is, whether its conductor and modulus are equal.

34.9.4 Passing between Dirichlet and Hecke Characters

`HeckeLift(chi)`

Given a Dirichlet character that is trivial on the units of the number field, this functions returns a Hecke character that extends its domain to all the ideals of the integer ring. Also returns a kernel, so as to span the set of all possible lifts.

`DirichletRestriction(psi)`

Given a Hecke character on the ideals of the integer ring of a number field, this functions returns the Dirichlet restriction of it on the field elements.

`NormInduction(K, chi)`

Given a Dirichlet character χ over the rationals, induce it to the number field K. That is, find ψ with $\psi(a) = \chi(\mathrm{N}a)$ with ψ primitive.

Example H34E16

This example tries to codify the terminology via a standard example with Dirichlet characters over the rationals. We construct various characters modulo 5.

```
> Q := NumberField(Polynomial([-1, 1]) : DoLinearExtension);
> O := IntegerRing(Q);
> I := 5*O;
> DirichletGroup(I);
Abelian Group isomorphic to Z/4
Group of Dirichlet characters of modulus of norm 5 mapping to
 Cyclotomic Field of order 4 and degree 2
```

The above group is the Dirichlet characters modulo 5. However, the odd characters are not characters on ideals, as they are nontrivial on the units. To pass to the Hecke characters, we need to enlarge the modulus to consider embeddings at the real place. Note that this will give four more characters, corresponding to multiplying the above by the character that has χ as $+1$ on positive elements and -1 on negative elements; such characters will not be periodic in the traditional sense of Dirichlet characters, but are still completely multiplicative.

```
> D := DirichletGroup(I, [1]); D; // include first real place
Abelian Group isomorphic to Z/2 + Z/4
Group of Dirichlet characters D of modulus of norm 5 and infinite
places [ 1 ] mapping to Cyclotomic Field of order 4 and degree 2
> [ IsTrivialOnUnits(x) : x in Elements(D) ];
[ true, false, false, true, true, false, false, true ]
>  HeckeLift(D.1); // non-trivial on units
Runtime error in 'HeckeLift': Character is nontrivial on the units
> hl := HeckeLift(D.1 * D.2);
> hl(2);
zeta_4
> hl(2) eq (D.1 * D.2)(2);
```

```
true
```

So only half of the 8 completely multiplicative characters on field elements lift to characters on ideals, and these correspond exactly the standard four Dirichlet characters modulo 5, though evinced in a different guise.

`DirichletCharacter(I, B)`

`DirichletCharacter(I, oo, B)`

`DirichletCharacter(G, B)`

`HeckeCharacter(I, B)`

`HeckeCharacter(I, oo, B)`

`HeckeCharacter(G, B)`

`RequireGenerators` BoolElt *Default :* `true`

Given either an ideal (and also possibly a set of real infinite places) or a `DirichletGroup`, and a tuple of 2-tuples each containing a field element and a element of `Integers(m)` for some m, construct a Dirichlet character that sends each field element to the cyclotomic unit corresponding to the residue element. The second member of each 2-tuple can alternatively be an element of some cyclotomic field.

The parameter `RequireGenerators` demands that the given field elements should generate the `RayResidueRing` of the ideal. The second return argument is a subgroup of the ambient `DirichletGroup` by which the returned character can be translated and still retain the same values on the given elements.

Similarly for `HeckeCharacter` – there the first element in each 2-tuple should be an ideal of the field, and `RequireGenerators` demands that these generate the `RayClassGroup` of the ideal.

Example H34E17

We define a character on $5O_K$ that sends $\sqrt{-23}$ to ζ_8^2 (note that $\sqrt{-23}$ has order 8 in the `RayResidueRing` to this modulus).

```
> K := QuadraticField(-23);
> I := 5*IntegerRing(K);
> chi, SG := DirichletCharacter
>           (I, <<K.1, Integers(8)!2>> : RequireGenerators := false);
> chi(K.1);
zeta_4
> (SG.1 * chi)(K.1);
zeta_4
```

And then we define one that sends $\sqrt{-23}$ to ζ_8^6 and $(3 + 2\sqrt{-23})$, an element of order 6 in the `RayResidueRing`, to ζ_{24}^8.

```
> data := <<K.1, Integers(8)!6>, <3+2*K.1,Integers(24)!8>>;
```

```
> chi, SG := DirichletCharacter(I, data);
> chi(K.1);
-zeta_4
> chi(3+2*K.1);
zeta_3
> #SG; // this subgroup SG is trivial, as the data determine chi
1
```

Note that we can replace the Integers(8)!6 in the first tuple by ζ_8^6.

```
> C<zeta8> := CyclotomicField(8);
> data2 := <<K.1, zeta8^6>, <3+2*K.1,Integers(24)!8>>;
> chi2 := DirichletCharacter(I, data2);
> chi eq chi2;
true
```

Now we give a example with Hecke characters over a cubic field. We also note that the evaluation of a character (either Dirichlet or Hecke) can be obtained in "raw" form as an element in a residue ring via the use of the `Raw` vararg.

```
> _<x> := PolynomialRing(Integers());
> K<s> := NumberField(x^3-x^2+7*x-6); // #ClassGroup(K) is 5
> I := Factorization(11*IntegerRing(K))[2][1]; // norm 121
> HG := HeckeCharacterGroup(I,[1]); // has 20 elements
> f3 := Factorization(3*IntegerRing(K))[1][1]; // order 10
> data := < <f3, Integers(10)!7> >;
> psi := HeckeCharacter(HG, data : RequireGenerators := false);
> psi(f3);
-zeta_10^2
> psi(f3) eq CyclotomicField(10).1^7;
true
> '@'(f3,psi : Raw); // get Raw form of evaluation
14
> Parent($1);
Residue class ring of integers modulo 20
> f113 := Factorization(113*IntegerRing(K))[1][1]; // order 4
> data2 := < <f113, Integers(4)!3> >;
> psi := HeckeCharacter(HG, <data[1], data2[1]>);
> psi(f113);
-zeta_4
```

`CentralCharacter(chi)`

`CentralCharacter(psi)`

Given a Dirichlet or Hecke character, compute its central character down to the rationals. This is defined by computing a Dirichlet character that is defined over **Q** and agrees with the given character on a set of generators of the residue ring of the norm of the modulus of the given character. The `AssociatedPrimitiveCharacter` of this is then returned. It should have the same value as the original character on all unramified primes (at least). Note that the central character will always be a Dirichlet character, as the class number of the rationals is 1.

Example H34E18

```
> K := NumberField(Polynomial([4,3,-1,1])); // x^3-x^2+3*x+4
> f7 := Factorization(7*Integers(K))[1][1];
> G:= DirichletGroup(f7^2,[1]);
> chi := G.1*G.2*G.3;
> cc := CentralCharacter(chi); Conductor(cc);
Principal Ideal, Generator: [49] // conductor 49
[ 1 ] // infinite place
> cc := CentralCharacter(chi^14); Conductor(cc);
Principal Ideal, Generator: [7] // conductor 7
[ ] // no infinite places
> ////////////////
> K := NumberField(Polynomial([-10,-9,-10,1]));
> #ClassGroup(K); // C7 class group
7
> f5 := Factorization(5*Integers(K))[1][1];
> H := HeckeCharacterGroup(f5,[1]);
> cc:=CentralCharacter(H.1); Conductor(cc);
Principal Prime Ideal, Generator: [5] // conductor 5
[ 1 ] // infinite place
> Order(H.1), Order(cc);
28 4
> IsTrivial(CentralCharacter(H.1^4));
true
```

`DirichletCharacterOverNF(chi)`

`DirichletCharacterOverQ(chi)`

These are utility functions to pass between the two types of Dirichlet character over **Q** in Magma. The first takes a Dirichlet character over the `Rationals()` and returns one over the rationals as a number field, and the second reverses this.

Example H34E19

```
> SetSeed(1);
> G := DirichletGroup(16*3^2*5^2*7*11, CyclotomicField(2^6*3*5));
> #G;
57600
> chi := Random(G);
> Order(chi);
30
> psi := DirichletCharacterOverNF(chi);
> Order(psi);
30
> #Parent(psi)`supergroup;
57600
> &and[chi(p) eq psi(p) : p in PrimesUpTo(1000)];
true
> DirichletCharacterOverQ(psi) eq chi;
true
```

34.9.5 L-functions of Hecke Characters

Given a primitive Hecke character ψ, one can define the associated L-function as

$$L(\psi, s) = \prod_{\mathfrak{p}} \left(1 - \psi(\mathfrak{p})/\mathrm{N}\mathfrak{p}^s\right)^{-1},$$

and this satisfies a functional equation whose conductor is the product of the conductor of ψ and the discriminant of (the integer ring) of the number field for ψ.

Example H34E20

```
> _<x> := PolynomialRing(Integers());
> K<s> := NumberField(x^5 - 2*x^4 + 2*x + 2);
> I2 := Factorization( 2 * IntegerRing(K) ) [1][1]; // ideal above 2
> I11 := Factorization( 11 * IntegerRing(K) ) [1][1]; // above 11
> I := I2*I11; Norm(I);
22
> H := HeckeCharacterGroup(I, [1]);
> #H;
2
> psi := H.1; IsPrimitive(psi);
false
> prim := AssociatedPrimitiveCharacter(psi); Norm(Conductor(prim));
11
> L := LSeries(prim);
> LSetPrecision(L, 10); LCfRequired(L); // number of terms needed
```

```
4042
> CheckFunctionalEquation(L); // 2 or 3 seconds
-3.492459655E-10
```

34.9.6 Hecke Grössencharacters and their L-functions

A limited ability to compute Grössencharacters and their L-functions exists, but it has only really been tested for complex quadratic fields and a bit for $\mathbf{Q}(\zeta_5)$. These are "quasi-characters" in that their image is not restricted to the unit circle (and 0). The implementation in MAGMA handles the "algebraic" characters of this sort, or those of type A_0; it also requires that the field of definition be a CM-field (an imaginary quadratic extension of a totally real field).

The natural definition of Grössencharacters would be on a coset of the dual group of the `RayResidueRing` extended by the `ClassGroup`, without any modding out by units (which gives the `RayClassGroup`). However, the MAGMA implementation uses a Hecke character combined with an auxiliary Dirichlet character to simulate this. Arithmetic with Grössencharacters in also possible, even though there is no underlying group structure. However, equality with Grössencharacters is not implemented (one needs to check that various class group representatives are compatible, etc.).

`Grossencharacter(psi, chi, T)`

`RawEval(I, GR)`

Given a Hecke character ψ and a Dirichlet character χ (of the same modulus) and a compatible ∞-type T return the associated Grössencharacter.

The ∞-type is a sequence of pairs of integers which correspond to embeddings, such that

$$\psi\big((\alpha)\big) = \prod_{i=1}^{\#T} (\alpha^{\sigma_i})^{T[i][1]} (\bar{\alpha}^{\sigma_i})^{T[i][2]}$$

for all α that are congruent to 1 modulo the modulus of ψ. For a Grössencharacter to exist it follows that the ∞-type must trivialise all (totally positive) units that are congruent to 1 modulo the modulus of ψ. Each pair in T must have the same sum.

The Dirichlet character χ must correspond to the action on the image of the `UnitGroup` in the `RayResidueRing` of the modulus. In particular, for every unit u we must have that

$$\chi(u) = \prod_{i=1}^{\#T} (u^{\sigma_i})^{T[i][1]} (\bar{u}^{\sigma_i})^{T[i][2]},$$

and since the ∞-type is multiplicative, we need only check this on generators of the units.

Evaluating a Grössencharacter returns a complex number, corresponding to some choice of internal embeddings. The use of `RawEval` on an ideal will return an element in an extension of the field K (to which the ∞-type is then applied) and two elements in cyclotomic fields, corresponding to evaluations for χ and ψ respectively.

`Grossencharacter(psi, T)`

Same as above, but MAGMA will try to compute a compatible Dirichlet character χ for the given data. If there is more than one possibility, an arbitrary choice could be made.

`Conductor(psi)`

`Modulus(psi)`

`IsPrimitive(psi)`

`AssociatedPrimitiveGrossencharacter(psi)`

The conductor of the Grössencharacter is the conductor of the product of the Dirichlet part with the `DirichletRestriction` of the Hecke part. A Grössencharacter is primitive if its modulus is the same as the conductor. When taking L-functions, as before the conductor is multiplied by the discriminant of the integer ring of the field.

`Extend(psi, I)`

`Restrict(psi, I)`

Extension and restriction of a Grössencharacter. Note that the second argument is an ideal, unlike the Dirichlet/Hecke cases, where it is a group of characters.

`CentralCharacter(psi)`

Compute the central character (down to $\mathbf{Q}$) of a Grössencharacter, normalizing the result to be weight 0, and returning it as a Dirichlet character (over $\mathbf{Q}$ as a number field).

`GrossenTwist(Y, D)`

Given a Grossencharacter Y and a list D of data of pairs (a, r), find a twist Ψ of Y (by a Hilbert character) such that $\Psi(a) = r$. This intrinsic checks that the data D uniquely specifies the character, and the r should be in $\mathbf{Z}$.

Example H34E21

First, an example of $[1, 0]$-type Grössencharacters on the Gaussian field, with modulus $\mathfrak{p}_2^3$ where $\mathfrak{p}_2$ is the (ramified) prime above 2. This induces the L-function for the congruent number curve.

```
> K<i> := QuadraticField(-1);
> I := (1+i)^3*IntegerRing(K);
> HG := HeckeCharacterGroup(I, []);
> DG := DirichletGroup(I, []); #DG;
4
> GR := Grossencharacter(HG.0, DG.1^3, [[1,0]]);
> L := LSeries(GR); CheckFunctionalEquation(L);
1.57772181044202361082345713057E-30
> CentralValue(L);
```

```
0.65551438857302995261620989747 5
> CentralValue(LSeries(EllipticCurve("32a")));
0.65551438857302995261620989747 3
```

Example H34E22

An example with the canonical Grössencharacter for $K = \mathbf{Q}(\sqrt{-23})$. The ramification here is only at the prime above 23.

```
> K<s> := QuadraticField(-23);
> I := Factorization(23*IntegerRing(K))[1][1]; // ramified place
> HG := HeckeCharacterGroup(I, []);
> DG := DirichletGroup(I, []); #DG;
22
> GR := Grossencharacter(HG.0, DG.1^11, [[1,0]]); // canonical character
> CheckFunctionalEquation(LSeries(GR));
-5.17492753824983744350093938826E-28
> H := K‘extension_field; H; // defined by internal code
Number Field with defining polynomial y^3 + 1/2*(s + 3) over K
```

The values of the Grössencharacter are in the given field extension of K. We can also twist the Grössencharacter by a Hecke character on I, either via the `Grossencharacter` intrinsic, or by direct multiplication.

```
> i2 :=  Factorization(2*IntegerRing(K))[1][1]; // ideal of norm 2
> (GR*HG.1)(i2); // evaluation at i2
-0.14015763895624666594418088012 0 - 1.40725116316960648195556086783*i
> GR2 := Grossencharacter(HG.1, DG.1^11, [[1,0]]); // psi over zeta_11
> GR2(i2);
-0.14015763895624666594418088012 0 - 1.40725116316960648195556086783*i
> RawEval(i2,GR2);  // first value is in the cubic extension of K
H.1
1
zeta_33^4
> CheckFunctionalEquation(LSeries(GR2));
-7.09974814698910624870555708755E-30
```

Example H34E23

An example from Fernando Rodriguez Villegas where the Grössencharacter yields an L-function with even functional equation, but vanishing central value. This is the cube of the canonical character on $\mathbf{Q}(\sqrt{-59})$, which has class number 3. The L-function can be alternatively realised from a weight 4 modular form of level 59^2.

```
> K := QuadraticField(-59);
> I := Factorization(59*IntegerRing(K))[1][1];
> H := HeckeCharacterGroup(I);
> DG := DirichletGroup(I);
> GR := Grossencharacter(H.0, DG.1^29, [[3,0]]); // cube of canonical char
```

```
> L := LSeries(GR);
> CheckFunctionalEquation(L);
0.00000000000000000000000000000
> Sign(L);
1.00000000000000000000000000000
> CentralValue(L);
3.51858026759864075475017925650E-30
> LSetPrecision(L, 9);
> LTaylor(L, 2, 3); // first 3 terms of Taylor series about s=2
-1.09144041E-12 + 9.82515510E-11*z + 2.87637101*z^2 - 7.65817878*z^3 + ...
```

The same Grössencharacter can be obtained from cubing the canonical character (of type $[1,0]$).

```
> GR3 := Grossencharacter(H.0, DG.1^29, [[1,0]])^3;
> CentralValue(LSeries(GR3));
3.51858026759864075475017925650E-30
```

Example H34E24

An example with $\mathbf{Q}(\zeta_5)$, comparing the central value to the periods derived from Γ-values.

```
> _<x> := PolynomialRing(Rationals());
> K<z5> := NumberField(x^4+x^3+x^2+x+1);
> p5 := Factorization(5*IntegerRing(K))[1][1]; // ramified prime above 5
> H := HeckeCharacterGroup(p5^2);
> DG := DirichletGroup(p5^2);  // need p5^2 to get chi with this oo-type
> chi := DG.1^2*DG.2; // could alternatively have Magma compute this
> GR := Grossencharacter(H.0, chi, [[3,0],[1,2]]);
```

We can compute that this ∞-type sends ζ_5 to $(\zeta_5^1)^3 \cdot (\zeta_5^4)^0 \cdot (\zeta_5^2)^1 \cdot (\zeta_5^3)^2 = \zeta_5^{11}$ under the default embedding, and thus the ideal needs to afford a character of order 5 for a Grössencharacter to exist.

```
> L := LSeries(GR);
> LSeriesData(L); // Conductor is Norm(p5^2) * disc(K) = 5^2 * 5^3
<4, [ 0, -1, 1, 0 ], 3125, ... >;
> CheckFunctionalEquation(L); // functional equation works
0.00000000000000000000000000000
> CentralValue(L); // same as Evaluate(L,2)
1.25684568045898366613593980559
> Gamma(1/5)^3 * Gamma(2/5)^3 / Gamma(3/5)^2 / Gamma(4/5)^2 / 5^(7/2);
1.25684568045898366613593980558
```

The $[[3,0],[2,1]]$ ∞-type sends ζ_5 to $\zeta_5^{3+0+2\cdot 2+3} = 1$, but we still need $\mathfrak{p}_5$ in the modulus to trivialise the units of infinite order.

```
> H := HeckeCharacterGroup( 1 * IntegerRing(K)); // try conductor 1
>  GR := Grossencharacter(H.0, [[3,0],[2,1]]);
Runtime error in 'Grossencharacter':
oo-type should be trivial on all totally positive units that are 1 mod I
Fails for -zeta_5^2 - 1 which gives -1.000000000 - 3.293785801E-101*$.1
```

```
> H := HeckeCharacterGroup(p5); // conductor of norm 5
> GR := Grossencharacter(H.0, [[3,0],[2,1]]); // finds a character
> L := LSeries(GR); // CheckFunctionalEquation(L);
> PI := Pi(RealField());
> CentralValue(L); // now recognise as a product via logs and LLL
0.74985924643337212300558568330 0
> A := [ Gamma(1/5), Gamma(2/5), Gamma(3/5), Gamma(4/5), 5, PI, $1 ];
> LOGS := [ ComplexField() ! Log(x) : x in A ];
> LinearRelation(LOGS : Al := "LLL");
[ -14, 2, -2, 14, 15, -4, 4 ]
```

Example H34E25

Twisting a Grössencharacter by a Hilbert character is equivalent to changing the embedding.

```
> K := QuadraticField(-39);
> I := 39*IntegerRing(K);
> F := &*[f[1] : f in Factorization(I)]; // ideal of norm 39
> H := HeckeCharacterGroup(F); H;
Abelian Group isomorphic to Z/4 + Z/12 given as Z/4 + Z/12
> Norm(Conductor(H.1)); // H.1 is a Hilbert character of norm 1
1
> GR := Grossencharacter(H.0, [[3,0]]); // third power
```

There are four Hilbert characters here (from the class group of K), and we twist the Grössencharacter by each.

```
> L0 := LSeries(AssociatedPrimitiveGrossencharacter(GR));
> L1 := LSeries(AssociatedPrimitiveGrossencharacter(GR*H.1));
> L2 := LSeries(AssociatedPrimitiveGrossencharacter(GR*H.1^2));
> L3 := LSeries(AssociatedPrimitiveGrossencharacter(GR*H.1^3));
> Ls := [ L0, L1, L2, L3 ]; for L in Ls do LSetPrecision(L, 10); end for;
> for L in Ls do [CentralValue(L), Sign(L)]; end for;
[ 1.335826177, 1.000000000 + 2.706585223E-10*i ]
[ -1.373433032*i, -0.9999999999 - 6.351223882E-11*i ]
[ 1.335826177, 1.000000000 - 2.706585223E-10*i ]
[ 1.373433032*i, -0.9999999999 + 6.351223882E-11*i ]
```

The embedding information is stored internally in `K'Hip`, and we modify this directly to get the same L-values via a different method.

```
> K`Hip; // extension of infinite place of K
[ [ 1, 1 ] place at infinity ]
> IP := InfinitePlaces(K`extension_field); IP;
[ [ 1, 1 ] place at infinity, [ 1, 2 ] place at infinity,
  [ 1, 3 ] place at infinity, [ 1, 4 ] place at infinity ]
> for ip in IP do K`Hip := [ ip ]; // change ip, but use same GR
>        L := LSeries(AssociatedPrimitiveGrossencharacter(GR));
>        LSetPrecision(L, 10); [CentralValue(L), Sign(L)]; end for;
[ 1.335826177, 1.000000000 - 2.706585223E-10*i ]
```

```
[ 1.373433032*i, -0.9999999999 + 6.351223882E-11*i ]
[ 1.335826177, 1.000000000 - 2.706585223E-10*i ]
[ -1.373433032*i, -0.9999999999 - 6.351223882E-11*i ]
```

Finally, we can note that all the Hilbert characters have sign $+1$ in their functional equations, though two of the twists of the Grössencharacter have sign -1.

```
> Ls := [ LSeries(AssociatedPrimitiveCharacter(H.1^k)) : k in [1..4] ];
> [ Sign(L) where _:=CheckFunctionalEquation(L) : L in Ls ];
[ 0.99999999999999999999999999997, 1.0000000000000000000000000000,
  0.99999999999999999999999999997, 1.0000000000000000000000000000 ]
```

Example H34E26

A final example with characters of trivial conductor, here of type $[2,0]$ in $\mathbf{Q}(\sqrt{-23})$.

```
> K<s> := QuadraticField(-23); // class number 3
> I := 1*IntegerRing(K);
> HG := HeckeCharacterGroup(I, []);
> GR := Grossencharacter(HG.0, [[2,0]]); // of oo-type (2,0)
> Evaluate(LSeries(GR), 2); // value at edge of critical strip
1.2381910021242604040079438479 5
> Evaluate(LSeries(GR*HG.1), 2); // twist by nontrivial Hecke char
0.67033720866583940374792247 7469
> Evaluate(LSeries(GR*HG.1^2), 2);
1.06110583266449728309907405960
```

The product of these three L-values should be related to values of the Γ-function at $k/23$ for integral k. (One could alternatively relate these L-values to periods of an elliptic curve over the Hilbert class field of K having ramification only above 23.)

```
> SetDefaultRealFieldPrecision(100);
> e1 := Evaluate(LSeries(GR : Precision:=100), 2);
> e2 := Evaluate(LSeries(GR*HG.1 : Precision:=100), 2);
> e3 := Evaluate(LSeries(GR*HG.1^2 : Precision:=100), 2);
> GAMMA := [Gamma(i/23) : i in [1..22]];
> A := GAMMA cat [3,23,Pi(RealField())] cat [e1,e2,e3];
> LOGS := [ComplexField()!Log(x) : x in A];
> LinearRelation(LOGS : Al:="LLL");
[ 2,  2,  2,  2, -2,  2, -2,  2,  2, -2, -2,
  2,  2, -2, -2,  2, -2,  2, -2, -2, -2, -2,
 -2, -7,  6, -2, -2, -2 ]
> &*[ GAMMA[i]^(2*(DirichletGroup(23).1)(i)) : i in [1..22] ];
24723927.962642907904478305429424516264331853471961573093155911 28
> 3^2 * 23^7 / Pi(RealField())^6 * (e1*e2*e3)^2;
24723927.962642907904478305429424516264331853471961573093155911 28
```

Example H34E27

An example from [vGvS93, §8.8]. Here the Grössencharacter is on an ideal of norm 2^4 in the cyclotomic field $\mathbf{Q}(\zeta_8)$. The Euler factors will factor in various fields. In Table 7.6 of the cited paper, one notes that the coefficients satisfy $a_{17} = -180$ and $a_{17^2} = 15878$.

```
> Q<z8> := CyclotomicField(8);
> p2 := Factorization(2*Integers(Q))[1][1];
> G := HeckeCharacterGroup(p2^4);
> psi := G.0; // trivial
> GR := Grossencharacter(psi, [[3,0],[1,2]]);
> L:=LSeries(GR);
> CheckFunctionalEquation(L);
6.3108872417680944432938285226E-30
> Factorization(EulerFactor(L,7 : Integral)); // p is 7 mod 8
[ <343*x^2 + 1, 2> ]
> K<s2> := QuadraticField(-2);
> _<t> := PolynomialRing(K);
> Factorization(EulerFactor(L,3 : Integral),K); // 3 mod 8
[ <t^2 + 1/81*(-2*s2 - 1), 1>, <t^2 + 1/81*(2*s2 - 1), 1> ]
> K<i> := QuadraticField(-1);
> _<t> := PolynomialRing(K);
> Factorization(EulerFactor(L,5 : Integral),K); // 5 mod 8
[ <t^2 + 1/3125*(-24*i + 7), 1>, <t^2 + 1/3125*(24*i + 7), 1> ]
> EulerFactor(L,17 : Integral); // -180 and 15878 as desired
24137569*x^4 - 884340*x^3 + 15878*x^2 - 180*x + 1
```

Example H34E28

This examples exhibits the use of `GrossenTwist`, and links a Grössencharacter to a hypergeometric datum. The chosen t-value is such that the degree 3 L-function is imprimitive, and it splits as $L(\chi_{12}, s+1)L(\Psi, s)$, where Ψ is defined over $\mathbf{Q}(\sqrt{-84})$, and has trivial modulus and $[2, 0]$ ∞-type; there are still four such characters (the class number is 4), and we want the one with $\Psi(p_2) = 2$ and $\Psi(p_3) = -3$. We then check the degree 3 Euler factors on all good primes up to 100.

```
> P := PrimesInInterval(5,100);
> H := HypergeometricData([2,3],[1,6]);
> t := -27;
> ZT := Translate(LSeries(KroneckerCharacter(12)),1);
> K := QuadraticField(-84);
> DATA2 := <Factorization(2*Integers(K))[1][1],2>;
> DATA3 := <Factorization(3*Integers(K))[1][1],-3>;
> G := HeckeCharacterGroup(1*Integers(K));
> GR := Grossencharacter(G.0,[[2,0]]);
> LGR := LSeries(GrossenTwist(GR,[* DATA2, DATA3 *]));
> PROD := LGR*ZT;
> assert &and[EulerFactor(PROD,p : Integral) eq
>     EulerFactor(H,t,p) : p in P];
```

34.10 Number Field Database

An optional database of number fields may be downloaded from the MAGMA website. This section defines the interface to that database.

There are databases for number fields of degrees 2 through 9. In the case of degree 2 the enumeration is complete in the discriminant range (discriminants of absolute value less than a million); the other databases include fields with small (absolute value of) discriminant, as well as various other fields that may be of interest. The selection of fields is eclectic, and it may well be that certain "obvious" ones are missing.

For each number field in the database, the following information is stored and may be used to limit the number fields of interest via the `sub` constructor: The discriminant; the signature; the Galois group; the class number; and the class group.

34.10.1 Creation

`NumberFieldDatabase(d)`

Returns a database object for the number fields of degree d.

`sub< D | dmin, dmax : parameters >`

`sub< D | dabs : parameters >`

`sub< D | : parameters >`

`Signature`	[RNGINTELT]	*Default :*
`Signatures`	[[RNGINTELT]]	*Default :*
`GaloisGroup`	RNGINTELT *or* GRPPERM	*Default :*
`ClassNumber`	RNGINTELT	*Default :*
`ClassNumberLowerBound`	RNGINTELT	*Default :* 1
`ClassNumberUpperBound`	RNGINTELT	*Default :* ∞
`ClassNumberBounds`	[RNGINTELT]	*Default :* $[1, \infty]$
`ClassGroup`	[RNGINTELT]	*Default :*
`ClassSubGroup`	[RNGINTELT]	*Default :* [ ]
`ClassSuperGroup`	[RNGINTELT]	*Default :*
`SearchByValue`	BOOLELT	*Default :* `false`

Returns a sub-database of D, restricting (or further restricting, if D is already a sub-database of the full database for that degree) the contents to those number fields satisfying the specified conditions. Note that (with the exception of `SearchByValue`, which does not actually limit the fields in the database) it is not possible to "undo" restrictions with this constructor — the results are always at least as limited as D is.

The valid non-parameter arguments are up to two integers specifying the desired range of discriminants in the result. If two integers are provided these are taken as the lower (`dmin`) and upper (`dmax`) bounds on the discriminant. If one integer is

provided it is taken as a bound (`dabs`) on the absolute value of the discriminant. If no integers are provided then the discriminant range is the same as for D.

The parameters `Signature` or `Signatures` may be used to specify the desired signature or signatures to match. A signature is specified as a sequence of two integers $[s_1, s_2]$ where $s_1 + 2s_2 = d$.

The parameter `GaloisGroup` may be used to specify the desired Galois group of the number field. It may be given as either a permutation group, or as the explicit index of this Galois group in the transitive groups database. (i.e., the first return value of `TransitiveGroupIdentification`.)

It is possible to require certain divisibility conditions on the class number. Internally, there are lower and upper bounds on this value, such that a number field will only match if its class number is divisible by the lower bound and divides the upper bound. These bounds may be set individually using `ClassNumberLowerBound` or `ClassNumberUpperBound`; setting `ClassNumber` is equivalent to setting both bounds to the same value. Both values may be specified at once by setting `ClassNumberBounds` to the sequence of the lower and upper bounds.

When finer control is desired, it is possible to specify desired sub- and supergroups of the class group. Each group is specified by the sequence of its Abelian invariants; the desired subgroup is set using `ClassSubGroup`, and the desired supergroup is set using `ClassSuperGroup`. Both may be set at once (thus requiring the group to match exactly) using `ClassGroup`.

When iterating through the database, the default is to iterate in order of the absolute value of the discriminant. Sometimes it is desirable to iterate in order of the actual value of the discriminant; this can be accomplished by setting the parameter `SearchByValue` to true.

34.10.2 Access

`Degree(D)`

Returns the degree of the number fields stored in the database.

`DiscriminantRange(D)`

Returns the smallest and largest discriminants of the number fields stored in the database.

`#D`

`NumberOfFields(D)`

Returns how many number fields are stored in the database.

`NumberOfFields(D, d)`

Returns how many number fields of discriminant d are stored in the database.

`NumberFields(D)`

Returns the sequence of number fields stored in the database.

`NumberFields(D, d)`

Returns the sequence of number fields of discriminant d stored in the database.

Example H34E29

We illustrate with some basic examples. We start with the degree 2 number fields and get some basic information about the database.

```
> D := NumberFieldDatabase(2);
> DiscriminantRange(D);
-999995 999997
> #D;
607925
```

There are 13 fields with discriminant of absolute value less than 20:

```
> D20 := sub<D | 20>;
> #D20;
13
> [ Discriminant(F) : F in D20 ];
[ -3, -4, 5, -7, -8, 8, -11, 12, 13, -15, 17, -19, -20 ]
```

Note that these were listed in order of absolute value of the discriminant; we can also list them in value order:

```
> [ Discriminant(F) : F in sub<D20 | : SearchByValue> ];
[ -20, -19, -15, -11, -8, -7, -4, -3, 5, 8, 12, 13, 17 ]
```

Two of these number fields have class number 2:

```
> NumberFields(sub<D20 | : ClassNumber := 2>);
[
    Number Field with defining polynomial x^2 + x + 4 over the Rational Field,
    Number Field with defining polynomial x^2 + 5 over the Rational Field
]
```

Example H34E30

Now we move onto the fields of degree five, and in particular those with signature [1,2].

```
> D := NumberFieldDatabase(5);
> #D;
289040
> D12 := sub<D |: Signature := [1,2]>;
> #D12;
186906
```

We consider how many of these have class number equal to four. Note the cumulative nature of the restrictions has come into play.

```
> #sub<D12 |: ClassNumber := 4>;
1222
```

```
> #sub<D |: ClassNumber := 4>;
1255
```

The number with class group specifically isomorphic to $C_2 \times C_2$ is much less:

```
> #sub<D12 |: ClassGroup := [2,2]>;
99
```

35 QUADRATIC FIELDS

Chapter 35
QUADRATIC FIELDS

35.1 Introduction

Quadratic fields in MAGMA can be created as a subtype of the number fields `FldNum`. The advantage of the special quadratic fields is that some special (faster) algorithms have been or will be implemented to deal with them; the functions for the special quadratic fields (created with the `QuadraticField` function) are described here. Functions which work generally for number fields and their orders are described in Chapter 34.

The categories involved are `FldQuad` for fields, `RngQuad` for their orders and `FldQuadElt` and `RngQuadElt` for their elements.

35.1.1 Representation

For every squarefree integer d (not 0 or 1) there is a unique quadratic field $\mathbf{Q}(\sqrt{d})$; for any integer k we have the field $\mathbf{Q}(\sqrt{k^2 d}) \cong \mathbf{Q}(\sqrt{d})$. Given any integer m, the function `QuadraticField` will create a structure corresponding to the quadratic field $\mathbf{Q}(\sqrt{d})$, where d is the squarefree kernel of m (d will have the same sign as m and its absolute value is the largest squarefree divisor of m). In MAGMA a list of quadratic fields currently present is maintained, and if $\mathbf{Q}(\sqrt{d})$ has been created before a reference on it will be returned: two fields with the same d are the same. The discriminant D of $\mathbf{Q}(\sqrt{d})$ will be $D = d$ if $d \equiv 1 \bmod 4$ and $D = 4d$ if $d \equiv 2, 3 \bmod 4$.

Elements of $\mathbf{Q}(\sqrt{d})$ are represented by a common positive denominator b and two integer coefficients: $\alpha = \frac{1}{b}(x + y\sqrt{d})$.

The ring of integers of $F = \mathbf{Q}(\sqrt{d})$ will be $O_F = \mathbf{Z} + \epsilon_d \mathbf{Z}$, where

$$\epsilon_d = \begin{cases} \sqrt{d} & \text{if } d \equiv 2, 3 \bmod 4, \\ \frac{1+\sqrt{d}}{2} & \text{if } d \equiv 1 \bmod 4. \end{cases}$$

Elements of O_F are represented by two integer coefficients $\alpha = x + y\epsilon_d$. The pair $1, \epsilon_d$ forms an integral basis for $F = \mathbf{Q}(\sqrt{d})$, but note that elements of F are represented using the basis of the equation order $(1, \sqrt{d})$ instead.

For any positive integer f there is a suborder of conductor f in O_F, whose elements are of the form $x + yf\epsilon_d$, for any integers x, y. The discriminant of the order of conductor f is $f^2 D$, where D is the field discriminant.

The equation order of F is $E_F = \mathbf{Z} + \sqrt{d}\mathbf{Z}$. Suborders of conductor f can be formed which will contain elements of the form $x + yf\sqrt{d}$ for any integers x and y.

35.2 Creation of Structures

Squarefree integers determine quadratic fields. Associated with any quadratic field is its ring of integers (maximal order) and an equation order, and for every positive integer f there exists an order of conductor f inside the maximal order.

For information on creating elements see Section 34.2.3.

`QuadraticField(m)`

Given an integer m that is not a square, create the field $\mathbf{Q}(\sqrt{d})$, where d is the squarefree part of m. It is possible to assign a name to $\sqrt{d}$ using angle brackets: `R<s> := QuadraticField(m)`.

`EquationOrder(F)`

Creation of the order $\mathbf{Z}[\sqrt{d}]$ in the quadratic field $F = \mathbf{Q}(\sqrt{d})$, with d squarefree.

`MaximalOrder(F)`
`IntegerRing(F)`
`RingOfIntegers(F)`

Given a quadratic field $F = \mathbf{Q}(\sqrt{d})$, with d squarefree, create its maximal order. This order is $\mathbf{Z}[\sqrt{d}]$ if $d \equiv 2, 3 \bmod 4$ and $\mathbf{Z}[\frac{1+\sqrt{d}}{2}]$ if $d \equiv 1 \bmod 4$.

`NumberField(O)`

Given a quadratic order, this returns the quadratic field of which it is an order.

`sub< O | f >`

Create the sub-order of index f in the order O of a quadratic field. If O is maximal, this will be the unique order of conductor f.

`IsQuadratic(K)`
`IsQuadratic(O)`

Return `true` if the field K or order O can be created as a quadratic field or order and the quadratic field or order if so.

Example H35E1

We create the quadratic field $\mathbf{Q}(\sqrt{5})$ and an order in it, and display some elements of the order in their representation as order element and as field element.

```
> Q<z> := QuadraticField(5);
> Q eq QuadraticField(45);
true
> O<w> := sub< MaximalOrder(Q) | 7 >;
> O;
Order of conductor 7 in Q
> w;
```

```
w
> Q ! w;
1/2*(7*z + 7)
> Eltseq(w), Eltseq(Q ! w);
[ 0, 1 ]
[ 7/2, 7/2 ]
> ( (7/2)+(7/2)*z )^2;
1/2*(49*z + 147)
>  Q ! w^2;
1/2*(49*z + 147)
> w^2;
7*w + 49
```

Example H35E2

We define an injection $\phi : \mathbf{Q}(\sqrt{5}) \to \mathbf{Q}(\zeta_5)$. First a square root of 5 is identified in $\mathbf{Q}(\zeta_5)$.

```
> Q<w> := QuadraticField(5);
> F<z> := CyclotomicField(5);
> C<c> := PolynomialRing(F);
> Factorization(c^2-5);
[
   <c - 2*z^3 - 2*z^2 - 1, 1>,
   <c + 2*z^3 + 2*z^2 + 1, 1>
]
> h := hom< Q -> F | -2*z^3 - 2*z^2 - 1 >;
> h(w)^2;
5
```

35.3 Operations on Structures

The majority of functions for quadratic fields and orders apply identically to number fields and orders in general. The functions which exist only for quadratic fields and orders are listed here along with those which deserve a special mention.

`AssignNames(~F, [s])`

`AssignNames(~O, [s])`

Procedure to change the name of the generator of a quadratic field F or an order O in a quadratic field to the string s. Elements of the quadratic field $\mathbf{Q}(\sqrt{d})$ with m squarefree will be printed in the form `1/b*(x + y*s)`, where b, x, y are integers. Similarly, for an order O of conductor f in a quadratic field elements will be printed in the format x `+` y`*s`.

This procedure only changes the name used in printing the elements of F or O, it does *not* make an assignment to an identifier s. To do this, use an assignment statement, or angle brackets when creating the field or order: `F<s> := QuadraticField(-3);`.

Note that since this is a procedure that modifies F or O, it is necessary to have a reference $\sim$ in the call to this function.

`Name(F, 1)`

`Name(O, 1)`

Given a quadratic field F or one of its orders O, return the element which has the name attached to it, that is, return $\sqrt{d}$ in the field, or $f\epsilon_d$ in a suborder of the maximal order or $f\sqrt{d}$ in a suborder of the equation order.

`FundamentalUnit(K)`

`FundamentalUnit(O)`

A generator for the unit group of the order O or the maximal order of the quadratic field K.

`Discriminant(K)`

The discriminant of the field K which is only defined up to squares. The discriminant will be the discriminant of the polynomial or better.

`Conductor(K)`

The conductor of the field K which is the order of the smallest cyclotomic field containing K and a sequence containing the ramified real places of K.

`Conductor(O)`

The conductor of the order O, which equals the index of O in the maximal order.

35.3.1 Ideal Class Group

The function `ClassGroup` is available for number fields and orders in general but a different and faster algorithm is used by default for the quadratics. All of the algorithms, except for the sieving method described in [Jac99] which uses the multiple polynomial quadratic sieve (MPQS), are based on binary quadratic forms, see `ClassGroup` on page 758 in Chapter 33 for details.

`ClassGroup(K)`

`ClassGroup(O)`

`FactorBasisBound`	FldReElt	*Default :* 0.1
`ProofBound`	FldReElt	*Default :* 6
`ExtraRelations`	RngIntElt	*Default :* 1
`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`ClassGroupSieve`	*Maximum :* 5

The class group of a maximal order O or the maximal order of the quadratic field K, as an abelian group. The function also returns a map between the group and the power structure of ideals of O or the maximal order of K. The parameter `Al` can be set to `"Sieve"` or `"NoSieve"` to control whether the sieving algorithm is used or not; by default it is used when the discriminant is greater than 10^{20}. For more details on the parameters see `ClassGroup` on page 758 in Chapter 33.

`ClassNumber(K)`
`ClassNumber(O)`

`FactorBasisBound`	FldReElt	*Default :* 0.1
`ProofBound`	FldReElt	*Default :* 6
`ExtraRelations`	RngIntElt	*Default :* 1
`Al`	MonStgElt	*Default :* "*Automatic*"

The class number of the maximal order O or the maximal order of the quadratic field K.

`PicardGroup(O)`
`PicardNumber(O)`

`FactorBasisBound`	FldReElt	*Default :* 0.1
`ProofBound`	FldReElt	*Default :* 6
`ExtraRelations`	RngIntElt	*Default :* 1
`Al`	MonStgElt	*Default :* "*Automatic*"

The picard group (the group of the invertible ideals of O modulo the principal ones) of the order O or the size of this group. `PicardGroup` also returns a map from the group to the ideals of O.

Example H35E3

We give examples of class group calculations using sieving. We also show the use of the mapping between the group and the set of ideals. First a field with negative discriminant.

```
> D:=-(10^(30) + 3 );
> K := QuadraticField(D);
> time G, m := ClassGroup(K : Al := "Sieve");
Time: 10.750
> G, m;
Abelian Group isomorphic to Z/125355959329602
Defined on 1 generator
Relations:
    125355959329602*G.1 = 0
Mapping from: GrpAb: G to Set of ideals of Maximal Order of K
> m(G.1);
Ideal
Two element generators:
```

```
    385706622580333
    1487695987023274464670383908888*$.2 + 307255216496036
> $1 @@ m;
G.1
```

And now a field with positive discriminant.

```
> K := QuadraticField(NextPrime(10^24));
> time G, m := ClassGroup(K : Al := "Sieve");
Time: 3.330
> G, m;
Abelian Group isomorphic to Z/3
Defined on 1 generator
Relations:
    3*$.1 = 0
Mapping from: GrpAb: G to Set of ideals of Maximal Equation Order of K
> m(G.1);
Ideal
Two element generators:
    3847
    $.2 + 616
> $1 @@ m;
G.1
> IsPrincipal($2^3);
true
```

QuadraticClassGroupTwoPart(K)

QuadraticClassGroupTwoPart(O)

QuadraticClassGroupTwoPart(d)

Factorization RngIntEltFact *Default :* []

Use the Bosma-Stevenhagen algorithm to compute the 2-part of the class group of a quadratic order. Returned are: an array of forms that generates the 2-part and an array that gives the orders of the respective elements. The Factorization of the given discriminant can be given as additional information.

Example H35E4

```
> G, f := QuadraticClassGroupTwoPart(33923894057872); G;
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/4 + Z/16 + Z/16
> Random(G);
11*G.1 + 2*G.2 + G.3 + G.4 + G.6
> f($1);
<-1212992,3947508,3780131>
> G, f := QuadraticClassGroupTwoPart(QuadraticField(33923894057872)); G;
Abelian Group isomorphic to Z/2 + Z/8 + Z/16
```

35.3.2 Norm Equations

For imaginary quadratic fields, (that is, for quadratic fields $\mathbf{Q}(\sqrt{m})$ with $m < 0$), the function `NormEquation` is provided specially for quadratics to find integral elements of a given norm. For real quadratic fields conics are used, see Section 119.5.1 for details.

`NormEquation(F, m)`

`NormEquation(F, m:` *parameters*`)`

`NormEquation(O, m)`

`NormEquation(O, m:` *parameters*`)`

`Factorization`	[<RngIntElt, RngIntElt>]	
`All`	BoolElt	*Default :* `true`
`Solutions`	RngIntElt	*Default :* All
`Exact`	BoolElt	*Default :* `false`
`Ineq`	BoolElt	*Default :* `false`
Verbose	`NormEquation`	*Maximum :* 1

Given quadratic field F and a non-negative integer m, return `true` if there exists an element α in the ring of integers O_F of F with norm m, and `false` otherwise. Instead of searching the maximal order O_F it is possible to search any suborder O of O_F for such element α by supplying O as a first argument.

For imaginary quadratic fields the method used is constructive (it uses Cornacchia's algorithm, see [Coh93] section 1.5.2), and if the value `true` is returned then a solution $[x]$ is also returned as a second return value.

Note that if the discriminant $F = \mathbf{Q}(\sqrt{d})$ with $d \equiv 1 \bmod 4$ (and squarefree) this function searches for a solution in integers to $x^2 + y^2 d = 4m$ (and the solution $\alpha = \frac{x+y\sqrt{d}}{2}$ is returned), whereas for $d \equiv 2, 3 \bmod 4$ a solution $\alpha = x + y\sqrt{d}$ with $x^2 + y^2 d = m$ in integers x, y is returned, if it exists. In an order of conductor f a search is conducted for a solution to the same equation with d replaced by $f^2 d$. Note that a version of `NormEquation` with integer arguments d and m also exists (see Section 18.12.2).

Unless m is the square of an integer, the factorization of m is used by the algorithm; if it is known, it may be supplied as the value of the optional parameter `Factorization` to speed up the calculation.

A verbose flag can be set to obtain some information on progress with the computation (see `SetVerbose` on page 102).

For real quadratic fields the same algorithm is used as for the general number fields. The last 4 parameters refer to this algorithm. See Section 34.7 for a description.

Example H35E5

```
> d := 302401481761723680;
```

```
> m := 76814814791186002463716;
> Q<z> := QuadraticField(-d);
> O<w> := sub< MaximalOrder(Q) | 6 >;
> f, s := NormEquation(O, m);
> s, Norm(s[1]);
406 + 1008*w 76814814791186002463716
```

35.4 Special Element Operations

There are a number of functions available only for elements of certain maximal orders. `Conjugate` is provided to return a quadratic element (instead of a real) as well as `ComplexConjugate`.

`a mod b`

The remainder on dividing a by b where a and b lie in the maximal order of $Q(\sqrt{d})$ for $d = -1, -2, -3, -7, -11, 2, 3, 5, 13$. `div` is provided for order elements in general, but for discriminants not in the above list `div` will fail if the division is not exact.

35.4.1 Greatest Common Divisors

`Gcd(a, b)`
`GCD(a, b)`
`GreatestCommonDivisor(a, b)`

The greatest common divisor of a and b in the maximal order of $\mathbf{Q}(\sqrt{d})$, where d must be one of the following values: $-1, -2, -3, -7, -11, 2, 3, 5, 13$.

`Lcm(a, b)`
`LCM(a, b)`
`LeastCommonMultiple(a, b)`

The least common multiple of a and b in the maximal order of $\mathbf{Q}(\sqrt{d})$, where d must be one of the following values: $-1, -2, -3, -7, -11, 2, 3, 5, 13$.

35.4.2 Modular Arithmetic

`Modexp(a, e, n)`

The computation of $a^e \bmod n$ in the maximal order of $\mathbf{Q}(\sqrt{d})$, where d is one of the following values: $-1, -2, -3, -7, -11, 2, 3, 5, 13$.

35.4.3 Factorization

MAGMA's factorization in maximal orders of quadratic number fields is based upon factoring the norm in the integers. Thus, the comments that are made about the `Factorization` command in the integers also apply here. Moreover, since the factorization may be off by a unit power, that power is also returned (the unit being -1, $\sqrt{-1}$, or $(1+\sqrt{-3})/2$).

`Factorization(n)`
`Factorisation(n)`

The factorization of n in the maximal order of the quadratic number field $Q(\sqrt{d})$, where d is one of: -1, -2, -3, -7, or -11. Returns the factorization along with the appropriate power of a unit (the unit being -1, $\sqrt{-1}$, or $(1+\sqrt{-3})/2$).

`TrialDivision(n, B)`

Trial division of n by primes of relative norm $\leq$ B in the maximal order of $Q(\sqrt{d})$, where d is one of: -1, -2, -3, -7, or -11. Returns the factored part, the unfactored part, and the power of the unit that the factorization is off by (the unit being -1, $\sqrt{-1}$, or $(1+\sqrt{-3})/2$).

35.4.4 Conjugates

`ComplexConjugate(a)`

The complex conjugate of quadratic field element a; returns a in a real quadratic field and $\bar{a} = x - y\sqrt{d}$ if $a = x + y\sqrt{d}$ in an imaginary quadratic field $\mathbf{Q}(\sqrt{d})$.

`Conjugate(a)`

The conjugate $x - y\sqrt{d}$ of $a = x + y\sqrt{d}$ in the quadratic field $\mathbf{Q}(\sqrt{d})$.

35.4.5 Other Element Functions

For the ring of integers of $\mathbf{Q}(\mathrm{i})$ the biquadratic residue symbol (generalizing the Legendre symbol) is available.

`BiquadraticResidueSymbol(a, b)`

Given a Gaussian integer a and a primary, non-unit Gaussian integer b, where a and b are coprime, return the value of the biquadratic character $\left(\frac{a}{b}\right)_4$. The value of this character is equal to i^k, for some $k \in \{0,1,2,3\}$. If a and b have a factor in common, the function returns 0, if b is not primary or b is a unit an error results.

`Primary(a)`

Return the unique associate $\bar{a}$ of the Gaussian integer a that satisfies

$$\bar{a} \equiv 1 \bmod (1+\mathrm{i})^3,$$

or 0 in case a is divisible by $1+\mathrm{i}$.

Example H35E6

The following example checks for primes p with $65 \leq p \leq 1000$ and $p \equiv 1 \bmod 4$ a result that was conjectured by Euler and proved by Gauss, namely that

$$z^4 \equiv 2 \bmod p \quad \text{has a solution} \iff p = x^2 + 64y^2 \quad \text{for some } x, y.$$

We use the function `NormEquation` to find the prime above p in the Gaussian integers, and we build the set of such primes for which 2 is a biquadratic residue (which means that $z^4 \equiv 2 \bmod p$ for some z).

```
> s := { };
> Q := QuadraticField(-1);
> M := RingOfIntegers(Q);
> for p := 65 to 1000 by 4 do
>    if IsPrime(p) then
>       _, x := NormEquation(Q, p);
>       if BiquadraticResidueSymbol(2, Primary(M!x[1])) eq 1 then
>          Include(~s, p);
>       end if;
>    end if;
> end for;
> s;
{ 73, 89, 113, 233, 257, 281, 337, 353, 577, 593, 601, 617, 881, 937 }
```

Next we create the set of all primes as above that are of the form $x^2 + 64y^2$. Note that we have to use `NormEquation` on a suborder of Q now, because we want to solve $x^2 + 64y^2 = p$, while `QuadraticField(-64)` returns just $\mathbf{Q}(\mathrm{i})$ in which we can only solve $x^2 + y^2 = p$.

```
> S := sub<MaximalOrder(Q) | 8>;
> t := { };
> for p := 65 to 1000 by 4 do
>    if IsPrime(p) then
>       if NormEquation(S, p) then
>           Include(~t, p);
>       end if;
>    end if;
> end for;
> t;
{ 73, 89, 113, 233, 257, 281, 337, 353, 577, 593, 601, 617, 881, 937 }
```

35.5 Special Functions for Ideals

Ideals of orders of quadratic fields inherit from ideals of orders of number fields (see Section 37.9 for the list of general functions and operations available). However there is also a correspondence between quadratic ideals and binary quadratic forms (see Chapter 33). The following functions make use of that correspondence.

`Content(I)`

The content of the ideal.

`Conjugate(I)`

The conjugate of the ideal.

`Discriminant(I)`

The discriminant of the quadratic form associated with I.

`QuadraticForm(I)`

The quadratic form associated with I.

`Ideal(f)`

The quadratic ideal with associated quadratic form f.

`Reduction(I)`

The quadratic ideal with associated quadratic form which is a reduction of the quadratic form associated to I.

36 CYCLOTOMIC FIELDS

Chapter 36
CYCLOTOMIC FIELDS

36.1 Introduction

Cyclotomic Fields (like the Quadratic Fields) are a subtype of the Number Fields (FldNum). They have some extra functionality which is described below and use some more efficient implementations. Orders of cyclotomic fields form the category RngCyc and the fields themselves FldCyc. Functions for cyclotomic fields and orders which work generally for number fields, their orders and elements are listed in Chapter 34.

There are two different representations of cyclotomic fields available:

* The "dense" representation: the field is conceptually represented as $Q(x)/f(x)$ where f is a cyclotomic polynomial, i.e., the minimal polynomial of a primitive root of unity.
* The "sparse" representation: Let $n = \prod p_i^{r_i}$ be the factorisation of n into prime powers and $n_i := p_i^{r_i}$. Then $Q(\zeta_n) = Q(\zeta_{n_1}, \ldots, \zeta_{n_r})$ and the field is represented as $Q(x_1, \ldots, x_r)/\langle f_{n_1}(x_1), \ldots, f_{n_r}(x_r)\rangle$.

As with the number fields, the non-simple representation, the issues are the same: the "sparse" representation allows for much larger fields – as long as the elements used have only few coefficients. The "dense" representation on the other hand has the asymptotically-fastest arithmetic.

36.2 Creation Functions

Functions are provided to create fields of the special type FldCyc. Orders and elements created from a field of this type will have the special types RngCyc and FldCycElt respectively and elements created from orders RngCycElt. These functions provide an object with the correct type which will allow the extra functions and efficient implementations to be used.

36.2.1 Creation of Cyclotomic Fields

Cyclotomic fields can be created from an integer specifying which roots of unity it should contain or from a collection of elements of an existing field or order. Cyclotomic polynomials can also be retrieved independently of the fields and orders.

`CyclotomicField(m)`

`Sparse` BOOLEAN *Default :* `false`

Given a positive integer m, create the field obtained by adjoining the m-th roots of unity to $\mathbf{Q}$. It is possible to assign a name to the primitive m-th root of unity ζ_m using angle brackets: `R<s> := CyclotomicField(m)`.

If `Sparse := true`, names for all the generating elements can be assigned.

`CyclotomicPolynomial(m)`

Given a positive integer m, create the cyclotomic polynomial of order m. This function is equivalent to `DefiningPolynomial(CyclotomicField(m))`.

`MinimalCyclotomicField(a)`

Given an element a from a cyclotomic field F or ring R, this function returns the smallest cyclotomic field or order thereof (possibly the rational field or the ring of integers) $E \subset F$ containing a.

`MinimalCyclotomicField(S)`

Given a set or sequence S of cyclotomic field or ring elements, this function returns the smallest cyclotomic field or ring (possibly the rational field or integers) G containing each of the elements of S.

Example H36E1

We will demonstrate the difference between the "dense" and the "sparse" representation on the cyclotomic field of order 100.

```
> K1 := CyclotomicField(100);
> K2 := CyclotomicField(100: Sparse := true);
> K2!K1.1;
zeta(100)_4*zeta(100)_25^19
```

Where `zeta(100)_25` indicates a 25th root of unity in a field of order 100.

```
> K1!K2.1;
zeta_100^25
```

36.2.2 Creation of Elements

For elements of cyclotomic number fields the following conventions are used. Primitive roots of unity ζ_m are chosen in such a way that $\zeta_m^{m/d} = \zeta_d$, for every divisor d of m; one may think of this as choosing $\zeta_m = \mathrm{e}^{\frac{2\pi \mathrm{i}}{m}}$ (where the roots of unity are $\zeta_m^k = \mathrm{e}^{\frac{2k\pi \mathrm{i}}{m}}$) in the complex plane for every m (a convention that is followed for the explicit embedding in the complex domains).

Elements of cyclotomic fields and orders can also be created using coercion (`!`) and the elt constructor (`elt<|>`) where the left hand side is the field or order the element will lie in. For details about coercion see Section 34.2.3.

`RootOfUnity(n)`

Create the n-th root of unity ζ_n in $\mathbf{Q}(\zeta_n)$.

`RootOfUnity(n, K)`

Given a cyclotomic field $K = \mathbf{Q}(\zeta_m)$ and an integer $n > 2$, create the n-th root of unity ζ_n in K. An error results if $\zeta_n \notin K$, that is, if n does not divide m (or $2m$ in case m is odd).

`Minimise(~a)`
`Minimize(~a)`

Given an element a in a cyclotomic field F or ring R, this procedure finds the minimal cyclotomic subfield $E \subset F$ or subring $E \subset F$ containing a, and coerces a into E. Note that E may be $\mathbf{Q}$ or $\mathbf{Z}$.

`Minimise(~s)`
`Minimize(~s)`

Given a set s of cyclotomic field or ring elements, this procedure finds the minimal cyclotomic field or ring E containing all of them, and coerces each element into E. The resulting set will have universe E. Note that E may be $\mathbf{Q}$ or $\mathbf{Z}$.

`Minimise(a)`
`Minimize(a)`

Given an element a in a cyclotomic field F or ring R, this function finds the minimal cyclotomic subfield $E \subset F$ or subring $E \subset R$ containing a, and coerces a into E. Note that E may be $\mathbf{Q}$ or $\mathbf{Z}$.

`Minimise(s)`
`Minimize(s)`

Given a set s of cyclotomic field or ring elements, this function finds the minimal cyclotomic field E containing all of them, and coerces each element into E. The resulting set will have universe E. Note that E may be $\mathbf{Q}$ or $\mathbf{Z}$.

36.3 Structure Operations

In cyclotomic fields the generic ring functions are supported (see Chapter 17). The functions listed below are those functions for cyclotomic fields which are additional to those for number fields. For the list of functions applying to general number fields see Section 34.2 and Section 34.3.

36.3.1 Invariants

`Conductor(K)`

The smallest n such that the field K is contained in $\mathbf{Q}(\zeta_n)$; for a cyclotomic field that is either the 'cyclotomic order' m (see below) or half that, depending on whether $m \equiv 2 \bmod 4$. The second return value is a sequence of the ramified real places of K.

`CyclotomicOrder(K)`

The value of m for the cyclotomic field $\mathbf{Q}(\zeta_m)$. Note that this will be the m with which the cyclotomic field was created.

`CyclotomicAutomorphismGroup(K)`

Returns the automorphism group of K as an abstract abelian group G and a map from G into the set of all automorphisms. Note that similar functionality is also available through `AutomorphismGroup` however, this function returns an abelian group and uses the fact that the automorphism group is already determined by the conductor.

`CyclotomicRelativeField(k, K)`

Given two cyclotomic fields $k \subseteq K$ a number field L/k is computed that is isomorphic to K.

36.4 Element Operations

For the full range of operations for elements of a number field or order see Section 34.4.

36.4.1 Predicates on Elements

Because of the nature of cyclotomic fields and orders, some properties of elements are easier to determine than in the general case.

`IsReal(a)`

Whether the cyclotomic field or ring element a is a real number, i.e., if it is invariant under the complex conjugation.

36.4.2 Conjugates

Elements of cyclotomic fields and orders can additionally have their complex conjugate computed. Conjugates are returned as cyclotomic elements (and not reals) and which conjugate is wanted can be indicated by providing a primitive root of unity.

`ComplexConjugate(a)`

The complex conjugate of cyclotomic field or ring element a.

`Conjugate(a, n)`

The image under the map $\zeta \mapsto \zeta^n$. The second argument (n) must be coprime to the conductor.

`Conjugate(a, r)`

The conjugate of the element $a \in \mathbf{Q}(\zeta_m)$ or its order, obtained by applying the field automorphism $\zeta_m \mapsto r$ where r is a primitive root of unity.

Example H36E2

The following lines of code generate a set W of minimal polynomials for the so-called Gaussian periods

$$\eta_d = \sum_{i=0}^{(l-1)/d-1} \zeta_l^{g^{di}}$$

where ζ_l is a primitive l-th root of unity (l is prime), and where g is a primitive root modulo l. These have the property that they generate a degree d cyclic subfield of $\mathbf{Q}(\zeta_l)$. We (arbitrarily) choose $l = 13$ in this example.

```
> R<x> := PolynomialRing(RationalField());
> W := { R | };
> l := 13;
> L<z> := CyclotomicField(l);
> M := Divisors(l-1);
> g := PrimitiveRoot(l);
> for m in M do
>    d := (l-1) div m;
>    g_d := g^d;
>    w := &+[z^g_d^i : i in [0..m-1] ];
>    Include(~W, MinimalPolynomial(w));
> end for;
```

Here is the same loop in just one line, using sequence reduction:

```
> W := { R | MinimalPolynomial(&+[z^(g^((l-1) div m))^i : i in [0..m-1] ]) :
>        m in M };
> W;
{
      x^12 + x^11 + x^10 + x^9 + x^8 + x^7 + x^6 + x^5 + x^4 + x^3 + x^2 +
       x + 1,
      x^6 + x^5 - 5*x^4 - 4*x^3 + 6*x^2 + 3*x - 1,
      x^3 + x^2 - 4*x + 1,
      x + 1
      x^4 + x^3 + 2*x^2 - 4*x + 3,
      x^2 + x - 3,
}
```

37 ORDERS AND ALGEBRAIC FIELDS

Chapter 37
ORDERS AND ALGEBRAIC FIELDS

37.1 Introduction

The number field module in MAGMA is based on the Kant/Kash system (Kant-V4) [KAN97], [KAN00], developed by the group of M. Pohst in Berlin.

The three main structures which this chapter is concerned with are FldNum (number fields), RngOrd (orders in number fields) and FldOrd (fields of fractions of RngOrd's). Elements in these have types FldNumElt, RngOrdElt and FldOrdElt and ideals have types RngOrdIdl and RngOrdFracIdl. While number fields, and their sub-types cyclotomic fields and quadratic fields, are also detailed in separate chapters, (chapter 34 for number fields, 36 for cyclotomics and 35 for quadratics), almost all functionality described here applies to those objects as well.

On top of all there is a combined type that will match all "number field" types: FldAlg will match all references of type FldNum, FldOrd, FldCyc, and FldQuad (and similarly FldAlgElt will match all element types: FldNumElt, FldOrdElt, FldCycElt and FldQuadElt).

Number fields support extended types, they can be indexed by the type of the coefficient ring: FldNum[FldRat] refers to an absolute extension over $\mathbf{Q}$, while FldNum[FldNum] refers to a relative extension.

In order to use them efficiently, one has to understand the relations between the parent structures.

The basic distinction is between the number field point of view (FldNum) and the order based view (FldOrd, RngOrd).

We will start with the number fields. Formally, in MAGMA, an object K of type FldNum is an algebraic extension of finite degree over a a number field k or $\mathbf{Q}$. Thus it can be thought of as constructed as a quotient ring of a univariate polynomial ring over the base field modulo some irreducible polynomial: $K = k[t]/(f(t)k[t])$ Or, the field may be constructed as a multivariate quotient: $K = k[s_1, \ldots, s_n]/(f_1(s_1), \ldots, f_n(s_n))$ where all the polynomials are univariate. However, a slightly different representation is used internally.

It is important to remember that $\mathbf{Q}$ is **not** a number field.

One has to distinguish between number fields with primitive element α:= K.1 which is a zero of f and number fields where no primitive element is known. In this case α_i:= K.i will be a zero of f_i.

However, number fields always have a 'power' basis, i.e. a basis containing only powers of the zero(s) of the defining polynomial(s) and products of those powers.

An important consequence of this representation as a quotient of a polynomial ring is that one cannot distinguish between e.g. $\mathbf{Q}[2^{(1/3)}]$ and $\mathbf{Q}[\zeta_3 2^{(1/3)}]$ – both of them are generated using a root of $t^3 - 2$. Therefore every non trivial extension generates a **new**

object – even if the same polynomial is used repeatedly, except when the user explicitly tells MAGMA to check whether the polynomial has been used before.

An absolute extension is always an extension of $\mathbf{Q}$. An arbitrary number field K can always be converted into an isomorphic extension of $\mathbf{Q}$ using a constructive variant of the primitive element theorem.

Likewise, if a subfield k of K is known, an isomorphic field as an extension of k can be computed.

The most important facts about the various representations are the following:

* Usually, arithmetic is fastest in absolute extensions. Thus, if one wants to do lots of basic arithmetic with the elements the transformation to an absolute representation is advisable. However, typically the operations are fastest when the elements are "small" in size.
* Invariants (like `Degree`, `Discriminant`, `Norm`, `Trace` etc.) are always relative to the current representation.
* Conversions of fields tend to be time consuming thus should be avoided if possible. However, once the different field representations are computed, the conversion of elements is not too time consuming.
* Some operations and invariants can (currently) only be done for absolute representations. Essentially, these are computations involving subfields and class and unit group computations.

Number fields support only arithmetic with their elements and the computation of some invariants (`GaloisGroup`, `Subfields`, `AutomorphismGroup`). Although invariants like the class group can be computed for `FldNum`s this is only a shortcut for the corresponding computations for the maximal orders so e.g. `ClassGroup(K)` is expanded to `ClassGroup(MaximalOrder(K))`.

The other parent data-types are orders (`RngOrd`) and their fields of fractions (`FldOrd`). Orders can be constructed in basically two ways:

* as finite extensions E of a (maximal) order m (or of $\mathbf{Z}$) by a zero of a monic integral polynomial $f \in m[t]$
* via a transformation from a different order.

The main restriction for the construction of orders is that the coefficient domain (`BaseRing`) must always be a maximal order if any structural computations are desired. An order O over some maximal order m is represented using a (pseudo) m-basis (of type `PMat` similar to the way modules over Dedekind rings (`ModDed`, `PMat`) are represented in general. Every other order must be free over its base ring.

An order O is equipped with a unique field of fractions, `FieldOfFractions(O)`, which has the same basis as the order and whose base field is the field of fractions of the base ring. The fields of fractions support almost no structural computations, they merely serve as a parent structure to any elements and ideals that (may) have denominators (i.e. that are non-integral w.r.t. the current structure).

From a practical point of view, orders and their field of fractions have two different element data types, namely elements (`RngOrdElt`) and ideals (`RngOrdIdl`) (resp. `FldOrdElt`

and RngOrdFracIdl). This is technically not quite correct since ideals have formally different parents but those parents are trivial and the important information in them is the order the ideal is of. Ideals behave much more like elements than structures – they have no elements and are not rings in general. Formally, the parent structures obey the following rules:

* MaximalOrder(BaseRing(K)) eq BaseRing(MaximalOrder(K)) for all number fields and fields of fractions K.
* BaseField(FieldOfFractions(O)) eq FieldOfFractions(BaseRing(O)) for all orders O.
* BaseField(NumberField(O)) eq NumberField(BaseRing(O)) for all orders O.
* all orders within the same field share the identical number field. For example: IsIdentical(NumberField(O), NumberField(MaximalOrder(O))), while the corresponding fields of fractions will have, in general, different bases.

There are a few functions where orders behave differently to most other MAGMA objects, mostly because orders are not necessarily free modules over their base ring:

* Parent(O.i) eq FieldOfFractions(O) and furthermore O.i in O is usually false.
* Eltseq of an order element returns a sequence over the field of fractions of the base ring.
* The O.i are typically not a basis of the order – just part of a pseudo basis. However, they always form a basis of the field of fractions.

Algebraic number fields will be referred to as *number fields*. If a field may be either a number field or field of fractions it will be referred to as an *algebraic field*.

37.2 Creation Functions

The following describes how number fields, orders and their fields of fractions may be created. It also shows some ways of creating elements of these rings and homomorphisms from these rings into an arbitrary ring.

37.2.1 Creation of General Algebraic Fields

Algebraic Number Fields can be created in a various ways, all involving polynomials. The fields can be created as absolute extensions, i.e. an extension of **Q** by an irreducible polynomial, or as a relative extension which is an extension of an algebraic field by a polynomial irreducible over that field. Fields of fractions can be created as FieldOfFractions(O) where O is some order or from an existing field of fractions by using some of the constructors and functions described below. See also the corresponding sections for number fields section 34.2.1, section 36.2 for cyclotomics and section 35.2 for quadratics.

NumberField(f)

Check	BOOLELT	*Default :* true
DoLinearExtension	BOOLELT	*Default :* false

Global	BoolElt	*Default :* false

Given an irreducible polynomial f of degree $n \geq 1$ over $K = \mathbf{Q}$ or some number field K, create the number field $L = K(\alpha)$ obtained by adjoining a root α of f to K. For details see NumberField in Section 34.2.1.

The angle bracket notation may be used to assign the root α to an identifier e.g. L<y> := NumberField(f) where y will be a root of f.

RationalsAsNumberField()

QNF()

This creates a number field isomorphic to $\mathbf{Q}$. It is equivalent to NumberField(x-1) : DoLinearExtension), where x is PolynomialRing(Rationals()).1.

The result is a field isomorphic to $\mathbf{Q}$, but regarded by Magma as a number field (while $\mathbf{Q}$ itself is not, since FldRat is not a subtype of FldNum). It therefore supports all of the number field functions, while the Rationals() do not. On the other hand, arithmetic will be slower.

Coercion can be used to convert to and from the Rationals().

NumberField(s)

Check	BoolElt	*Default :* true
DoLinearExtension	BoolElt	*Default :* false
Abs	BoolElt	*Default :* false

Let K be a possibly trivial algebraic extension of $\mathbf{Q}$. Given a sequence s of nonconstant polynomials $s_1, \ldots, s_m$, that are irreducible over K, create the number field $L = K(\alpha_1, \ldots, \alpha_m)$ obtained by adjoining a root α_i of each s_i to K. For details see NumberField in Section 34.2.1.

ext< F | s1, ..., sn >

ext< F | s >

Check	BoolElt	*Default :* true
Global	BoolElt	*Default :* false
Abs	BoolElt	*Default :* false
DoLinearExtension	BoolElt	*Default :* false

Create the algebraic field defined by extending F by the polynomials s_i or the polynomials in the sequence s. Similar as for NumberField(S) described above, F may be $\mathbf{Q}$ or a field of fractions. If F is a field of fractions a field of fractions will be returned otherwise a number field will be returned. A tower of fields similar to that of NumberField is created and the same restrictions as for that function apply to the polynomials that can be used in the constructor.

`RadicalExtension(F, d, a)`

`Check`	BoolElt	*Default :* `true`

Let F be an algebraic field. Let a be an integral element of F chosen such that a is not an n-th power for any n dividing d. Returns the algebraic field obtained by adjoining the d-th root of a to F.

`SplittingField(F)`

`Abs`	BoolElt	*Default :* `true`
`Opt`	BoolElt	*Default :* `true`

Given an algebraic field F, return the splitting field of its defining polynomial. The roots of the defining polynomial in the splitting field are also returned.

If `Abs` is `true`, the resulting field will be an absolute extension, otherwise a tower is returned.

If `Opt` is `true`, an attempt of using `OptimizedRepresentation` is done. If successful, the resulting field will have a much nicer representation. On the other hand, computing the intermediate maximal orders can be extremely time consuming.

`SplittingField(f)`

Given an irreducible polynomial f over $\mathbf{Z}$, return its splitting field.

`SplittingField(L)`

`Abs`	BoolElt	*Default :* `false`
`Opt`	BoolElt	*Default :* `false`

Given a sequence L of polynomials over a number field or the rational numbers, compute a common splitting field, i.e. a field K such that every polynomial in L splits into linear factors over K. The roots of the polynomials are returned as the second return value.

If the optional parameter `Abs` is `true`, then a primitive element for the splitting field is computed and the field returned will be generated by this primitive element over $\mathbf{Q}$. If in addition `Opt` is also `true`, then an optimized representation of K is computed as well.

`sub< F | e1, ..., en >`

Given an algebraic field F with ground field G and n elements $e_i \in F$, return the algebraic field $H = G(e_1, \ldots, e_n)$ generated by the e_i (over G), as well as the embedding homomorphism from H to F.

`MergeFields(F, L)`

`CompositeFields(F, L)`

Let F and L be absolute algebraic fields. Returns a sequence of fields $[M_1, \ldots, M_r]$ such that each field M_i contains both a root of the generating polynomial of F and a root of the generating polynomial of L.

In detail: Suppose that F is the smaller field (wrt. the degree). As a first step we factorise the defining polynomial of L over F. For each factor obtained, an extension of F is constructed and then transformed into an absolute extension. The sequence of extension fields is returned to the user.

`Compositum(K, L)`

For absolute number fields K and L, at least one of which must be normal, find a smallest common over field. Note that in contrast to `CompositeFields` above the result here is essentially unique since one field was normal.

`Compositum(K, A)`

For an normal number field K and abelian extension A of some subfield of K, find a smallest common over field. Note that in contrast to `CompositeFields` above the result here is essentially unique since K is normal.

`OptimizedRepresentation(F)`

`OptimisedRepresentation(F)`

`OptimizedRepresentation(F, d)`

`OptimisedRepresentation(F, d)`

Given an algebraic field F with ground field $\mathbf{Q}$, this function will attempt to find an isomorphic field L with a better defining polynomial (in the sense defined below) than the one used to define F. If such a polynomial is found then L is returned; otherwise F will be returned.

If the argument d is not specified, a polynomial g with integer coefficients is defined to be better than f if it is monic, irreducible, defines a number field isomorphic to F and its discriminant is smaller (in absolute value) than that of f. If a second argument d is specified, then g is defined to be better if in addition to the previous requirements d is not an index divisor, that is, if d does not divide the index (defined in the Invariants sub–section) $[O_L : E_L]$ of the equation order E_L of L in the maximal order O_L, (which are defined in the next sub–section).

Note however, that as a first step this function will determine the maximal order of F which may take some time if the field is large.

Example H37E1

Some results of `OptimizedRepresentation` are shown.

```
> R<x> := PolynomialRing(Rationals());
> K := NumberField(x^4-420*x^2+40000);
> L := OptimizedRepresentation(K);
> L ne K;
true
> L;
Number Field with defining polynomial x^4 - 4*x^3 -
    17*x^2 + 42*x + 59 over the Rational Field
> L eq OptimizedRepresentation(L);
> f := DefiningPolynomial(L);
> Z := IntegerRing();
> Factorization(Z ! Discriminant(f));
[ <2, 18>, <5, 8>, <41, 2> ]
> g := x^4 - 4*x^3 - 17*x^2 + 42*x + 59;
> Factorization(Z ! Discriminant(g));
[ <2, 4>, <3, 4>, <5, 2>, <41, 2> ]
> OL := MaximalOrder(L);
> EL := EquationOrder(L);
> Index(OL, EL);
36
> OptimizedRepresentation(L, 2) eq L;
true
```

As we see from this computation, the prime 5 (as well as 41) divides the discriminant of g twice. This means that, potentially, 5 would still divide the index of the equation order in the maximal order O_L of L. However, in fact E_L has only index 36 in O_L.
The optimized representation of L such that 2 does not divide the index of E_L in O_L is L so 2 does divide the index seemingly contrary to the description above. However, if a more optimal representation cannot be found then the field is returned which is what happens here.

37.2.2 Creation of Orders and Fields from Orders

The maximal order $\mathcal{O}_K$ of an algebraic field and the equation order of a number field can be obtained from the field. Other orders of a field are unitary subrings of finite index in the ring of integers; they contain a subset of the integral elements in the field. The equation order $\mathcal{E}_K = \mathbf{Z}[\alpha]$ of $K = \mathbf{Q}(\alpha) \cong \mathbf{Q}[X]/f(X)$, where K is a number field defined by a monic integral polynomial, has the same basis as K, a power basis. Obviously $\mathcal{E}_K \subset \mathcal{O}_K$ since the minimal polynomial of α is integral and monic. Once an order is created in Magma further orders can be created from it.

`EquationOrder(f)`

`Check` BoolElt *Default :* `true`

Given an irreducible non-constant monic integral polynomial $f \in R[X]$, return the equation order $E = \mathbf{R}[X]/f(X)$ corresponding to f. If the optional parameter `Check` is set to `false` then the polynomial will not be checked for irreducibility.

`EquationOrder(K)`

Return the equation order corresponding to the polynomial with which the number field K was defined. K must have been defined by a monic integral polynomial. Thus this function returns the extension of the equation order of the ground field of K by the defining polynomial of K.

`SubOrder(O)`

Provided the order O is not an equation order, O is a transformation of some order O'. This function returns O'.

`EquationOrder(O)`

A suborder of the order O which is defined by a polynomial. e.g. $R[x]/f$ where R is a polynomial ring over the coefficient ring of O and f is in R. It will also be the final order of `SubOrder(SubOrder(... SubOrder(O)))`. O must have a monic defining polynomial for the equation order to exist.

`Integers(O)`
`RingOfIntegers(O)`
`IntegerRing(O)`

Returns the ring of integers in the order O, ie. O itself.

Example H37E2

Once a number field $K = \mathbf{Q}(\alpha)$ has been created, one can obtain the equation order $E = \mathbf{Z}[\alpha]$ and the ring of integers O_K simply as follows.

```
> R<x> := PolynomialRing(Integers());
> K := NumberField(x^4-420*x^2+40000);
> E := EquationOrder(K);
> O := MaximalOrder(K);
> Index(O, E);
64000
```

Note that entirely different things happen here: for the equation order nothing has to be computed, but the determination of the maximal order involves the complicated Round 2 (or 4) algorithm. In our particular example above, E is a subring of index $2^9 \cdot 5^3$ in O (see also the example for orders and ideals in the subsection 37.2.3.1 where a maximal order is created).

`sub< O | a1, ..., ar >`

Create the suborder of the order O generated (as an algebra over $\mathbf{Z}$) by the elements $a_1, \ldots, a_r \in O$, that is, create $\mathbf{Z}[a_1, \ldots, a_r]$. If the algebra does not have full rank as a sub-module of O, an error results. Note, however, that it is currently *not* required that 1 is in the sub-ring.

`ext< O | a1, ..., ar >`

Given an order O, and elements $a_1, \ldots, a_r$ lying in the maximal order of O, create the order $O[a_1, \ldots, a_r]$. Note that using this constructor O can only be extended to be as large as the maximal order. This does not cause the maximal order to get computed. See also `Order` for a different version that allows parameters to improve efficiency.

`ext< O | f >`

Given an order O and a polynomial f of degree n with coefficients in O, create the extension E of O by a root of f which forms a free module of rank n over O : $E \cong O[\alpha]$; it is necessary for f to be irreducible over O.

`FieldOfFractions(O)`

Return the field containing all fractions of elements of O. The angle bracket notation can be used to assign names to the basis elements of F and assign these elements to variables, e.g. `F<x, y> := FieldOfFractions(MaximalOrder(x^2 + 3))`.

`Order(F)`

The order of which F was created as its field of fractions. This function is an inverse to `FieldOfFractions`.

`NumberField(O)`

The number field of an order is recursively defined by:

1. the number field of $\mathbf{Z}$ is $\mathbf{Q}$
2. the number field of O is the number field of the coefficient ring of O, (i.e. the order over which O is defined), with an element α adjoined where α is a root of the defining polynomial of O.

`NumberField(F)`

The number field of `Order(F)` for a field of fractions F.

Example H37E3

The following illustrates the relationship between the bases of an order, its field of fractions and its number field.

```
> R<x> := PolynomialRing(Integers());
> f := x^5 + 5*x^4 - 75*x^3 + 250*x^2 + 65625;
> M := MaximalOrder(f);
> M;
Maximal Order of Equation Order with defining polynomial x^5 + 5*x^4 - 75*x^3 +
    250*x^2 + 65625 over its ground order
> Basis(FieldOfFractions(M));
[
    M.1,
    M.2,
    M.3,
    M.4,
    M.5
]
> Basis(NumberField(M));
[
    1,
    $.1,
    $.1^2,
    $.1^3,
    $.1^4
]
> Basis(M);
[
    M.1,
    M.2,
    M.3,
    M.4,
    M.5
]
> M.1 eq 1;
true
> M.2 eq NumberField(M).1;
false
> E := EquationOrder(M);
> NumberField(M) eq NumberField(E);
true
> Basis(FieldOfFractions(E), NumberField(M));
[
    1,
    $.1,
    $.1^2,
    $.1^3,
    $.1^4
```

```
]
> M!Basis(FieldOfFractions(E))[1];
[1, 0, 0, 0, 0]
> M!Basis(FieldOfFractions(E))[2];
[0, 5, 0, 0, 0]
> M!NumberField(M).1;
[0, 5, 0, 0, 0]
```

`OptimizedRepresentation(O)`
`OptimisedRepresentation(O)`
`OptimizedRepresentation(O, d)`
`OptimisedRepresentation(O, d)`

Given an order O with ground ring $\mathbf{Z}$, this function will attempt to find an isomorphic maximal order M with a better defining polynomial than the one used to define O. If such a polynomial is found then M is returned; otherwise O will be returned.

If the argument d is not specified, a polynomial g with integer coefficients is defined to be better than f if it is monic, irreducible, defines an order isomorphic to O and its discriminant is smaller in absolute value than that of f. If a second argument d is specified, then g is defined to be better if in addition to the previous requirements d is not an index divisor, that is, if d does not divide the index (defined in the Invariants sub–section) $[M : E_M]$ of the equation order E_M of M in M.

`O + P`

Add two orders O and P having the same equation order. Computes the smallest common over order.

`O meet P`

The intersection of two orders O and P having the same equation order.

`AsExtensionOf(O, P)`

Return the order O as an transformation of the order P where O and P have the same coefficient ring.

`Order(O, T, d)`

`Check` BoolElt *Default :* `true`

Let O be an absolute order with basis $b_1, \ldots, n_n$, $T = (T_{i,j}) \in \mathrm{GL}(n, \mathbf{Q}) \cap \mathrm{Mat}(n, \mathbf{Z})$ and $d \in \mathrm{N}$. This function creates the order with basis $(1/d \sum_{j=1}^{n} T_{i,j} b_j)_{i \le i \le n}$. `Check` can be set to `false` when the order is large to avoid checking that the result actually is an order.

`Order(O, M)`

Let O be an order with (pseudo) basis $b_1, \ldots, b_n$ and $M = \sum_{i=1}^{n} A_i \alpha_i \subseteq k^n$ be an o_k-module where o_k is the coefficient ring of O. This function creates the order $\sum_{i=1}^{n} A_i c_i$ where $c_i := \sum_{j=1}^{n} \alpha_{i,j} b_j$. If `Check` is set to `false`, then it will not be checked that the result actually is an order (potentially expensive).

`Order( [ e`$_1$`, ... e`$_n$` ] )`

`Verify`	BOOLELT	*Default :* `true`
`Order`	BOOLELT	*Default :* `false`

Given n elements $e_1, \ldots, e_n$ in an algebraic extension field F over $\mathbf{Q}$ create the minimal order O of F which contains all the e_i. If `Verify` is `true`, it is verified that the e_i are integral algebraic numbers. This can be a lengthy process if the field is of large degree.

Setting `Order` to `true` assumes that the given elements actually form a basis for the new order, thus it avoids testing for multiplicative closure. Without this parameter the order returned will have a canonical basis chosen with no direct relation to the input. By default, products of the generators will be added until the module is closed under multiplication.

37.2.3 Maximal Orders

The maximal order $\mathcal{O}_K$ is the ring of integers of an algebraic field consisting of all integral elements of the field; that is, elements which are roots of monic integer polynomials. It may also be called the number ring of a number field.

There are a number of algorithms which MAGMA uses whilst computing maximal orders. Each maximal order is a sum of p-maximal orders. The main algorithm used for p-maximal orders is a mixture of the Round–2 and Round–4 methods ([Coh93, Bai96, Poh93, PZ89]) for absolute extensions and a variant of the Round–2 for relative extensions ([Coh00, Fri97]).

However if the field is a radical (pure) extension, there is another algorithm available which is used to calculate each p-maximal order. In this case we can compute a pseudo basis for the p-maximal orders knowing only the valuation of the constant coefficient of the defining polynomial at p [Sut12].

The Round–2 and Round–4 algorithms can be selected by setting the parameter `Al` to `"Round2"` and `"Round4"` respectively. Another option for this parameter and for computation of p-maximal orders is the `"Pauli"` method. This method is only available for equation orders in simple relative extensions. It uses the factorization of the defining polynomial over the completion of the order.

Alternatively, if the discriminant of the maximal order is already known, the parameters `Discriminant` or `Ramification` can be used. If the input is an order O and the `Discriminant` or `Ramification` parameters are supplied an algorithm which can compute the maximal order given the discriminant of the maximal order will be used. `Discriminant` must be an integer if O is an absolute order and must be an ideal of the coefficient ring of O if O is a relative order. `Ramification` must contain integers if O is an absolute

order and must contain ideals of the coefficient ring of O if O is a relative order. The ramification sequence is taken to contain prime factors of the discriminant. Only one of these parameters can be specified and if one of them is then `Al` cannot be specified. This algorithm is based on [Bj94], Theorems 1.2 and 7.6.

`MaximalOrder(O)`

`Al`	MonStgElt	*Default :* "*Auto*"

`MaximalOrder(F)`
`IntegerRing(F)`
`Integers(F)`
`RingOfIntegers(F)`

`Discriminant`	Any	*Default :*
`Ramification`	SeqEnum	*Default :*
Verbose	`MaximalOrder`	*Maximum :* 5

Return the maximal order or ring of integers of the number field F. When the input is an order O or a field of fractions of an order O return the order containing O which is the largest order in the number field of O.

An integral basis for F can be found as the basis of the maximal order.

For information on the parameters, see the introduction to this section above, 37.2.3.

`MaximalOrder(f)`

`Check`	BoolElt	*Default :* `true`
`Al`	MonStgElt	*Default :* "*Auto*"
`Discriminant`	Any	*Default :*
`Ramification`	SeqEnum	*Default :*
Verbose	`MaximalOrder`	*Maximum :* 5

This is equivalent to `MaximalOrder(NumberField(f))`.

The `Check` parameter if set to `false` will prevent checking of the polynomial for irreducibility.

For information on the other parameters, see the introduction to this section above.

Example H37E4

The following shows the advantage of the `Ramification` parameter to the `MaximalOrder` function.

```
> R<t> := PolynomialRing(Integers());
> f1 := t^14 - 63*t^12 - 9555*t^11 + 118671*t^10 - 708246*t^9 - 17922660*t^8 +
> 859373823*t^7 + 2085856500*t^6 - 117366985106*t^5 - 335941176396*t^4 +
> 4638317668005*t^3 + 17926524826973*t^2 + 7429846568445*t+ 91264986397629;
> d1 := [2, 3, 5, 7, 59];
```

```
> time MaximalOrder(f1:Ramification := d1);

The last line did not complete running in over 7 hours.

37.2.3.1 Orders and Ideals

Orders may be created using ideals of another order. Ideals are discussed in Section 37.9. The following intrinsics form part of the computation of maximal orders as discussed above in Section 37.2.3.

`pMaximalOrder(O, p)`

`Al` MonStgElt *Default :* "*Auto*"

The p-maximal overorder of O (see also the example below). This is the largest overorder P such that the index $(P : O)$ is a power of p, a prime in the coefficient ring of O. The options for the `Al` parameter are the same as those for `MaximalOrder`.

If O is a kummer extension then specific code is used to calculate each p-maximal order, rather than the Round 2 or Round 4 methods. In this case we know 1 or 2 elements which generate the p-maximal order and can easily write the order down.

`pRadical(O, p)`

Returns the p-radical of an order O for a prime p in the coefficient ring of O, defined as the ideal consisting of elements of O for which some power lies in the ideal pO.

It is possible to call this function for p not prime (so long as p is greater than the degree of O if it is an integer). In this case the p-trace-radical will be computed, i.e.

$$\{x \in F \mid \mathrm{Tr}(xO) \subseteq p\mathbf{Z}\}.$$

If p is square free and all divisors are larger than the field degree, this is the intersection of the radicals for all l dividing p. In particular together with `MultiplicatorRing` this can sometime be used to compute maximal orders without factoring the discriminant [Bj94, Fri00] or at least "good" approximations.

`MultiplicatorRing(I)`

Returns the multiplicator ring M of the ideal I of the order O, that is, the subring of elements of the field of fractions K of O multiplying I into itself: $M = \{x \in F : xI \subset I\}$.

Example H37E5

To illustrate how the Round 2 algorithm for the determination of the ring of integers works, we present an implementation of it in the MAGMA language. The key functions are `MultiplicatorRing` and `pRadical`, called by the following function `pMaximalOverOrder`;

```
> pMaximalOverOrder := function(ord, p)
>        ovr := MultiplicatorRing(pRadical(ord, p));
>        print "index is", Index(ovr, ord);
>        return (Index(ovr, ord) eq 1) select ovr else $$(ovr, p);
> end function;
```

which finds the largest overorder in which the given order has p-power index. This function is now simply applied to the equation order, for each prime dividing the discriminant:

```
> Round2 := function(E, K)
>        // E should be some order of a number field K
>        d := Discriminant(E);
>        fact := Factorization(Abs(d));
>        print fact;
>        M := E;
>        for x in fact do
>             M := M+pMaximalOverOrder(E, x[1]);
>        end for;
>        print "index of equation order in maximal order is:", Index(M, E);
>        return M;
> end function;
```

In our running example, this produces the following output:

```
> R<x> := PolynomialRing(Integers());
> K := NumberField(x^4-420*x^2+40000);
> E := EquationOrder(K);
> Round2(E, K);
[ <2, 18>, <5, 8>, <41, 2> ]
index is 2
index is 4
index is 8
index is 4
index is 2
index is 1
index is 5
index is 25
index is 1
index is 1
index of equation order in maximal order is: 64000
Transformation of E
Transformation Matrix:
[800   0   0   0]
[  0 400   0   0]
[  0 200  20   0]
```

```
[400 180   0   1]
Denominator: 800
```

37.2.4 Creation of Elements

Elements of algebraic fields and of orders are displayed quite differently. Algebraic field elements are always printed as a linear combination with rational coefficients of the basis elements of the field. For number fields which have a power basis this is also a polynomial in the primitive element of the field with rational coefficients; that is, an element of $G[x]/f$, where f was the defining polynomial of the field over the ground field G. Since in general G will be an algebraic field itself, elements in relative extensions, i.e. G strictly bigger than $\mathbf{Q}$, will be printed as linear combinations with linear combinations as coefficients and for number fields this will look like multivariate polynomials. In fact they are recursively defined univariate polynomials.

Elements of orders are displayed as sequences of integer coefficients, referring to the basis of the order. To convert this $\mathbf{Z}$-basis representation to a polynomial expression in the primitive element of an associated number field, the element should be coerced into the number field (using `!`). To print the element as a linear combination of the basis elements, coerce the element into the field of fractions.

```
F ! a
```
```
elt< F | a >
```

Coerce a into the field F. Here a may be an integer or a rational field element, or an element from a subfield of F, or from an order in such.

```
F ! [a0, a1, ..., am−1]
```
```
elt< F | [ a0, a1, ..., am−1 ] >
```
```
elt< F | a0, a1, ..., am−1 >
```

Given the algebraic field, F of degree m over its ground field G and a sequence $[a_0, \ldots, a_{m-1}]$ of elements of G, construct the element $a_0\alpha_0 + a_1\alpha_1 + \cdots a_{m-1}\alpha_{m-1}$ of F where the α_i are the basis elements of F.

```
O ! a
```
```
elt< O | a >
```

Coerce a into the order O. Here a is allowed to be an integer, or an integral element of an associated algebraic field of O, or an element of a quotient order.

`O ! [a0, a1, ..., am−1]`

`elt< O | [ a0, a1, ..., am−1 ] >`

`elt< O | a0, a1, ..., am−1 >`

Given the order O of degree m and elements $a_0, a_1, \ldots, a_{m-1}$ in the ground order of O, construct the element $a_0\alpha_0 + a_1\alpha_1 + \cdots + a_{m-1}\alpha_{m-1}$ of O, where $\alpha_0, \ldots, \alpha_{m-1}$ is the basis for the order.

`Random(F, m)`

`Random(O, m)`

A random element of the algebraic field F or order O. The maximal size of the coefficients is determined by m.

`Random(I, m)`

A random element of the ideal I as an element of the field of fractions of the associated order. The maximal size of the coefficients with respect to the ideal basis is determined by m.

Example H37E6

Here are three ways of creating the same integral element in K as an element of the maximal order and its field of fractions.

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^4-420*x^2+40000);
> O := MaximalOrder(K);
> e := O ! (y^2/40 + y/4);
> f := elt< O | [0, 0, 1, 0]>;
> f eq e;
true
> F<a, b, c, d> := FieldOfFractions(O);
> g := F![0, 0, 1, 0];
> g eq e;
true
> g;
c
```

These constructions would have failed if the element was not in O.

`One(K)` `One(O)` `Identity(K)` `Identity(O)`

`Zero(K)` `Zero(O)` `Representative(K)` `Representative(O)`

37.2.5 Creation of Homomorphisms

To specify homomorphisms from algebraic fields or orders in algebraic fields, it is necessary to specify the image of the generating elements, and possible to specify a map on the ground field.

```
hom< F -> R | r >
```

```
hom< F -> R | h, r >
```

Given an algebraic field F, defined as an extension of the ground field G, as well as some ring R, build the homomorphism ϕ obtained by sending the defining primitive element α of F to the element $r \in R$.

If F is a field of fractions then r will be the image of the primitive element of the field of fractions of the equation order of `Order(F)`.

It is possible (if $G = \mathbf{Q}$) and sometimes necessary (if $G \neq \mathbf{Q}$) to specify a homomorphism ϕ on F by specifying its action on G by providing a homomorphism h with G as its domain and R its codomain together with the image of α. If R does not cover G then the homomorphism h from G into R is necessary to ensure that the ground field can be mapped into R.

```
hom< O -> R | r >
```

```
hom< O -> R | h, r >
```

Given an order O, a ring R and an element $r \in R$, construct a homomorphism ϕ by sending the primitive element of the equation order of O to r.

To be more precise: Let K be the field of fractions of O, k be the base field of K i.e. the field of fractions of the base ring of O, and $N :=$ `NumberField(O)`. As a k–algebra K is generated by $x := K!N.1$, so x is zero of `DefiningPolynomial(O)`. The element r given in the map construction will be the image of x.

When O is an equation order e.g. if O was defined using a monic integral polynomial x will be `O.2`.

As in the field case it is possible to specify a map on the coefficient ring of O (ring over which O is defined) with codomain R. This is necessary if R does not cover the coefficient ring of O.

Example H37E7

We show a way to embed the field $\mathbf{Q}(\sqrt{2})$ in $\mathbf{Q}(\sqrt{2}+\sqrt{3})$. The application of the homomorphism suggests how the image could have been chosen.

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^2-2);
> KL<w> := NumberField(x^4-10*x^2+1);
> H := hom< K -> KL | (9*w-w^3)/2 >;
> H(y);
1/2*(-w^3 + 9*w)
> H(y)^2;
```

```
2
```

Homomorphisms can be created between any order or algebraic field and any ring.

```
> f := x^4 + 5*x^3 - 25*x^2 + 125*x + 625;
> M := MaximalOrder(f);
> F<a, b, c, d> := FieldOfFractions(M);
> FF := FiniteField(5, 3);
> F;
Field of Fractions of M
> FF;
Finite field of size 5^3
> h := hom< F -> FF | Coercion(Rationals(), FF), 3*FF.1>;
> h;
Mapping from: FldOrd: F to FldFin: FF
>  h(a); h(b);
1
>> h(a); h(b);
          ^
Runtime error in map application: Application of map failed
> h(5*b); h(5*5*c); h(5*5*5*d);
FF.1^94
FF.1^64
FF.1^34
```

This unexpected behaviour occurs because when the basis of F is expressed with respect to the power basis of the number field they have denominator divisible by 5. A more well–behaved example is shown below.

```
> FF := FiniteField(11, 5);
> h := hom< F -> FF | Coercion(Rationals(), FF), 7*FF.1>;
> h(a);
1
> h(b); h(c); h(d);
FF.1^48316
FF.1^96632
FF.1^144948
> 7*FF.1;
FF.1^112736
> 5*h(b);
FF.1^112736
> PrimitiveElement(F);
5/1*b
```

`hom< O -> R | `$b_1, ..., b_n$` >`

`hom< O -> R | m, `$b_1, ..., b_n$` >`

Return the map from the order O of an algebraic number field to the ring R mapping the basis elements to $b_1, .., b_n$. If given, the map m should be from the coefficient ring of O to R and will be used to map the coefficients of the basis elements. If not given the coefficient ring of O should by covered by R.

`IsRingHomomorphism(m)`

Return whether the vector space homomorphism m is a homomorphism of rings.

37.3 Special Options

It is possible to obtain output generated by the KANT package using the verbose printing feature of MAGMA, furthermore, the general style of the output can be changed. It is also possible to alter the precision used for internal real computations.

`SetVerbose(s, n)`

There are a number of verbose flags `s` applying to the functions described in this chapter. The flags and their levels `n` are mentioned in the descriptions of the functions which use them.

Note however, that setting the verbose levels may produce unexpected results since the effective scope of the flags is a little bit vague. Consider the following example:

```
> SetVerbose("MaximalOrder", 1);
> SetVerbose("Factor", 1);
> L := NumberField(PolynomialRing(Rationals()).1^2-10);
Factorize square-free polynomial over Z of degree 2
Deflation factor: 2
Number of deflated factors: 1
Factor inflated polynomial 0 of degree 2
Total factorization time: 0.000
Final irreducibility test factorization:
<x^2 - 10, 0>
> Regulator(L);

1.818446459232066823483698963560708993786253942768999999999
```

The first few lines of output are generated, because the creation of number fields involves a test of irreducibility for the defining polynomial(s).

The next group of lines come from the computation of the maximal order which is used for the regulator computation.

In general the amount of output generated increases with the value supplied. Furthermore, the output corresponding to larger values gets more and more technical.

`SetKantPrinting(f)`

Kant-style printing means that integers and rational numbers will be printed as integers and rational numbers. Especially in relative extensions this produces easier to read output - but it is no longer possible to paste the output back into the system again. Turns Kant-style printing on if f is `true` and off if f is `false`.

`SetKantPrecision(n)`

`SetKantPrecision(O, n)`

`SetKantPrecision(O, n, m)`

`SetKantPrecision(F, n)`

`SetKantPrecision(F, n, m)`

For internal real computations, some number field functions use real arithmetic to a fixed precision; therefore every algebraic field and every order comes equipped with some real-rings.

Initially, the precision (in decimal digits) will be the maximum of the set precision P, 20 and four times the degree of the algebraic field (order) in which calculations are performed. By default $P = 52$.

In addition all unit computations use a second real-ring in which the default precision is always twice the ordinary precision. This ring can be set using the third argument of `SetKantPrecision`.

Furthermore, the computation of the zeroes of the defining polynomial of the field or order uses a third, independent, precision which initially is the maximum of 32 and the (binary) logarithm of the largest coefficient of the defining polynomial.

Note however, that several functions will work automatically with a much larger precision if necessary to guarantee P digits for the user. Generally all functions take care of the necessary precision. Only under rare circumstances will any computation fail because of precision loss.

Certain calculations that fail if the precision is too small may succeed after restarting with increased precision.

If the order O or field F is given, then the precision change will apply only in the context of that order (field).

37.4 Structure Operations

In the lists below F usually refers to an algebraic field, K to a number field and O to an order.

37.4.1 General Functions

Number fields form the MAGMA category `FldNum`, orders form `RngOrd` and their fields of fractions form `FldOrd`. The notional power structures exist as parents of algebraic fields and their orders, no operations are allowed.

`Category(F)` `Parent(F)` `Category(O)` `Parent(O)`

`AssignNames(~K, s)`

Procedure to change the names of the generating elements in the number field K to the contents of the sequence of strings s.

The i-th sequence element will be the name used for the generator of the $(i-1)$-st subfield down from K as determined by the creation of K, the first element being used as the name for the generator of K. In the case where K is defined by more than one polynomial as an absolute extension, the ith sequence element will be the name used for the root of the ith polynomial used in the creation of K.

This procedure only changes the names used in printing the elements of K. It does *not* assign to any identifiers the value of a generator in K; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies K, it is necessary to have a reference `~K` to K in the call to this function.

`Name(K, i)`
`K . i`

Given a number field K, return the element which has the i-th name attached to it, that is, the generator of the $(i-1)$-st subfield down from K as determined by the creation of K. Here i must be in the range $1 \leq i \leq m$, where m is the number of polynomials used in creating K. If K was created using multiple polynomials as an absolute extension, `K.i` will be a root of the ith polynomial used in creating K.

`AssignNames(~F, s)`

Assign the strings in the sequence s to the names of the basis elements of the field of fractions F.

`F . i`
`Name(F, i)`

Return the ith basis element of the field of fractions F.

`O . i`

Return the ith basis element of the order O.

37.4.2 Related Structures

Each order and field has other orders and fields which are related to it in various ways.

`GroundField(F)`
`BaseField(F)`
`CoefficientField(F)`
`CoefficientRing(F)`

Given an algebraic field F, return the algebraic field over which F was defined. For an absolute number field F, the function returns the rational field $\mathbf{Q}$.

`BaseRing(O)`
`CoefficientRing(O)`

Given an order O, this returns the order over which O was defined. For an absolute order O this will be the integers $\mathbf{Z}$.

`AbsoluteField(F)`

Given an algebraic field F, this returns an isomorphic number field L defined as an absolute extension (i.e. over $\mathbf{Q}$).

`AbsoluteOrder(O)`

Given an order O, this returns an isomorphic order O' defined as an order in an absolute extension (over $\mathbf{Q}$).

`SimpleExtension(F)`
`SimpleExtension(O)`

Given an algebraic field F or an order O, this returns an isomorphic field L defined as an absolute simple extension or the Z-isomorphic order in it.

`RelativeField(F, L)`

Given algebraic fields L and F such that MAGMA knows that F is a subfield of L, return an isomorphic algebraic field M defined as an extension over F.

Example H37E8

It is often desirable to build up a number field by adjoining several algebraic numbers to $\mathbf{Q}$. The following function returns a number field that is the composite field of two given number fields K and L, provided that $K \cap L = \mathbf{Q}$; if K and L have a common subfield larger than $\mathbf{Q}$ the function returns a field with the property that it contains a subfield isomorphic to K as well as a subfield isomorphic to L.

```
> R<x> := PolynomialRing(Integers());
> Composite := function( K, L )
>     T<y> := PolynomialRing( K );
>     f := T!DefiningPolynomial( L );
```

```
>     ff := Factorization(f);
>     LKM := NumberField(ff[1][1]);
>     return AbsoluteField(LKM);
> end function;
```

To create, for example, the field $\mathbf{Q}(\sqrt{2}, \sqrt{3}, \sqrt{5})$, the above function should be applied twice:

```
> K := NumberField(x^2-3);
> L := NumberField(x^2-2);
> M := NumberField(x^2-5);
> KL := Composite(K, L);
> S<s> := PolynomialRing(BaseField(KL));
> KLM<w> := Composite(KL, M);
> KLM;
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

Note, that the same field may be constructed with just one call to `NumberField` followed by `AbsoluteField`:

```
> KLM2 := AbsoluteField(NumberField([x^2-3, x^2-2, x^2-5]));
> KLM2;
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

or by

```
> AbsoluteField(ext<Rationals() | [x^2-3, x^2-2, x^2-5]>);
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

In general, however, the resulting polynomials of KLM and $KLM2$ will differ. To see the difference between `SimpleExtension` and `AbsoluteField`, we will create `KLM2` again:

```
> KLM3 := NumberField([x^2-3, x^2-2, x^2-5]: Abs);
> AbsoluteField(KLM3);
Number Field with defining polynomials [ x^2 - 3, x^2 - 2,
    x^2 - 5] over the Rational Field
> SimpleExtension(KLM3);
Number Field with defining polynomial s^8 - 40*s^6 + 352*s^4 - 960*s^2 + 576
over the Rational Field
```

`Simplify(O)`

Given an order O, obtained by a chain of transformations from an equation order E, return an order that is given directly by a single transformation over E.

`LLL(O)`

Given an order O, return an order O' obtained from O by a transformation matrix T, which is returned as a second value. O' will have a LLL-reduced basis.

Example H37E9

Using LLL to reduce the basis of an order is shown.

```
> M := MaximalOrder(x^4-14*x^3+14*x^2-14*x+14);
> L, T := LLL(M);
> L;
Maximal Order, Transformation of M
Transformation Matrix:
[  1   0   0   0]
[ -3   1   0   0]
[  3 -13   1   0]
[ -7   1 -13   1]
> T;
[  1   0   0   0]
[ -3   1   0   0]
[  3 -13   1   0]
[ -7   1 -13   1]
> Basis(M);
[
    M.1,
    M.2,
    M.3,
    M.4
]
> Basis(L, M);
[
    [1, 0, 0, 0],
    [-3, 1, 0, 0],
    [3, -13, 1, 0],
    [-7, 1, -13, 1]
]
> L eq M;
true
```

Even though L and M are considered to be equal because they contain the same elements L has a basis which is LLL reduced but M does not.
Following on from the orders and ideals example (H37E5) we have

```
> R<x> := PolynomialRing(Integers());
> K := NumberField(x^4-420*x^2+40000);
> E := EquationOrder(K);
> O := Round2(E, K);

```

`PrimeRing(F)` `PrimeField(F)` `PrimeRing(O)`
`Centre(F)` `Centre(O)`

`Embed(F, L, a)`

Install the embedding of a simple field F in L where the image of the primitive element of F is the element a of L. This embedding will be used in coercing from F into L.

`Embed(F, L, a)`

Install the embedding of the non-simple field F in L where the image of the generating elements of F are in the sequence a of elements of L. This embedding will be used in coercing from F into L.

`EmbeddingMap(F, L)`

Returns the embedding map of F in L if an embedding is known.

Example H37E10

MAGMA does not recognize two independently created number fields as equal since more than one embedding of a field in a larger field may be possible. To coerce between them then it is convenient to be able to embed them in each other.

```
> k := NumberField(x^2-2);
> l := NumberField(x^2-2);
>  l!k.1;
>> l!k.1;
    ^
Runtime error in '!': Arguments are not compatible
LHS: FldNum
RHS: FldNumElt
> l eq k;
false
> Embed(k, l, l.1);
> l!k.1;
l.1
> Embed(l, k, k.1);
> k!l.1;
k.1
```

`Embed` is useful in specifying the embedding of a field in a larger field.

```
> l<a> := NumberField(x^3-2);
> L<b> := NumberField(x^6+108);
> Root(L!2, 3);
1/18*b^4
> Embed(l, L, $1);
> L!l.1;
1/18*b^4
```

Another embedding would be

```
> Roots(PolynomialRing(L)!DefiningPolynomial(l));
[
    <1/36*(-b^4 - 18*b), 1>,
    <1/36*(-b^4 + 18*b), 1>,
    <1/18*b^4, 1>
]
> Embed(l, L, $1[1][1]);
> L!l.1;
1/36*(-b^4 - 18*b)
```

`Lattice(O)`

`MinkowskiLattice(O)`

Given an absolute order O, returns the lattice determined by the real and complex embeddings of O.

`MinkowskiSpace(F)`

The Minkowski vector space V of the absolute field F as a real vector space, with inner product given by the T_2-norm (`Length`) on F, and by the embedding $F \to V$.

`Completion(K, P)`

`Completion(O, P)`

`comp< K|P >`

`comp< O|P >`

`Precision` RngIntElt *Default :* 50

For an absolute extension K of $\mathbf{Q}$ or O of $\mathbf{Z}$, compute the completion at a prime ideal P which must be either a prime ideal of the maximal order or unramified. The result will be a local field or ring with precision `Precision` or e`*Precision` if the ideal is ramified with ramification degree e.

The returned map is the canonical injection into the completion. It allows pointwise inverse operations.

`Completion(K, P)`

`Precision` RngIntElt *Default :* 50

For an absolute extension K over $\mathbf{Q}$ and a (finite) place P, compute the completion at P. The precision and the map are as described for `Completion`.

`LocalRing(P, prec)`

The completion of `Order(P)` at the prime ideal P up to precision `prec`.

37.4.3 Representing Fields as Vector Spaces

It is possible to express a number field or a field of fractions as a vector space of any subfield using the intrinsics below. Such a construction also allows one to find properties of elements over these subfields.

`Algebra(K, J)`

`Algebra(K, J, S)`

Returns the associative structure constant algebra which is isomorphic to the algebraic field K as an algebra over J. Also returns the isomorphism from K to the algebra mapping w^i to the $i+1$st unit vector of the algebra where w is a primitive element of K.

If a sequence S is given it is taken to be a basis of K over J and the isomorphism will map the ith element of S to the ith unit vector of the algebra.

VectorSpace(K, J)

KSpace(K, J)

VectorSpace(K, J, S)

KSpace(K, J, S)

The vector space isomorphic to the algebraic field K as a vector space over J and the isomorphism from K to the vector space. The isomorphism maps w^i to the $i+1$st unit vector of the vector space where w is a primitive element of K.

If S is given, the isomorphism will map the ith element of S to the ith unit vector of the vector space.

Example H37E11

We use the `Algebra` of a relative number field to obtain the minimal polynomial of an element over a subfield which is not in its coefficient field tower.

```
> K := NumberField([x^2 - 2, x^2 - 3, x^2 - 7]);
> J := AbsoluteField(NumberField([x^2 - 2, x^2 - 7]));
> A, m := Algebra(K, J);
> A;

37.4.4 Invariants

Some information describing an order can be retrieved.

`Characteristic(F)` `Characteristic(O)`

`Degree(O)`
`Degree(F)`

Given an algebraic field F, return the degree $[F : G]$ of F over its ground field G. For an order O it returns the relative degree of O over its ground order.

`AbsoluteDegree(O)`
`AbsoluteDegree(F)`

Given an order O or an algebraic field F, return the absolute degree of O over $\mathbf{Z}$ or F over $\mathbf{Q}$.

`Discriminant(O)`

`Discriminant(F)`

Given an extension F of $\mathbf{Q}$, return the discriminant of F. This discriminant is defined to be the discriminant of the order of the field of fractions or the equation order of a number field.

The discriminant of any order O defined over $\mathbf{Z}$ is by definition the discriminant of its basis, where the discriminant of any sequence of elements ω_i from K is defined to be the determinant of the trace matrix of the sequence.

The discriminant of absolute fields and orders is an integer.

The discriminant in a relative extension is the ideal generated by the discriminants of all sequences of elements ω_i from O, where the discriminant of a sequence is defined to be the determinant of its trace matrix. This can only be computed in when the coefficient ring of O is maximal or when O has a power basis.

The discriminant of relative orders is an ideal of the base ring.

`AbsoluteDiscriminant(O)`

Given an order O, return the absolute value of the discriminant of O regarded as an order over $\mathbf{Z}$.

`AbsoluteDiscriminant(K)`

Given an algebraic field K, return the absolute value of the discriminant of K regarded as an extension of $\mathbf{Q}$.

`ReducedDiscriminant(O)`

`ReducedDiscriminant(F)`

The reduced discriminant of an order O is defined as the maximal elementary divisor (elementary ideal) of the torsion module $O^{\#}/O$ where $O^{\#}$ is the dual module to O with respect to the trace form. The reduced discriminant of an algebraic field is that of the order of a field of fractions and that of the equation order of a number field.

For absolute extensions this is the largest entry of the Smith normal form of the `TraceMatrix`. For relative extensions, in addition to the `TraceMatrix` one has to consider the coefficient ideals.

For orders with a power basis, this is (a generator of) the inverse of the ideal generated by the cofactors X and Y of $Xf + Yf' = 1$ where f is the defining polynomial of the order and f' its first derivative.

`Regulator(O: parameters)`

`Current` BoolElt *Default :* `false`

`Regulator(K)`

Given a number field K or an order O, return the regulator of K or O, as a real number. Note that this will trigger the computation of the maximal order and its unit group if they are not known yet. This only works in an absolute extension.

If `Current` is `true` and a maximal system of independent units is known, then the regulator of that system is returned. In this case no effort is spent to produce a system of fundamental units.

`RegulatorLowerBound(O)`
`RegulatorLowerBound(K)`

Given an order O or number field K, return a lower bound on the regulator of O or K. This only works in an absolute extension.

`Signature(O)`
`Signature(F)`

Given an absolute algebraic field F, or an order O of F, returns two integers, one being the number of real embeddings, the other the number of pairs of complex embeddings of F.

`UnitRank(O)`
`UnitRank(K)`

The unit rank of the order O or the number field K (one less than the number of real embeddings plus number of pairs of complex embeddings).

`Index(O, S)`

The module index of order S in order O, for orders $S \subset O$. O and S must have the same equation order and S must be a suborder of O.

`DefiningPolynomial(F)`
`DefiningPolynomial(O)`

Given an algebraic field F, the polynomial defining F as an extension of its ground field G is returned. For an order O, a integral polynomial is returned that defines O over its coefficient ring.

For non simple extensions, this will return a list of polynomials.

`Zeroes(O, n)`
`Zeros(O, n)`
`Zeroes(F, n)`
`Zeros(F, n)`

Given an absolute algebraic field F or an order O in F, and an integer n, return the zeroes of the defining polynomial of F with a precision of exactly n decimal digits. The function returns a sequence of length the degree of F; all of the real zeroes appear before the complex zeroes.

Example H37E12

The information provided by `Zeros` and `DefiningPolynomial` is illustrated below.

```
> L := NumberField(x^6+108);
> DefiningPolynomial(L);
x^6 + 108
> Zeros(L, 30);

```

`Different(O)`

The different of a maximal order $O \subset K$ is defined as the inverse ideal of $\{x \in K \mid \mathrm{Tr}(xO) \subset O\}$.

`Conductor(O)`

The conductor of an order O is the largest ideal of its maximal order that is still contained in O: $\{x \in M \mid xM \subseteq O\}$.

37.4.5 Basis Representation

The basis of an order or algebraic field can be expressed using elements from any compatible ring. Basis related matrices can be formed.

`Basis(O)`

`Basis(O, R)`

`Basis(F)`

`Basis(F, R)`

Return the current basis for the order O or algebraic field F over its ground ring as a sequence of elements of its field of fractions or as a sequence of elements of R.

`IntegralBasis(F)`

`IntegralBasis(F, R)`

An integral basis for the algebraic field F is returned as a sequence of elements of F or R if given. This is the same as the basis for the maximal order. Note that the maximal order will be determined (and stored) if necessary.

Example H37E13

The following illustrates how a basis can look different when expressed in a different ring.

```
> f := x^5 + 5*x^4 - 75*x^3 + 250*x^2 + 65625;
> M := MaximalOrder(f);
> M;
Maximal Order of Equation Order with defining polynomial x^5 + 5*x^4 - 75*x^3 +
    250*x^2 + 65625 over its ground order
> Basis(M);
[
    M.1,
    M.2,
    M.3,
    M.4,
    M.5
]
> Basis(NumberField(M));
[
    1,
    $.1,
    $.1^2,
    $.1^3,
    $.1^4
]
> Basis(M, NumberField(M));
[
    1,
    1/5*$.1,
```

```
    1/25*$.1^2,
    1/125*$.1^3,
    1/625*$.1^4
]
```

`AbsoluteBasis(K)`

Returns an absolute basis for the algebraic field K, i.e. a basis for K as a $\mathbf{Q}$ vector space. The basis will consist of the products of the basis elements of the intermediate fields. The expansion is done depth-first.

`BasisMatrix(O)`

Given an order O in a number field K of degree n, this returns an $n \times n$ matrix whose i-th row contains the (rational) coefficients for the i-th basis element of O with respect to the power basis of K. Thus, if b_i is the i-th basis element of O,

$$b_i = \sum_{j=1}^{n} M_{ij} \alpha^{j-1}$$

where M is the matrix and α is the generator of K.

The matrix is the same as `TransformationMatrix(O, E)`, where E is the equation order for K, except that the entries of the basis matrix are from the subfield of K, instead of the coefficient ring of the order.

`TransformationMatrix(O, P)`

Returns the transformation matrix for the transformation between the orders O and P with common equation order of degree n. The function returns an $n \times n$ matrix T with integral entries as well as a common integer denominator. The rows of the matrix express the n basis elements of O as a linear combination of the basis elements of P. Hence the effect of multiplying T on the left by a row vector v containing the basis coefficients of an element of O is the row vector $v \cdot T$ expressing the same element of the common number field on the basis for P.

`CoefficientIdeals(O)`

The coefficient ideals of the order O of a relative extension. These are the ideals $\{A_i\}$ of the coefficient ring of O such that for every element e of O, $e = \sum_i a_i * b_i$ where $\{b_i\}$ is the basis returned for O and each $a_i \in A_i$.

Example H37E14

We continue our example of a field of degree 4.
The functions `Basis` and `IntegralBasis` both return a sequence of elements, that can be accessed using the operators for enumerated sequences. Note that if, as in our example, O is the maximal order of K, both functions produce the same output:

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> O := MaximalOrder(K);
> I := IntegralBasis(K);
> B := Basis(O);
> I, B;
[
    1,
    1/2*y,
    1/40*(y^2 + 10*y),
    1/800*(y^3 + 180*y + 400)
]
[
    0.1,
    0.2,
    0.3,
    0.4
]
> Basis(O, K);
[
    1,
    1/2*y,
    1/40*(y^2 + 10*y),
    1/800*(y^3 + 180*y + 400)
]
```

The `BasisMatrix` function makes it possible to move between orders, in the following manner. We may regard orders as free **Z**-modules of rank the degree of the number field. The basis matrix then provides the transformation between the order and the equation order. The function `ElementToSequence` can be used to create module elements.

```
> BM := BasisMatrix(O);
> Mod := RSpace(RationalField(), Degree(K));
> z := O ! y;
> e := z^2-3*z;
> em := Mod ! ElementToSequence(e);
> em;
(  0 -26  40   0)
> f := em*BM;
> f;
```

```
( 0 -3  1  0)
```

So, since f is represented with respect to the basis of the equation order, which is the power basis, we indeed get the original element back. Of course it is much more useful to go in the other direction, using the inverse transformation. We check the result in the last line:

```
> E := EquationOrder(K);
> f := y^3+7;
> fm := Mod ! ElementToSequence(f);
> e := fm*BM^-1;
> e;
(-393 -360    0  800)
> &+[e[i]*B[i] : i in [1 .. Degree(K)] ];
-393/1*0.1 - 360/1*0.2 + 800/1*0.4
> K!$1;
y^3 + 7
```

`MultiplicationTable(O)`

Given an order O of some number field K of degree n, return the multiplication table with respect to the basis of O as a sequence of n matrices of size $n \times n$. The i-th matrix will have as its j-th row the basis representation of $b_i b_j$, where b_i is the i-th basis element for O.

`TraceMatrix(O)`

`TraceMatrix(F)`

Return the trace matrix of an order O or algebraic field F, which has the trace $\mathrm{Tr}(\omega_i \omega_j)$ as its i, j-th entry where the ω_i are the basis for O or F.

Example H37E15

We continue our example of a field of degree 4.
The multiplication table of the order O consists of 4 matrices, such that the i-th 4×4 matrix ($1 \leq i \leq 4$) determines the multiplication by the i-th basis element of O as a linear transformation with respect to that basis. Thus the third row of $T[2]$ gives the basis coefficients for the product of $B[2]$ and $B[3]$, and we can use the sequence reduction operator to calculate $B[2] * B[3]$ in an alternative way:

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> O := MaximalOrder(K);
> B := Basis(O);
> B[2];
0.2
> T := MultiplicationTable(O);
> T[2];
[  0   1   0   0]
```

```
[  0  -5  10   0]
[ -5  -7   5  10]
[-25  -7  15   0]
>  &+[ T[2][3][i]*B[i] : i in [1..4] ];
-5/1*0.1 - 7/1*0.2 + 5/1*0.3 + 10/1*0.4
> B[2]*B[3];
-5/1*0.1 - 7/1*0.2 + 5/1*0.3 + 10/1*0.4
```

The trace matrix may be found either by using the built-in function or by the one-line definition given below (for a field of degree 4):

```
> TraceMatrix(O);
[  4   0  21   2]
[  0 210 105 215]
[ 21 105 173 118]
[  2 215 118 226]
> MatrixRing(RationalField(), 4) ! [Trace(B[i]*B[j]): i, j in [1..4] ];
[  4   0  21   2]
[  0 210 105 215]
[ 21 105 173 118]
[  2 215 118 226]
```

37.4.6 Ring Predicates

Orders and algebraic fields can be tested for having several properties that may hold for general rings.

`N eq O`

Two orders are equal if the transformation matrix taking one to the other is integral and has determinant 1 or -1. For the transformation matrix to exist the orders must have the same number field.

`F eq L`

Returns `true` if and only if the fields F and L, are the same.

No two algebraic fields which have been created independently of each other will be considered equal since it is possible that they can be embedded into a larger field in more than one way.

`IsCommutative(R)` `IsUnitary(R)` `IsFinite(R)`

`IsOrdered(R)` `IsField(R)`

`IsNumberField(R)` `IsAlgebraicField(R)`

`IsEuclideanDomain(F)`

This is not a check for euclidean number fields. This function will always return an error.

```
IsSimple(F)
```
```
IsSimple(O)
```

Checks if the field F or the order O is defined as a simple extension over the base ring.

```
IsPID(F)
```
```
IsUFD(F)
```
```
IsPrincipalIdealRing(F)
```

Always `true` for fields.

```
IsPID(O)
```
```
IsUFD(O)
```
```
IsPrincipalIdealRing(O)
```

Always `false` for orders. Even if the class number is 1, orders are not considered to be PIDs.

```
IsDomain(R)
```
```
F ne L
```
```
O ne N
```
```
O subset P
```
```
K subset L
```
```
HasComplexConjugate(K)
```

This function returns `true` if there is an automorphism in the field K that acts like complex conjugation.

```
ComplexConjugate(x)
```

For an element x of a field K where `HasComplexConjugate` returns `true` (in particular this includes totally real fields, cyclotomic and quadratic fields and CM-extensions), the conjugate of x is returned.

37.4.7 Order Predicates

Since orders are rings with additional properties, special predicates are applicable.

```
IsEquationOrder(O)
```

This returns `true` if the basis of the order O is an integral power basis, `false` otherwise.

```
IsMaximal(O)
```

This returns `true` if the order O in the field F is the maximal order of F, `false` otherwise. The user is warned that this may trigger the computation of the maximal order.

```
IsAbsoluteOrder(O)
```

Returns `true` iff the order O is a constructed as an absolute extension of $\mathbf{Z}$.

`IsWildlyRamified(O)`

Returns `true` iff the order O is wildly ramified, i.e. if there is a prime ideal P of O such that the characteristic of its residue class field divides its ramification index.

`IsTamelyRamified(O)`

Returns `true` iff the order O is not wildly ramified, i.e. if for all prime ideals P of O the characteristic of its residue class field does not divide the ramification index.

`IsUnramified(O)`

Returns `true` iff the order O is unramified at the *finite* places.

37.4.8 Field Predicates

Here all the predicates that are specific to algebraic fields are listed.

`IsIsomorphic(F, L)`

Given two algebraic fields F and L, this returns `true` as well as an isomorphism $F \to L$, if F and L are isomorphic, and it returns `false` otherwise.

`IsSubfield(F, L)`

Given two algebraic fields F and L, this returns `true` as well as an embedding $F \hookrightarrow L$, if F is a subfield of L, and it returns `false` otherwise.

`IsNormal(F)`

Returns `true` if and only if the algebraic field F is a normal extension. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois group computation.

`IsAbelian(F)`

Returns `true` if and only if the algebraic field F is a normal extension with abelian Galois group. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois Group computation.

`IsCyclic(F)`

Returns `true` if and only if the algebraic field F is a normal extension with cyclic Galois group. At present this may only be applied if F is an absolute extension or simple relative extension. In the relative case the result is obtained via Galois and automorphism group.

`IsAbsoluteField(K)`

Returns `true` iff the algebraic field K is a constructed as an absolute extension of $\mathbf{Q}$.

`IsWildlyRamified(K)`

Returns `true` iff the algebraic field K is wildly ramified, i.e. if there is a prime ideal P of K (its maximal order) such that the characteristic of its residue class field divides the ramification index.

`IsTamelyRamified(K)`

Returns `true` iff the algebraic field K is not wildly ramified, i.e. if for all prime ideals P of the maximal order of K, the characteristic of its residue class field does not divide the ramification index.

`IsUnramified(K)`

Returns `true` iff the algebraic field K is unramified at the *finite* places.

`IsQuadratic(K)`

If the number field K is quadratic, return `true` and an isomorphic quadratic field.

`IsTotallyReal(K)`

Tests if the number field F is totally real, ie. if all infinite places are real. For absolute fields this is equivalent to the defining polynomial having only real roots.

37.4.9 Setting Properties of Orders

Several properties of orders can be set to be known and/or to have a given value.

`SetOrderMaximal(O, b)`

Set the order O to be maximal if b is `true` or known to be non maximal if b is `false`.

`SetOrderTorsionUnit(O, e, r)`

Set the torsion unit of the order O to be the element e with order r.

`SetOrderUnitsAreFundamental(O)`

Mark the currently known units of the order O to be fundamental.

37.5 Element Operations

37.5.1 Parent and Category

`Parent(a)` `Parent(w)` `Category(a)` `Category(w)`

37.5.2 Arithmetic

The table below lists the generic arithmetic functions on algebraic field and order elements. Note that automatic coercion ensures that the binary operations `+`, `-`, `*`, and `/` may be applied to an element of an algebraic field and an element of one of its orders; the result will be an algebraic field element. Since division of order elements does not generally result in an order element, the operation `/` applied to two elements of an order returns an element in the field of fractions of the order; similarly if the exponent k in `a^k` is negative.

For finding the value of an element mod an ideal or the inverse of an element mod an ideal see Section 37.9.6.

`+ a` `- a`

`a + b` `a - b` `a * b` `a / b` `a ^ k`

`w div v`

The quotient of the order element w by the order element v; v must divide w exactly, (v and w must be elements of the same order.)

`Modexp(a, n, m)`

Given a non-negative integer n and an integer m greater than 1, this function returns the modular power $a^n \ mod \ m$ of the order element a.

`Sqrt(a)`

`SquareRoot(a)`

Returns the square root of the element a if it exists in the order or field containing a.

`Root(a, n)`

Returns the n-th root of the element a if it exists in the order or field containing a.

`IsPower(a, k)`

`IsSquare(a)`

Return `true` if the element a is a kth power, (respectively square) and the root in the order or field containing a if so.

`Denominator(a)`

Returns the denominator of the element a, that is the least common multiple of the denominators of the coefficients of a.

`Numerator(a)`

Returns the numerator of the element a, that is the element multiplied by its denominator.

`Qround(E, M)`

`ContFrac` BoolElt *Default :* `true`

Finds an approximation of the field element E where the denominator is bounded by the integer M. If `ContFrac` is `true`, the approximation is computed by applying the continued fraction algorithm to the coefficients of E viewed over Q.

37.5.3 Equality and Membership

Elements may also be tested for whether they lie in an ideal of an order. See Section 37.9.5.

`a eq b` `a ne b`

`a in F`

37.5.4 Predicates on Elements

In addition to the generic predicates `IsMinusOne`, `IsZero` and `IsOne`, the predicates `IsIntegral` and `IsPrimitive` are defined on elements of algebraic fields and orders.

`IsIntegral(a)`

Returns `true` if the element a of an algebraic field F or of an order in F is contained in the ring of integers of F, `false` otherwise. This is vacuously true for order elements. We use the minimal polynomial to determine the answer, which means that the calculation of the maximal order is *not* triggered if it is not known yet. When a is a field element a denominator d such that $d * a$ is integral is also returned on request.

`IsPrimitive(a)`

Returns `true` if the element a of the algebraic field F or one of its orders O generates F.

`IsTorsionUnit(w)`

Returns `true` if and only if the order element w is a unit of finite order.

`IsPower(w, n)`

Given an element w in an order O and an integer $n > 1$, this function returns `true` if and only if there exists an element $v \in O$ such that $w = v^n$; if `true`, such an element v is returned as well.

`IsTotallyPositive(a)`

`IsTotallyPositive(a)`

Returnes `true` iff all real embeddings of the element a are positive. For elements in absolute fields this is equivalent to all real conjugates being positive.

`IsZero(a)` `IsOne(a)`

`IsMinusOne(a)` `IsUnit(a)`

`IsNilpotent(a)` `IsIdempotent(a)`

`IsZeroDivisor(a)` `IsRegular(a)`

`IsIrreducible(a)` `IsPrime(a)`

37.5.5 Finding Special Elements

Generators of fields can be retrieved.

`K . 1`

Return the image α of x in $G[x]/f$ where f is the first defining polynomial of K and G is the base field of K.

In case of simple extensions this will be a primitive element.

`PrimitiveElement(K)`

`PrimitiveElement(F)`

Returns a primitive element for the simple algebraic field, that is an element whose minimal polynomial has the same degree as the field. For a number field K this is $K.1$ but for a field of fractions this is $F!K.1$ where K is the number field of F.

For non-simple fields, a random element is returned.

`Generators(K)`

The list of generators of K over its coefficient field, that is a sequence containing a root of each defining polynomial is returned.

`Generators(K, k)`

A list of generators of K over k is returned. That is a sequence containing a root of each defining polynomial for K and its subfield down to the level of k is returned.

`PrimitiveElement(O)`

Returns a primitive element for the field of fractions of the order O, that is an element whose minimal polynomial has the same degree as the field.

37.5.6 Real and Complex Valued Functions

The functions here return (sequences of) real or complex numbers. The precision of these numbers is governed by the appropriate order's or field's internal precision. See Section 37.3 for more information.

`AbsoluteValues(a)`

Return a sequence of length $r_1 + r_2$ of the real absolute values of the conjugates of the element a. The first r_1 values are the absolute values of the real embeddings of the element, the next r_2 are the lengths of the complex embeddings with their weight factors. That is, if the real conjugates of a are w_i, for $1 \leq i \leq r_1$, and the complex conjugates of a are $x_i \pm iy_i$ (for $1 \leq i \leq r_2$), then `AbsoluteValues` returns $[|w_1|, \ldots, |w_{r_1}|, \sqrt{\frac{x_{r_1+1}^2+y_{r_1+1}^2}{2}}, \ldots \sqrt{\frac{x_{r_1+r_2}^2+y_{r_1+r_2}^2}{2}}]$.

`AbsoluteLogarithmicHeight(a)`

Let P be the minimal polynomial of the element a over $\mathbf{Z}$, with leading coefficient a_0 and roots $\alpha_1, \ldots, \alpha_n$. Then the absolute logarithmic height is defined to be

$$h(\alpha) = \frac{1}{n} \log(a_0 \prod_{j=1}^{n} \max(1, |\alpha_j|)).$$

`Conjugates(a)`

The real and complex conjugates of the given algebraic number a, as a sequence of n complex numbers. The r_1 real conjugates appear first, and are followed by r_2 pairs of complex conjugates. The field should be an absolute extension. The ordering of the conjugates is consistent for elements of the same field (or even for elements of different fields that have the same defining polynomial).

`Conjugate(a, k)`

Equivalent to `Conjugates(a)[k]`.

`Conjugate(a, l)`

Let $l := [l_1, \ldots, l_n]$ be a sequence of positive integers and assume that the field K, the parent of a is given as a tower with n steps, $\mathbf{Q} \subseteq K_1 \subseteq \ldots \subseteq K_n = K$. This function computes the image of a in $\mathbf{C}$ or $\mathbf{R}$ under the embedding determined by l, that is under embedding obtained by extending the l_1 embedding of K_1 to K_2, then extending the l_2nd of those embeddings to K_3, ...

`Length(a)`

Return the T_2-norm of the element a, which is a real number. This equals the sum of the (complex) norms of the conjugates of a.

`Logs(a)`

Return the sequence of length $r_1 + r_2$ of logarithms of the absolute values of the conjugates of a number field or order element $a \neq 0$.

`CoefficientHeight(E)`

`CoefficientHeight(E)`

Computes the coefficient height of the element E, that is for an element of an absolute field it returns the maximum of the denominator and the largest coefficient wrt. to the basis of the parent. For elements in relative extensions, it returns the maximal coefficient height of all the coefficients wrt. the basis of the parent.

This function indicates in some way the difficulty of operations involving this element.

`CoefficientLength(E)`

`CoefficientLength(E)`

Computes the coefficient length of the element E, that is for an element of an absolute field it returns the sum of the denominator and the absolute values of all coefficients wrt. to the basis of the parent. For elements in relative extensions, it returns the sum of the coefficient length of all the coefficients wrt. the basis of the parent.

This function gives an indication on the amount of memory occupied by this element.

Example H37E16

Using the functions `Conjugates` and `Basis`, it is easy to write an alternative discriminant function.

```
> disc := func< O | Determinant( MatrixAlgebra(ComplexField(20), Degree(O) )
>        ! [ Conjugates(Basis(O)[i])[j] : i, j in [1 .. Degree(O)] ] )^2 >;
> R<x> := PolynomialRing(Integers());
> O := MaximalOrder(NumberField(x^4 - 420*x^2 + 40000));
> disc(O);
42025
> Discriminant(O);
42025
```

Thus, the new discriminant function returns a complex approximation to the built-in function `Discriminant`, giving the above result for the maximal order O of the previous example.
Here is an alternative way of getting the T_2 norm returned by `Length`, using the complex `Norm` function, together with the `Conjugates` function.

```
> norm := func< a | &+[ Norm(Conjugates(a)[i]) : \
>                       i in [1 .. Degree(Parent(a))] ] >;
```

37.5.7 Norm, Trace, and Minimal Polynomial

The norm, trace and minimal polynomial of order and algebraic field elements can be calculated both with respect to the coefficient ring and to **Z** or **Q**.

`Norm(a)`

`Norm(a, R)`

The relative norm $\mathrm{N}_{\mathrm{L/F}}(\mathrm{a})$ over F of the element a of L where F is the field or order over which L is defined as an extension. If R is given the norm is calculated over R. In this case, R must occur as a coefficient ring somewhere in the tower under L.

`AbsoluteNorm(a)`

`NormAbs(a)`

The absolute norm $\mathrm{N}_{\mathrm{L}/\mathbf{Q}}(\mathrm{a})$ over **Q** of the element a of L (or one of its orders).

`Trace(a)`

`Trace(a, R)`

The relative trace $\mathrm{Tr}_{L/F}(a)$ over F of the element a of L where F is the field or order over which L is defined as an extension. If R is given the trace is computed over R. In this case, R must occur as a coefficient ring somewhere in the tower under L.

`AbsoluteTrace(a)`

`TraceAbs(a)`

The absolute trace $\mathrm{Tr}_{L/\mathbf{Q}}(a)$ over **Q** of the element a of L (or one of its orders).

`CharacteristicPolynomial(a)`

`CharacteristicPolynomial(a, R)`

Given an element a from an algebraic field or order L, returns the characteristic polynomial of the element over R if given or the subfield or suborder F otherwise where F is the field or order over which L is defined as an extension.

`AbsoluteCharacteristicPolynomial(a)`

Given an element a from an algebraic field or one of its orders, this function returns the characteristic polynomial of the element. For field elements the polynomial will have coefficients in the rational field, for order elements the coefficients will be in the ring of integers.

`MinimalPolynomial(a)`

`MinimalPolynomial(a, R)`

Given an element a from an algebraic field or order L, returns the minimal polynomial of the element over R if given otherwise the subfield or suborder F where F is the field or order over which L is defined as an extension.

`AbsoluteMinimalPolynomial(a)`

Given an element a from an algebraic field or one of its orders, this function returns the minimal polynomial of the element. For field elements the polynomial will have coefficients in the rational field, for order elements the coefficients will be in the ring of integers.

`RepresentationMatrix(a)`

`RepresentationMatrix(a, R)`

Return the representation matrix of a, that is, the matrix which represents the linear map given by multiplication by a. If a is an order element, this matrix is with respect to the basis for the order; if a is an algebraic field element, the basis for the field is used. The ith row of the representation matrix gives the coefficients of aw_i with respect to the basis $w_1, \ldots, w_n$.

If R is given the matrix is over R and with respect to the basis of the order or field over R.

`AbsoluteRepresentationMatrix(a)`

Return the representation matrix of a relative to the $\mathbf{Q}$-basis of the field constructed using products of the basis elements, where a is an element of the relative number field L.

Let $L_i := \sum L_{i-1}\omega_{i,j}$, $L := L_n$ and $L_0 := \mathbf{Q}$. Then the representation matrix is computed with respect to the $\mathbf{Q}$-basis $(\prod_j \omega_{i_j,j})_{i\in I}$ consisting of products of basis elements of the different levels.

Example H37E17

We create the norm, trace, minimal polynomial and representation matrix of the element $\alpha/2$ in the quartic field $\mathbf{Q}(\alpha)$.

```
> R<x> := PolynomialRing(Integers());
> K<y> := NumberField(x^4-420*x^2+40000);
> z := y/2;
> Norm(z), Trace(z);
2500 0
> MinimalPolynomial(z);
ext<Q|>.1^4 - 105*ext<Q|>.1^2 + 2500
> RepresentationMatrix(z);
[     0    1/2      0      0]
[     0      0    1/2      0]
[     0      0      0    1/2]
[-20000      0    210      0]
```

The awkwardness of the printing of the minimal polynomial above can be overcome by providing a parent for the polynomial, keeping in mind that it is a univariate polynomial over the rationals:

```
> P<t> := PolynomialRing(RationalField());
> MinimalPolynomial(z);
```

```
t^4 - 105*t^2 + 2500
```

37.5.8 Other Functions

Elements can be represented by sequences and matrices. Valuation can also be calculated.

`ElementToSequence(a)`

`Eltseq(a)`

For an element a of an algebraic field F, a sequence of coefficients of length degree of F with respect to the basis is returned. For an element of an order O, the sequence of coefficients of the element with respect to the basis of O are returned.

Note however that the universe of the sequence if always a field since in general in relative extensions integral coefficients cannot be achieved.

`Eltseq(E, k)`

For an algebraic number $E \in K$ and a ring k which occurs somewhere in the defining tower for K, return the list of coefficients of E over k, that is, apply `Eltseq` to E and to its coefficients until the list is over k.

`Flat(e)`

The coefficients of the algebraic field element e wrt. to the canonical Q basis for its field. This is performed by iterating `Eltseq` until the coefficients are rational numbers. For number field elements the coefficients obtained match the coefficients wrt. to `AbsoluteBasis`.

`a[i]`

The coefficient of the ith basis element in the algebraic field or order element a.

`ProductRepresentation(a)`

Return sequences P and E such that the product of elements in P to the corresponding exponents in E is the algebraic number a.

`ProductRepresentation(P, E)`

`PowerProduct(P, E)`

Return the element a of the universe of the sequence P such that a is the product of elements of P to the corresponding exponents in the sequence E.

`Valuation(w, I)`

Given a prime ideal I and an element w of an order or algebraic field, this function returns the valuation $v_I(w)$ of w with respect to I; this valuation will be a non-negative integer. Ideals are discussed in Section 37.9.

`Decomposition(a)`

`Decomposition(a)`

The factorization of the order or algebraic field element a into prime ideals.

`Divisors(a)`

For an element a in a maximal order return a sequence containing (up to units) all the elements which divide a. The elements of the sequence will be generators for all principal ideals returned by `Divisors(Parent(a)*a)`.

`Index(a)`

The index of the module $\mathbf{Z}[a]$ in O where a lies in O, an order over $\mathbf{Z}$. If a is not a primitive element the index is infinite.

`Different(a)`

The different of the element a of an order of a number field.

37.6 Ideal Class Groups

This section describes the functions related to finding class groups and class numbers for (the maximal order O of) an absolute number field.

The method usually employed is the *relation* method ([Heß96, Coh93]), basically consisting of the following steps. In the first step a list of prime ideals of norm below a given bound is generated, the *factor basis*. In the second step a search is conducted to find in each of the prime ideals a few elements for which the principal ideals they generate factor completely over the factor basis. Using these *relations*, a generating set for the ideal class group is derived (via matrix echelonization), and in the final step it is verified that the correct orders for the generators have been found.

To determine the class group or class number correctly one has to make sure that all ideals having norm smaller than the Minkowski bound or smaller than the Bach bound, if one assumes the generalized Riemann hypothesis, are taken into consideration, and that the final stage, which may be time consuming, is properly executed. Optional arguments allow the user to override these, but correctness of such results can not be guaranteed.

It should be stressed that by default a guaranteed result is computed using the Minkowski bound. Thus even for innocent looking fields it may take considerable time. In comparison, pari (as of version 2.0) will by default use a much smaller bound giving results that are not guaranteed even under GRH. On the other hand, it will be much faster. It is possible to use the same bounds in Magma. In this case the running times will be similar.

When the discriminant of an order is very large (above 10^{30}) a sieving method developed by [Bia] is used. Using this method the relations are derived using an analogue of the number field sieve. Lattice sieving and the special-Q are also used. The verbose flag `"ClassGroupSieve"` can be set to view information about the computation.

Once a class group computation has been completed, the results are stored with the order.

All functions mentioned in this section support the verbose flag `ClassGroup` up to a maximum value of 5.

Ideals in MAGMA are discussed in Section 37.9.

`DegreeOnePrimeIdeals(O, B)`

Given an order O as well as a positive integer bound B, return a sequence consisting of all prime ideals in O whose norm is a rational prime not exceeding the bound B.

`ClassGroup(O: parameters)`

`ClassGroup(K: parameters)`

`Bound`	RNGINTELT	*Default :* MinkowskiBound
`Proof`	MONSTGELT	*Default :* "*Full*"
`Enum`	BOOLELT	*Default :* `true`
`Al`	MONSTGELT	*Default :* "*Automatic*"
Verbose	`ClassGroup`	*Maximum :* 5
Verbose	`ClassGroupSieve`	*Maximum :* 5

The group of ideal classes for the ring of integers O of the number field K is returned as an abelian group, together with a map from this abstract group to O. The map admits inverses and can therefore be used to compute "discrete logarithms" for the class group.

With the default values for the optional parameters the Minkowski bound is used and the last step of the algorithm verifies correctness (see the explanation above), hence a fully proven result is returned.

If `Bound` is set to some positive integer M, M is used instead of the Minkowski bound. The validity of the result still depends on the `"Proof"` parameter.

If `Proof := "GRH"`, everything remains as in the default case except that a bound based on the GRH is used to replace the Minkowski bound. This bound may be enlarged setting the `Bound` parameter accordingly. The result will hence be correct under the GRH.

If `Proof := "Bound"`, the computation stops if an independent set of relations between the prime ideals below the chosen bound is found. The relations may not be maximal.

If `Proof := "Subgroup"`, a maximal subset of the relations is constructed. In terms of the result, this means that the group returned will be a subgroup of the class group (i.e. the list of prime ideals considered may be to small).

If `Proof := "Full"` (the default) a guaranteed result is computed. This is equivalent to `Bound := MinkowskiBound(K)` and `Proof := "Subgroup"`.

If only `Bound` is given, the `Proof` defaults to `"Subgroup"`.

Finally, giving `Proof := "Current"` is the same as repeating the last call to `ClassGroup()`, but without the need to explicitly restate the value of `Proof` or `Bound`. If there was no prior call to `ClassGroup`, a fully proven computation will be carried out.

If `Enum := false`, then instead of enumerating short elements to get relations, MAGMA will use random linear combinations of a reduced basis instead. For "small" fields this will typically slow down the computations, but for large fields it is sometimes not possible to find any point using enumeration so that this is necessary for "large" fields. Unfortunately, there is no known criterion to decide beforehand if a field is "large" or "small".

If `Al` is set to `"Sieve"` (regardless of the size of the discriminant) or the discriminant of O is greater than 10^{30} then the sieving method developed by [Bia] is used. If `Al` is set to `"NoSieve"` then this sieving method will not be used regardless of the size of the discriminant.

`RingClassGroup(O)`

`PicardGroup(O)`

For a (possibly non-maximal) order O, compute the ring class group (Picard group) of O, ie. the group of invertible ideals in O modulo pricipal ideals. The algorithm and its implementation are due to Klüners and Pauli, [PK05].

`ConditionalClassGroup(O)`

`ConditionalClassGroup(K)`

The class group of the order O or the number field K assuming the generalized Riemann hypothesis.

`ClassGroupPrimeRepresentatives(O, I)`

For the maximal order O of some absolute number field k and an ideal I of O, compute a set of prime ideals in O that are coprime to I and represent all ideal classes. The map, mapping elements of the class group to the primes representing the ideal class is returned.

`ClassNumber(O: parameters)`

`ClassNumber(K: parameters)`

`Bound`	RNGINTELT	*Default :* MinkowskiBound
`Proof`	MONSTGELT	*Default :* "*Full*"
`Al`	MONSTGELT	*Default :* "*Automatic*"
Verbose	`ClassGroup`	*Maximum :* 5
Verbose	`ClassGroupSieve`	*Maximum :* 5

Return the class number of the ring of integers O of a number field K. The options for the parameters are the same as for `ClassGroup`.

`BachBound(K)`
`BachBound(O)`

An integral upper bound for norms of generators of the ideal class group for the number field K or the maximal order O assuming the generalized Riemann hypothesis.

`MinkowskiBound(K)`
`MinkowskiBound(O)`

An unconditional integral upper bound for norms of the generators of the ideal class group for the number field K or the maximal order O.

`FactorBasis(K, B)`
`FactorBasis(O, B)`

Given the maximal order O, or a number field K with maximal order O, this function returns a sequence of prime ideals of norm less than a given bound B.

`FactorBasis(O)`

Given the maximal order O where the class group has previously been computed, this function returns a sequence of prime ideals that have been used as factor basis for the class group computation. In addition the used upper bound for the factor basis is returned. This bound can be different from the bound passed in using the `Bound := bound` parameter.

`RelationMatrix(K, B)`
`RelationMatrix(O, B)`

Given a maximal order O, or a number field K with maximal order O, generate relations for each prime ideal in the factor basis for O with bound B on the norms of the ideals. The relations are given by rows in a matrix. If at some stage the relations generate the trivial group, no more relations are generated.

`RelationMatrix(O)`

Given a maximal order O where the class group has been computed previously, the resulting relation matrix is returned.

`Relations(O)`

Given a maximal order O where the class group has been computed previously, the vector containing the order elements used to compute the class group is returned.

`ClassGroupCyclicFactorGenerators(O)`

Let a_i be the generators for the cyclic factors of the class group of O. This function returns generators for $a_i^{c_i}$ where c_i is the order of a_i in the class group.

Example H37E18

We give an example of a class group calculation, illustrating some of the functions.

```
> R<x> := PolynomialRing(Integers());
> O := MaximalOrder(x^2-10);
> C, m := ClassGroup(O);
> C;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*C.1 = 0
> m(C.1);
Prime Ideal of O
Two element generators:
    [2, 0]
    [0, 1]
> p := Decomposition(O, 31)[1][1];
> p;
Prime Ideal of O
Two element generators:
    [31, 0]
    [45, 1]
> p @@ m;
0
> IsPrincipal(p);
true
> p := Decomposition(O, 37)[1][1];
> p @@ m;
C.1
> IsPrincipal(p);
false
> MinkowskiBound(O);
3
> F, B := FactorBasis(O);
> B;
33
```

Even though the `MinkowskiBound` is only 3, we take 33 as the bound. The reason for this behaviour is that the factor base has to have at least some elements (about 20) if it is non-empty. Otherwise the search for relations is hopeless.

```
> r := Relations(O);
> M := RelationMatrix(O);
> [ Valuation(r[1][1], x) : x in F];
[ 0, 0, 0, 0, 0, 1, 1, 0 ]
> M[1];
```

```
(0 0 0 0 0 1 1 0)
```

As one can see, the `RelationMatrix` basically stores the valuation of the elements of `Relations` at the prime ideal contained in `FactorBasis`.

```
> f,g := IsPrincipal(m(C.1)^2);
> f;
true
> g;
[2, 0]
> ClassGroupCyclicFactorGenerators(0);
[
    [2, 0]
]
```

Now we will consider some larger fields to demonstrate the effect of the `"Bound"` parameter:

```
> K := NumberField(x^5-14*x^4+14*x^3-14*x^2+14*x-14);
> MinkowskiBound(K);
21106
> BachBound(K);
7783
> time ClassGroup(K);
Abelian Group isomorphic to Z/10
Defined on 1 generator
Relations:
    10*$.1 = 0
Mapping from: Abelian Group isomorphic to Z/10
Defined on 1 generator
Relations:
    10*$.1 = 0 to Set of ideals of Maximal Equation Order with defining
polynomial x^5 - 14*x^4 + 14*x^3 - 14*x^2 + 14*x - 14 over Z
Time: 14.600
```

Note, that is an unconditional result. As one can see, the `BachBound` (proven under GRH) is much smaller than `MinkowskiBound`. The difference shows up in the running time:

```
> K := NumberField(x^5-14*x^4+14*x^3-14*x^2+14*x-14);
> time _, _ := ClassGroup(K: Bound := BachBound(K));
Time: 7.080
```

In comparison, pari (2.0.20) uses an even smaller bound as default, namely `BachBound(K)/40` for fields of degree > 2 and `BachBound(K)/20` for quadratics.

```
> K := NumberField(x^5-14*x^4+14*x^3-14*x^2+14*x-14);
> time _, _ := ClassGroup(K: Bound := Floor(BachBound(K)/40));
Time: 1.300
```

In comparison, `bnfinit` in pari (version 2.0.20) takes about 1.4 seconds for this example.
Note, that in general one cannot use arbitrarily small bounds. If they are too small, the computation time will increase again as the system will not be able to find any relations.

Example H37E19

We give some examples of class group computations using the sieving algorithm.

```
> R<x> := PolynomialRing(IntegerRing());
> f := x^3 + 3592347*x^2 - 6*x + 3989864;
> K<y> := NumberField(f);
> time G, m := ClassGroup(K : Al := "Sieve", Proof := "GRH");
Time: 3.200
> G, m;
Abelian Group isomorphic to Z/6
Defined on 1 generator
Relations:
    6*G.1 = 0
Mapping from: GrpAb: G to Set of ideals of Maximal Order of Equation Order with
defining polynomial x^3 + 3592347*x^2 - 6*x + 3989864 over Z
> m(G.1);
Ideal
Two element generators:
    [4373, 0, 0]
    [2118, 1, 0]
> $1 @@ m;
G.1
> IsPrincipal($2^6);
true
> f:= x^5 + 3330*x^3 - 50*x + 107392;
> K<y> := NumberField(f);
> time G, m := ClassGroup(K : Al := "Sieve", Proof := "GRH");
Time: 9.930
> G, m;
Abelian Group of order 1
Mapping from: GrpAb: G to Set of ideals of Maximal Order of Equation Order with
defining polynomial x^5 + 3330*x^3 - 50*x + 107392 over Z
```

It is also possible to drive the class group computation "by hand", that is one can call the individual parts one by one to for example re-create a class group computation:

`FactorBasisCreate(O,B)`

Creates a class group process by computing a factor basis containing all ideals of norm $\leq B$ in the order O and returning this factor basis.

`EulerProduct(O, B)`

Computes an approximation to the Euler product for the order O using only prime ideals over prime numbers of norm $\leq B$.

`AddRelation(E)`

Adds a relation (order element) E to the class group process of the parent of E. This function returns `true` exactly when the element factors over the factor basis and if the new relation matrix is of full rank.

`EvaluateClassGroup(O)`

Finalizes a class group process for the order O, that is, it computes (if possible) the class group structure based on the current relation matrix and a basis of the unit group generated by the nullspace of the relation matrix.

This function returns `true` when the class group is determined by the current data. In order to use this function, one has to create a factor basis and then add enough relations.

`CompleteClassGroup(O)`

This function completes an already started class group process for the order O by using the internal functions to look for relations until the class group can be determined.

`FactorBasisVerify(O, L, U)`

This function verifies the "completeness" of the current factor basis for the order O with respect to the prime ideals of norm between L and U. That is, for all prime ideals which norm is between L and U, the function tries to find a relation between the new prime ideal and the prime ideals already in the factor basis. If successful, this means that the new prime ideal does not contribute anything to the class group that is not already known and can therefore safely be ignored.

This function does not return if unsuccessful.

`ClassGroupSetUseMemory(O, f)`

For an order O where the class group is already computed, decide if results of the discrete logarithm computation for the class group are stored. For example if the order O is going to be used extensively as a coefficient ring for class field computations, then every time discrete logatrithms of ray class groups are computed, a discrete logarithm computation in the class group is triggered. In particular when investigating the cohomology of various extensions over O, this involves testing the same ideals over and over again. Setting the flag f to `true` will help to keep computation times down - at the expense of additional use of memory. This functionality is disabled by default.

`ClassGroupGetUseMemory(O)`

For an order O where the class group has been computed check if discrete logarithm values should be stored or not.

37.6.1 Setting the Class Group Bounds Globally

It is possible to preset the bounds to be used in all class group computations. Two bounds can be specified: the first controls the size of the factor base used in the first stage of the class group computation, and the second is the bound used in the checking stage (this controls the level of rigour of the computation).

The bounds may be specified using either of the intrinsics below; `SetClassGroupBounds` is a simple special case of `SetClassGroupBoundMaps`, provided for the user's convenience.

`SetClassGroupBounds(n)`

`SetClassGroupBounds(string)`

This determines the bounds that will be used in all subsequent calls to `ClassGroup`. The argument can be an integer n (then the bounds are both set to this constant). Alternatively the argument can be a string: either "GRH" (then the bounds will guarantee correctness assuming GRH) or "PARI" (this is intended to give roughly the same level of rigour as PARI).

`SetClassGroupBoundMaps(f1, f2)`

This determines the bounds that will be used in all subsequent calls to `ClassGroup`. The arguments should be maps from `PowerStructure(RngOrd)` (which is the parent object of all orders in number fields) to integers.

The bounds used when `ClassGroup` is called for a number field will be the bounds for the maximal order of that field.

Example H37E20

We select some bounds which will then be used in all calls to `ClassGroup`. (The class group computations will be rigorous, but will use a relatively small factor base for the first part of the computation).

```
> map1 := map< PowerStructure(RngOrd) -> Integers() |
>                              order :-> BachBound(order) div 10 >;
> map2 := map< PowerStructure(RngOrd) -> Integers() |
>                              order :-> MinkowskiBound(order) >;
> SetClassGroupBoundMaps( map1, map2);
```

37.7 Unit Groups

The relation method, outlined in the previous section, can also be used for unit group calculations. Therefore, unit group calculations including those triggered as a side effect may cause the creation of factor bases and relations. Other methods such as Dirichlet's method are also implemented which may be faster in certain circumstances. Descriptions of the algorithms can be found in [PZ89], (pp. 343–344), and in [Poh93]. These methods will only work for absolute extensions.

In general, the unit group related functions support a verbose flag `UnitGroup` up to a maximum of 6.

`UnitGroup(O)`

`MultiplicativeGroup(O)`

`UnitGroup(K)`

`MultiplicativeGroup(K)`

`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`UnitGroup`	*Maximum :* 6

Given an order O in a number field, this function returns an (abstract) abelian group U, as well as a bijection m between U and the units of the order. The unit group consists of the torsion subgroup, generated by the image `m(U.1)` and a free part, generated in O by the images `m(U.i)` for $2 \leq i \leq r_1 + r_2$.

If the argument to this function is a number field K, the unit group of its maximal order is returned. Note that the maximal order may have to be determined first.

The parameter `Al` can be used to specify an algorithm. It should be one of `"Automatic"`, (default, a choice will be made for the user) `"ClassGroup"`, `"Dirichlet"`, `"Mixed"` (the best known Dirichlet method), `"Relation"` or `"Short"` (which is a variation of `"Mixed"`). In the case of real quadratic fields, a continued fraction algorithm is available, `"ContFrac"`.

`UnitGroupAsSubgroup(O)`

For a (possibly non-maximal) order O in some absolute field K, return the unit group of O as a subgroup of the unit group of the maximal order of O. The algorithm and its implementatio is due to Klüners and Pauli, [PK05].

`TorsionUnitGroup(O)`

`TorsionUnitGroup(K)`

The torsion subgroup of the unit group of the order O, or, in case of a number field K, of its maximal order O. The torsion subgroup is returned as an abelian group T, together with a map m from the group to the order O. The torsion subgroup will be cyclic, and is generated by `m(T.1)`.

`IndependentUnits(O)`

`IndependentUnits(K)`

`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`UnitGroup`	*Maximum :* 6

Given an order O, this function returns a sequence of independent units; they generate a subgroup of finite index in the full unit group. Given a number field K, the function is applied to the maximal order of K. The function returns an abelian group generated by the independent units as well as a homomorphism from the group to the order.

The parameter `Al` can be used to specify an algorithm. It should be one of `"Automatic"`, `"ClassGroup"`, `"Dirichlet"`, `"Mixed"` (the best known Dirichlet-like method), `"Relation"`. or `"Short"` (which is a variation of `"Mixed"`). In the case of real quadratic fields, a continued fraction algorithm is available, `"ContFrac"`.

`pFundamentalUnits(O, p)`

`pFundamentalUnits(K, p)`

`Al`	MonStgElt	*Default :* "*Automatic*"
Verbose	`UnitGroup`	*Maximum :* 6

Given an order O in a number field, this function returns an (abstract) abelian group U, as well as a map m from U to the order. U will be a subgroup (of finite index) of the unit group G such that p does not divide the index $(G : U)$ where p is the prime number given. If a field K is given rather than an order, the above is computed for the maximal order of K.

The parameter `Al` has the same options as for `UnitGroup`.

`MergeUnits(K, a)`

`MergeUnits(O, a)`

Verbose	`UnitGroup`	*Maximum :* 6

For an order O or a number field with maximal order O and a unit $a \in O$, add the unit to the already known subgroup of U_O that is stored in O. Returns `true` if and only if the rank of the currently known unit group of O or K increases when a is merged with it.

`UnitRank(O)`

`UnitRank(K)`

Return the unit rank of the ring of integers O of a number field K.

Example H37E21

In our field defined by $x^4 - 420 * x^2 + 40000$, we obtain the class and unit groups as follows.

```
> R<x> := PolynomialRing(Integers());
> f := x^4 - 420*x^2 + 40000;
> K<y> := NumberField(f);
> C := ClassGroup(K);
> C;
Abelian Group of order 1
> U := UnitGroup(K);
> U;
Abelian Group isomorphic to Z/2 + Z + Z + Z
Defined on 4 generators
Relations:
      2*U.1 = 0
> T := TorsionUnitGroup(K);
> T;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*T.1 = 0
```

`IsExceptionalUnit(u)`

An element x of an order O is an exceptional unit if both x and $x - 1$ are units in O. This function returns `true` if and only if the order element u is an exceptional unit.

`ExceptionalUnitOrbit(u)`

If u is an exceptional unit of an order O, then all of the units $u_1 = u$, $u_2 = \frac{1}{u}$, $u_3 = 1 - u$, $u_4 = \frac{1}{1-u}$, $u_5 = \frac{u-1}{u}$, $u_6 = \frac{u}{u-1}$ are exceptional. The set $\Omega(u)$ formed by $u_1, \ldots, u_6$ is called the *orbit* of u. Usually it will have 6 elements. This function returns a sequence containing the elements of $\Omega(u)$.

`ExceptionalUnits(O)`

Verbose `UnitEq` *Maximum :* 5

This function returns a sequence S of units of the order O such that any exceptional unit u of O is either in S or is in the orbit of some element of S.

37.8 Solving Equations

MAGMA can solve norm, Thue, index form and unit equations.

37.8.1 Norm Equations

Norm equations in the context of number fields occur in many applications. While MAGMA contains efficient algorithms to solve norm equations it is important to understand the difference between the various types of norm equations that occur. Given some element θ in a number field k together with a finite extension K/k, there are two different types of norm equations attached to this data:

- Diophantine norm equations, that is norm equations where a solution $x \in K$ is restricted to a particular order (or any additive subgroup), and
- field theoretic norm equations where any element in $x \in K$ with $N(x) = \theta$ is a solution.

While in the first case the number of *different* (up to equivalence) solutions is finite, no such restriction holds in the field case. On the other hand, the field case often allows to prove the existence or non-existence of solutions quickly, while no efficient tests exist for the Diophantine case. So it is not surprising that different methods are applied for the different cases. We will discuss the differences with the individual intrinsics.

`NormEquation(O, m)`

`All`	BOOLELT	*Default :* `true`
`Solutions`	RNGINTELT	*Default :* All
`Exact`	BOOLELT	*Default :* `false`
`Ineq`	BOOLELT	*Default :* `false`

Given an order O and an element m of the ground ring of O which can be a positive integer or an element of a suborder, this intrinsic solves a Diophantine norm equation.

This function returns a boolean indicating whether an element $\alpha \in O$ exists such that $\mathrm{N}_{\mathrm{F/L}}(\alpha)$, the norm of α with respect to the subfield L of F (the field of fractions of O), equals m, and if so, a sequence of length at most `Solutions` of solutions α.

The parameter `Exact` may be used to indicate whether an exact solution is required (with `Exact := true`) or whether a solution up to a torsion unit suffices.

The maximal number of required solutions can be indicated with the `Solutions` parameter, but setting `All := true` will override this and the search will find all solutions.

If the order is absolute, then the parameter `Ineq` may be set to true. If so, all solutions x with $|N(x)| <= m$ will be found using a variation of Fincke's ellipsoid method ([Fin84, PZ89]).

Depending on whether the order is absolute maximal, absolute or (simple) relative, different algorithms are used.

If the order is an absolute maximal order, MAGMA will, in a first step, enumerate all integral ideals having the required norm (up to sign). Next, all the ideals are tested for principality using the class group based method. If `Exact := true`, then

a third step is added: we try to find a unit in O of norm -1. This unit is used to sign adjust the solution(s). If there is no such unit, we drop all solutions of the wrong sign.

If the order is absolute, but not maximal, the norm equation is first solved in the maximal order using the above outlined method. In a second step, a complete set of representatives for the unit group of the maximal order modulo the units of O is computed and MAGMA attempts to combine solutions in the maximal order with those representatives to get solutions in O.

If `Solutions` is set, the search stops after the required number of solutions is found.

In case the order is of type `RngOrd` and in some imaginary quadratic field, the norm function is a positive definite quadratic form, thus algorithms based on that property are used. In case the right hand side m equals ± 1, lattice based methods are applied.

If `Ineq` is `true`, which is only supported for absolute fields, lattice enumeration techniques ([Fin84, PZ89]) based on Fincke's ellipsoid method are used.

If the order is (simply) relative different algorithms are implemented, depending on the number of solutions sought. However, common to all of them is that they (partially) work in the `AbsoluteOrder` of O.

If O is a relative maximal order and if we only want to find 1 solution (or to prove that there is none), MAGMA first looks for (integral) solutions in the field using an S-unit based approach as outlined in `NormEquation`. This step gives an affine subspace of the S-unit group that contains all integral solutions of our equation. In a second step, a simplex based technique is used to find totally positive elements in the subspace.

In `All` is given or `Solutions` is > 1, then lattice based methods are used ([Fie97, Jur93, FJP97]).

`NormEquation(F, m)`

`Primes`	ESEQ OF PRIME IDEALS	*Default :* []
`Nice`	BOOLELT	*Default :* `true`

Given a field F and an element m of the base field of F, this function returns a boolean indicating whether an element $\alpha \in F$ exists such that $\mathrm{N}_{F/L}(\alpha)$, the norm of α with respect to the base field L of F equals m, and if so, a sequence of length 1 of solutions α.

The field theoretic norm equations are all solved using S-units. Before discussing some details, we outline the method.

- Determine a set S of prime ideals. We try to obtain a solution as a S-unit for this set S.
- Compute a basis for the S-units
- Compute the action of the norm-map
- Obtain a solution as a preimage.

In general, no effective method is known for the first step. If the field is relative normal however, it is known that is S generates the class group of F and if m is a S-unit, then S is large enough (*suitable* in ([Coh00, 7.5]) [Fie97, Sim02, Gar80]. Thus to find S we have to compute the class group of F. If a (conditional) class group is already known, it is used, otherwise an *unconditional* class group is computed. The initial set S consists of all prime ideals occurring in the decomposition of $m\mathbf{Z}_F$. Note that this step includes the factorisation of m and thus can take a long time is m is large.

Next, we determine a basis for the S-unit group and the action of the norm on it. This give the norm map as a map on the S-unit group as an abstract abelian group.

Finally, the right hand side m is represented as an element of the S-unit group and a solution is then obtained as a preimage under the norm map.

If `Nice` is true, then MAGMA attempts to find a smaller solution by applying a LLL reduction to the original solution.

If `Primes` is give it must contain a list of prime ideals of L. Together with the primes dividing m it is used to form the set S bypassing the computation of an unconditional class group in this step. If L is not normal this can be used to guarantee that S is large enough. Note that the class group computation is still performed when the S-units are computed. Since the correctness of the S-unit group (we need only p-maximality for all primes dividing the (relative) degree of L) can be verified independently of the correctness of the class group, this can be used to derive provable results in cases where the class group cannot be computed unconditionally.

By default, the `MaximalOrder(L)` is used to compute the class group. If the attribute `NeqOrder` is set on L it must contain a maximal order of L. If present, this order will be used for all the subsequent computations.

`NormEquation(m, N)`

`Raw`	BOOLELT	*Default :* `false`
`Primes`	ESEQ OF PRIME IDEALS	*Default :* []

Let N be a map on the multiplicative group of some number field. Formally N may also be defined on the maximal order of the field. This intrinsic tries to find a pre-image for m under N.

This function works by realising N as a endomorphism of S-units for a suitable set S.

If N is a relative norm and if L is (absolutely) normal then the set S as computed for the field theoretic norm equation is guaranteed to be large enough to find a solution if it exists. Note: this condition is not checked.

If `Primes` is given it will be supplemented by the primes dividing m and then used as the set S.

If `Raw` is given, the solution is returned as an unevaluated power product. See the example for details.

The main use of this function is for Galois theoretical constructions where the subfields are defined as fields fixed by certain automorphisms. In this situation the norm function can be realised as the product over the fixed group. It is therefore not necessary to compute a (very messy) relative representation of the field.

`IntegralNormEquation(a, N, O)`

`Nice`	BoolElt	*Default :* `true`

For a an integer or a unit in some number field, N being a multiplicative function on some number field k which is the field of fractions of the order O, try to find a unit in O that is the preimage of a under N. In particular, N restricted to O must be an endomorphism of O. If `Nice` is `true`, the solution will be size-reduced. In particular when the conductor of O in the maximal order of k is large, and therefore the unit index $(Z_k)^* : O^*$ is large as well, this function is much more efficient than the lattice based approach above.

`SimNEQ(K, e, f)`

`S`	[RngOrdIdl]	*Default :* `false`
`HasSolution`	BoolElt	*Default :* `false`

For a number field K and subfield elements $e \in k_1$ and $f \in k_2$, try to find a solution to the simultaneous norm equations $N_{K/k_1}(x) = e$ and $N_{K/k_2}(x) = f$. The algorithm proceeds by first guessing a likely set S of prime ideals that will support a solution - it is exists. Initially S will contain all ramified primes in K, the support of e and f and enough primes to generate the class group of K. In case K is normal over Q this set is large enough to support a solution if there is a solution at all. For arbitrary fields that is most likely not the case. However, if `S` is passed in as a parameter then the set used internally will contain at least this set. If `HasSolution` is `true`, Magma will add primes to S until a solution has been found. This is useful in situations where for some theoretical reason it is known that there has to be a solution.

Example H37E22

We try to solve $N(x) = 3$ in some relative extension: (Note that since the larger field is a quadratic extension, the second call tells us that there is no integral element with norm 3)

```
> x := PolynomialRing(Integers()).1;
> O := MaximalOrder(NumberField([x^2-229, x^2-2]));
> NormEquation(O, 3);
false
> NormEquation(FieldOfFractions(O), 3);
true [
  5/1*$.1*O.1 + 2/3*$.1*O.2
```

```
]
```

Next we solve the same equation but come from a different angle, we will define the norm map as an element of the group ring and, instead of explicitly computing a relative extension, work instead with the implicit fix-field.

```
> K := AbsoluteField(FieldOfFractions(O));
> t := K!NumberField(O).2;
> t^2;
2/1*K.1
> A, _, mA := AutomorphismGroup(K);
> F := sub<A | [ x : x in A | mA(x)(t) eq t]>;
> N := map<K -> K | x:-> &* [ mA(y)(x) : y in F]>;
> NormEquation(3, N);
true [
    5/1*K.1 + 2/3*K.3
]
```

Finally, to show the effect of `Raw`:

```
> f, s, base := NormEquation(3, N:Raw);
> s;
[
    (0 -1 0 -2 0 1 0 0 0 -1 0 1 0 0 0 0 0 0 0 0 0 0 0
       0 0 0 0 0 1 0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0
       0 0 0 0 0 0 0 0 1 0)
]
> z := PowerProduct(base, s[1]);
> z;
5/1*K.1 + 2/3*K.3
> N(z);
3/1*K.1;
```

37.8.2 Thue Equations

Thue equations are Diophantine equations of the form $f(x, y) = k$, where k is some integer constant and f is a homogeneous polynomial in two variables. Methods for computing all solutions to such equations are known, although the search space may be larger than is practical. To work with such equations in MAGMA a Thue object (category `Thue`) must be created to store information related to the computations. To solve Thue equations the reduction of Bilu and Hanrot ([BH96]) is used.

`Thue(f)`

Given a polynomial f of degree at least 2 over the integers, this function returns the 'Thue object' corresponding to f; such objects are used by the functions for solving Thue equations. They are printed as the homogeneous version of f.

`Thue(O)`

Given an order O with $\mathbf{Z}$ as its coefficient ring, this function returns the Thue object corresponding to the defining polynomial of O.

`Evaluate(t, a, b)`

`Evaluate(t, S)`

Given a Thue object t and integers a, b, this function returns the evaluation of the homogeneous polynomial f involved in t at (a, b), that is $f(a, b)$. The second form takes as argument the sequence $[a, b]$ instead. This can be convenient if checking the results from an inexact solution.

`Solutions(t, a)`

`Exact`	BoolElt	*Default :* `true`
Verbose	`ThueEq`	*Maximum :* 5

Given a Thue object t and an integer a, this function returns a sequence consisting of all sequences of two integers $[x, y]$ which solve the equation $f(x, y) = a$, where f is the (homogeneous form of) the Thue equation associated with t. If the optional parameter `Exact` is set to `false` then solutions to $f(x, y) = -a$ will also be found.

Example H37E23

A use of thue equations is shown.

```
> R<x> := PolynomialRing(Integers());
> f := x^3 + x + 1;
> T := Thue(f);
> T;
Thue object with form:  X^3 + X Y^2 + Y^3
> Evaluate(T, 3, 2);
47
> Solutions(T, 4);
[]
> Solutions(T, 7);
[]
> Solutions(T, 47);
[
    [ -1, 4 ],
    [ 3, 2 ]
]
> S := Solutions(T, -47 : Exact := false);
> S;
[
    [ -3, -2 ],
    [ -1, 4 ],
    [ 1, -4 ],
    [ 3, 2 ]
```

```
]
> [Evaluate(T, s) : s in S];
[ -47, 47, -47, 47 ]
```

37.8.3 Unit Equations

Unit equations are equations of the form

$$a\epsilon + b\eta = c$$

where a, b and c are some algebraic numbers and ϵ and η are unknown units in the same field.

`UnitEquation(a, b, c)`

Verbose `UnitEq` *Maximum :* 5

Return the sequence of 1×2 matrices $(e1, e2)$ such that $ae_1 + be_2 = c$ for number field elements a, b and c, where e_1 and e_2 are units in the maximal order. The algorithm uses Wildanger's method ([Wil97, Wil00]).

Example H37E24

Usage of `UnitEquation` is shown.

```
> R<x> := PolynomialRing(Integers());
> K<a> := NumberField(x^7 - x^6 + 8*x^5 + 2);
> UnitEquation(a^7, 4*a^2 + a^80, a^7 + a^80 + 4*a^2);
[
    [[1, 0, 0, 0, 0, 0, 0] [1, 0, 0, 0, 0, 0, 0]]
]
```

37.8.4 Index Form Equations

Given an absolute number field K with some order O, index form equations are equations of the form $(O : Z[\alpha]) = k$ where k is some positive integer.

In particular, if $k = 1$ this function will find "all" integral power bases.

In this context "all" means up to equivalence, where two solutions α and β are equivalent iff $\alpha = \pm\beta + r$ for some integer r.

If the field degree is larger than 4, the field must be normal and an integral power basis must already be known.

The implementation follows [Wil97, Wil00] for large degree equations, [GPP93, GPP96] for quartics and [GS89] for cubic fields.

`IndexFormEquation(O, k)`

Verbose `IndexFormEquation` *Maximum :* 5

Given an absolute order O, this function will find "all" (up to equivalence) solutions $\alpha \in OP$ to $(O : Z[\alpha]) = k$.

Example H37E25

We try to compute all integral power bases of the field defined by a zero of $x^4 - 14x^3 + 14x^2 - 14x + 14$:

```
> x := PolynomialRing(Integers()).1;
> O := MaximalOrder(x^4-14*x^3+14*x^2-14*x+14);
> IndexFormEquation(O, 1);
[
    [0, 1, 0, 0]
    [0, 1, -13, 1],
    [0, 1, -1, 1],
]
> [ MinimalPolynomial(x) :x in $1 ];
[
    x^4 - 14*x^3 + 14*x^2 - 14*x + 14,
    x^4 - 28*x^3 + 56*x^2 + 3962*x - 28014,
    x^4 - 2044*x^3 + 6608*x^2 - 7126*x + 2562
]
> [ Discriminant(x) : x in $1 ] ;
[ -80240048, -80240048, -80240048 ]
> Discriminant(O);
-80240048
```

37.9 Ideals and Quotients

Ideals of orders are of two types. All ideals are fractional and inherit from type `RngOrdFracIdl`. Integral ideals can have (the sub–)type `RngOrdIdl`. Some functions only apply to integral ideals and only ideals with the integral type can be prime. An ideal with fractional type but trivial denominator can be converted to have the integral type and any integral ideal can be converted to fractional type.

Ideals can be taken of orders over $\mathbf{Z}$ and orders defined over a maximal order. A few functions are not implemented for the latter.

Where an element or elements are returned from a function the elements are usually in the field of fractions if the ideal has the fractional type and in the order if it has integral type.

37.9.1 Creation of Ideals in Orders

The general ideal constructor can be used to create ideals in orders of algebraic fields, as described below. Since ideals in orders are allowed to be *fractional ideals*, algebraic field elements are allowed as generators. Ideals can also be created how they are written on paper: as an element multiplied by an order.

```
x * O
O * x
```

Create the ideal $x * O$ for element x and order O. If the ideal is integral it will be returned with the integral type.

```
F !! I
O !! I
```

Make the ideal I either fractional (first case where F is a field of fractions compatible with the order of I) or integral (second case where O is an order compatible with the order of I).

```
ideal< O | a1, a2, ... , am >
ideal< O | x >
ideal< O | M, d >
ideal< O | M, I1, ..., In >
```

Given an order O, as well as anything that can be used to produce a sequence of elements of the field of fractions of O return the ideal generated by those elements. If the ideal is integral then it will be returned with the integral type.

A single integer may be given in which case the principal ideal it generates will be returned. A matrix or a module over an order (`ModDed`) (or a matrix and ideals which the module could be created from) can be supplied as the basis for the resulting ideal. An optional second argument is a denominator given as an integer, (except when ideals are given).

Example H37E26

We give an example of the creation of an ideal generated by an element from an order.

```
> R<x> := PolynomialRing(Integers());
> f := x^4-420*x^2+40000;
> K<y> := NumberField(f);
> E := EquationOrder(K);
> O := MaximalOrder(K);
> elt := O ! (y^2/40+y/4);
> elt in E;
false
> I := ideal< O | elt >;
> I;
Principal Ideal of O
```

```
Generator:
    [0, 0, 1, 0]
> FieldOfFractions(O)!!I;
Principal Ideal of O
Generator:
    0.3
> O!!$1 eq I;
true
```

37.9.2 Invariants

Some information describing an ideal can be retrieved.

`Order(I)`

The order O which the ideal I is of.

`Denominator(I)`

The denominator of the fractional ideal I. This is the smallest positive integer d such that $d * I$ is an integral ideal.

`PrimitiveElement(I)`
`UniformizingElement(P)`

A primitive element of an ideal I is an element a which is in I but not in the square of I. This function returns such an element a. `UniformizingElement` returns the primitive element of a prime ideal.

`Index(O, I)`

The index of the integral ideal I, when viewed as a submodule of the order O. This is the same as the cardinality of the finite quotient ring O/I.

`Norm(I)`

The norm of the fractional ideal I. This returns the index of the ideal if the ideal is integral, and is defined on fractional ideals by multiplicativity so that the norm of I^{-1} equals the reciprocal of the norm of I.

`MinimalInteger(I)`

Given an ideal I of an order in some number field, the function returns the least positive integer contained in the ideal.

`Minimum(I)`

Given an ideal I, this function returns the least positive integer m if the ideal is integral or the least positive rational r if is fractional contained in I.

`AbsoluteNorm(I)`

The absolute norm of the fractional ideal I. This returns the index of the ideal if the ideal is integral, and is defined on fractional ideals by multiplicativity so that the norm of I^{-1} equals the reciprocal of the norm of I.

`CoefficientHeight(I)`

`CoefficientHeight(I)`

For an ideal I the coefficient height is defined to be the maximum integer occurring in the current representation of the ideal: If the ideal is given via two elements, this will be the maximal coefficient height of the generators, otherwise the maximal entry of the basis matrix.

`CoefficientLength(I)`

`CoefficientLength(I)`

For an ideal I the coefficient length is defined to be the size of the current representation: If the ideal is given via two elements, this will be the sum of the coefficient lengths of the generators, otherwise the sum of the entries of the basis matrix.

`RamificationIndex(I, p)`

`RamificationDegree(I, p)`

For a prime ideal I of an order O such that $p \in I$ returns the maximal exponent e such that I^e divides the principal ideal pO. If p is not given it is taken to be the minimal integer of I.

`RamificationDegree(I)`

`RamificationIndex(I)`

Computes the relative ramification index of the prime ideal I over the coefficient ring. To be more precise: Let I be an prime ideal of some order O with coeffcient ring o. Then $I \cap o$ is an prime ideal p in o. The ramification index $e = e(I|p)$ is the maximal exponent e such that I^e divides pO.

`ResidueClassField(O, I)`

`ResidueClassField(I)`

If I is a prime ideal of O, this function returns the finite field F isomorphic to O/I and the map $O \to F$.

`Degree(I)`

`InertiaDegree(I)`

Given a prime ideal I this function returns the relative degree f of the residue class field of the ideal I. To be more precise: Let I be a prime ideal in some order O with coefficient ring o. Then $p := o \cap I$ is a prime ideal in o and the residue class field O/I is a finite extension of degree $f = f(I|p)$ of the residue class field o/p.

`Valuation(I, p)`

Given an ideal I and a prime ideal p in an order O, returns the valuation $v_p(I)$ of I at p, that is, the number of factors p in the prime ideal decomposition of I. Note that, since the ideal I is allowed to be a fractional ideal, the returned value may be a negative integer.

`Content(I)`

The content of the ideal I, i.e. the maximal ideal of the base ring dividing I.

Example H37E27

The retrieval of some properties of an ideal is illustrated.

```
> R<x> := PolynomialRing(Integers());
> M := MaximalOrder(x^5 + 4*x^4 - x^3 + 7*x^2 - 1);
> R<x> := PolynomialRing(M);
> O := MaximalOrder(x^3 - 2);
> M;
Maximal Equation Order with defining polynomial x^5 + 4*x^4 - x^3 + 7*x^2 - 1
over Z
> O;
Maximal Order of Equation Order with defining polynomial x^3 - [2, 0, 0, 0, 0]
over M
> I := 19/43*M.4*O.3*O;
> I;
Fractional Principal Ideal of O
Generator:
    19/43*M.4*O.3
> Order(I);
Maximal Order of Equation Order with defining polynomial x^3 - [2, 0, 0, 0, 0]
over M
> Denominator(I);
86
> Denominator(O.3);
2
> PrimitiveElement(I);
19/43*M.4*O.3
> Norm(I);
Fractional Ideal of M
Basis:
[6859    0    0    0    0]
[   0 6859    0    0    0]
[   0    0 6859    0    0]
[   0    0    0 6859    0]
[   0    0    0    0 6859]
Denominator: 159014
> Minimum(I);
19/43
```

```
> p := Factorization(3*M.2*O)[1][1];
> Valuation(I, p);
0
```

37.9.3 Basis Representation

The basis of an ideal can be computed as well as related matrices.

`Basis(I)`

`Basis(I, R)`

Given an ideal I of an order O of the algebraic field F, this function returns a basis for I as a sequence of elements of F (if fractional), O (if integral) or the ring R if given.

`BasisMatrix(I)`

Returns the basis matrix for the ideal I of the order O. The basis matrix consists of the elements of a basis for the ideal written as rows of rational coefficients with respect to the basis of O. The entries of the matrix are elements of $\mathbf{Z}$ for an integral ideal of an order over $\mathbf{Z}$ only or the field of fractions of the coefficient ring of O.

`TransformationMatrix(I)`

Returns the transformation matrix for the ideal I of the order O, as well as a denominator. The transformation matrix consists of the elements of a basis for the ideal written as rows of coefficients with respect to the basis of the order O. The entries of the matrix are elements of $\mathbf{Z}$ for an integral ideal of an order over $\mathbf{Z}$ or the field of fractions of the coefficient ring of O.

`CoefficientIdeals(I)`

The coefficient ideals of the ideal I in a relative extension. These are the ideals $\{A_i\}$ of the coefficient ring of the order of I such that for every element $e \in I$, $e = \sum_i a_i * b_i$ where $\{b_i\}$ is the basis returned for I and each $a_i \in A_i$.

Example H37E28

Continuing from the last example, the use of the basis functions for ideals is shown.

```
> Basis(I);
[
    19/43*M.4*O.3,
    19/86*M.4*O.1,
    19/43*M.4*O.2
]
> Basis(I, NumberField(O));
[
    19/86*$.1^3*$.1^2,
```

```
    19/86*$.1^3,
    19/86*$.1^3*$.1
]
> BasisMatrix(I);
[0 0 19/43*M.4]
[19/86*M.4 0 0]
[0 19/43*M.4 0]
> TransformationMatrix(I);
[M.1 0 0]
[0 M.1 0]
[0 0 M.1]
1
```

For relative extensions, a different method is available:

`Module(I)`

For an ideal I in some relative extension, return a Dedekind module over the coefficient ring with the "same" basis.

37.9.4 Two–Element Presentations

All ideals of maximal orders can be generated by one or two elements of the field of fractions of the order they are an ideal of.

`Generators(I)`

Given a (fractional) ideal I of O, return a sequence containing two elements that generate I as an ideal. The elements will be in the order iff the ideal is integral, otherwise they will come from the field of fractions of O.

`TwoElement(I)`

Given a (fractional) ideal I of O, return two elements of (the field of fractions of) O that generate I as an ideal.

`TwoElementNormal(I)`

Given an integral ideal I of O (a maximal order over $\mathbf{Z}$), return two elements of O that form a two-element normal presentation for I, as well as an integer g such that I is g-normal.

Example H37E29

The generators and two element presentation of I are compared.

```
> Generators(I);
[
    19/43*M.4*O.3
]
> TwoElement(I);
19/43*M.4*O.3
19/43*M.4*O.3
```

37.9.5 Predicates on Ideals

Ideals may be tested for various properties and whether given elements lie in the ideal.

`I eq J` `I ne J`

`x in I` `x notin I` `I subset J`

`IsIntegral(I)`

Returns `true` if and only if the fractional ideal I is integral.

`IsZero(I)`

Returns `true` if the ideal I is the zero ideal, `false` otherwise.

`IsOne(I)`

Returns `true` if the ideal I is the ideal generated by 1, `false` otherwise.

`IsPrime(I)`

Returns `true` if and only if the ideal I is a prime ideal, and `false` otherwise. If I has the integral type and is not prime, the function also returns a proper (ideal) divisor.

Currently, this function becomes very slow as the norm of the ideal becomes large.

`IsPrincipal(I)`

Verbose `ClassGroup` *Maximum :* 5

Returns `true` if the fractional ideal I of the order O is a principal ideal, otherwise `false`. If I is principal, a generator (as an element of the field of fractions of O) is also returned.

If it is known or easy to decide whether I is principal the function will return quickly. If it is necessary to compute the class group of O the function will be slower. If the generator is required this may cause the function to take longer as well.

`IsRamified(P)`

Returns `true` iff the ramification index of the prime ideal P is greater than 1.

`IsRamified(P, O)`

Returns `true` iff for any prime ideal Q lying above P in the order O, the ramification index of Q is greater than 1. P must be a prime ideal of the base ring of O or a prime number (if O is an absolute order).

`IsTotallyRamified(P)`

Returns `true` iff the ramification index of the prime ideal P equals the degree of its order over the base field.

`IsTotallyRamified(P, O)`

Returns `true` iff for any prime ideal Q lying above P in the order O, the ramification index of Q equals the field degree. P must be a prime ideal of the base ring of O or a prime number (if O is an absolute order).

`IsTotallyRamified(K)`

Returns `true` if all primes dividing the discriminant the maximal order of the algebraic field K are totally ramified over the coefficient field of K.

`IsTotallyRamified(O)`

Returns `true` if all primes dividing the discriminant of the maximal order O are totally ramified over the coefficient ring of O.

`IsWildlyRamified(P)`

Returns `true` iff the ramification index of the prime ideal P is a multiple of the characteristic of the residue class field of P.

`IsWildlyRamified(P, O)`

Returns `true` iff for any prime ideal Q of the order O lying above P, the ramification index $e(Q|P)$ is a multiple of the characteristic of the residue class field of Q. P must be a prime ideal of the base ring of O or a prime number (if O is an absolute order).

`IsTamelyRamified(P)`

Returns `true` iff the prime ideal P is not wildly ramified.

`IsTamelyRamified(P, O)`

Returns `true` iff the prime ideal or integer P is not wildly ramified in the order O.

`IsUnramified(P)`

Returns `true` iff the ramification index of the prime ideal P is 1.

`IsUnramified(P, O)`

Returns `true` iff for all prime ideals Q lying above P in the order O, the ramification index of Q is 1. P must be a prime ideal of the base ring of O or a prime number (if O is an absolute order).

`IsInert(P)`

Returns `true` iff the inertia degree of the prime ideal P is the field degree.

`IsInert(P, O)`

Returns `true` iff the prime integer or ideal P in the base ring of the order O is inert, i.e. PO is an unramified prime ideal of O.

`IsSplit(P)`

Returns `true` iff the prime ideal P is not the only prime ideal which lies above its intersection with the base ring of its order.

`IsSplit(P, O)`

Returns `true` iff at least two prime ideals in the order O lie above the prime integer or ideal P of the base ring of O.

`IsTotallySplit(P)`

Returns `true` iff there are as many prime ideals lying above the intersection of the prime ideal P with the base ring of its order as the degree of the order of P.

`IsTotallySplit(P, O)`

Returns `true` iff as many prime ideals in the order O lying above the prime integer or ideal P of the base ring of O as the degree of O.

37.9.6 Ideal Arithmetic

Ideals can be multiplied in several ways, divided and added. Powers of ideals, the least common multiple and the intersection of two ideals can also be calculated.

`I * J`

The product IJ of the (fractional) ideals I and J, generated by the products of elements in I and elements in J.

`x * I`
`I * x`

Given an element x of (or coercible into) a field of fractions F, and a (fractional) ideal I in the order of F, return the product of the ideal and the principal ideal generated by x.

`&*L`

The product of all ideals in the sequence or set L.

`I / J`
`I div J`

The quotient of the (fractional) ideals I and J of an maximal order O. This is the fractional ideal K of O with the property that $JK = I$.

`I div J`

For integral ideals I and J of some maximal order such that J divides I (or, equivalently, J is contained in I), return the integral ideal I/J.

`I / x`

Given an ideal I and an element x construct the fractional ideal I/x.

`I + J`

The sum of the (fractional) ideals I and J, generated by the sums of elements in I and elements in J.

`I ^ k`

The k-th power of the (fractional) ideal I (for an integer k). If I has integral type and k is negative the result will have fractional type.

`I eq J`

Tests if the ideals I and J are equal.

`I subset J`

Tests if the two ideals I and J of the same order are contained in each other. For invertible ideals this is equivalent to checking if J divides I,

`E in I`

Tests if the element E is actually in the ideal I. The element and the ideal have to be compatible, i.e., live in the same number field.

`LCM(I, J)`
`Lcm(I, J)`
`LeastCommonMultiple(I, J)`

Return the least common multiple of ideals I and J. They must both be of the same maximal order.

`GCD(I, J)`
`Gcd(I, J)`
`GreatestCommonDivisor(I, J)`

The greatest common divisor of the ideals I and J of some maximal order of an algebraic number field.

`Content(M)`

For a matrix M with entries in some number field k, compute the gcd of all elements as principal ideals in the maximal order of k.

`I meet J`

The intersection of the (fractional) ideals I and J. For ideal in the maximal order this is the same as the lcm.

`&meetS`

The intersection of all ideals I of the sequence or set S. For ideals in some maximal order this is the same as the lcm.

`I meet R`
`R meet I`

The intersection of the ideal I with the compatible ring R. If $R = \mathbf{Q}$ an error will occur since ideals of $\mathbf{Q}$ cannot be created. If such information is required use `Minimum` instead. An ideal of R is returned.

`a mod I`

A representative of the element a of an order O in the quotient O/I.

`InverseMod(E, M)`
`Modinv(E, M)`

An element y such that $y * E = 1 \bmod M$ where M is an integral ideal or an integer and E is an element of an order.

`ColonIdeal(I, J)`
`IdealQuotient(I, J)`

The colon ideal $[I : J]$ or (I/J) is defined as $\{x \in F : xJ \subseteq I\}$ where F is the field of fractions of the order the ideals I and J belong to.

For ideals of a maximal order (or in general for *invertible* ideals) this is equivalent to I/J, otherwise only `J*ColonIdeal(I, J) subset 1*Order(I)` holds.

`IntegralSplit(I)`

Given an ideal I, return an integral ideal J and a minimal positive integer d such that $I = J/d$.

37.9.7 Roots of Ideals

It is possible to ask for the k-th root of an ideal where k is a positive integer.

`Root(I, k)`

Find the kth root of the ideal I if it exists.

`IsPower(I, k)`

Return `true` if the ideal I is a kth power of an ideal and the ideal it is a power of otherwise `false`.

`SquareRoot(I)`

`Sqrt(I)`

Return the square root of the ideal I if I is square.

`IsSquare(I)`

Return `true` if the ideal I is the square of an ideal and the ideal it is a square of otherwise `false`.

37.9.8 Factorization and Primes

The factorization of an ideal into prime ideals and the divisors of an ideal can be determined.

`Decomposition(O, p)`

Verbose `IdealDecompose` *Maximum :* 5

Given an order O and a rational prime number p or a prime ideal p of the coefficient ring of O, return a sequence of tuples consisting of prime ideals and exponents, according to the decomposition of p in O.

`DecompositionType(O, p)`

Verbose `IdealDecompose` *Maximum :* 5

Given an order O and a rational prime number p or a prime ideal p of the coefficient ring of O, return the decomposition type, ie. a sequence of tuples consisting of the degree of the prime ideals and their ramification index, according to the decomposition of p in O.

`Factorization(I)`

`Factorisation(I)`

Verbose `IdealDecompose` *Maximum :* 5

Returns the prime ideal factorization of an ideal I in an order O, as a sequence of 2-tuples (prime ideal and integer exponent).

`Divisors(I)`

Return the ideals which divide the ideal I which must be of a maximal order.

`Support(I)`

For a non-zero ideal I of some maximal order, return the set of prime ideals p dividing I.

`Support(L)`

`GaloisStable`	BoolElt	*Default :* `false`
`CoprimeOnly`	BoolElt	*Default :* `false`
`UseBernstein`	BoolElt	*Default :* `false`

For a sequence L of ideals in some maximal order (or of number field elements representing principal ideals), return the set of prime ideals dividing at least one of the ideals. If `CoprimeOnly` is given, the set returned will not in general be containing prime ideals, but will satisfy the following:

Every ideal in L can be uniquely decomposed into a power product of ideals in the set returned

The set is minimal and closed under gcd, ie. for two elements in the set, their gcd will be one.

If the number field is normal and if `GaloisStable` is given, then the set returned will be closed under the action of the galois group. Depending on the (unknown) factorisation pattern of the ideals, taking the Galois action into account will in general refine the coprime factorisation.

In general, this function will first construct a coprime basis, and the factorise the result of this step.

If `UseBernstein` is given, then Dan Berstein's asymptoically fast algorithm ([Ber05], which runs in time essentially linear in $\#L$) is used.

`CoprimeBasis(L)`

`GaloisStable`	BoolElt	*Default :* `false`
`UseBernstein`	BoolElt	*Default :* `false`

Given a sequence L of ideals in some maximal order, a coprime basis C for L is constructed. That means

- every element in L has a unique representation as a power product with elements in C
- C is closed under gcd, the ideals in C are pairwise coprime.

If the field is normal and if `GaloisStable` is given, the input sequence is supplemented by the action of the automorphism group, thus potentially refining the coprime basis.

If `UseBernstein` is given then instead of the naive algorithm with quadratic complexity in $\#L$, an asymptotically fast, almost linear algorithm by Dan Berstein is used, [Ber05].

`CoprimeBasisInsert(~L, I)`

`GaloisStable`	BoolElt	*Default :* `false`
`UseBernstein`	BoolElt	*Default :* `false`

Given a coprime basis in the sequence L, enlarge it by the ideal I, ie. enlarge L in such a way that L stays a coprime basis but allows the decomposition of I as well. If the ideals are in a normal field and if `GaloisStable` is given, then in addition of I all its Galois conjugates are inserted as well. Furthermore, a fractional ideal is always decomposed into the numerator and denominator ideal, ach of which is inserted independently.

If `UseBernstein` is given then instead of the naive algorithm with quadratic complexity in $\#L$, an asymptotically fast, almost linear algorithm by Dan Berstein is used, [Ber05].

`PowerProduct(B, E)`

Given sequences B of ideals of some maximal order and E of integers, compute the ideal $\prod B[i]^{E[i]}$.

37.9.9 Other Ideal Operations

Various other functions can be applied to ideals. In addition to those listed, the completion of an order at a prime ideal can also be taken (see Completion on page 891 and Chapter 47).

`ChineseRemainderTheorem(I1, I2, e1, e2)`

`ChineseRemainderTheorem(X, M)`

`CRT(I1, I2, e1, e2)`

`CRT(X, M)`

Returns an element e of the order O such that $(e_1 - e)$ is in the ideal I_1 of O and $(e_2 - e)$ is in the ideal I_2. If a sequence of elements X and a sequence of ideals M is given then the element e will be such that $(X[i] - e)$ is in $M[i]$ for all i.

`CRT(I1, L1, e1, L2)`

`ChineseRemainderTheorem(I1, L1, e1, L2)`

Returns an element e of the order O such that $(e_1 - e)$ is in the ideal I_1 of O and the signs of the conjugates listed in $L1$ are the same as in $L2$.

$L1$, a sorted sequence of integers $0 < l_i <= r1$, is meant to be formal product of infinite places. The signs of the l_i'th conjugate of e will be the same as the sign of $L2[i]$.

`Idempotents(I, J)`

For coprime integral ideals I and J return `true` and elements $i \in I$ and $j \in J$ such that $i + j = 1$.

`CoprimeRepresentative(I, J)`

`MakeCoprime(I, J)`

Given two integral ideals I and J in the same maximal order, find an element q in the field of fractions of this order such that qI is coprime to J.

`ClassRepresentative(I)`

Let I be an ideal in the absolute maximal order O of the number field K. Further, assume that the class group of O has been computed. The class group calculation will have chosen a set of ideal class representatives. This function returns the representative ideal for the ideal class to which I belongs.

`Lattice(I)`

`MinkowskiLattice(I)`

Given an ideal I in an absolute order, returns the lattice determined by the real and complex embeddings of I.

`Different(I)`

The different of the (possibly fractional) ideal I of an order of an algebraic number field.

`Codifferent(I)`

The codifferent of the ideal I. This will be the inverse of the different of I if I is an ideal of a maximal order.

`SUnitGroup(I)`

`SUnitGroup(S)`

`Raw`	BoolElt	*Default :* `false`
Verbose	`ClassGroup`	*Maximum :* 5

An element mu of F, the field of fractions of the order of I, is an S-unit iff $v_p(mu) = 0$ for all p not in S. This function returns the group of S-units of the prime ideals given either as a sequence S of ideals or as a product ideal I. The map from the group into the order containing the ideals is also returned.

If `Raw` is `true` then a product representation of the units is returned instead. That means a sequence L of order elements is determined such that the S-unit group is contained in their multiplicative span. The S-unit group is represented as the $\mathbf{Z}$-module of the exponent vectors for L that give rise to some S-unit. Formally we obtain the S-unit group as an abstract abelian group A, a map from A into some large `RSpace` and the sequence L.

Example H37E30

First we compute the 3-units of $\mathbf{Q}(\sqrt{10})$.

```
> K := QuadraticField(10);
> M := MaximalOrder(K);
> U, mU := SUnitGroup(3*M);
> U;
Abelian Group isomorphic to Z/2 + Z + Z + Z
Defined on 4 generators
Relations:
    2*U.1 = 0
> mU;
Mapping from: GrpAb: U to Field of Fractions of M
> u := mU(U.3); u;
7/1*M.1 - 2/1*M.2
> Decomposition(u);
[
  <Prime Ideal of M
    Two element generators:
      3
      $.2 + 1, 2>
]
```

So u is indeed a 3 unit, as the factorization contains only prime ideals over 3. Next we do the same computation but using the `Raw` option:

```
> U, mU, base := SUnitGroup(3*M:Raw);
> mU;
Mapping from: GrpAb: U to Full RSpace of degree 14 over Integer Ring
> mU(U.3);
( 0  2  1  0  0  0  0  0  0  0 -2)
> PowerProduct(base, $1);
7/1*M.1 - 2/1*M.2
> base[2]^2 * base[3]^1 * base[11]^-2;
7/1*M.1 - 2/1*M.2
```

This representation is of particular importance for large degree fields or fields with large units. To illustrate this, consider the following field from the pari-mailing list:

```
> K := NumberField(Polynomial([ 13824, -3894, -1723, 5, 1291, 1 ]));
> L := LLL(MaximalOrder(K));
> C, mC := ClassGroup(L:Bound := 500);
> U, mU, base := SUnitGroup(1*L:Raw);
> logs := Matrix([Logs(x) : x in Eltseq(base)]);
> mU(U.3)*logs;
(2815256.998090806477937318458440358713392011019115562
    -636746.052519109818325583483504897441603096166734 57
```

```
-770882.44652629342064307574571528191509290934280166)
```

As the logarithm of the absolute value of the real embeddings is of the order 10^6, we expect that a basis representation will have coefficients requiring roughly 10^6 digits. While it is feasible to compute them (using `PowerProduct`), this will take a long time.

`SUnitAction(SU, Act, S)`

`Base` SeqEnum[RngOrdElt] *Default :* []

Given a description of the S-unit group as computed by `SUnitGroup` and a (multiplicative) map of the underlying number field, this function computes the induced map on the abstract abelian group.

The argument S should be a sequence of ideals as in `SUnitGroup`. The argument SU should either be the map returned by `SUnitGroup(S)` as second return value - in which case `Base` is trivial (and not specified) or the second return value of `SUnitGroup(S:Raw)` in which case `Base` should equal the third computed value.

The argument Act must be any (multiplicative) function of the underlying number field or any order, that acts on the S-unit group.

On return, a endomorphism of the domain of SU is obtained.

`SUnitAction(SU, Act, S)`

`Base` SeqEnum[RngOrdElt] *Default :* []

Given a description of the S-unit group as computed by `SUnitGroup` and a sequence of (multiplicative) maps of the underlying number field, this function computes the induced maps on the abstract abelian group.

The argument S should be a sequence of ideals as in `SUnitGroup`. The argument SU should either be the map returned by `SUnitGroup(S)` as second return value - in which case `Base` is trivial (and not specified) or the second return value of `SUnitGroup(S:Raw)` in which case `Base` should equal the third computed value.

The argument Act must be a sequence of (multiplicative) functions of the underlying number field or any order, that acts on the S-unit group.

On return, a sequence of endomorphisms of the domain of SU is obtained.

`SUnitDiscLog(SU, x, S)`

`SUnitDiscLog(SU, L, S)`

`Base` SeqEnum[RngOrdElt] *Default :* []

Given a description of the S-unit group as computed by `SUnitGroup` and a (multiplicative) map of the underlying number field, this function computes the induced map on the abstract abelian group.

The argument S should be a sequence of ideals as in `SUnitGroup`. The argument SU should either be the map returned by `SUnitGroup(S)` as second return value - in which case `Base` is trivial (and not specified) or the second return value of `SUnitGroup(S:Raw)` in which case `Base` should equal the third computed value.

This function solves the discrete logarithm problem for the S-unit group and the algebraic number x. That is, an element in the abstract abelian group representing the S-unit group is computed which corresponds to x. If a list of algebraic numbers L is passed into this function, the discrete logarithm is computed for each of them.

Example H37E31

```
> M := MaximalOrder(Polynomial([ 25, 0, -30, 0, 1 ]));
> S := [ x[1] : x in Factorisation(30*M)];
> U, mU := SUnitGroup(S);
> L := Automorphisms(NumberField(M));
> s2 := SUnitAction(mU, L[2], S);
> s2;
Mapping from: GrpAb: U to GrpAb: U
> L[2](mU(U.2)) eq mU(s2(U.2));
```

Now the same in `Raw` representation:

```
> R, mR, Base := SUnitGroup(S:Raw);
> S2 := SUnitAction(mR, L[2], S:Base := Base);
> [S2(R.i) : i in [1..Ngens(R)]];
[
    R.1,
    R.1 - R.2,
    R.3,
    R.1 + R.3 - R.4,
    R.1 + R.5,
    R.1 + R.3 + R.7,
    R.1 - R.3 + R.6,
    R.8
]
```

If we combine `SUnitAction` with `SUnitDiscLog` we can solve norm equations:

```
> N := map<M -> M | x:-> L[1](x) * L[2](x)>;
> NR := SUnitAction(mR, N, S:Base := Base);
```

Now `NR` is the norm function with respect to the field fixed by `L[2]`.

```
> SUnitDiscLog(mR, FieldOfFractions(M)!5, S:Base := Base);
2*R.5
> $1 in Image(NR);
true
> $2 @@ NR;
R.2 + R.5
> PowerProduct(Base, mR($1));
-3/1*M.1 - 2/1*M.2 + M.4
> N($1);
[5, 0, 0, 0]
```

37.9.10 Quotient Rings

Quotients of orders defined over maximal orders and their integral ideals can be formed resulting in an object with type `RngOrdRes`. Elements of such orders can be created and elementary arithmetic and predicates may be applied to them.

37.9.10.1 Operations on Quotient Rings

The creation of quotient rings and the functions which may be applied to them are described.

`quo< O | I >`

`quo< O | M >`

`quo< O | S >`

Creates the quotient ring $Q = O/I$ of the order O. The right hand side of the constructor may contain an ideal or anything that the ideal constructor can create an ideal from.

`UnitGroup(OQ)`

`MultiplicativeGroup(OQ)`

Returns an abelian group and the map from the group into OQ. OQ must be a quotient of an absolute maximal order.

`Modulus(OQ)`

Return the denominator of the quotient ring OQ, i.e. I where $OQ = O/I$.

Example H37E32

Creation of quotient rings in shown. The orders are the same as for the ideal examples, however an integral ideal is now required.

```
> I := Denominator(I)*I;
> I;
Principal Ideal of O
Generator:
    38/1*M.4*O.3
> Basis(I);
[
    38/1*M.4*O.3,
    19/1*M.4*O.1,
    38/1*M.4*O.2
]
> Q := quo<Order(I) | I>;
> Q;
Quotient Ring of Principal Ideal of O
Generator:
    [[0, 0, 0, 0, 0], [0, 0, 0, 0, 0], [0, 0, 0, 38, 0]]
> Modulus(Q);
```

```
Principal Ideal of O
Generator:
    [[0, 0, 0, 0, 0], [0, 0, 0, 0, 0], [0, 0, 0, 38, 0]]
```

37.9.10.2 Elements of Quotients

Functions for elements of the quotient rings are predominantly arithmetic.

`OQ ! a`

Coerce the element a into the quotient OQ where a is anything that can be coerced into the order OQ is a quotient of.

`a mod I`

A canonical representative of the element a (belonging to an order O) in the quotient ring O/I.

`a * b` `a + b` `a - b` `a / b` `- a` `a ^ n`

`a eq b` `a ne b`

`IsZero(a)`

Returns `true` if and only if the quotient ring element a is the zero element of the quotient ring OQ.

`IsOne(a)`

Returns `true` if and only if the quotient ring element a is the one element of the quotient ring OQ.

`IsMinusOne(a)`

Returns `true` if and only if the quotient ring element a is the minus one element of the quotient ring OQ.

`IsUnit(a)`

Returns `true` if and only if the quotient ring element a has an inverse in the quotient ring OQ.

`Eltseq(a)`

`ElementToSequence(a)`

The coefficients of the quotient ring element a in the field of fractions of the coefficient ring of the order of the quotient ring containing a.

37.9.10.3 Reconstruction

Given an element e in some order O, known modulo some ideal I, a common problem in several algorithms is to recover e, ie. a unique minimal element $f \in O$ such that $e - f \in I$ and f is as "small" as possible. An equally common variation would be to ask for some field element f/d with d an integer, such that $f - de \in I$ and f as well as d are small.

In the case of O being the ring of integers and I a power of a prime (ideal), this is usually done by moving to the symmetric residue system in the first case and by rational reconstruction in the second. Here, we use techniques based on the LLL algorithm as described in [FF00].

Since the method is more complicated than in the case of the integer ring, one first has to create a "reconstruction environment" of type `RngOrdRecoEnv`, which is subsequently used to reconstruct any number of elements.

`ReconstructionEnvironment(p, k)`

`ReconstructionEnvironment(p, k)`

Given a (prime) ideal p and an exponent k, initialize the reconstruction process for the ideal $I = p^k$, that is, the object returned can be used to reconstruct elements from "approximations" modulo p^k.

`Reconstruct(x, R)`

`Reconstruct(x, R)`

`UseDenominator` BoolElt *Default :* `false`

Given an order element e, thought to be an approximation modulo p^k where p and k are stored in the reconstruction environment R, return the unique minimal f in the same order such that $e - g \in p^k$. Is `UseDenominator` is `true`, then a field element is computed, otherwise a ring element will be found.

`ChangePrecision(~ R, k)`

Change the ideal $I = p^l$ stored in R to p^k.

Example H37E33

We illustrate the use of the reconstruction environment to find roots of some polynomial over a number field. We will first compute the roots over some completion, up to some precision, then "list" the elements back from the completion into the starting order and finally use reconstruction to get the roots.

```
> f := Polynomial([1,1,1,1,1]);
> M := MaximalOrder(f);
> P := Decomposition(M, 11)[1][1]; P;
Prime Ideal of M
Two element generators:
    [11, 0, 0, 0]
    [2, 1, 0, 0]
> C, mC := Completion(M, P:Precision :=  10);
```

```
> fC := Polynomial([c@ mC : c in Eltseq(f)]);
> rt := Roots(fC); rt;
> R := ReconstructionEnvironment(P, 10);
> [Reconstruct((x[1]) @@ mC, R) : x in rt];
[
    M.4,
    M.3,
    -M.1 - M.2 - M.3 - M.4,
    M.2
]
> [ Evaluate(f, x) : x in $1];
[
    0,
    0,
    0,
    0
 ]
```

37.10 Places and Divisors

A place of a number field K is a class of absolute values (valuations) that induce the same topology on the field. By a famous theorem of Ostrowski, places of number fields are either finite, in which case they are in a one-to-one correspondence with the on-zero prime ideals of the maximal order, or infinite. The infinite places are identified with the embedding of K into $\mathbf{R}$ or with pairs of embeddings into $\mathbf{C}$.

The group of divisors is formally the free group generated by the finite places and the $\mathbf{R}$-vectorspace generated by the infinite ones.

For more information see Section 34.8.

37.10.1 Creation of Structures

`Places(K)`

`DivisorGroup(K)`

The set of places of the number field K and the group of divisors of K respectively.

37.10.2 Operations on Structures

`d1 eq d2` `p1 eq p2`

`NumberField(P)`

`NumberField(D)`

The number field for which P is the set of places or D is the group of divisors.

37.10.3 Creation of Elements

`Place(I)`

The place corresponding to prime ideal I.

`Decomposition(K, p)`
`Decomposition(K, I)`

A sequence of tuples of places and multiplicities. When a finite prime (integer) p is given, the places and multiplicities correspond to the decomposition of p in the maximal order of K. When the infinite prime is given, a sequence of all infinite places is returned.

`Decomposition(K, p)`

For a number field K and a place p of the coefficient field of K, compute all places (and their multiplicity) that extend p. For finite places this is equivalent to the decomposition of the underlying prime ideal. The sequence returned will contain the places of K extending p and their ramification index.

For an infinite place p, this function will compute all extensions of p in K. In this case, the integer returned in the second component of the tuples will be 1 if p is complex or if p is real and extends to a real place and 2 otherwise.

`Decomposition(m, p)`
`Decomposition(m, p)`

For an extension K/k of number fields (where k can be Q as well), given by the embedding map $m : k \to K$, decompose the place p of k in the larger field. In case $k = Q$, the place is given as either a prime number or zero to indicate the infinite place. The sequence returned contains pairs where the first component is a place above p via m and the second is the ramification index.

`InfinitePlaces(K)`
`InfinitePlaces(O)`

A sequence containing all the infinite places of the number field K or the order O is returned.

`Divisor(pl)`

The divisor $1 * pl$ for a place pl.

`Divisor(I)`

The divisor which is the linear combination of the places corresponding to the factorization of the ideal I and the exponents of that factorization.

`Divisor(x)`

The principal divisor xO where O is the maximal order of the underlying number field of which x is an element. In particular, this computes a finite divisor.

`RealPlaces(K)`

For a number field K all sequence containing all real (infinite) places is computed. For an absolute field this are precisely the embeddings into R coming from the real roots of the defining polynomial.

37.10.4 Arithmetic with Places and Divisors

Divisors and places can be added, negated, subtracted and multiplied and divided by integers.

`d1 + d2` `- d` `d1 - d2` `d * k` `d div k`

37.10.5 Other Functions for Places and Divisors

`Valuation(a, p)`

The valuation of the element a of a number field or order at the place p.

`Valuation(I, p)`

The valuation of the ideal I at the finite place p.

`Support(D)`

The support of the divisor D as a sequence of places and a sequence of the corresponding exponents.

`Ideal(D)`

The ideal corresponding to the finite part of the divisor D.

`Evaluate(x, p)`
`Evaluate(x, p)`
`Evaluate(x, p)`

The evaluation of the number field element x in the residue class field of the place p, ie. for a finite place p this corresponds to the image under the residue class field map for the underlying prime ideal. For infinite places, this returns the corresponding conjugate, ie. a real or complex number.

`RealEmbeddings(a)`
`RealEmbeddings(a)`

The sequence of real embeddings of the algebraic number a is computed, ie. a is evaluated at all real places of the number field.

`RealSigns(a)`

`RealSigns(a)`

A sequence containing ± 1 depending on whether the evaluation of the number field element a at the corresponding real place is positive of negative.

`IsReal(p)`

For an infinite place p, returns `true` if the corresponding embedding is real, ie. if `Evaluate` at p will give real results.

`IsComplex(p)`

For an infinite place p, return `true` if the corresponding embedding is complex, ie. if `Evaluate` at p will generally yield complex results.

`IsFinite(p)`

For a place p of a number fiel, return if the place is finite, ie. if it corresponds to a prime ideal.

`IsInfinite(p)`

For a place p of a number field return if the place is infinite, ie. if it corresponds to an embedding of the number field into the real or complex numbers. If the place is infinite, the index of the embedding it corresponds to is returned as well.

`Extends(P, p)`

For two places P of K and p of k where K is an extension of k, check whether P extends p. For finite places, this is equivalent to checking if the prime ideal corresponding to P dives, in the maximal order of K the prime ideal of p. For infinite places `true` implies that for elements of k, evaluation at P and p will give identical results.

`InertiaDegree(P)`

`Degree(P)`

For a place P of a number field, return the inertia degree of P. That is for a finite place, return the degree of the residue class field over it's prime field, for infinite places it is always 1.

`Degree(D)`

For a divisor D of a number field, the degree is the weighted sum of the degrees of the supporting places, the weights being the multiplicities.

`NumberField(P)`

For a place P or divisor D of a number field, return the underlying number field.

`ResidueClassField(P)`

For a place P of a number field, compute the residue class field of P. For a finite place this will be a finite field, namely the residue class field of the underlying prime ideal. For an infinite place, the residue class field will be the field of real or complex numbers.

`UniformizingElement(P)`

For a finite place P of a number field, return an element of valuation 1. This will be the uniformizing element of the underlying prime ideal as well.

`LocalDegree(P)`

The degree of the completion at the place P, ie. the product of the inertia degree times the ramification index.

`RamificationIndex(P)`

The ramification index of the place P. For infinite real places this is 1 and 2 for complex places.

`DecompositionGroup(P)`

For a place P of a normal number field, return the decomposition group as a subgroup of the (abstract) automorphism group.

38 GALOIS THEORY OF NUMBER FIELDS

Chapter 38
GALOIS THEORY OF NUMBER FIELDS

The Galois theory of number fields deals with the group of automorphisms of a number field, the group of automorphisms of the normal closure of a number field and with the subfields of a given number field. While all three problems are, at least in theory, dealt with easily using the main theorems of Galois theory, they correspond to completely different and independent algorithmic problems.

The first task, that of computing automorphisms of normal extensions of $\mathbf{Q}$ (and of abelian extensions of number fields) can be thought of a special case of factorisation of polynomials over number fields: the automorphisms of a number field are in one-to-one correspondence with the roots of the defining equation in the field. However, the computation follows a different approach and is based on some combinatorial properties. It should be noted, though, that the algorithms only apply to normal fields; i.e., they cannot be used to find non-trivial automorphisms of non-normal fields!

The second task, namely that of computing the Galois group of the normal closure of a number field, is of course closely related to the problem of computing the Galois group of a polynomial. The method implemented in Magma allows the computation of Galois groups of polynomials (and number fields) of arbitrarily high degrees and is independent of the classification of transitive permutation groups. The result of the computation of a Galois group will be a permutation group acting on the roots of the (defining) polynomial, where the roots (or approximations of them) are explicitly computed in some suitable p-adic field; thus the splitting field is not (directly) part of the computation. The explicit action on the roots allows one, for example, to compute algebraic representations of arbitrary subfields of the splitting field, even the splitting field itself, provided the degree is not too large.

The last main task dealt with in this chapter is the computation of subfields of a number field. While of course this can be done using the main theorem of Galois theory (the correspondence between subgroups and subfields), the computation is completely independent; in fact, the computation of subfields is usually the first step in the computation of the Galois group. The algorithm used here is mainly combinatorical.

Finally, this chapter also deals with applications of the Galois theory:

- the computation of subfields and subfield towers of the splitting field
- solvability by radicals: if the Galois group of a polynomial is solvable, the roots of the polynomial can be represented by (iterated) radicals.
- basic Galois-cohomology; i.e., the action of the automorphisms on the ideal class group, the multiplicative group of the field and derived objects.

38.1 Automorphism Groups

Automorphisms of an algebraic field and the group they form can be calculated. Furthermore, field invariants that relate to the automorphism group can be determined.

`Automorphisms(F)`

`Abelian`	BoolElt	*Default :* `false`
Verbose	`AutomorphismGroup`	*Maximum :* 3

Given an algebraic field F, return the automorphisms of F as a sequence of maps. If the extension is known to be abelian, the parameter `Abelian` should be set to `true` in which case a much more efficient algorithm [Klü97, AK99] will be employed. If F is not a normal extension, the automorphisms are obtained by a variation of the polynomial factorisation algorithm.

`AutomorphismGroup(F)`

`Abelian`	BoolElt	*Default :* `false`
Verbose	`AutomorphismGroup`	*Maximum :* 3

Given an algebraic field F, that is either a simple normal extension of $\mathbf{Q}$ or simple abelian extension of $\mathbf{Q}$, return the automorphism group G of K as a permutation group of degree n, where n is the degree of the extension. If the extension is known to be abelian, the parameter `Abelian` should be set to `true` in which case a much more efficient algorithm [Klü97, AK99] will be employed. If F is not a normal extension of $\mathbf{Q}$ an error will occur. In addition to returning G, the function also returns the power structure Aut of all automorphisms of F, and the transfer map ϕ from G into Aut.

Example H38E1

We consider the extension obtained by adjoining a root of the irreducible polynomial $x^4 - 4x^2 + 1$ to $\mathbf{Q}$.

```
> Q := RationalField();
> R<x> := PolynomialRing(Q);
> K<w> := NumberField(x^4 - 4*x^2 + 1);
> A := Automorphisms(K);
> A;
[
    Mapping from: FldNum: K to FldNum: K,
    Mapping from: FldNum: K to FldNum: K,
    Mapping from: FldNum: K to FldNum: K,
    Mapping from: FldNum: K to FldNum: K
]
> for phi in A do phi(w); end for;
w
w^3 - 4*w
-w^3 + 4*w
```

```
-w
```

Taking the same field K we use instead the function `AutomorphismGroup`:

```
> G, Aut, tau := AutomorphismGroup(K);
> for x in G do tau(x)(w); end for;
w
w^3 - 4*w
-w^3 + 4*w
-w
```

`AutomorphismGroup(K, F)`

Computes the group of K automorphisms of F as a permutation group together with a list of all automorphisms and a map between the permutation group and explicit automorphisms of the field.

This function computes the automorphism group of F over $\mathbf{Q}$ first.

`DecompositionGroup(p)`

For an ideal p of the maximal order of some absolute normal field F with group of automorphisms G, compute the decomposition group, i.e. the subgroup U of the automorphism group such that:

$$U := \{s \in G | s(p) = p\}$$

If F is not a normal extension of $\mathbf{Q}$ an error will occur.

`RamificationGroup(p, i)`

For an ideal p of the maximal order M of some absolute normal field F with group of automorphisms G, compute the i-th ramification group, i.e. the subgroup U of the automorphism group such that:

$$U := \{s \in G | s(x) - x \in p^{i+1} \text{for all } x \text{ in } M\}$$

If F is not a normal extension of $\mathbf{Q}$ an error will occur.

`RamificationGroup(p)`

This is just an abbreviation for `RamificationGroup(p, 1)`.

`InertiaGroup(p)`

This is just an abbreviation for `RamificationGroup(p, 0)`.

`FixedField(K, U)`

Given a normal field K over $\mathbf{Q}$ and a subgroup U of the `AutomorphismGroup(K)`, compute the subfield L that is fixed by U.

This function is inverse to `FixedGroup`.

If K is not a normal extension of $\mathbf{Q}$ an error will occur.

`FixedField(K, S)`

For an algebraic field K and a list S of automorphism of K, compute the maximal subfield of K fixed by S.

`FixedGroup(K, L)`

Given a normal field K over $\mathbf{Q}$ and a subfield L, compute the subgroup U of the `AutomorphismGroup(K)` that fixes L.

This function is inverse to `FixedField`.

If K is not a normal extension of $\mathbf{Q}$ an error will occur.

`FixedGroup(K, L)`

Given a normal field K over $\mathbf{Q}$ and a sequence of number field elements L, compute the subgroup U of the `AutomorphismGroup(K)` that fixes L.

If K is not a normal extension of $\mathbf{Q}$ an error will occur.

`FixedGroup(K, a)`

Given a normal field K over $\mathbf{Q}$ and a number field element a, compute the subgroup U of the `AutomorphismGroup(K)` that fixes a.

This function is inverse to `FixedField`.

If K is not a normal extension of $\mathbf{Q}$ an error will occur.

`DecompositionField(p)`

This is an abbreviation for `FixedField(K, DecompositionGroup(p))` where K is the number field of the order of p.

`RamificationField(p, i)`

This is an abbreviation for `FixedField(K, RamificationGroup(p, i))` where K is the number field of the order of p.

`RamificationField(p)`

This is an abbreviation for `FixedField(K, RamificationGroup(p))` where K is the number field of the order of p.

`InertiaField(p)`

This is an abbreviation for `FixedField(K, InertiaField(p))` where K is the number field of the order of p.

Example H38E2

We will demonstrate the various groups and fields. In order to do so, we first construct a non-trivial normal field.

```
> o := MaximalOrder(ext<Rationals()|>.1^4-3);
> os := MaximalOrder(SplittingField(NumberField(o)));
> P := Decomposition(os, 2)[1][1];
> G, M := RayClassGroup(P^3);
> G;
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*G.1 = 0
```

Since G is cyclic and the module P invariant under the automorphisms of os, the class field corresponding to G will be normal over Q. It Galois group over Q will be an extension of D_4 by C_2.

```
> A := AbelianExtension(M);
> O := MaximalOrder(EquationOrder(A));
> Oa := AbsoluteOrder(O);
> Ka := NumberField(Oa);
> Gal, _, Map := AutomorphismGroup(Ka);
> Gal;
Permutation group Gal acting on a set of cardinality 16
Order = 16 = 2^4
    (1, 2, 7, 5)(3, 8, 6, 10)(4, 12, 14, 9)(11, 16, 13, 15)
    (1, 3, 7, 6)(2, 8, 5, 10)(4, 13, 14, 11)(9, 16, 12, 15)
    (1, 4)(2, 9)(3, 11)(5, 12)(6, 13)(7, 14)(8, 15)(10, 16)
```

Now, let us pick some ideals. The only interesting primes are the primes dividing the discriminant, which in this case will be the primes over 2 and 3.

```
> P2 := Decomposition(Oa, 2)[1][1];
> P3 := Decomposition(Oa, 3)[1][1];
```

First, the valuation of the different of Oa at $P2$ should be $\sum_{i=0}^{\infty}(\#G(P2,i)-1)$ where $G(P2,i)$ is the i-th ramification group.

```
> s := 0; i := 0;
> repeat
>   G := RamificationGroup(P2, i);
>   s +:= #G-1;
>   print i, "-th ramification group is of order ", #G;
>   i +:= 1;
> until #G eq 1;
0 -th ramification group is of order  8
1 -th ramification group is of order  8
2 -th ramification group is of order  2
3 -th ramification group is of order  2
```

```
4 -th ramification group is of order  2
5 -th ramification group is of order  2
6 -th ramification group is of order  1
> s;
18
> Valuation(Different(Oa), P2);
18
```

According to the theory, $P2$ should be totally ramified over the inertia field and unramified over Q:

```
> K2 := InertiaField(P2);
> M2 := MaximalOrder(K2);
> K2r := RelativeField(K2, Ka);
> M2r := MaximalOrder(K2r);
> p2 := M2 meet (MaximalOrder(K2r)!!P2);
> IsInert(p2);
true
> IsTotallyRamified(M2r!!P2);
true
```

Now we try the same for $P3$. Since 3 is split in Ka, we may consider an additional field: the decomposition field. It should be the maximal subfield if K such that 3 is neither inert ($f = 1$) nor ramified ($e = 1$), therefore 3 has to split totally.

```
> D3 := DecompositionField(P3);
> D3M := MaximalOrder(D3);
> IsTotallySplit(3, D3M);
true
```

The inertia field is the maximal subfield such that 3 is unramified. It has to be an extension of $D3$.

```
> I3 := InertiaField(P3);
> I3;
Number Field with defining polynomial $.1^4 +
    80346384509631057182412*$.1^3 +

82869371250900344499670337698224 64
```

This (polynomial) discriminant is huge, in fact it is so large that we should avoid the factorisation. We already know the discriminant of Ka. The discriminant of $I3$ has to be a divisor - so we can

use the `Discriminant` parameter to `MaximalOrder`: (We are going to need the `MaximalOrder` for the following embedding.)

```
> I3M := MaximalOrder(EquationOrder(I3):
> Discriminant := Discriminant(Oa));
> I3M := MaximalOrder(I3);
```

$D3$ should be a subfield of $I3$, so lets verify it:

```
> IsSubfield(D3, I3);
true Mapping from: FldNum: D3 to FldNum: I3
```

As a side-effect, MAGMA is now aware of the embedding and will use it. Without the `IsSubfield` call, the `RelativeField` function will fail.

```
> I3r := RelativeField(D3, I3);
> I3rM := MaximalOrder(I3r);
> K3r := RelativeField(D3, Ka);
> K3rM := MaximalOrder(K3r);
> IsInert(K3rM!!P3 meet D3M, I3rM);
true
```

The last step: verify that $P3$ is totally ramified over $I3$:

```
> K3r := RelativeField(I3, Ka);
> K3rM := MaximalOrder(K3r);
> IsTotallyRamified(K3rM!!P3 meet I3M, K3rM);
true
```

Using the decomposition group, we can get the splitting behaviour of any prime in any subfield of Ka.

```
> L := SubgroupLattice(Gal);
> [ IsNormal(Gal, L[x]) : x in [1..#L]];
[ true, true, true, true, false, false, false, false, true,
true, true, true, true, true, true, false, false, false,
false, true, true, true, true, true, true, true, true ]
> U := L[5];
> k := FixedField(Ka, U);
> kM := MaximalOrder(EquationOrder(k):
>   Discriminant := Discriminant(Oa));
> kM := MaximalOrder(k);
> Kr := RelativeField(k, Ka);
> KrM := MaximalOrder(Kr);
> P43 := Decomposition(Oa, 43)[1][1];
> V := DecompositionGroup(P43);
```

The splitting behaviour is determined by the double coset decomposition of Gal with respect to U and V:

```
> f, I := CosetAction(Gal, U);
> orbs := Orbits(f(V));
> reps := [];
```

```
> for o in orbs do
>   _, x := IsConjugate(I, 1, Rep(o));
>   Append(~reps, x @@ f);
> end for;
> reps;
[
    Id(G),
    (1, 2, 7, 5)(3, 8, 6, 10)(4, 12, 14, 9)(11, 16, 13, 15),
    (1, 7)(2, 5)(3, 6)(4, 14)(8, 10)(9, 12)(11, 13)(15, 16),
    (1, 8)(2, 6)(3, 5)(4, 15)(7, 10)(9, 13)(11, 12)(14, 16),
]
> #reps;
4
```

So there will be at least 4 prime ideals over 43 in k:

```
> L := [ ];
> for i in reps do
>   Append(~L, kM meet KrM !! Map(i)(P43));
> end for;
> [ IsPrime(x) : x in L];
[ true, true, true, true ]
> LL := Decomposition(kM, 43);#LL;
4
> [ Position(L, x[1]) : x in LL];
[ 4, 3, 1, 2 ]
```

`FrobeniusElement(K, p)`

Compute a Frobenius element at p in the Galois group of the Galois closure of K. This is a permutation on the roots of a polynomial defining K, which can be recovered as `DefiningPolynomial(A)` for any Artin representation A of K; the Frobenius element is well-defined up to conjugacy and modulo inertia.

Example H38E3

We take a polynomial whose Galois group is D_5 and compute Frobenius elements at $p = 2$ and $p = 5$. They in two different conjugacy classes of 5-cycles in the Galois group.

```
> load galpols;
> f:=PolynomialWithGaloisGroup(5,2);
> assert IsIsomorphic(GaloisGroup(f),DihedralGroup(5));
> K:=NumberField(f);
> FrobeniusElement(K,2);
(1, 5, 4, 3, 2)
> FrobeniusElement(K,5);
(1, 3, 5, 2, 4)
```

38.2 Galois Groups

Finding Galois groups (of normal closures) of algebraic fields is a hard problem, in general. All practical currently-used algorithms fall into two groups: The absolute resolvent method [SM85] and the method of Stauduhar [Sta73].

The MAGMA implementation is based on an extension of the method of Stauduhar [GK00, Gei03] and recent work by Klüners and Fieker [FK12].

For polynomials over $\mathbf{Z}, \mathbf{Q}$, number fields and global function fields and irreducible polynomials over function fields over $\mathbf{Q}$, MAGMA is able to compute the Galois group without any a-priori restrictions on the degree. Note, however, that the running time and memory constraints can make computations in degree > 50 impossible, although computations in degree > 200 have been successful as well. In contrast to the absolute resolvent method, it also provides the explicit action on the roots of the polynomial f which generates the algebraic field. On demand, the older version which is restricted to a maximum degree of 23, is still available.

Roughly speaking, the method of Stauduhar traverses the subgroup lattice of transitive permutation groups of degree n from the symmetric group to the actual Galois group. This is done by using so-called relative resolvents. Resolvents are polynomials whose splitting fields are subfields of the splitting field of the given polynomial which are computed using approximations of the roots of the polynomial f.

If the field (or the field defined by a polynomial) has subfields (i.e. the Galois group is imprimitive) the current implementation changes the starting point of the algorithm in the subgroup lattice, to get as close as possible to the actual Galois group. This is done via computation of subfields of a stem field of f, that is the field extension of $\mathbf{Q}$ which we get by adjoining a root of f to $\mathbf{Q}$. Using this knowledge of the subfields, the Galois group is found as a subgroup of the intersection of suitable wreath products which may be easily computed. This intersection is a good starting point for the algorithm.

If the field (or the field defined by a polynomial) does not have subfields (i.e. the Galois group is primitive) we use a combination of the method of Stauduhar and the absolute resolvent method. The Frobenius automorphism of the underlying p-adic field or the complex conjugation, when using complex approximations of the roots of the polynomial f, already determines a subgroup of the Galois group, which is used to speed up computations in the primitive case.

`GaloisGroup(f)`

`Prime`	RngElt	*Default :*
`ShortOK`	BoolElt	*Default :* `false`
`Ring`	GaloisData	*Default :*
`NextPrime`	UserProgram	*Default :*
Verbose	`GaloisGroup`	*Maximum :* 5
Verbose	`Invariant`	*Maximum :* 3

Given a polynomial f over the integers, rationals, a number field or an order thereof, compute the Galois group of a splitting field for f, ie. determine the subgroup

of the permutations of the roots of f in a splitting field that correspond to field automorphisms. The method applied here is a variant of Stauduhar's algorithm, but with no dependency on the explicit classification of transitive groups and thus no a-priori degree limitation. It must be stated though that this function does not return proven results, if such results are necessary, one needs to call `GaloisProof` afterwards.

The prime to use for splitting field computations can be given via the parameter `Prime`. The method of choosing of primes for splitting field computations can be given by the parameter `NextPrime`.

`GaloisGroup(K)`

`Prime`	RngElt	*Default :*
`ShortOK`	BoolElt	*Default :* `false`
`Ring`	GaloisData	*Default :*
`NextPrime`	UserProgram	*Default :*
`Current`	BoolElt	*Default :* `false`
`Subfields`	BoolElt	*Default :* `true`
`Old`	BoolElt	*Default :* `false`
`Type`	MonStgElt	*Default :* "p-Adic"
`Prec`	RngIntElt	*Default :* 20
`Time`	Rec	*Default :*
Verbose	`GaloisGroup`	*Maximum :* 5
Verbose	`Invariant`	*Maximum :* 3

Given a number field K, compute the Galois group of a normal closure of K. The group is returned as an abstract permutation group acting on the roots of the defining polynomial of k in a suitable splitting field. The method applied here is a variant of Stauduhar's algorithm, but with no dependency on the explicit classification of transitive groups and thus no a-priori degree limitation. It must be stated though that this function does not return proven results, if such results are necessary, one needs to call `GaloisProof` afterwards.

The prime to use for splitting field computations can be given via the parameter `Prime`. The method of choosing of primes for splitting field computations can be given by the parameter `NextPrime`.

`GaloisProof(f, S)`

`GaloisProof(K, S)`

Given the result of a (conditional) computation by `GaloisGroup` for either an irreducible polynomial over the integers or an absolute number field, try to find proofs for the conditional steps of the algorithm. The method employed here is to show that a suitable absolute resolvent polynomial has a factor of a specific degree that can be used to differentiate between the possible groups.

`GaloisRoot(f, i, S)`

`Prec`	RngIntElt	*Default :* 20
`Bound`	RngIntElt	*Default :* 0

Given a polynomial f and the result S of a computation of its Galois group, return the ith root in the ordering obtained form the Galois process to the given precision. The precision can be specified either directly by setting `Prec` to the desired p-adic precision or by giving a bound B in `Bound`. In the latter case the p-adic precision k will be calculated such that $p^k > B$.

`GaloisRoot(i, S)`

Given the result S of a computation of a Galois group and an integer i, compute the ith conjugate of the primitive element used during the computation. The precision can be specified either directly by setting `Prec` to the desired p-adic precision or by giving a bound B in `Bound`. In the latter case the p-adic precision k will be calculated such that $p^k > B$.

`Stauduhar(G, H, S, B)`

Verbose	`GaloisGroup`	*Maximum :* 5
Verbose	`Invariant`	*Maximum :* 3
`AlwaysTransform`	BoolElt	*Default :* `false`
`Coset`	SeqEnum	*Default :*
`PreCompInvar`	UserProgram	*Default :*

This function gives access to a single step of the Stauduhar method: Let G be a permutation group known to contain the Galois group of the object under investigation with the numbering of the "roots" determined by S. Furthermore, let B be a bound on the absolute value of the complex roots of the object and H be a (maximal) subgroup of G. Under these circumstances, the intrinsic will decide if there is some $g \in G$ such that the Galois group is contained in H^g. The primary return value can be:

1 if the Galois group is proven to be a subgroup of H^g up to precision problems, indicated by the 3rd value

-1 if there is a proof that the Galois group is contained in a proper subgroup of G and maybe in H^g

-2 if the Galois group may be in H^g, but we could not prove that it is in a proper subgroup of G

0 the Galois group is not contained in a conjugate of H.

In case of a non-zero result, the second return value will be the element g conjugating H, the third value will be `true` or `false`, depending on whether the p-adic bound used were proven or heuristic and the fourth value is the invariant used to separate the groups.

The optional parameter `Coset` can be used to pass a transversal of G/H in, while `PreCompInvar` should contain a suitable invariant separating G and H if set.

`IsInt(x, B, S)`

Given an element x in the splitting field determined by S and a bound B on the complex absolute value, determine if there exists an element $y \in \mathbf{Z}$ or an extension of $\mathbf{Z}$ defined by the polynomial the Galois group is being computed for, such that $y = x$ up the precision of x and such that $|y| < B$. In case such a y exists, it is returned as a second return value.

Example H38E4

A Galois group computation is shown below.

```
> Z:= Integers();
> P<x>:= PolynomialRing(Z);
> G, R, S := GaloisGroup(x^6-108);
> G;
Permutation group G acting on a set of cardinality 6
Order = 6 = 2 * 3
    (1, 5, 3)(2, 6, 4)
    (1, 2)(3, 6)(4, 5)
> R;
[ -58648*$.1 + 53139 + O(11^5), 58648*$.1 - 19478 +
O(11^5), -43755*$.1 - 72617 + O(11^5), 58648*$.1 -
    53139 + O(11^5), -58648*$.1 + 19478 + O(11^5),
    43755*$.1 + 72617 + O(11^5) ]
> S;
GaloisData over Z_11
> time G, _, S := GaloisGroup(x^32-x^16+2);
Time: 65.760
> #G;
2048
```

Some examples for the relative case

```
> load galpols;
> f := PolynomialWithGaloisGroup(9, 14);
> G := GaloisGroup(f);
> TransitiveGroupIdentification(G);
14 9
> M := MaximalOrder(f);
> kM := FieldOfFractions(M);
> f:= Factorisation(Polynomial(kM, f))[2][1];
> f;
$.1^8 + (-2/1*kM.1 + kM.2)*$.1^7 + (-60/1*kM.1 -
    2/1*kM.2 + kM.3)*$.1^6 + (120/1*kM.1 - 60/1*kM.2 -
    2/1*kM.3 + kM.4)*$.1^5 + (980/1*kM.1 + 120/1*kM.2 -
    60/1*kM.3 - 2/1*kM.4 + kM.5)*$.1^4 + (-1808/1*kM.1
    + 980/1*kM.2 + 120/1*kM.3 - 60/1*kM.4 - 2/1*kM.5 +
    kM.6)*$.1^3 + (-4012/1*kM.1 - 1808/1*kM.2 +
    980/1*kM.3 + 120/1*kM.4 - 60/1*kM.5 - 2/1*kM.6 +
```

```
    kM.7)*$.1^2 + (4936/1*kM.1 - 4013/1*kM.2 -
    1809/1*kM.3 + 979/1*kM.4 + 118/1*kM.5 - 60/1*kM.6 -
    4/1*kM.7 + 3/1*kM.8)*$.1 - 208769062021/1*kM.1 +
    51146604497/1*kM.2 - 30878218588/1*kM.3 +
    50063809507/1*kM.4 - 52067647419/1*kM.5 -
    94281823910/1*kM.6 + 69906801827/1*kM.7 -
    182364865509/1*kM.8 + 214706745867/1*kM.9
> g, r, p:= GaloisGroup(f);
> TransitiveGroupIdentification(g);
5 8
```

Since g is derived from a factor of the original f, the Galois group should be isomorphic to a subgroup of G:

```
> Subgroups(G:OrderEqual := #g);
Conjugacy classes of subgroups
------------------------------
[1]     Order 8            Length 9
        Permutation group acting on a set of
        cardinality 9
        Order = 8 = 2^3
            (2, 4, 5, 3)(6, 8, 7, 9)
            (2, 7, 5, 6)(3, 9, 4, 8)
            (2, 5)(3, 4)(6, 7)(8, 9)
> IsIsomorphic(g, $1[1]`subgroup);
true Homomorphism of GrpPerm: g, Degree 8, Order 2^3
into GrpPerm: $, Degree 9, Order 2^3 induced by
    (1, 2, 3, 8)(4, 5, 6, 7) |--> (2, 4, 5, 3)(6, 8, 7, 9)
    (1, 7, 3, 5)(2, 6, 8, 4) |--> (2, 7, 5, 6)(3, 9, 4, 8)
```

38.2.1 Straight-line Polynomials

One of the most important tools in the computational Galois theory are invariants, that is multivariate polynomials that are invariant under some permutation group. While invariant theory in general is a rich and classical branch of mathematics, and is supported by a powerful magma module, Chapter 110, the more specific needs in the Galois theory are best met with a different set of functions. Invariants, in this chapter are multivariate polynomials in straight-line representation, the polynomials are represented as programs without branches. The category of this polynomials is of type `RngSLPol` and its elements are of type `RngSLPolElt`. A consequence of this representation is that certain operations are very fast, while others are impossible - or at least very difficult. For example, representing $(a-b)^{1000}(a+b)^{1000} - (a^2-b^2)^{1000}$ is trivial, this is a short program with just a few steps:

1 subtract b from a

2 raise to the 1000th power

3 add a and b

4 raise to the 1000th power

5 multiply the results of steps 2 and 4

6 subtract b^2 from a^2 and raise to the 1000th power

7 subtract the result of step 7 from 5

Now, while it is trivial to evaluate this polynomial at, for example, any pair of elements in any finite ring, it is very difficult to see that, in fact, the polynomial is identical to zero – when expanded as a polynomial.

`SLPolynomialRing(R, n)`

`Global` BoolElt *Default :* `false`

Creates the ring of multivariate straight-line polynomials over the ring R with n indeterminates.

`Name(R, i)`

`R . i`

Return the ith indeterminate of the SL-polynomial ring R.

`BaseRing(R)`

`CoefficientRing(R)`

Return the coefficient ring of R.

`Rank(R)`

Return the rank of the SL-polynomial ring, ie the number of independent indeterminates over the coefficient ring.

`SetEvaluationComparison(R, F, n)`

For a SL-polynomial ring R, prepare "probabilistic" comparison of straight-line polynomials, using evaluation at n tuples drawn at random from the finite field F.

In order to allow a probabilistic test for "equality" of SL-polynomials in places where a strict, deterministic test is not necessary, this allows to compare SL-polynomials through their values at random evaluation points.

`GetEvaluationComparison(R)`

Return the finite field and the number of random samples used to compare polynomials. If `SetEvaluationComparison` has not been called, the 1st return value will be `false` while the second is undefined.

`x * y` `x + y` `x - y` `- x`

`Derivative(x, i)`

The ith partial derivative of the SL-polynomial x.

38.2.2 Invariants

At the core of the computation of Galois groups is the single Stauduhar step where, for a group G and a (maximal) subgroup U the programme decides if the Galois group is a subgroup of U - provided it was contained in G. This is achieved by evaluating a G-relative U-invariant polynomial $f \in \mathbf{Z}[x_1, \ldots, x_n]$ (or $f \in \mathbf{F}_q[t][x_1, \ldots, x_n]$ when the characteristic of the coefficient ring of the input polynomial is prime). In this subsection several functions are collected that allow a user to access MAGMA's internally used invariants. In what follows, an invariant is always a multivariate polynomial f in n indeterminates where n is the degree of G i.e. $G < S_n$. Invariants are represented as straight-line polynomials that allow the very compact representation and fast evaluation of polynomials.

`GaloisGroupInvariant(G, H)`

`DoCost`	BOOLELT	*Default :* `false`
`Worklevel`	RNGINTELT	*Default :* -1
Verbose	`GaloisGroup`	*Maximum :* 3

For subgroups $H < G$ of the symmetric group on n elements, where H is maximal in G and G is transitive, compute a G-relative H-invariant. This is done by carefully comparing certain group theoretical properties of the group pair in question to find invariant polynomials of special types that are easy to evaluate. If this fails, generic invariants will be used.

If `DoCost` is `true`, two values are returned: the first return value in this case is an estimate for the number of multiplications necessary to evaluate the invariant, while the second value is a function that can be evaluated without arguments to compute the invariant. This is done to allow to compare invariants by their computational complexity before actually committing and computing them explicitly as this can be very time consuming.

If `Worklevel` is set to an integer different from -1 only certain types of invariants are tested for suitability for this particular pair of groups. In this case a special return value of `false` indicates that MAGMA was unable to find an invariant at this level. Roughly speaking, the higher the `Worklevel`, the more time-consuming the invariant will be, both in terms of the time spend in finding as well as the time necessary to evaluate the invariant.

`RelativeInvariant(G, H)`

`IsMaximal`	BOOLELT	*Default :* `false`
`Risk`	BOOLELT	*Default :* `false`
Verbose	`Invariant`	*Maximum :* 3

For a pair of subgroups $H < G$ of the symmetric group where H is not necessarily maximal in G, find a G-relative H-invariant polynomial. The computation splits into three phases:

- First, a subgroup chain between H and G is computed such that each step in the chain is a maximal subgroup.

- Second, for each pair $U_i < U_{i+1}$ of maximal subgroups one fixed invariant is computed
- Third, in the last step, the invariants are combined to produce a G-relative H-invariant.

If `IsMaximal` is set to `true`, MAGMA will not compute a subgroup chain but instead assume that H is a maximal subgroup of G. If `Risk` is `true`, then MAGMA will use `GaloisGroupInvariant` to compute invariants on each level. By default, MAGMA will use generic invariants (ie. orbit sums of monomials) on each level. The problem with using special invariants as produced by `GaloisGroupInvariant` is that in the third step we can no longer guarantee that the invariant returned will be a true G-relative H-invariant as the G-stabilizer might be too large. On the other hand, the special invariants are much faster to evaluate and will give the desired result almost always.

`CombineInvariants(G, H1, H2, H3)`

Given a subgroup $G < S_n$ and three maximal subgroups H_1, H_2 and H_3 of G two of which have already known invariants, try to derive an invariant for H_3 from the known ones. The input for H_1 and H_2 consists of a tuple with two (or three) entries, the first specifying the actual subgroupm the second the G-relative H_i-invariant and the optional third a Tschirnhaus transformation that should be done before the invariant is evaluated.

They typical situation in which this function is used is the case of H_1 and H_2 being index 2 subgroups of G. In this case elementary theory immediately guarantees a third subgroup H_3 of index 2. For this function to work, the core of $H_1 \cap H_2$ must be contained in H_3. This is only useful if the index of the core is not too large.

`IsInvariant(F, p)`

`Sign` BOOLELT *Default :* `false`

For a multivariate polynomial F in straight-line representation and a permutation p this functions test if $F^p eq F$ with a high probability. In particular, this function will evaluate F at random elements in some large finite field, then permute the evaluation points by p and evaluate again. If the values agree, the polynomial is most likely invariant under p, if they disagree than the polynomial is definitely not invariant. The probability of failure is related to the probability of guessing a zero of a multivariate polynomial at random.

In order to get a proof for the invariants, one can convert F into a standard multivariate polynomial and check directly that this is invariant. However, for the invariants typically constructed in the Galois package, the conversion into a multivariate polynomial will not be possible due to the large degree of the polynomial and the resulting large number of terms.

If `Sign` is set to `true`, the function checks instead for $F^p = -F$.

`Bound(I, B)`

Given a multivariate polynomial I in straight-line representation and an integer B, compute an integer M such that

$$|I(x_1, \ldots, x_n)| \leq M$$

for all complex numbers $|x_i| \leq B$, it it returns a bound for the size of an evaluation of I.

`Bound(I, B)`

Given a multivariate polynomial I in straight-line representation and B, a power series over the integers, compute a power series M such that for all choices of power series x_i such that the coefficients of x_i are bounded in absolute value by those of B we have that the power series

$$I(x_1, \ldots, x_n)$$

has coefficients bounded by those of M.

38.2.3 Subfields and Subfield Towers

The result of a Galois group computation contains, in addition to the Galois group as an abstract group, the explicit action of the group on the roots of the underlying polynomial in some splitting field. This explicit action, together with the availability of invariants for group pairs, can be used to compute arbitrary subfields of the splitting field.

`GaloisSubgroup(K, U)`

`GaloisSubgroup(S, U)`

`GaloisSubgroup(f, U)`

Verbose `Invariant` *Maximum :* 2

Given either a polynomial f or number field K or a successful computation of a Galois group in S and a subgroup $U < G$ where G is the Galois group, find a defining polynomial for the subfield of the splitting field that is fixed by U.

`GaloisQuotient(K, Q)`

`GaloisQuotient(f, Q)`

`GaloisQuotient(S, Q)`

Verbose `Invariant` *Maximum :* 2

Given either a polynomial f or number field K or a successful computation of a Galois group in S and a permutation group Q, find all subfields of the splitting field that have a Galois group isomorphic to Q. This is done by finding all subgroups U of the Galois group G such that the permutation action of G on the cosets G/U is isomorphic to Q.

`GaloisSubfieldTower(S, L)`

`Risk`	BoolElt	*Default :* `false`
`MinBound`	RngIntElt	*Default :* 1
`MaxBound`	RngIntElt	*Default :* ∞
`Inv`	[RngSLPolElt]	*Default :* `false`
Verbose	`GaloisTower`	*Maximum :* 2

For data computed as the third return value of `GaloisGroup` and a subgroup chain $U_1 > U_2 > \ldots > U_s$, compute the corresponding tower of fixed fields K_i that is fixed by the operation of U_i on the roots of f as ordered in S.

Currently, this function only works for polynomials defined over $\mathbf{Q}$ or absolute extensions of $\mathbf{Q}$.

The first return value is the largest number field in the tower, that is the field fixed by the smallest group in the chain as an extension of the fixed field of the second group ..... The second return value is a sequence of tuples each containing the data used to generate one step:

- The first item is the invariant used in this step. This corresponds directly to the choice of the primitive element.
- The second item is the Tschirnhaus transformation on this level
- The third item is a transversal of U_i over U_{i+1}, the fixed ordering of which gives the ordering of the "relative conjugates"

The third and fourth return values can be used to algebraically identify arbitrary elements of the splitting field that are defined by multivariate polynomials. The third is a function that takes a vector of p-adic conjugates and returns an algebraic representation of the element, the fourth takes an invariant and computes precision bounds for the precision necessary so that the algebraic recognition will work.

If `Risk` is set to `true`, then for non-maximal subgroup pairs $U_i > U_{i+1}$ the "risky" version of `RelativeInvariant` is used.

The parameter `MinBound` can be used to specify a minimal p-adic precision that should be used internally. This can be used to avoid the calculation of an increase in precision which can be costly. On the other hand, to work in larger precision than necessary also incurs a time penalty.

The parameter `MaxBound` can be used to limit the p-adic precision used internally. Especially when the chain get longer, the internally used precision estimates become more and more pessimistic thus forcing higher and higher precision. In certain cases when it is possible to verify the correctness of the result independently, a smaller precision can speed the computation up considerably.

If the parameter `Inv` is given it should contain a sequence of invariants, the i-th entry need be an U_i relative U_{i+1} invariant. The invariants used correspond almost directly to the relative primitive elements computed at each step in the tower. This is useful in situation where either certain primitive elements are necessary or where certain invariants are known.

`GaloisSplittingField(f)`

`Galois`	TUP<GRPPERM, [RNGELT], GALOISDATA>	
`Roots`	BOOLELT	*Default :* `true`
`AllAuto`	BOOLELT	*Default :* `false`
`Stab`	BOOLELT	*Default :* `true`
`Chain`	[GRPPERM]	*Default :* `false`
`Inv`	[RNGSLPOLELT]	*Default :* `false`
`Name`	MONSTGELT	*Default :* `false`

For a polynomial f in $\mathbf{Z}[t]$, $\mathbf{Q}[t]$ or over an absolute number field this function computes the splitting field of f as a tower of fields. The various parameter can be used to force certain subfield towers and/ or compute additional data. By default `Stab` is set to `true`, which means that the splitting field will be the tower corresponding to the chain of stabilizers of $\{1\}$, $\{1,2\}$, ..., $\{1,\ldots,n\}$. Also by default `Roots` is set to `true`, which means that the roots of f are expressed as elements of the splitting field. If `Roots` is set to `false`, only the field is computed and returned.

The third return value will be the Galois group, the optional fourth value the automorphisms.

If the parameter `Galois` is used, it should contain a list or triplet containing the output of `GaloisGroup(f);`.

If `Chain` is set to a sequence of subgroups, this chain is used to compute a subfield tower. In this case the first elements must be G, the full Galois group. If `Chain` is used, `Inv` can be used to provide the invariants as well.

If `AllAuto` is set to `true`, the full automorphism group of the splitting field is computed as a sequence of sequences giving the all the roots of the relative polynomials.

If `Name` is given, it should be set to a string. In this case the primitive element of the i-subfield in the tower will be called `Name.i`.

Example H38E5

We start with a small example, to illustrate some of the parameters and their influence:

```
> P<x> := PolynomialRing(IntegerRing());
> f := x^3-2;
> GaloisSplittingField(f);
Number Field with defining polynomial $.1^2 +
    $.1*$.1 + $.1^2 over its ground field
[
    $.1,
    $.1,
    -$.1 - $.1
]
Symmetric group acting on a set of cardinality 3
Order = 6 = 2 * 3
```

```
    (1, 2, 3)
    (1, 2)
> K, R, G := $1;
> K:Maximal;
  K
  |
  |
  $1
  |
  |
  Q
K  : $.1^2 + $.1*$.1 + $.1^2
$1 : x^3 - 2
> [x^3 : x in R];
[
    2,
    2,
    2
]
```

The fact that by default all generators are called `$.1` makes this hard to read, so let us assign other names:

```
> GaloisSplittingField(f:Name := "K");
Number Field with defining polynomial K1^2 + K2*K1
    + K2^2 over its ground field
[
    K2,
    K1,
    -K1 - K2
]
Symmetric group G acting on a set of cardinality 3
Order = 6 = 2 * 3
    (1, 2, 3)
    (1, 2)
> (K where K := $1):Maximal;
  $1<K1>
    |
    |
  $2<K2>
    |
    |
    Q
$1 : K1^2 + K2*K1 + K2^2
$2 : x^3 - 2
```

So now we can easily see that the splitting field is a relative quadratic extension of the degree 3 stem field. Now we try a different subgroup chain:

```
> G, r, S := GaloisGroup(f);
```

```
> GaloisSplittingField(f:Galois := <G, r, S>,
>     Chain := CompositionSeries(G), Name := "K", AllAuto);
Number Field with defining polynomial K1^3 - 2
over its ground field
[
    K1,
    1/6*K2*K1,
    1/6*(-K2 - 6)*K1
]
Symmetric group G acting on a set of cardinality 3
Order = 6 = 2 * 3
    (1, 2, 3)
    (1, 2)
[
    [
        K2,
        -K2 - 6
    ],
    [
        K1,
        1/6*K2*K1,
        1/6*(-K2 - 6)*K1
    ]
]
> (K where K := $1):Maximal;
  $1<K1>
    |
    |
  $2<K2>
    |
    |
    Q
$1 : K1^3 - 2
$2 : x^2 + 6*x + 36

> f := x^10 - 20*x^8 + 149*x^6 - 519*x^4 + 851*x^2 - 529;
> G, r, S := GaloisGroup(f);G,r,S;
> TransitiveGroupIdentification(G);
8 10
> TransitiveGroupDescription(G);
[2^4]5
```

Thus the Galois group of f is isomorphic to ${}_{10}T_8$ of type `[2^4]5` and order 80.
We first compute the splitting field directly:

```
>  time _ := SplittingField(f);
```

This takes a long time, mainly because of the type of the Galois group which will require a field tower involving 5 steps and factorisation of a polynomial in such a tower. Now, we try the same

by using the Galois information:

```
> time K, R := GaloisSplittingField(f:Name := "K");
Time: 4.740
> K:Maximal;
  K<K1>
    |
    |
  $1<K2>
    |
    |
  $2<K3>
    |
    |
  $3<K4>
    |
    |
    Q
K  : K1^2 + 1/23*(-12*K4^8 + 217*K4^6 - 1374*K4^4
    + 3606*K4^2 - 3381)
$1 : K2^2 + 1/23*(18*K4^8 - 314*K4^6 + 1877*K4^4 -
    4512*K4^2 + 3588)
$2 : K3^2 + 1/23*(-5*K4^8 + 77*K4^6 - 377*K4^4 +
    663*K4^2 - 437)
$3 : x^10 - 20*x^8 + 149*x^6 - 519*x^4 + 851*x^2 -
    529
> [ Evaluate(f, x) eq 0 : x in R];
[ true, true, true, true, true, true, true, true,
true, true ]
```

From the type of the Galois group, `[2^4]5` we expect G to have a normal subgroup A of type C_2^4 such that the quotient G/A is a cyclic group of order 5. To find that subfield we can for example use the Galois computations again:

```
> A := NormalSubgroups(G:OrderEqual := 16)[1]`subgroup;
> GaloisSubgroup(S, A);
x^5 + 1682*x^4 + 715964*x^3 + 99797360*x^2 +
    5206504944*x + 88019915488
(x5 + x10)
```

The second return value $x_5 + x_{10}$ also tells us that the primitive element of the subfield is the sum of two roots of f, namly the 5-th and 10-th in our fixed ordering.
Suppose we want to work in the degree 16 extension over this field, that is we want to work in the fixed field of the trivial subgroup over the field fixed by A:

```
> K, D, Reco, Bnd := GaloisSubfieldTower(S, [A, sub<G|>]);
>  GK := GaloisGroup(K);
>  #GK;
16
>  AbelianInvariant(GK);
```

```
[ 2, 2, 2, 2 ]
```

As an abstract field, K as the splitting field can be described as a quotient of $\mathbf{Q}[x_1, \ldots, x_{10}]/I$ for some suitable ideal I also known as the Galois ideal. On the other hand, by tensoring with some p-adic complection $\mathbf{Q}_p$ we get an embedding of K into $K_p^{\#G} =: \Gamma$. The sequence D that is returned as the 2nd value contains the information necessary to map elements in $\mathbf{Z}[x_1, \ldots, x_{10}]$ via Γ to K. Suppose we want to find x_1, ie. a root of f in K. We first have to get the p-adic image in Γ, with appropriate precision. Step one is to define a suitable multivariate polynomial i that will represent x_1.
The second step is to compute an integer B such that all complex conjugates if i are bounded by B in absolute value. For this we can use information about the size of the roots of f stored in S. The next step now is to get a bound for the p-adic precision.

```
> R := SLPolynomialRing(Integers(), 10);
> i := R.1;
> B := S‘max_comp;
> bound := Bnd(B);
```

Now, we need to get the p-adic conjugates of x_1, ie. the image in Γ. The third entry in each of the elements of D contains coset representatives that give the relative conjugates:

```
> rt := [GaloisRoot(i, S:Bound := bound) : i in [1..10]];
> con := CartesianProduct(Reverse([x[3]: x in D]));
> gamma := [Evaluate(i, PermuteSequence(rt, &*p)) : p in con];
> im := Reco(gamma: Bound := B);
> time Evaluate(f, im) eq 0;
```

Before we try to find an automorphism of the base field using this method we want to find the primitive element of the base field of K. The primitive element is essentially given by the 1st part of D. Note that here a Tschirnhaus-tranformation was necessary.

```
> i := D[1][1]; t := D[1][2];
> B := Bound(i, Evaluate(t, S‘max_comp));
> bound := Bnd(B);
> rt := [GaloisRoot(i, S:Bound := bound) : i in [1..10]];
> rt := [Evaluate(t, x) : x in rt];
> gamma := [Evaluate(i, PermuteSequence(rt, &*p)) : p in con];
> im := Reco(gamma : Bound := B);
> im;
$.1
> im eq K.2;
true;
```

Now for the automorphism - all we have to change is to permute the roots as we already have the permutation group.

```
> rt := PermuteSequence(rt, Random(G));
> gamma := [Evaluate(i, PermuteSequence(rt, &*p)) : p in con];
> au := Reco(gamma : Bound := B);
> au;
```

```
1/92*(-9*$.1^4 + 386*$.1^3 - 5854*$.1^2 + 37120*$.1 - 82288)
```

In order to "find" arbitrary (integral) elements this way one has to

- define the element as a multivariate polynomial in the roots, i
- with the aid of `Bound` and the knowledge of the complex roots of f, find a bound B of the complex embeddings of i and use `Bnd` as above to find a bound M on the p-adic precision
- use the information in D to compute i in Γ, ie all p-adic conjugates in the "correct" ordering
- use `Reco` to find the algebraic representation.

38.2.4 Solvability by Radicals

For a polynomial $f \in \mathbf{Z}[t]$ with solvable Galois group it is well known that the roots of f can be expressed as nested radicals. On the other hand no good algorithm is known to achieve this. Here we use the explicit action of the Galois group of f as a permutation group on the p-adic roots to compute such an representation.

`SolveByRadicals(f)`

`Prime`	RngIntElt	*Default :* `false`
`Name`	MonStgElt	*Default :* `false`
`Galois`	Tup<GrpPerm, [RngElt], GaloisData>	
`UseZeta_p`	BoolElt	*Default :* `false`
`MaxBound`	RngIntElt	*Default :* ∞
Verbose	`GaloisTower`	*Maximum :* 3

For a polynomial $f \in \mathbf{Z}[t]$ with solvable Galois group, a splitting field as a tower of radical extensions is computed together with algebraic representations of the roots of f as elements in the splitting field. The third return value contains the non-trivial roots of unity which are used.

If the parameter `Galois` is used, it should contain a list or triplet containing the output of `GaloisGroup(f);`.

If `Prime` is used, and `Galois` is unspecified, the value of `Prime` is passed onto the Galois group computation and can therefore be used to choose the p-adic field.

If `UseZeta_p` is set to `true`, then the expression for the roots of p will contain pure radicals and roots of unity. By default, if `UseZeta_p` is `false`, radical expressions for the roots of unit necessary will also be computed.

If `MaxBound` is given, it will be used as an upper bound for the p-adic precision used internally. Expecially when the radical tower contains many steps, the internally used precision estimates become more and more pessimistic, thus resulting in larger and larger precision.

If `Name` is set to some string, the i-th level primitive element in the tower will be called `Name.i`.

CyclicToRadical(K, a, z)

Let K/k be a number field with cyclic automorphism group of order n generated by $K.1 \to a$ and z be a n-th root of unity in k. This function will return a field L isomorphic to K such that L is a Kummer extension, ie. the defining polynomial for L will be of the form $t^n - b$ for some b in the coefficient field k of K. The second returned value contains the roots of f in L while the third return value contains the roots of unity used.

Example H38E6

```
> P<x> := PolynomialRing(IntegerRing());
> f := x^6 - x^5 - 6*x^4 + 7*x^3 + 4*x^2 - 5*x + 1;
> K, R := SolveByRadicals(f:Name := "K.");
> K:Maximal;
   K<K.1>
      |
      |
  $1<K.2>
      |
      |
  $2<K.3>
      |
      |
  $3<K.4>
      |
      |
      Q
K  : K.1^3 + 1/2*(3*K.4 - 11)*K.2 + 1/2*(-27*K.4 + 23)
$1 : K.2^2 - 5
$2 : K.3^3 - 228*K.4 + 532
$3 : K.4^2 + 3
> [ Evaluate(f, x) eq 0 : x in R];
[ true, true, true, true, true, true ]
```

Note that every step in the tower defining K is radical, ie. given by an equation of type $x^n - a$.

38.2.5 Linear Relations

An important question for various problems is that of finding all linear (additive) relations between the roots of some integral polynomial. While there is a obvious algorithm if the splitting field can be constructed explicitly, there is no obvious way of doing it in general. In this section we provide two algorithms to find those and more general relations and a third that can verify arbitrary relations.

`LinearRelations(f)`

`Proof`	BoolElt	*Default :* `true`
`Galois`	Tup<GrpPerm, [RngElt], GaloisData>	
`UseAction`	BoolElt	*Default :* `false`
`UseLLL`	BoolElt	*Default :* `true`
`Power`	RngIntElt	*Default :* 1
`kMax`	RngIntElt	*Default :* ∞
`LogLambdaMax`	RngIntElt	*Default :* ∞

Given an integral monic polynomial f, this function finds a basis for the module of additive relations between the roots of f in some algebraic closure. The ordering of the roots is the same as chosen by the computation of the Galois group of f, in fact, the roots used are precisely the ones returned by `GaloisRoot`. The output consists of a basis for the relation module encoded in a matrix and the Galois data encoding the ordering of the roots. The algorithm is described in [dGF07].

If `Power` is set to an integer larger than one, the module of relations between the powers of the roots is computed.

`LinearRelations(f, I)`

`Proof`	BoolElt	*Default :* `true`
`Galois`	Tup<GrpPerm, [RngElt], GaloisData>	
`UseAction`	BoolElt	*Default :* `false`
`UseLLL`	BoolElt	*Default :* `true`
`Power`	RngIntElt	*Default :* 1
`kMax`	RngIntElt	*Default :* ∞
`LogLambdaMax`	RngIntElt	*Default :* ∞

Let f be an integral monic polynomial and α_1, ..., α_n be the roots of f in some splitting field in a fixed ordering. The field and the ordering used here are the ones chosen by the computation of the Galois group of f. The splitting field K of f be represented as a quotient $\mathbf{Q}[x_1, \ldots, x_n]/J$ for some suitable ideal J, thus elements in K can be represented as multivariate polynomials in the roots α_i. The sequence I that is passed into this function is interpreted to contain elements in K given via the polynomials in I. This function computes a basis for the module of relations between the elements represented by I. The algorithm is described in [dGF07].

`VerifyRelation(f, F)`

`Galois`	Tup<GrpPerm, [RngElt], GaloisData>	
`kMax`	RngIntElt	*Default :* ∞

Let f be an integral monic polynomial and α_1, ..., α_n be the roots of f in some splitting field in a fixed ordering. The field and the ordering used here are the ones chosen by the computation of the Galois group of f. The splitting field K of f be

represented as a quotient $\mathbf{Q}[x_1, \ldots, x_n]/J$ for some suitable ideal J, thus elements in K can be represented as multivariate polynomials in the roots α_i. For a polynomial F in the roots of f, this function verifies if F evaluated at the roots of f equals zero, ie. if F describes a relation between the roots. The algorithm is described in [dGF07].

Example H38E7

The following example originates in a paper [BDE$^+$] where, among other things, polynomials are constructed whose roots have a maximal number of linear dependencies. Note, that the polynomial constructed here is not extremal.

```
> G := ShephardTodd(8);
> R := InvariantRing(G);
> p := PrimaryInvariants(R);
> p;
[
    x1^8 + (-4*i - 4)*x1^7*x2 + 14*i*x1^6*x2^2 + (-14*i +
        14)*x1^5*x2^3 - 21*x1^4*x2^4 + (14*i + 14)*x1^3*x2^5
        - 14*i*x1^2*x2^6 + (4*i - 4)*x1*x2^7 + x2^8,
    x1^12 + (-6*i - 6)*x1^11*x2 + 33*i*x1^10*x2^2 + (-55*i +
        55)*x1^9*x2^3 - 231/2*x1^8*x2^4 + (66*i +
        66)*x1^7*x2^5 + (-66*i + 66)*x1^5*x2^7 -
        231/2*x1^4*x2^8 + (55*i + 55)*x1^3*x2^9 -
        33*i*x1^2*x2^10 + (6*i - 6)*x1*x2^11 + x2^12
]
> f := Resultant(p[1]-2, p[2]-3, 2);
> f := Polynomial(Rationals(), UnivariatePolynomial(f));
> IsPower(f, 4);
true 27/4*x^24 - 135*x^16 + 405*x^12 - 405*x^8 + 162*x^4 - 1
> _, f := $1;
> GG, R, S := GaloisGroup(f);
> #GG;
192
> rel := LinearRelations(f:Galois := <GG, R, S>);
> #rel;
20
> rel[3];
[ 0, 0, 0, -1, 0, -1, 1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0 ]
> IR := SLPolynomialRing(Integers(), 24);
> r := &+ [rel[3][i]*IR.i : i in [1..24]];
> r;
(x7 + ((-1 * x4) + (-1 * x6)))
> VerifyRelation(f, r:Galois := <GG, R, S>);
true
```

Now we use this to construct a field of degree 192 over Q where the conjugates of a primitive element span only a 4-dimensional vectorspace. We first define an invariant (a multivariate poly-

nomial) that corresponds to a primitive element. This can be verified by computing all p-adic conjugates and checking that they are pairwise different.

```
> i := &+ [ i*IR.i : i in [1..23]];
> I := [Apply(g, i) : g in GG];
> #{Evaluate(i, R) : i in I};
192
```

So, since $i = \sum i\alpha_i$ is a linear combination of the roots α_i of f, the dimension of the vectorspace spanned by the conjugates of i is 4 again. Note that this is a property of the polynomial not of the field.

```
> i := RelativeInvariant(GG, sub<GG|>);
> I := [Apply(g, i) : g in GG];
> #{Evaluate(i, R) : i in I};
192
>  #LinearRelations(f, I:Galois := <GG, R, S>, Proof := false);
```

38.2.6 Other

`ConjugatesToPowerSums(I)`

For elements in a sequence I, compute the sequence containing the power sums $\sum I_i^j$ for $j = 1, \ldots, \#I$. If I is interpreted to contain the Galois conjugates of some algebraic number (or the roots of some polynomial) then this computed the power sums.

`PowerSumToElementarySymmetric(I)`

Given a sequence I of elements, interpreted as power sums of some algebraic number x, use Newton's relations to compute the elementary symmetric functions in the conjugates of x. In general for this to succeed, the characteristic of the underlying ring needs to be larger than the length of the sequence.

38.3 Subfields

This section contains functions for the computation of all subfields of any number field or all subfields of a given degree of a simple absolute algebraic field or a simple relative extension.

These computations are independent of the computation of the Galois groups, but similiarly there is no limit on the degrees of the field.

The algorithms used are Klüner's method as presented in [Klü95, Klü97, KP97, Klü98] and the newer method of Klüners, van Hoeij and Novocin [vHKN11].

`Subfields(K, n)`

Verbose	`Subfields`	*Maximum :* 4

Given a simple absolute algebraic field or a simple relative extension K and an integer n greater than 1, this function returns a sequence of pairs (2-tuples) containing the subfields of K of degree n together with the embedding homomorphisms of each subfield into K. It is possible that the sequence contains isomorphic fields, but the embeddings will be distinct in such a situation.

`Subfields(K)`

`Al`	MonStgElt	*Default :* "*Default*"
`Current`	BoolElt	*Default :* `false`
`Proof`	RngIntElt	*Default :* 1
Verbose	`Subfields`	*Maximum :* 4

Given an algebraic field K, this function returns a sequence of pairs (2-tuples) containing the subfields of K (except $\mathbf{Q}$) together with the embedding homomorphisms of each subfield into K. It is possible that the sequence contains isomorphic fields.

For fields K which are extensions of an algebraic number field the more recent algorithm developed by Klüners and van Hoeij [vHKN11] is used. For fields K which are extensions of $\mathbf{Q}$, this algorithm can be selected by setting the parameter `Al` to `"KluenersvanHoeij"` or may be chosen by `"Default"` as the optimal algorithm. By default, the `"Klueners"` algorithm is chosen if the defining polynomial of K factors into large degree factors (with respect to the degree of K) over the residue field of some prime or the coefficients of the defining polynomial are large, otherwise `"KluenersvanHoeij"` is used which is optimal when the defining polynomial only has small degree factors (with respect to the degree of K) over the residue fields of some number of primes, that is, K has a large number of subfields.

38.3.1 The Subfield Lattice

Subfields of number fields can also be retrieved in the form of a lattice from which additional information can be discovered.

`SubfieldLattice(K)`

Verbose	`Subfields`	*Maximum :* 4

The lattice of subfields of an absolute number field K.

`#L`

The number of fields in the lattice L.

`Representative(L)` `Rep(L)`

`Bottom(L)`

The bottom element of the subfield lattice L (this corresponds to $\mathbf{Q}$).

`Top(L)`

The top element of the subfield lattice L (this corresponds to the original number field).

`Random(L)`

A random element of the subfield lattice L.

`L ! n`
`L[n]`

The n-th element of the subfield lattice L.

`NumberField(e)`

The number field corresponding to the given subfield lattice element e.

`EmbeddingMap(e)`

The mapping from `NumberField(e)` into the top number field of the subfield lattice.

`Degree(e)`

The (absolute) degree of the number field corresponding to the subfield lattice element e.

`e eq f`

Returns `true` if and only if the subfield lattice elements e and f are equal.

`e subset f`

Returns `true` f and only if e is a subfield of f.

`e * f`

The smallest field containing both e and f.

`e meet f`

The intersection of e and f. This is the largest field common to both of them.

`&meetS`

The intersection of the subfields in the sequence S.

`MaximalSubfields(e)`

The sequence of maximal subfield lattice elements contained in e.

`MinimalOverfields(e)`

The sequence of minimal subfield lattice elements containing e.

Example H38E8

A subfield lattice is shown.

```
> Zx<x> := PolynomialRing(Integers());
> K<a> := NumberField(x^8 - x^4 + 1);
> L := SubfieldLattice(K);
> L;
Subfield Lattice of K
[1] Rational Field
[2] Subfield generated by a root of x^2 - 4*x + 1
[3] Subfield generated by a root of x^2 - 26*x + 241
[4] Subfield generated by a root of x^2 - 10*x + 241
[5] Subfield generated by a root of x^2 + 1
[6] Subfield generated by a root of x^2 - 10*x + 1
[7] Subfield generated by a root of x^2 - 6*x + 1
[8] Subfield generated by a root of x^2 + x + 1
[9] Subfield generated by a root of x^4 + 4*x^2 + 1
[10] Subfield generated by a root of x^4 - x^2 + 1
[11] Subfield generated by a root of x^4 - 8*x^3 + 20*x^2 - 16*x + 1
[12] Subfield generated by a root of x^4 - 4*x^3 + 8*x^2 - 4*x + 1
[13] Subfield generated by a root of x^4 - 6*x^3 + 13*x^2 - 6*x + 1
[14] Subfield generated by a root of x^4 - 4*x^3 + 8*x^2 + 4*x + 1
[15] Subfield generated by a root of x^4 - 2*x^3 + 5*x^2 + 2*x + 1
[16] Subfield generated by a root of x^8 - x^4 + 1
```

Observe that subfields 2, 5 and 8 give the square roots of 2, -1 and 3, respectively. Since these are incommensurate radicals the field generated by them has degree 8 and so must be isomorphic to K.

```
> K2 := AbsoluteField( NumberField([ x^2 + 1, x^2 - 2, x^2 - 3 ]));
> K2;
Number Field with defining polynomial x^8 - 16*x^6 + 88*x^4 + 192*x^2 + 144
over the Rational Field
> IsIsomorphic(K2, K);
true
```

In fact, K is just a "better" version of K2.

```
> OptimizedRepresentation(K2);
Number Field with defining polynomial x^8 - x^4 + 1 over the Rational Field
Mapping from: FldNum: K2 to Number Field with defining polynomial x^8 - x^4 + 1
over the Rational Field
```

38.4 Galois Cohomology

MAGMA has some rudimentary functions to aid computations in Galois cohomology of number fields.

`Hilbert90(a, M)`

S	[RngOrdIdl]	*Default :* `false`

Let K be a number field and $M : K \to K$ be an automorphism of K furthermore, denote by k the fixed field of M, thus M generates the automorphism group of the relative cyclic extension K/k. For some element a in K, such that $N_{K/k}(a) = 1$, this function will find some element b such that $a = b/M(b)$. If `S` is given it should contain a sequence of prime ideals such that there exists some b in the S-unit group over S.

`SUnitCohomologyProcess(S, U)`

ClassGroup	BoolElt	*Default :* `false`
Ramification	BoolElt	*Default :* `false`

Let k be a normal number field with (abstract) automorphism group G. For a set of prime ideals S of k, which is closed under the action of the subgroup U of G, a process is created that allows working with the cohomology of the multiplicative group of k - partially represented by a group of S-units. If `ClassGroup` is given, the set S is enlarged to support the current generators of the class group. If `Ramification` is present, then all ramified primes are also included in S.

During the computations with this object the set S can be increased to allow the representation of a larger number of elements.

`IsGloballySplit(C, l)`

Sub	GrpPerm	*Default :* `false`
Verbose	Cohomology	*Maximum :* 2

For a cohomology process C as created by `SUnitCohomologyProcess` and a 2-cocyle $l : U \times U \to k$ given as a MAGMA-function, decide if l is split, ie. if there exists a 1-cochain $m : U \to k$ such that $\delta m = l$ for the cohomological coboundary map δ. If `Sub` is given it has to be a subgroup of the automorphism group of the number field underlying the cohomology process, otherwise the full automorphism group is used. This allows to restrict a cocyle easily.

As a fixed cocyle l assumes only finitely many values, we can consider it as a cocyle with values in some suitable S-unit group. Similarly, it is exists, m also has values in some S'-unit group for a potentially larger set S'. This function first tries to "remove" ideals from the support of l, to make the set S as small as possible. Then the set is enlarged to make sure that m, if exists, can be found with values in the $S' = S$-unit group. Since the final problem now involves only finitely generated abelian groups, it can be solved by MAGMA's general cohomology machinery.

`IsSplitAsIdealAt(I, l)`

`Sub` GrpPerm *Default :* `false`

Let U be a subgroup of the automorphism group G of some number field k, $l : U \times U \to k^*$ a 2-cocyle and I some ideal in k. If `Sub` is given, U is taken to be `Sub`, otherwise $U := G$. Assuming that each element $l(u, v)$ has a valuation at all ideals in the U-orbit of I, ie. we have a unique decomposition of ideals $l(u, v) = J^{x(u,v)}A(u, v)$ for integers $x(u, v)$ and ideals $A(u, v)$ coprime to J for all J in I^U. Then we can use l to define a cocyle with values in I^U which is a finitely generated group. This function determines if this cocycle splits, and if so, computes a 1-cochain with values in I^U for some fixed ordering of I^U. The cochain and I^U are returned on success.

39 CLASS FIELD THEORY

Chapter 39
CLASS FIELD THEORY

39.1 Introduction

This chapter presents the facilities provided in MAGMA for class field theory. The main objects of interest are abelian extensions of number fields (`FldAb`) and maps between abelian groups and ideal groups.

Class field theory is concerned with the classification of all abelian extensions of a given field. In particular, this covers abelian extensions of number fields, local fields and global function fields. While this chapter deals with the number field case only, MAGMA can also perform computations in the other cases. For the case of global function fields, see Chapter 43 and for the case of p-adic local fields, Section 47.14.

Abstractly, class field theory parametrizes abelian extensions in terms of abelian groups defined with respect to the base field. In MAGMA, ray class groups and their quotients are used to define the extensions. Ray class groups and their quotients are always represented as maps between a finite abelian group (`GrpAb`) and the power structure of ideals (`PowIdeal`). The maps are usually obtained as products of the map returned by ray class groups and quotient maps.

In theory, a class field is completely determined by the corresponding class group (map). Currently there is only a small number of invariants that can be computed directly from the map; for most other properties the class field has to be converted into a number field by computing a set of defining equations.

39.1.1 Overview

Class field theory classifies all abelian extensions of a given number field k in terms of quotients of ray class groups. Ray class groups should be thought of as generalized class groups in that they can be defined similarly to class groups:

$$1 \to U \to k^* \to I \to \mathrm{Cl} \to 1$$

where k^* is the multiplicative group of k, U is the group of units, and I the group of fractional ideals. (Recall, the class group is defined as the quotient of the ideals modulo the principal ideals). To define ray class groups we need to refine all of the above terms. Let $o = \mathbf{Z}_k$ be the ring of integers in k and fix an integral ideal $\mathfrak{m}_0$ in o. Furthermore, let $\mathfrak{m}_\infty$ be a subset of the real embeddings of k into $\mathbf{C}$ and, formally, $\mathfrak{m} := (\mathfrak{m}_0, \mathfrak{m}_\infty)$. Then for $x \in k$ define

$$x \bmod^* \mathfrak{m} = 1 \quad \text{iff} \begin{cases} v_{\mathfrak{p}}(x-1) \geq v_{\mathfrak{p}}(\mathfrak{m}_0) & \text{for all prime ideals } \mathfrak{p} \\ s(x) > 0 & \text{for } s \in \mathfrak{m}_\infty \end{cases}$$

Let $I^{\mathfrak{m}}$ denote the group of fractional ideals that are coprime to $\mathfrak{m}_0$, $U_{\mathfrak{m}}$ the units u such that $u \bmod^* \mathfrak{m} = 1$ and $P_{\mathfrak{m}}$ the elements $x \in k$ such that $x \bmod^* \mathfrak{m} = 1$. Then

$$1 \to U_{\mathfrak{m}} \to P_{\mathfrak{m}} \to I^{\mathfrak{m}} \to \mathrm{Cl}_{\mathfrak{m}} \to 1$$

defines the ray class groups modulo $\mathfrak{m}$. For $\mathfrak{m} = (1o, \emptyset)$, this corresponds to the usual class group. Given two moduli $\mathfrak{m}$ and $\mathfrak{n}$ such that $\mathfrak{m}_0 | \mathfrak{n}_0$ and $\mathfrak{m}_\infty \subseteq \mathfrak{n}_\infty$ we have canonical surjections

$$\mathrm{Cl}_{\mathfrak{n}} \to \mathrm{Cl}_{\mathfrak{m}}\,.$$

Now, let H be a subgroup such that $P_{\mathfrak{m}} < H < I^{\mathfrak{m}}$. There exists a minimal $\mathfrak{n}$ such that the canonical embedding $\mathrm{Cl}_{\mathfrak{m}}/H \to \mathrm{Cl}_{\mathfrak{n}}$ is injective. This $\mathfrak{n}$ is called the conductor of H.

The main theorem of class field theory asserts the following correspondence between abelian extensions K/k of k and quotients of ray class groups: Let K/k be abelian and $G := \mathrm{Gal}(K/k)$ the group of k-automorphisms of K. For each prime ideal $\mathfrak{p}$ of k that is unramified in K, let $\mathrm{Frob}(\mathfrak{p}, K/k)$ be the Frobenius automorphism, i.e. the unique $s \in G$ such that $s(x) = x^N \bmod \mathfrak{p}$ for all $x \in k$. Extend this map multiplicatively to all ideals coprime to $d_{K/k}$, the discriminant of K/k. This is known as the Artin-map and is denoted by $(b, K/k)$. Class field theory asserts the existence of some modulus $\mathfrak{m}$ and a subgroup H such that $G \cong \mathrm{Cl}_{\mathfrak{m}}/H$ by the Artin-map.

Conversely, for each ray class group $\mathrm{Cl}_{\mathfrak{m}}$ and each subgroup $P_{\mathfrak{m}} < H$ there is an abelian extension K/k with the above property.

The correspondence is one-to-one if one restricts to pairs $\mathrm{Cl}_{\mathfrak{m}}$ and H such that $\mathfrak{m}$ is the conductor of H.

For $\mathfrak{m} = (1o, \emptyset)$, the corresponding field K is called the Hilbert class field of k (in the wide sense).

Perhaps best understood is the Hilbert class field. As conjectured by Hilbert and proved by Furtwängler, all ideals of k become principal in the Hilbert class field H_k. Futhermore, H_k is the maximal unramified abelian extension of k.

A different interpretation of H is provided by norm groups. We have

$$H = \langle N_{K/k}(b) | b \in I_K^{\mathfrak{m}} \rangle$$

This result may be used to convert an abelian number field into an abelian extension. In addition, class field theory asserts that, for an arbitrary normal extension K/k, the norm group defined above corresponds to the maximal abelian subfield.

39.1.2 Magma

In Magma maps are used to represent the ideal groups. If necessary, the map can be augmented by supplying $\mathfrak{m}$ i.e. an integral ideal $\mathfrak{m}_0$ and a sequence of indices of the real places in $\mathfrak{m}_\infty$. The map returned as a second return value from `ClassGroup` or `RayClassGroup` carries the necessary information to recover $\mathfrak{m}$, even if this is hidden from the user. As an example, we consider the Hilbert class field of $k := \mathbf{Q}(\alpha)$ with $\alpha^3 + \alpha^2 + 3\alpha - 6 = 0$ with class group C_4.

Example H39E1

```
> k := NumberField(Polynomial([ -6, 3, 1, 1 ]));
```

Now, the easiest way to get the Hilbert class field is to call `HilbertClassField` directly on k:

```
> K := HilbertClassField(k);
> K;
Number Field with defining polynomial $.1^4 + (76*k.1^2 - 420*k.1 - 488)*$.1^2\
 +    32080*k.1^2 + 41984*k.1 + 95168 over k
```

Let us now verify some of the properties, starting with the discriminant. Since K/k is totally unramified, the discriminant of the maximal order should be 1:

```
> O := MaximalOrder(K);
> O;
Maximal Order of Equation Order with defining polynomial x^4 + [-488, -420,
    76]*x^2 + [95168, 41984, 32080] over its ground order
> Discriminant(O);
Ideal
Basis:
[1 0 0]
[0 1 0]
[0 0 1]
```

Now let us check that all ideals of k are principal in K. In order to do so, it is sufficient to demonstrate that a generator of the class group becomes principal:

```
> g, m := ClassGroup(k);
> g;m;
Abelian Group isomorphic to Z/4
Defined on 1 generator
Relations:
    4*g.1 = 0
Mapping from: GrpAb: g to Set of ideals of Maximal Equation Order with
defining polynomial x^3 + x^2 + 3*x - 6 over its ground order
> i := m(g.1);
> I := O!!i;
> IsPrincipal(I);
true
> f,g := IsPrincipal(I);
> g;
[[2193497788678474035456, -1238066307883451022336,
-2319265120953032748288], [394272965034846395136,
-222653406238254306432, -417025104282566694144],
[167087257584, 71708840496, 32825469008], [495632919,
-279332235, -523526213]] / 10917386545536
```

However, to use the more sophisticated functions, the construction of the class fields needs to be done step–by–step. We first create an abelian extension as an object of type `FldAb`. Since we wish

to see how much of the class group becomes trivial in the quadratic subfield K_1 of K (capitulates in K_1), we also define this.

```
> aK := AbelianExtension(m);
> g, m := ClassGroup(k);
> q, mq := quo<g | 2*g.1>;
> m2 := Inverse(mq)*m;m2;
Mapping from: GrpAb: q to Set of ideals of Maximal
Equation Order with defining polynomial x^3 + x^2 + 3*x
    - 6 over Z
Composition of Mapping from: GrpAb: q to GrpAb: g and
Mapping from: GrpAb: g to Set of ideals of Maximal
Equation Order with defining polynomial x^3 + x^2 + 3*x
    - 6 over Z
> aK2 := AbelianExtension(m2);
```

This demonstrates a very important technique: the creation of a quotient group of the class group together with the corresponding map.
A few invariants such as degree and discriminant may be calculated directly from `aK` without the (costly) computation of a defining equation.

```
> Discriminant(aK);
Principal Ideal
Generator:
    [1, 0, 0]
[ 4, 4 ]
```

The second return value denotes the signature of the field as an extension of $\mathbf{Q}$.
Now we compute a defining equation for `aK2` and see what happens to the class group of k.

```
> O := MaximalOrder(aK2);O;
Maximal Order of Equation Order with defining
polynomial x^2 + [-5, -2, -1] over its ground order
> O!!m(g.1);
> IsPrincipal($1);
false
> IsPrincipal($2^2);
true
```

So only "half" of the class group capitulates in `aK2`, the reminding part collapses in `aK`.

39.2 Creation

The most powerful way to create class fields or abelian extensions in MAGMA is to use the AbelianExtension function that enables the user to create the extension corresponding to some ideal group.

So, before we can describe the creation functions for the class fields, we have to deal with the ideal groups.

39.2.1 Ray Class Groups

The classical approach to class field theory, which is well suited for computation, is based on *ideal groups* which are generalisations of the ideal class group.

In this section we describe in detail how to create *full* ideal groups, mainly ray class groups. As ray class groups are closely related to the unit groups of residue class rings of maximal order, these too are presented here.

In addition to the functions listed here, the CRT on page 946 is relevant in this context.

```
RayClassGroup(I)
```

```
RayClassGroup(I, T)
```

Given an integral ideal I belonging to the maximal order of a number field, the *ray class group modulo* I is the quotient of the subgroup generated by the ideals coprime to I by the subgroup generated by the principal ideals generated by elements congruent to 1 modulo I and T if present.

The sequence T contains the numbers $[i_1, \ldots, i_r]$ of certain real infinite places. When the sequence is supplied, the generators of the principal ideals must take positive values at the places indicated by T. The sequence T must be strictly ascending containing only positive integers, each not exceeding the number of real embeddings.

This function requires the class group to be known. If it is not already stored, it will be computed in such a way that its correctness is not guaranteed. However, it will almost always be correct. If the user requires a guaranteed result, then the class group must be verified by the user or computed up to the proof level required beforehand.

The ray class group is returned as an abelian group A, together with a mapping between A and a set of representatives for the ray classes.

The algorithm used is a mixture of Pauli's approach following Hasse ([Pau96, HPP97]) and Cohen's method ([CDO96, CDO97, Coh00]).

```
RayClassGroup(D)
```

Given a divisor (or place) of an absolute number field, compute the Ray class group defined modulo the divisor.

This function requires the class group to be known. If it is not already stored, it will be computed in such a way that its correctness is not guaranteed. However, it will almost always be correct. If the user requires a guaranteed result, then the

class group must be verified by the user or computed up to the proof level required beforehand.

The ray class group is returned as an abelian group A, together with a mapping between A and a set of representatives for the ray classes.

The algorithm used is a mixture of Pauli's approach following Hasse ([Pau96, HPP97]) and Cohen's method ([CDO96, CDO97, Coh00]).

Example H39E2

Some ray class groups are computed below. The example merely illustrates the fact that ray class groups tend to grow if their defining modul grows and can be arbitrarily large. This should be compared to class groups where it is rather difficult to give examples of fields having "large" class groups — unless one takes imaginary quadratic fields.

```
> R<x> := PolynomialRing(Integers());
> o := MaximalOrder(x^2-10);
> RayClassGroup(2*o, [1,2]);
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0
Mapping from: Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0 to Set of ideals of o
> RayClassGroup(2*o);
Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*$.1 = 0
Mapping from: Abelian Group isomorphic to Z/2
Defined on 1 generator
Relations:
    2*$.1 = 0 to Set of ideals of o
```

As one can see, the inclusion of the infinite places only added a C_2 factor to the group. In general, a set of infinite places containing n elements can at most add n C_2 factors to the group without infinite places.
Now we enlarge the modulus by small primes. As one can see, the ray class group gets bigger.

```
> RayClassGroup(8*3*5*7*11*13*101*o);
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/4 + Z/4 + Z/24 + Z/24 + Z/120 +
Z/600
Defined on 9 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0
```

```
    2*$.3 = 0
    8*$.4 = 0
    24*$.5 = 0
    4*$.6 = 0
    120*$.7 = 0
    12*$.8 = 0
    600*$.9 = 0
Mapping from: Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/4 + Z/4 + Z/24 +
Z/24 + Z/120 + Z/600
Defined on 9 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0
    2*$.3 = 0
    8*$.4 = 0
    24*$.5 = 0
    4*$.6 = 0
    120*$.7 = 0
    12*$.8 = 0
    600*$.9 = 0 to Set of ideals of o
```

`RayResidueRing(I)`

`RayResidueRing(I, T)`

Given an integral ideal I belonging to the maximal order of a number field, the *ray residue ring modulo* I is the unit group of the maximal order modulo I extended by one C_2 factor for each element of T. The sequence T should be viewed as a condition on the signs of the numbers factored out.

Let I be an integral ideal of an absolute maximal order and let T be a set of real places given by an increasing sequence containing integers i, $1 \leq i \leq r_1$ where r_1 is the number of real zeros of the defining polynomial of the field. This function computes the group of units $\mathrm{mod}^*(I, T)$. The result is a finite abelian group and a map from the group to the order to which the ideal belongs.

When T is not given the unit group of the residue ring mod m is returned. This is equivalent to formally setting $T := [\,]$ to be the empty sequence.

`RayResidueRing(D)`

Given an effective divisor D of a number field, compute the unit group of the residue class ring defined modulo the divisor, ie. compute the group of elements that for the finite places in the support of D approximate 1 and have positive sign at the real infinite places of the support of D.

39.2.2 Selmer groups

Let S be a finite set of prime ideals in a number field K. For an integer p, the p-Selmer group of S is defined as

$$K_p(S) := \{x \in K^\times/(K^\times)^p \mid v_Q(x) = 0 \bmod p \ \forall Q \notin S\}$$

$K_p(S)$ is a finite abelian group of exponent p.

`pSelmerGroup(p, S)`

`Integral`	BoolElt	*Default :* `true`
`Nice`	BoolElt	*Default :* `true`
`Raw`	BoolElt	*Default :* `false`

For a prime integer p and a set of prime ideals S in a number field K, the function returns the p-Selmer group of S as an abstract group G, together with a map m from K to G. The map comes with an inverse.

In principle, the domain of m is the set of x in K satisfying the condition in the definition of $K_p(S)$ above. When $m(x)$ is invoked for x in K, it is assumed without checking that x satisfies the condition. If x does not, either a runtime error occurs, or the map returns a random element of G. (Checking the condition would require a far more expensive computation. The algorithm identifies the class of x in $K_p(S)$ by computing the multiplicative orders of residues of x, and of the group generators, modulo some unrelated primes.)

The role of the optional parameters is as follows. The p-Selmer group is realized as a subgroup of a quotient of a suitable group of $\tilde{S}$-units of the number field, the images of the map returned by `pSelmerGroup` are $\tilde{S}$-units. Initially, $\tilde{S}$ is chosen as S and then enlarged until the p-part of the ideal class group of K is generated by the ideals in S. The parameter `Raw` is related to the same parameter in `SUnitGroup`, see SUnitGroup for more information. If the parameter is set to `true`, the objects returned as images of the `pSelmerGroup` map are exponent vectors that are applied to a fixed sequence of elements to get actual S-units, see the following example for a demonstration.

In addition to changing the return type, `Raw` also implies a reduction of the results, elements returned under `Raw` are reduced by removing the projection of the lattice generated by pth powers of $\tilde{S}$-units. As a side effect of this reduction, elements are no longer guaranteed to be integral. To offset this, the parameter `Integral` can be set to `true`, in which case the sequence of multiplicative generators will be extended to contain uniformizing elements for all ideals in $\tilde{S}$ and the exponent vectors will be supplemented accordingly to achieve integrality.

Example H39E3

We compute the 3-Selmer group of $\mathbf{Q}(\sqrt{10})$ with respect to the primes above 2, 3, 11:

```
> k := NumberField(Polynomial([-10, 0,1]));
```

```
> m := MaximalOrder(k);
> lp := Factorization(2*3*11*m);
> S := [ i[1] : i in lp];
> KpS, mKpS := pSelmerGroup(3, Set(S));
> KpS;
Abelian Group isomorphic to Z/3 + Z/3 + Z/3 + Z/3 + Z/3
Defined on 5 generators
Relations:
    3*KpS.1 = 0
    3*KpS.2 = 0
    3*KpS.3 = 0
    3*KpS.4 = 0
    3*KpS.5 = 0
> mKpS;
Mapping from: RngOrd: m to GrpAb: KpS given by a rule
> mKpS(m!11);
KpS.2
> mKpS(m!11*2);
KpS.2 + 2*KpS.3 + 2*KpS.5
> mKpS(m!11*2*17^3);
KpS.2 + 2*KpS.3 + 2*KpS.5
```

So as long as the argument to `mKpS` is only multiplied by cubes, the image will be stable. Next, we do the same again, but this time using `Raw`:

```
> KpS, mKpS, mB, B := pSelmerGroup(3, Set(S):Raw);
> B;
(-m.1 -11/1*m.1 3/1*m.1 2/1*m.1 13/1*m.1 5/1*m.1 31/1*m.1
    3/1*m.1 - 2/1*m.2 3/1*m.1 + 2/1*m.2 m.1 - 2/1*m.2 m.1
    + 2/1*m.2 m.2 m.1 + m.2 m.1 - m.2 -2/1*m.1 - m.2 m.2
    3/1*m.1 3/1*m.1 11/1*m.1)
> #Eltseq(B);
19
> mB;
Mapping from: GrpAb: KpS to Full RSpace of degree 19 over
Integer Ring given by a rule [no inverse]

```

39.2.3 Maps

`InducedMap(m1, m2, h, c)`

Given maps $m_1 : G_1 \to I_1$, $m_2 : G_2 \to I_2$ from some finite abelian groups into the ideals of some maximal order, and a map $h : I_1 \to I_2$ on the ideals, compute the map induced by h on the abelian groups.

For this to work, m_1, and m_2 need to be maps that can be used to define abelian extensions. This implies that m_i has to be a composition of maps where the last component is either the map returned by `ClassGroup` or by `RayClassGroup`. The argument c should be a multiple of the minima of the defining moduli.

The result is the map as defined by

```
hom<G_1 -> G_2 | [ h(r_1(G_1.x)) @@ r_2 : x in [1..Ngens(G_1)]]>
```

For larger modules however, this function is much faster than the straightforward approach. This function tries to find a set of "small" generators for both groups. Experience shows that ray class groups (and their quotients) can usually defined by a "small" set of "small" prime ideals. Since solving the discrete logarithm in ray class groups depends upon solving the discrete logarithm for class groups which is quite slow for "large" ideals, it is much faster in general to use this rather roundabout approach. "Small" ideal in this context means "small" norm.

`InducedAutomorphism(r, h, c)`

An abbreviation for `InducedMap(r, r, h, c)`.

Example H39E4

Consider a "large" ray class group over $k := \mathbf{Q}[\sqrt{10}, \zeta_{16}]$

```
> k := NumberField([Polynomial([-10, 0, 1]), CyclotomicPolynomial(16)]);
> k := OptimizedRepresentation(AbsoluteField(k));
> o := MaximalOrder(k);
> ClassGroup(o:Bound := 500);
Abelian Group of order 1
Mapping from: Abelian Group of order 1 to Set of ideals of o
> IndependentUnits(o);
> SetOrderUnitsAreFundamental(o);
> p := &* [113, 193, 241];
> r, mr := RayClassGroup(p*o);
> #r; Ngens(r);
170613117637701990523621885614354740012596396318100496286167859 2\
000000000
26
```

The automorphisms of k act on this group. One way of obtaining the action is:

```
> autk := Automorphisms(k);
> time m1 := hom<r -> r | [ autk[2](mr(r.i))@@ mr : i in [1..Ngens(r)]]>;
```

```
Time: 26.300
```

In contrast, using `InducedAutomorphism`:

```
> time InducedAutomorphism(mr, autk[2], p);
Time: 19.080
```

Now we increase p:

```
> p *:= 257*337;
> r, mr := RayClassGroup(p*o);
> #r; Ngens(r);
383174842075502327821254012562863503503880824795585976926638885 1\
825941987170813422862370672745342599097489263347018928299704320 0\
0000000
42
> time m1 := hom<r -> r | [ autk[2](mr(r.i))@@ mr : i in [1..Ngens(r)]]>;
Time: 115.120
> time InducedAutomorphism(mr, autk[2], p);
Time: 82.390
```

For "small" examples the direct approach is much faster, but for large ones, especially if one is only interested in certain quotients, the other approach is faster.

39.2.4 Abelian Extensions

The ultimate goal of class field theory is the classification of all abelian extensions of a given number field. Although the theoretical question was settled in the 1930's, it is still difficult to explicitly compute defining equations for class fields. For extensions of imaginary quadratic fields, there are well known analytic methods available. This section explains the basic operations implemented to create class fields in MAGMA.

`RayClassField(m)`
`AbelianExtension(m)`
`RayClassField(m, I, T)`
`AbelianExtension(m, I, T)`
`RayClassField(m, I)`
`AbelianExtension(m, I)`

Given a map $m : G \to I_k$ where G is a finite abelian group and I_k is the set of ideals of some absolute maximal order construct the class field defined by m.

More formally, m^{-1} must be a homomorphism from some ray class group R onto an finite abelian group G. If either I or I and T are given, they must define R. This implies that I has to be an integral ideal and that T has to be a sequence containing the relevant infinite places. Otherwise, MAGMA will try to extract this information from m. The class field defined by m has Galois group isomorphic to $R/\ker(m^{-1})$ under the Artin map.

Note that MAGMA cannot check whether the map passed in is valid. If an invalid map is supplied, the output will most likely be garbage.

`AbelianExtension(I)`

Creates the full ray class field modulo the ideal I.

`RayClassField(D)`

Create the full Ray class field defined modulo the divisor D, ie. an abelian extension that is unramified outside the support of D and such that the (abelian) automorphism group is canonically isomorphic to the ray class group modulo D.

`AbelianpExtension(m, p)`

For a map m as in `AbelianExtension` and a prime number p, create the maximal p-field, i.e. the maximal subfield having degree a p–power.

Example H39E5

The abelian extensions of $\mathbf{Q}$ are known to lie in some cyclotomic field.
We demonstrate this by computing the 12-th cyclotomic field using class fields:
Unfortunately, as ray class groups are not defined for $\mathbf{Z}$ in MAGMA, we must work in a degree 1 extension of $\mathbf{Q}$:

```
> x := ext<Rationals()|>.1;
> Q := ext<Rationals()| x-1 :DoLinearExtension>;
> M := MaximalOrder(Q);
```

The ray class group that defines $\mathbf{Q}(\zeta_{12})$ is defined mod$(12, \infty)$ where ∞ is the unique infinite place of $\mathbf{Q}$. There are at least two ways of looking at this: First, since $Q(\zeta_{12})$ is a totally complex field, the infinite place of $\mathbf{Q}$ must ramify (by convention: $\mathbf{C}$ is ramified over $\mathbf{R}$), so we must include the infinite place in the definition of the ray class group.
Secondly, the ray class group mod(12) without the infinite place is too small. We know $\phi(12) = 4$, $(\mathbf{Z}/12\mathbf{Z})^* = \{1, 5, 7, 11\} = \{\pm 1, \pm 5\}$. As ideals we have $(1) = o = (-1) = (11)$ and $(5) = (-5) = (7)$ so that $\mathrm{Cl}_{12} \cong C_2$. By introducing $T = [1]$, we distinguish ± 1 and ± 5.

```
> G, m := RayClassGroup(12*M, [1]);
> G;
Abelian Group isomorphic to Z/2 + Z/2
Defined on 2 generators
Relations:
    2*G.1 = 0
    2*G.2 = 0
> A := AbelianExtension(m);
> E := EquationOrder(A);
> Ea := SimpleExtension(E);
> Ma := MaximalOrder(Ea);
> Discriminant(Ma);
144
> Factorization(Polynomial(Ma, CyclotomicPolynomial(12)));
[
```

```
    <ext<Ma|>.1 + [0, 1, 0, -1], 1>,
    <ext<Ma|>.1 + [0, -1, 0, 0], 1>,
    <ext<Ma|>.1 + [0, 1, 0, 0], 1>,
    <ext<Ma|>.1 + [0, -1, 0, 1], 1>
]
```

The main advantage of this method over the use of the cyclotomic polynomials is the fact that we can directly construct certain subfields:

```
> x := ext<Integers()|>.1;
> M := MaximalOrder(x^2-10);
> G, m := RayClassGroup(3615*M, [1,2]);
> G; m;
Abelian Group isomorphic to Z/2 + Z/2 + Z/4 + Z/80 + Z/240
Defined on 5 generators
Relations:
    4*G.1 = 0
    80*G.2 = 0
    240*G.3 = 0
    2*G.4 = 0
    2*G.5 = 0
Mapping from: GrpAb: G to Set of ideals of M
```

We will only compute the 5-part of this field:

```
> h := hom<G -> G | [5*G.i : i in [1..#Generators(G)]]>;
> Q, mq := quo<G|Image(h)>;
> mm := Inverse(mq) * m;
> mm;
Mapping from: GrpAb: Q to Set of ideals of M
> A := AbelianExtension(mm);
> E := EquationOrder(A);
> E;
Non-simple Equation Order defined by x^5 - [580810, 0]*x^3 +
    [24394020, -40656700]*x^2 + [15187310285, 2799504200]*x
    + [1381891263204, 530506045900], x^5 - [580810, 0]*x^3 +
    [-109192280, 34848600]*x^2 + [30584583385,
    16797025200]*x + [-341203571896, 109180663800] over its
ground order
> C := Components(A);
```

The function `Components` gives a list of cyclic extensions of M that correspond to the cyclic factors of G.

```
> GaloisGroup(NumberField(C[1]));
Permutation group acting on a set of cardinality 5
Order = 5
    (1, 4, 2, 5, 3)
[ -9 + O(41), 15 + O(41), 6 + O(41), 18 + O(41), 11 + O(41) ]
GaloisData over Z_Prime Ideal
Two element generators:
```

```
[41, 0]
[25, 1] - relative case
> GaloisGroup(NumberField(C[2]));
Order = 5
    (1, 4, 2, 5, 3)
[ 38 + O(79), -28 + O(79), -31 + O(79), 27 + O(79), -6 + O(79) ]
GaloisData over Z_Prime Ideal
Two element generators:
[79, 0]
[57, 1] - relative case
```

Thus the Galois group is indeed proven to be $C_5 \times C_5$.

`AbelianExtension(I, P)`

Creates the full ray class field modulo the ideal I and the infinite places in P.

`HilbertClassField(K)`

Creates the Hilbert class field of K, i.e. the maximal unramified abelian extension of K. This is equivalent to `AbelianExtension(1*MaximalOrder(K))`.

`MaximalAbelianSubfield(M)`
`MaximalAbelianSubfield(F)`
`MaximalAbelianSubfield(K)`

`Conductor` [RngOrdIdl, [RngIntElt]] *Default :* [ ]

Let k be the coefficient field of the given number field K. This function creates the maximal abelian extension A of k inside K. If `Conductor` is given, it must contain a multiple of the true conductor. If no value is specified, the discriminant of K is used.

The correctness of this function is based on some heuristics. The algorithm is similar to [Coh00, Algorithm 4.4.3]

`AbelianExtension(K)`
`AbelianExtension(M)`

`Conductor` [RngOrdIdl, [RngIntElt]] *Default :* [ ]

Creates an abelian extension A of k the coefficient field of the input K that is isomorphic to K. If a value for `Conductor` is given, it must contain a multiple of the true conductor, otherwise the discriminant of K is used to be more specific, in case K is a number field, the discriminant of it's maximal order is used as an initial guess, while for field of fractions of orders (K of type `FldOrd`), the defining order gives the initial guess.

In contrast to `MaximalAbelianSubfield`, provided the field is abelian, this function always computes a correct answer.

Example H39E6

We will compute the Hilbert class field of the sextic field defined by a zero of the polynomial $x^6 - 3x^5 + 6x^4 + 93x^3 - 144x^2 - 153x + 2601$ which has a class group isomorphic to $C_3 \times C_3$.

```
> m := LLL(MaximalOrder(Polynomial([2601, -153, -144, 93, 6, -3, 1 ])));
```

The call to LLL is not necessary, but quite frequently class group computations are faster if the order basis is LLL-reduced first.

```
> a,b := ClassGroup(m:Bound := 300);a;
Abelian Group isomorphic to Z/3 + Z/3
Defined on 2 generators
Relations:
    3*a.1 = 0
    3*a.2 = 0
```

`HilbertClassField` on `m` computes a Non-simple number field defining the Hilbert class field of `m`.

```
> H := HilbertClassField(NumberField(m)); H;
Number Field with defining polynomial [ $.1^3 + 1/595*(-460*$.1^5
    + 2026*$.1^4 - 4052*$.1^3 - 52572*$.1^2 + 229338*$.1 -
    529159), $.1^3 + 1/37485*(82*$.1^5 + 4344*$.1^4 + 8805*$.1^3
    + 15990*$.1^2 + 410931*$.1 + 1098693)] over its ground field
> time _ := MaximalOrder(H);
Time: 56.150
```

However, in order to access more of the structural information of `H` we have to create it as an abelian extension, using `b`.

```
> A := AbelianExtension(b);
> HH := NumberField(A);
```

Now we are able to compute the maximal order of `HH` using `A` and verify the discriminant:

```
> time M := MaximalOrder(A:Al := "Discriminant");
Time: 3.260
> Discriminant(M);
Ideal of m
Basis:
[1 0 0 0 0 0]
[0 1 0 0 0 0]
[0 0 1 0 0 0]
[0 0 0 1 0 0]
[0 0 0 0 1 0]
[0 0 0 0 0 1]
```

Note, that as a side effect, the maximal order of `HH` is now known:

```
> time MaximalOrder(HH);
Maximal Order of Equation Order with defining polynomials x^3 + [841, 841, 312,
    -534, 222, 0], x^3 + [25, -2, -9, 7, -11, -8] over m
```

```
Time: 0.000
```

We will continue this example following the next section.

39.2.5 Binary Operations

The model underlying the class field theory as implemented in MAGMA is based on the (generalized) ideal class groups. Based on this group-theoretical description, certain binary operations are easily possible:

`A eq B`

Gives two abelian extensions with the same base field, decide if they are the same.

`A subset B`

Gives two abelian extensions with the same base field, decide if they are contained in each other.

`A * B`

Given two abelian extensions with the same base field, find the smallest abelian extension containing both.

`A meet B`

Given two abelian extensions with the same base field, find the largest common subfield.

39.3 Galois Module Structure

If the base field k for class field constructions is normal with respect to some subfield k_0, i.e. k/k_0 is normal with Galois group G and if the defining modulus of the ideal group is G–invariant, then G acts on the ideal group. The following functions view ideal groups as Galois modules. Given an abelian extension A and parameters `All` and `Over`, we will consider this setup:

Let k be the `BaseField` of A and k_1 the coefficient field of k. If `All` is `true`, let $g := \mathrm{Aut}(k/k_1)$, otherwise, $g := \langle$`Over`$\rangle$. In both cases we define $k_0 := \mathrm{Fix}(k, g)$. In particular, if k is normal over the coefficient field k_1 then $k_0 = k_1$ and g is the full Galois group.

In general g is not required to contain k_1 automorphisms, so that any subset of the **Q** automorphism group is valid as input. By construction, k is normal over k_0, and g acts on the ideals of k. In general however, g does not act on the ideal groups used to define A.

39.3.1 Predicates

`IsAbelian(A)`

`All`	BoolElt	*Default :* `false`
`Over`	[Map]	*Default :* []

Returns `true` if and only if the abelian extension A is abelian over k_0.

`IsNormal(A)`

`All`	BoolElt	*Default :* `false`
`Over`	[Map]	*Default :* []

Returns `true` if and only if the abelian extension A is normal over k_0. This tests whether the defining ideal group is a g-module.

`IsCentral(A)`

`All`	BoolElt	*Default :* `false`
`Over`	[Map]	*Default :* []

Returns `true` if and only if the abelian extension A is central over k_0. If k is cyclic over k_0 then this is equivalent to checking if A is abelian over k_0. This tests whether the defining ideal group is a g–module with trivial action: If N is the norm group of A, the group extension

$$1 \to N \to G \to g \to 1$$

is central.

39.3.2 Constructions

`GenusField(A)`

`All`	BoolElt	*Default :* `false`
`Over`	[Map]	*Default :* []

The genus field is the maximal abelian extension of k_0 that is contained in the abelian extension A. The result of this function is an abelian extension of k_0.

`H2_G_A(A)`

For A such that A is normal over $\mathbf{Q}$ with base field k that is normal too, compute the 2nd cohomology group of the Galois group of k acting on the ideal group defining A.

`NormalSubfields(A)`

`Quot`	SeqEnum[RngIntElt]	*Default :* []

For an abelian extension, normal over Q and defined over a normal number field k as base field, return a list of all normal intermediate fields. If `Quot` is given, restrict to fields where the norm group has the abelian invariants as specified in `Quot`.

`AbelianSubfield(A, U)`

`FixedField(A, U)`

`IsNormal` BoolElt *Default :* `false`

For an abelian extension A with norm group map $G \to I$ for some finite abelian group G and a subgroup $U < G$, define the field corresponding to G/U, ie. the field fixed by U. If `IsNormal` is given then any cohomology information that is present is transferred to the new field - if possible.

`CohomologyModule(A)`

For an abelian extension A defined over some normal field k/Q, compute the cohomology module (see Chapter 68). The maps returned give the transition between the Z-modules used in the cohomology package and the ideal groups used to define A.

The first map returned maps between the automorphism group of k (as an permutation group) and the actual automorphisms of the field. It is obtained as the third return value of `AutomorphismGroup`.

The second map maps between the ideal group used to create A and a standart representation of the same group.

The third map maps between the standart representation of the norm group and the Z-module.

39.4 Conversion to Number Fields

Although in theory an abelian extension "uniquely" defines a number field and therefore all its properties, not all of them are directly accessible (in Magma at least). The functions listed here perform the conversion to a number field, the most important being of course the function that computes defining equations.

`EquationOrder(A)`

Verbose `ClassField` *Maximum :* 5

Given an abelian extension A of a number field, using the algorithm of Fieker ([Fie00, Coh00]) defining equations for A are computed. For each cyclic factor of prime power degree, one polynomial will be constructed. Depending on the size of the cyclic factors encountered, this may be a very lengthy process.

`NumberField(A)`

Converts the abelian extension A into a number field. This is equivalent to `NumberField(EquationOrder(A))`.

`MaximalOrder(A)`

`Al`	MonStgElt	*Default :* "*Kummer*"
`Partial`	BoolElt	*Default :* `false`

Computes the maximal order of the abelian extension A. The result is the same as that given by `MaximalOrder(EquationOrder(A))` but this functions uses the special structure of A and should be much faster in general.

The first step involves computing the maximal orders of each component.

If `Al eq "Kummer"` the maximal order computation uses Kummer theory to compute maximal orders of kummer extensions known to each component then intersects these with the component to gain the maximal order of that component [Sut12].

If `Al eq "Round2"`, the ordinary round 2 maximal order function is used on the components.

If `Al eq "Discriminant"`, the discriminant of the components is passed into the maximal order computation.

In the second step, the components are combined into an approximation of the full maximal order of A.

If `Partial` is `true`, the computations stop at this point, otherwise `MaximalOrder` is again called and the discriminant of A is passed in.

`Components(A)`

Verbose	`ClassField`	*Maximum :* 5

A list of relative extensions is determined. One extension per cyclic factor is computed.

`Generators(A)`

The first return value is a sequence of generating elements for `NumberField(A)`, the second contains the same elements but viewed as elements of the Kummer extension used in the construction. The third list contains the images of the second list under the action of a generator of the automorphism group corresponding to this cyclic factor.

39.5 Invariants

Several invariants of an abelian extension can easily be obtained from the ideal groups without first computing defining equations for the field.

`Discriminant(A)`

Let A be an abelian extension. Based on the conductor-discriminant relation made explicit by [Coh00, Section 3.5.2], the discriminant of the class field A is computed. This does not involve the computation of defining equations. The second return value is the signature of the resulting field.

`AbsoluteDiscriminant(A)`

The absolute discriminant of A as a number field over $\mathbf{Q}$.

`Conductor(A)`

Computes the conductor of the abelian extension A, i.e. the smallest ideal and the smallest set of infinite places that are necessary to define A. The algorithm used is based on [Pau96, HPP97].

`Degree(A)`

The degree of the abelian extension A.

`AbsoluteDegree(A)`

The degree of the abelian extension A over $\mathbf{Q}$.

`CoefficientRing(A)`
`CoefficientField(A)`
`BaseField(A)`

The base field of the abelian extension A, that is `FieldOfFractions(BaseRing(A))`.

`BaseRing(A)`
`CoefficientRing(A)`

The base ring of the abelian extension A, that is the maximal order used to define the underlying ray class group.

`NormGroup(A)`

The norm group (see the definition of norm group on page 1000) used to define the abelian extension A.

`DecompositionField(p, A)`

The decomposition field of the finite prime p in the abelian extension A as an abelian (sub)extension.

`DecompositionField(p, A)`

The decomposition field of the place p in the abelian extension A as an abelian extension.

`DecompositionGroup(p, A)`
`DecompositionGroup(p, A)`

The decomposition group of the finite prime p in the abelian extension A. The abelian group returned is a subgroup of the norm group.

`DecompositionGroup(p, A)`

The decomposition group of the place p in the abelian extension A. The abelian group returned is a subgroup of the `NormGroup`.

`DecompositionType(A, p)`

The "type" of the decomposition of the finite prime ideal p in the abelian extension A as a sequence of pairs $\langle f, e \rangle$ giving the degrees and the ramification indices.

`DecompositionType(A, p)`

The "type" of the decomposition of the place p in the abelian extension A as a sequence of pairs $\langle f, e \rangle$ giving the degrees and the ramification indices.

`DecompositionType(A, p)`

`Normal` BoolElt *Default :* `false`

The "type" of the decomposition over $\mathbf{Q}$ of the prime number p in the abelian extension A as a sequence of pairs $\langle f, e \rangle$ giving the degrees and the ramification indices. If `Normal` is set to `true` then the algorithm assumes that the base field of A is normal. This is used to speed up the computations.

`DecompositionTypeFrequency(A, l)`

`Normal` BoolElt *Default :* `false`

Computes the decomposition type of all elements in l and returns them as a multi-set. The list l must only contain objects for which `DecompositionType` is defined. If `Normal eq true` then the underlying `DecompositionType` function must be able to deal with it too. If `Normal` is set to `true` then the algorithm assumes that the base field of the abelian extension A is normal. This is used to speed up the computations.

`DecompositionTypeFrequency(A, a, b)`

`Normal` BoolElt *Default :* `false`

Computes the decomposition type over $\mathbf{Q}$ in the abelian extension A of all prime numbers $a \leq p \leq b$ and returns them as a multi set.

If `Normal` is set to `true` then the algorithm assumes that the base field of A is normal. This is used to speed up the computations.

39.6 Automorphisms

The group of relative automorphisms of the abelian extension is isomorphic via the Artin map to the ideal group used to define the field. After defining equations are computed, the user can explicitly map ideals that are coprime to the defining modulus to automorphisms of the field.

`ArtinMap(A)`

Returns a map from the defining group (considered as a "subgroup" of the ideals of the base ring) into the automorphisms of the abelian extension A over the base field.

By the defining property of class fields, this map induces an isomorphism on the defining group (as an abelian group) onto the relative automorphisms of A.

Since this function constructs the number field defined by A, this may involve a lengthy calculation.

`FrobeniusAutomorphism(A, p)`

Computes the relative automorphism of the abelian extension A that is the Frobenius automorphism of p. Since this function constructs the number field defined by A, this may involve a lengthy calculation.

`AutomorphismGroup(A)`

`All`	BoolElt	*Default :* `false`
`Over`	[Map]	*Default :* []

If `IsNormal` is true for the abelian extension A with the given parameters, then the automorphism group of A over k_0 is computed. Since this function constructs the number field defined by A, this may involve a lengthy calculation.

`ProbableAutomorphismGroup(A)`

`Factor`	RingIntElt	*Default :* 1

In case of A and it's base field k both begin normal over $\mathbf{Q}$, the automorphism group G of $A/\mathbf{Q}$ is a group extension of the abelian group coming from the definition of A and the automorphism group of $k/\mathbf{Q}$. This functions sets up the corresponding group extension problem and uses `DistinctExtensions` to compute all group theoretical possibilities for G. In case of several possible groups, a further selection based on cycle types and their frequencies is attempted. The optional parameter `Factor` is passed on to `ImproveAutomorphismGroup` to control the amount of time spent on improving the guess.

While this function can be much faster than the direct computation of the automorphism group, the result of this computation is in general not guaranteed. Furthermore, as there are groups that cannot be distinguished by cycle types and their frequencies alone, correctness cannot be achieved by increasing the value of `Factor`. The intended use of this function is to have a (reasonable fast) method of checking is the field under consideration has an interesting group before an unnecessary long call to `AutomorphismGroup` is attempted.

`ImproveAutomorphismGroup(F, E)`

`Factor` RngIntElt *Default :* 1

Given the output of `ProbableAutomorphismGroup` or `ImproveAutomorphismGroup` try to improve the quality of the guess by splitting more primes to get more data for a cycle-type frequency analysis.

Example H39E7

We will demonstrate the use of `ProbableAutomorphismGroup` by investigating extensions of $\mathbf{Q}(\sqrt{10})$:

```
> k := NumberField(Polynomial([-10, 0, 1]));
> R, mR := RayClassGroup(4*3*5*MaximalOrder(k));
> s := [x`subgroup : x in Subgroups(R:Quot := [2,2])];
> a := [ AbelianExtension(Inverse(mq)*mR) where
>                              _, mq := quo<R|x> : x in s ];
> n := [ x : x in a | IsNormal(x:All)];
> ProbableAutomorphismGroup(n[2]);
Finitely presented group on 3 generators
Relations
    $.2^2 = Id($)
    $.3^2 = Id($)
    ($.2, $.3) = Id($)
    ($.1, $.2^-1) = Id($)
    $.1^-1 * $.3 * $.1 * $.3^-1 * $.2^-1 = Id($)
    $.1^2 = Id($)
```

This shows that since there is only one group extension of a V_4 by C_2 with the action induced from the action of the Galois group of k on R, the Automorphism group is already determined. On the other hand, for the first subgroup there are more possibilities:

```
> g, c := ProbableAutomorphismGroup(n[1]);
> #c;
2
```

We will try to find the "correct" guess by looking at the orders of elements which correspond to decomposition types and their frequencies:

```
> {* Order(x) : x in CosetImage(c[1], sub<c[1]|>) *};
{* 1, 2^^7 *}
> {* Order(x) : x in CosetImage(c[2], sub<c[2]|>) *};
{* 1, 2^^3, 4^^4 *}
```

So, if we find a prime of degree 4 we know it's the second group. Looking at the frequencies, we can be pretty confident that we should be able to find a suitable prime - if it exists. Since among the first 100 primes there is not a single prime with a factor of degree 4 we are pretty confident that the first group is the correct one. By setting the verbose level, we can see how the decision is made:

```
> SetVerbose("ClassField", 2);
```

```
> _ := ImproveAutomorphismGroup(n[1], c:Factor := 2);
Orders and multiplicities are  [
    {* 1, 2^^7 *},
    {* 1, 2^^3, 4^^4 *}
]
Probable orders and multiplicities are  {* 1^^3, 2^^34 *}
Error terms are  [ 0.006993296366796325415873541339 07,
0.993006703633203674584126458661 ]
```

This indicates that out of 37 primes considered, non had a degree 4 factor, thus we are confident that the first group is the correct one.

`AbsoluteGaloisGroup(A)`

Given an abelian extension, compute it's Galois group over **Q**, ie. the abstract automorphism group of a **Q**-normal closure of A. This function requires the defining equations for A as a number field to be known, but is considerably faster than calling `GaloisGroup` for the number field directly. The group is returned as an permutation group. All roots of the defining polynomial of the coefficient field of A as well as of the defining polynomials of A itself are returned in some local field. The zeros as well as data required for further computations are contained in the 3rd return value.

`TwoCocycle(A)`

For an abelian extension that is normal over Q and defined over a normal base field k/Q, the automorphism group of A/Q is a group extension of the Galois group of k by A. As a group extension it corresponds to an element in the second cohomology group and can be represented by an explicit 2-cocyle with values in the norm group. This function computes such a cocycle. It can be used as an element of the second cohomology group of the cohomology module of A, see `CohomologyModule`.

39.7 Norm Equations

For cyclic fields Hasse's famous norm theorem states that when considering the solvability of norm equations, local solvability everywhere is equivalent to global solvability. Unfortunately, this local-global principle fails in general even for fields with Galois group isomorphic to Klein's group V_4. The extent of this failure is measured by the number knot which is the quotient of the numbers that are everywhere local norms by the global norms. As it turns out, the structure and size of this quotient can be easily computed, so that it is possible to test if Hasse's theorem is sufficient.

As a second consequence, solvability can be decided by looking at the maximal p-subfields for all primes that divide the degree of the field. Even better, a global solution can be obtained by combining solutions from the maximal p-subfields.

It is important to note that local solvability can be decided by analyzing the ideal groups only. Thus, all the "local" functions will avoid computing defining equations and are therefore reasonably fast.

`IsLocalNorm(A, x, p)`

Returns `true` if and only if x is a local norm in the abelian extension A at the finite prime p, i.e. if x is a norm in the extension of the local field obtained by taking the completion at p.

`IsLocalNorm(A, x, i)`

Returns `true` if and only if x is a local norm in the abelian extension A at the infinite prime i.

`IsLocalNorm(A, x, p)`

Returns `true` if and only if x is a local norm in the abelian extension A at the place p, i.e. if x is a norm in the extension of the local fields obtained by taking the completion at p.

`IsLocalNorm(A, x)`

Returns `true` if and only if x is a local norm everywhere in the abelian extension A.

`Knot(A)`

The (number) knot is defined as the quotient group of the group consisting of those elements of the base field of the abelian extension A that are local norms everywhere modulo the elements that are norms. Therefore, if the knot is trivial, an element is a local norm if and only if it is a norm.

Hasse's norm theorem states that for cyclic fields A the knot is always trivial. In general, this is not true for non-cyclic fields.

`NormEquation(A, x)`

Checks if x is a norm, and if so returns an element of the pre-image. As a first step this function verifies if x is a local norm. If x passes this test, the number field of A is computed and by combining solutions of the norm equation in certain subfields a solution in A is constructed. If the knot is non-trivial, the last step may fail.

This function can be extremely time consuming as not only defining equations for A are computed but class groups in some of them. For large A this is much more efficient than just solving the norm equation in the number field.

`IsNorm(A, x)`

As a first step, this function verifies if x is a local norm. If x passes this test, MAGMA verifies whether the knot is trivial. If it is, `true` is returned. However, if the knot is non-trivial, then the function `NormEquation` is invoked.

Example H39E8

We illustrate the power of the class field theoretic approach with the following example from group theory. We want to solve for elements of norm 2 or 5 in the field $\mathbf{Q}(\zeta_5)(\eta)$ where $\eta^{20} - \zeta_5\eta^{10} + \zeta_5^2 = 0$ over the cyclotomic field. This field has degree 80 over $\mathbf{Q}$ and is therefore far too large for a direct method.

```
> k := CyclotomicField(5);
> kt := ext<k|>;
> K := NumberField(kt.1^20 - k.1*kt.1^10 +k.1^2);
```

Now we convert K into an abelian extension of k:

```
> A := AbelianExtension(K);
> A;
FldAb, defined by (<[590490000000000000000000, 0, 0, 0]>, [])
of structure: Z/2 + Z/10
> Conductor(A);
Ideal
Two element generators:
    [37500, 0, 0, 0]
    [12060, 15120, 7440, 1680]
[]
```

We now recreate A using the smaller conductor. This will significantly speed up the following computations.

```
> m_0, m_inf := $1;
> A := AbelianExtension(K : Conductor := [* m_0, m_inf *]);
```

We first check the local solvability:

```
> IsLocalNorm(A, BaseRing(A)!2);
false
> IsLocalNorm(A, BaseRing(A)!5);
true
> Knot(A);
Abelian Group isomorphic to Z/2
Defined on 1 generator in supergroup:
    $.1 = $.1
Relations:
    2*$.1 = 0
```

Since the knot is isomorphic to a C_2, the local solvability is not sufficient, but we can attempt to solve the equation:

```
> NormEquation(A, BaseRing(A)!5);
true [
    1/10*(-3*zeta_5^3 - 6*zeta_5^2 + zeta_5 -
        7)*$.1*$.2*$.3^4 + 1/10*(9*zeta_5^3 + 3*zeta_5^2 +
        2*zeta_5 + 6)*$.1*$.2*$.3^3 + 1/10*(-6*zeta_5^3 +
        3*zeta_5^2 - 3*zeta_5 + 1)*$.1*$.2*$.3^2 +
```

```
        1/10*(-3*zeta_5^3 - 6*zeta_5^2 + zeta_5 -
        7)*$.1*$.2*$.3 + 1/2*(2*zeta_5^3 + zeta_5^2 + zeta_5
        + 2)*$.1*$.2 + 1/10*(-12*zeta_5^3 - 4*zeta_5^2 -
        6*zeta_5 - 13)*$.1*$.3^4 + 1/10*(11*zeta_5^3 +
        2*zeta_5^2 + 13*zeta_5 + 4)*$.1*$.3^3 +
        1/10*(zeta_5^3 + 2*zeta_5^2 - 7*zeta_5 +
        9)*$.1*$.3^2 + 1/10*(-12*zeta_5^3 - 4*zeta_5^2 -
        6*zeta_5 - 13)*$.1*$.3 + 1/2*(2*zeta_5^3 - zeta_5^2
        + 2*zeta_5 + 1)*$.1 + 1/10*(-zeta_5^3 + 3*zeta_5^2 -
        3*zeta_5 + 1)*$.2*$.3^4 + 1/10*(-2*zeta_5^3 +
        zeta_5^2 + 4*zeta_5 - 3)*$.2*$.3^3 +
        1/10*(3*zeta_5^3 - 4*zeta_5^2 - zeta_5 +
        2)*$.2*$.3^2 + 1/10*(-zeta_5^3 + 3*zeta_5^2 -
        3*zeta_5 + 1)*$.2*$.3 + 1/2*(-zeta_5^3 - zeta_5^2 -
        1)*$.2 + 1/10*(-14*zeta_5^3 - 13*zeta_5^2 - 2*zeta_5
        - 21)*$.3^4 + 1/10*(22*zeta_5^3 + 4*zeta_5^2 +
        11*zeta_5 + 13)*$.3^3 + 1/10*(-8*zeta_5^3 +
        9*zeta_5^2 - 9*zeta_5 + 8)*$.3^2 +
        1/10*(-14*zeta_5^3 - 13*zeta_5^2 - 2*zeta_5 -
        21)*$.3 + 1/2*(5*zeta_5^3 + zeta_5^2 + 3*zeta_5 + 4)
]
> _, s := $1;
> Norm(s[1]);
5
```

Thus, the largest field we had to work in was of degree 16.

39.8 Attributes

In this rather technical section, we describe the programming interface to the abelian extension module. Most of the internal representation is available as attributes and may be used to extend the package.

39.8.1 Orders

The only attribute of orders `RngOrd` that is of interest here concerns cyclotomic extensions. The first and usually most time consuming step while computing defining extensions is to adjoin certain roots of unity and to compute class groups of these rather large fields.

The cyclotomic extensions are stored and are available via an attribute. This attribute is a read-only attribute.

`o‘CyclotomicExtensions`

If defined, `CyclotomicExtensions` is a list of records, each containing data for one cyclotomic extension, i.e. for an order o this is an extension of the form $O := o[\zeta_l]$ for a prime power $l = p^n$. The components are

`Abs` : a maximal order Oa of O given as an absolute extension

`Rel` : O as an extension of o

`p2n` : the "l", i.e. the cyclotomic order

`Zeta` : a primitive lth root of unity as an element of the absolute extension `Abs`

`Aut` : a list of records describing generators for the automorphism group of O over o. If p is an odd prime then the list will always be of length 1. This list consists of the following components:

`Aut‘Abs` : the automorphism as an automorphism of Oa

`Aut‘Rel` : the automorphism as an automorphism of O. Note that in general this is not an o-automorphism, as o itself may contain roots of unity.

`Aut‘Order` : the order of the automorphism

`Aut‘r` : the image of ζ_l, this automorphism sends ζ_l to ζ_l^r.

Due to possible common subfields of o and $\mathbf{Q}(\zeta_k)$, the degree of O over o may be smaller than expected. Furthermore, Oa will be in optimized representation.

Example H39E9

We will demonstrate this with the Hilbert class field of $\mathbf{Q}(\sqrt{-1001})$:

```
> Zx<x> := PolynomialRing(Integers());
> k := NumberField(x^2+1001);
> g, m :=ClassGroup(k); g;
Abelian Group isomorphic to Z/2 + Z/2 + Z/10
Defined on 3 generators
Relations:
    2*$.1 = 0
    2*$.2 = 0
    10*$.3 = 0
> K := HilbertClassField(k);
Number Field with defining polynomial [ $.1^2 - 2*k.1 + 136,
    $.1^2 - 4*k.1 - 47, $.1^2 + 2*k.1 - 136, $.1^5 + 37210*$.1^3
    + (-2104500*k.1 + 61148840)*$.1^2 + (-292068000*k.1 +
    14636593760)*$.1 + 305212632000*k.1 - 1779009360128] over k
> o := MaximalOrder(k);
> c := o‘CyclotomicExtensions;
> #c;
2
```

Since there are two non-isomorphic direct cyclic factors of prime power order in the class group of k, we have two cyclotomic extensions stored in o. One has order 2 and the other has order 5:

```
> c[1]‘p2n;
```

```
2
> c[2]‘p2n;
5
```

Since the order 2 extension is essentially trivial, we will discuss the other extension in detail.

```
> c[2]‘Abs;
Maximal Order of Equation Order with defining polynomial x^8 +
    4*x^7 + 4016*x^6 + 12034*x^5 + 6032056*x^4 + 12044060*x^3 +
    4016040045*x^2 + 4010020020*x + 1000000005005 over Z
> c[2]‘Rel;
Maximal Equation Order with defining polynomial x^4 + x^3 + x^2 +
    x + [1, 0] over o
```

The relative extension is generated by a root of the 5th-cyclotomic polynomial of degree 4, so there are no common subfields. The corresponding absolute extension has degree 8. As one can see, the class group (at least a conditional class group) is known:

```
> c[2]‘Abs:Maximal;
   F[1]
    |
   F[2]
  /
 /
Q
F  [ 1]     Given by transformation matrix
F  [ 2]     x^8 + 4*x^7 + 4016*x^6 + 12034*x^5 + 6032056*x^4 +
    12044060*x^3 + 4016040045*x^2 + 4010020020*x + 1000000005005
Discriminant: 4016024016004000000
Index: 4100090871676479535981/1
Class Number 12800
Class Group Structure C2 * C4 * C20 * C80
Signature: [0, 4]
```

We will illustrate the `Aut` entries by showing their effect on ζ_5. Since the maps operate between the number fields rather than the orders, we will coerce the results back into the orders for clarity. The only difference between `Rel` and `Abs` is that `Rel` implements the automorphism in the relative extension.

```
> Oa := c[2]‘Abs;
> z := c[2]‘Zeta; z;
[0, 1, 0, 0, 0, 0, 0, 0]
> Oa!c[2]‘Aut[1]‘Abs(z);
[0, 0, 1, 0, 0, 0, 0, 0]
> z^c[2]‘Aut[1]‘r;
[0, 0, 1, 0, 0, 0, 0, 0]
```

The `Order` entry gives the order of the automorphism:

```
> c[2]‘Aut[1]‘Order;
4
```

```
> Oa!c[2]‘Aut[1]‘Abs(z);
[0, 0, 1, 0, 0, 0, 0, 0]
> Oa!(c[2]‘Aut[1]‘Abs($1));
[-1, -1, -1, -1, 0, 0, 0, 0]
> Oa!(c[2]‘Aut[1]‘Abs($1));
[0, 0, 0, 1, 0, 0, 0, 0]
> Oa!(c[2]‘Aut[1]‘Abs($1));
[0, 1, 0, 0, 0, 0, 0, 0]
```

As a by–product one can see the optimized representation: the first four basis elements are clearly 1, ζ_5, ζ_5^2, ζ_5^3 which are the T_2 shortest integral elements in m.

39.8.2 Abelian Extensions

Abelian extensions have several attributes. Most of them are only useful in programming.

`A‘Components`

This read-only atribute contains a record for each cyclic factor of prime power degree that occurs in the abelian extension. In order to describe the contents we have to fix some definitions. Let o be the base ring of the abelian extension A. Then O will be the maximal order of the cyclotomic extension $o[\zeta_l]$ as an extensions of $\mathbf{Z}$. The algorithm for the computation of defining extensions will firstly compute a generator $a \in O$ such that $O(a^{1/l})$ equals $A(\zeta_l)$. This element will be a certain S-unit of O.

The components are

`Basis` : a matrix B containing order elements. This represents a “multiplicative basis” for the generator a and all the S-units that are used.

`GenRaw` : the exponent vector G defining a, i.e.

$$a = \prod_i {B_{1,i}}^{G_{i,1}}.$$

`UnitsRaw` : a matrix U defining a basis for the group of S-units, i.e.

$$u_j = \prod_i {B_{1,i}}^{U_{j,i}}.$$

`S` : a list containing the prime ideals of S

`Gen` : a as an element of Oa

`GenAut` : the image of a generator for the class field (an image of `Class Field.2`) in the field of fractions of O under a generator for the cyclic group corresponding to this component.

`GenInv` : $1/a$ as an element of the field of fractions of Oa

`O` : the big Kummer extension $Oa(a^{1/l})$

`ClassField` : an equation order for the cyclic extension corresponding to this component. This will be an extension of o.

`Artin` : the Artin map on the big Kummer extension $o[\zeta_l](U_S^{1/l})$ where the automorphisms are represented as elements in some abelian group of type $C_l^{\#S}$.

`A‘DefiningGroup`

`A‘NormGroup`

These two attributes give access to the ideal group used to define A, and they have the same structure. `DefiningGroup` is the group used to create A in the first place whereas `NormGroup` contains the group defined modulo the conductor. The user needs to call the function `Conductor` in order to define this component. These attributes are read-only.

The records contain the following components:

`Map` : the map as passed into the `AbelianExtension` constructor, respectively, an equivalent map.

`m0` : the "finite" part of the modulus underlying `Map`

`m_inf` : the "infinite" part of the modulus underlying `Map`

`RcgMap` : if present, contains the map returned from the call to `RayClassGroup` with `m0` and `m_inf`.

`GrpMap` : if present, the "rest" of `Map`, i.e. `Map` = `RcgMap` ∘ `GrpMap`.

`A‘IsAbelian`

Stores the result of a call to `IsAbelian` with parameter `All := true`.

`A‘IsNormal`

Stores the result of a call to `IsNormal` with parameter `All := true`.

`A‘IsCentral`

Stores the result of a call to `IsCentral` with parameter `All := true`.

Example H39E10

To illustrate the preceeding examples we will investigate the 3-part of the ray class field modulo 36 over $\mathbf{Z}[\sqrt{10}]$:

```
> Zx<x> := PolynomialRing(Integers());
> o := MaximalOrder(x^2+10);
> r, mr := RayClassGroup(36*o);
> q, mq := quo<r| [r.i*3 : i in [1..Ngens(r)]]>;
> A := AbelianExtension(Inverse(mq)*mr); A;
FldAb, defined by (<[36, 0]>, [])
```

```
of structure: Z/3 + Z/3
```

At this stage, the only attribute that is assigned is `DefiningGroup`.

```
> la := GetAttributes(FldAb);
> [ <assigned A``i, i> : i in la];
[ <false, Components>, <true, DefiningGroup>, <false, IsAbelian>,
<false, IsCentral>, <false, IsNormal>, <false, NormGroup> ]
```

So let us have a closer look at `DefiningGroup`:

```
> d := A`DefiningGroup;
> d;
rec<recformat<Map, m0, m_inf, RcgMap, GrpMap> | Map := Mapping
from: GrpAb: q to Set of ideals of o
Composition of Mapping from: GrpAb: q to GrpAb: r and
Mapping from: GrpAb: r to Set of ideals of o, m0 := Principal
Ideal of o
Generator:
    [36, 0], m_inf := [], RcgMap := Mapping from: GrpAb: r to Set
of ideals of o, GrpMap := Mapping from: GrpAb: q to GrpAb: r>
```

As one can see, `Map` is the original map used to define A. Note that this is the composition of `RcgMap` and `GrpMap`, the first being equivalent to `mr`, the second to `mq`. Furthermore, the defining modulus is now available in `m0` and `m_inf`.
After having set up A, we now need to transform it into a number field in order for the `Components` to be assigned:

```
> K := NumberField(A);
> K;
Number Field with defining polynomial [ $.1^3 - 3*$.1 - 6*$.1 -
    11, $.1^3 - 3*$.1 - 6*$.1 + 11] over its ground field
> c := A`Components;
> #c;
2
```

We will focus on the first component only.

```
> B := c[1]`Basis;
> a := &* [ B[1][i] ^ c[1]`GenRaw[i][1] : i in [1..Ncols(B)]];
-11/1*$.2 + 4/1*$.3 + 2/1*$.4
> c[1]`Gen;
[0, -11, 4, 2]
> $1 eq $2;
true
> c[2]`GenInv * a eq 1;
true
```

In S we need all primes dividing the degree 9 of our extension, all primes dividing the modulus 36 and enough primes to generate the 3-part of the class group. Since the class group can be generated by the prime ideal over 2, this leaves us with only two prime ideals in S. Since k is imaginary quadratic, the base field $k[\zeta_3]$ is totally complex of degree 4 which implies unit rank 1.

So the free rank of our S-unit group will be 3, and since we have to take care of the torsion unit, `GenRaw` will have 4 columns.

```
> #c[1]‘S;
2
> UnitRank(o);
1
> Ncols(c[1]‘UnitsRaw);
4
> U := c[1]‘UnitsRaw;
> u := [ &* [B[1][i] ^ U[i][j] : i in [1..Ncols(B)]] : j in [1..4]];
```

Now u_1 should be a fundamental unit for Oa, u_2 and u_3 are S-units and u_4 is the torsion unit, since we adjoin the 3rd-roots of unity, this will be a 6th root of unity.

```
> Oa := Parent(B[1][1]);
> Oa!u[1];
[0, -11, 4, 2]
> IsUnit($1);
true
> Decomposition(u[2]);
[
    <Prime Ideal of Oa
    Two element generators:
        [3, 0, 0, 0]
        [-9, 0, 1, 2], 1>
]
> u[4]^6 eq 1;
```

Now O should be an extension of Oa:

```
> c[1]‘O:Maximal;
         F[1]
           /
          /
      E2[1]
        /
       /
   E1[1]
  /
 /
Q
F  [ 1]     x^3 + [[0, -4], [11, -2]]
E 2[ 1]     x^2 + x + [1, 0]
E 1[ 1]     x^2 + 10
Index : <[[1, 0], [0, 0]]>
```

The class field K we are seeking is a subfield of O:

```
> c[1]‘ClassField;
Equation Order with defining polynomial x^3 + [-3, 0]*x + [-11,
```

```
    -6] over o
> g := c[1]‘ClassField.2;
> c[1]‘O!g;
[[[0, 0], [0, 0]], [[1, 0], [0, 0]], [[11, 2], [11, -2]]]
```

Note that the absolute term of the defining polynomial is a. Since `GenAut` is an image of g, its minimal polynomial should be the same as that of g:

```
> MinimalPolynomial(g);
$.1^3 - 3/1*o.1*$.1 - 11/1*o.1 - 6/1*o.2
> Evaluate($1, c[1]‘GenAut);
0
```

39.9 Group Theoretic Functions

39.9.1 Generic Groups

Quite frequently in computational algebra one constructs a set of objects that generate a group under some operation. Generic groups are finite groups that are defined by generators that have implicit relations. In order to use them, one has to provide a function for the multiplication of two elements and one to check equality. If known, the identity object can also be passed in.

Generic groups are used in the class field package for the automorphism groups. A frequent situation is that one knows certain automorphisms (as maps) and would like to get the group generated by them. If the group is reasonably small, this can be done using the functions in this section.

All functions here rely on the group being small enough to allow complete enumeration of all elements.

The main application are situations where multiplication of the actual objects is time consuming so one would like to transfer as much as possible to some abstract finite group.

`GenericGroup(X)`

`Id`	ANY	*Default :*
Verbose	`GrpGen`	*Maximum :* 3

Creates the group G generated by the elements of `X`. The function assumes that the group is finite. The second return value is a map from G onto a list of elements of G which are of the same type as the elements of `X`.

Since this function will enumerate all group elements, the group cannot be too large.

`AddGenerator(G, x)`

Verbose `GrpGen` *Maximum :* 3

Adds a new generator `x` to G. If `x` was already in G, the value `false` is returned and the other return values are unassigned. Otherwise, the new group and the corresponding map is returned.

G has to be a generic group as returned by `GenericGroup`.

The function applies a version of Dimino's algorithm [But91a] to find all elements of G with as few operations as possible.

`FindGenerators(G)`

Given a generic group G as returned by `GenericGroup`, find a small set of generators.

40 ALGEBRAICALLY CLOSED FIELDS

Chapter 40
ALGEBRAICALLY CLOSED FIELDS

40.1 Introduction

MAGMA contains a system [Ste02, Ste10] for computing with algebraically closed fields, which have the property that they always contain all the roots of any polynomial defined over them. It is of course not possible to construct explicitly the closure of a field, but the system works by automatically constructing larger and larger algebraic extensions of an original base field as needed during a computation, thus giving the illusion of computing in the algebraic closure of the base field.

Such a system was already proposed before (the D5 system [DDD85]), but this has difficulty with the parallelism which occurs when one must compute with several conjugates of a root of a reducible polynomial, leading to situations where a certain expression evaluated at a root is invertible but evaluated at a conjugate of that root is not invertible.

MAGMA's system has no such problem and one can compute with the field just like any other field in MAGMA; all standard algorithms which work over generic fields or which use factorization work automatically without having to be adapted to handle the many conjugates of a root.

Especially significant is also the fact that all the Gröbner basis algorithms work well over such fields. One can compute the variety of any zero-dimensional multivariate polynomial ideal over the algebraic closure of its base field. Puiseux expansions of polynomials are also successfully computed using an algebraically closed field.

40.2 Representation

An algebraically closed field is based on an affine algebra (or quotient ring of a multivariate polynomial ring by an ideal of "relation" polynomials). The defining polynomials of this affine algebra are not necessarily irreducible – the system avoids factorization over an algebraic number field when possible, and automatically splits the defining polynomials of the affine algebra when factors are found during computations with the field. These factors often arise automatically because of the structure of the algorithm which is computing over the field.

Many technical optimizations have been designed to make the system practical. For example, the most expensive arithmetic operation by far in the whole system is, quite surprisingly, the testing of whether an element of the field is zero or not (which is utterly trivial for most other rings, of course)! To allow for the parallelism amongst conjugates to work, MAGMA performs a recursive GCD computation with the element, considered as a polynomial in its highest variable, and the appropriate defining polynomial, to determine the result. If the GCD is non-trivial, then this forces a splitting of the defining polynomial,

all elements of the field are reduced, and the original element may now be zero. More details concerning the internal design of the system can be found in [Ste10].

Care must be taken with the interpretation of the roots of a polynomial in this system. The roots of polynomials are only defined algebraically, and the user may wish to identify them with some particular elements of the complex field, for example, but one cannot assume that the system will follow the embedding one wishes. An example will demonstrate. Suppose that α is a root of $x^2 - 2$, β is a root of $x^2 - 3$, and γ is a root of $x^2 - 6$. Does $\gamma = \alpha \cdot \beta$ or does $\gamma = -\alpha \cdot \beta$? The system will have to make a choice between the two possibilities if the situation arises, but the choice which it will make cannot be predicted beforehand. That is, even if we might like to interpret things as $\alpha = \sqrt{2}$, $\beta = \sqrt{3}$ and $\gamma = \sqrt{6}$ (referring to the positive real roots in each case), it cannot be assumed that this will hold in the particular algebraically closed field, since the roots are only defined algebraically.

In the following descriptions, the adjective *invariable*, applied to a value, means that the mathematical value of a function will not change, despite simplifications, etc. which may occur after the function is called. That is, the value returned by the function may be considered constant with respect to the `eq` operator. A value may print differently later (because of simplifications of the field), but the mathematical value will never change.

In contrast, the adjective *variable* means that the mathematical value of a function may change (as a result of simplifications). This is usually only a property of access-like functions like `Degree(A, v)` (see below). But the fact that most functions below have invariable return values enables the illusion of a true field to be sustained.

Separate algebraic fields should be created for separate problems which involve root taking (if the roots of the different problems are unrelated). Otherwise it may be unnecessarily expensive to compute in the field with roots of unrelated polynomials.

Currently, the base field of an algebraic closure may be a finite field, the rational field **Q**, or a rational function field over a finite field or **Q**.

40.3 Creation of Structures

`AlgebraicClosure(K)`

Create the algebraic closure **A** of the field K. Currently K may be **Q**, a finite field or a rational function field over a finite field or the rational field.

`AlgebraicClosure()`

Create the algebraic closure **A** of the rational field **Q**.

`AssignNamePrefix(A, S)`

(Procedure.) Given an algebraically closed field A and a string S, reassign the string prefix of the names of A to be S. By default, this prefix is `"r"`. When new variables are introduced by root taking, they are named by this prefix with the number appended (see `A.i` below).

40.4 Creation of Elements

The usual way of creating elements within an algebraically closed field A is by coercion from the base field into A, or by construction of roots of polynomials over A (and this may be done indirectly via other functions).

40.4.1 Coercion

`A ! a`

Given a finite field A create the element specified by a; here a is allowed to be an element coercible into A, which means that a may be

(i) an element of A;

(ii) an integer or rational.

`One(A)` `Identity(A)`

`Zero(A)` `Representative(A)`

These generic functions create `A!1`, `A!1`, `A!0` and `A!0`, respectively.

40.4.2 Roots

`Roots(f)`

`Roots(f, A)`

`Max` RngIntElt *Default :*

Given a polynomial f over an algebraically closed field A, or given a polynomial f over some subring of A together with A itself, this function computes all roots of f in A, and returns a sorted sequence of tuples (pairs), each consisting of a root of f in A and its multiplicity. Since A is algebraically closed, f always splits completely.

If the parameter `Max` is set to a non-negative number m, at most m roots are returned. This feature can be quite useful when one wishes, say, only one root of a polynomial and not all the conjugates of the root, as they will cause the field to have more variables than necessary and this can make the full simplification of the field much more difficult later (if that is requested).

Note that the function `Factorization(f)` is also supported, and simply returns the linear factors and multiplicities corresponding to the roots returned by `Roots(f)`.

`RootOfUnity(n, A)`

Return a primitive n-th root of unity in A, i.e., an element $\omega \in A$ such that $\omega^n = 1$ and $\omega^i \neq 1$ for $1 \leq i < n$. This always exists since the field is algebraically closed, and the return value is invariable. This function is equivalent to `Roots(CyclotomicPolynomial(n), A: Max := 1)[1, 1]`.

`SquareRoot(a)`

`Sqrt(a)`

A square root of the element a from the field A, i.e., an element y of A such that $y^2 = a$. A square root always exists since the field is algebraically closed, and the return value is invariable.

`IsSquare(a)`

Return `true` and a square root of the element a from the field A, i.e., `true` and an element y of A such that $y^2 = a$. A square root always exists since the field is algebraically closed, and the return value is invariable.

`Root(a, n)`

Return an n-th root of the element a from the field A, i.e., an element y of A such that $y^n = a$. A root always exists since the field is algebraically closed, and the return value is invariable.

`IsPower(a, n)`

Return `true` and an n-th root of the element a from the field A, i.e., `true` and an element y of A such that $y^n = a$. A root always exists since the field is algebraically closed, and the return value is invariable.

40.4.3 Variables

`A . i`

Return the i-th variable of A. i must be between 1 and the rank of A (the current number of variables in A). Initially A has no variables, and new variables are only created by calling `Roots` above (or similar functions such as `Sqrt`). As long as `Prune` or `Absolutize` are not called (which shift the variable numbers – see below), the return value of this function is invariable, so $A.i$ for fixed i will always return the same mathematical object despite any simplifications or constructions of new roots. New roots are always assigned higher generator numbers.

Example H40E1

We first show the most common way of creating roots: by the `Roots` function.

```
> A := AlgebraicClosure();
> P<x> := PolynomialRing(IntegerRing());
> r := Roots(x^3 + x + 1, A);
> r;
[
    <r1, 1>,
    <r2, 1>,
    <r3, 1>
]
> A;
```

```
Algebraically closed field with 3 variables
Defining relations:
[
    r3^3 + r3 + 1,
    r2^3 + r2 + 1,
    r1^3 + r1 + 1
]
> a := r[1,1];
> a^3 + a;
-1
> A.1;
r1
> A.2;
r2
> A.3;
r3
> A.1 eq a;
true
```

It is often useful to use the `Max` parameter with the `Roots` function. Note that in this case A does not have the extra variables found in the previous example.

```
> A := AlgebraicClosure();
> r := Roots(x^3 + x + 1, A: Max := 1);
> A;
Algebraically closed field with 1 variable
Defining relations:
[
    r1^3 + r1 + 1
]
```

One can also create elements by `Sqrt`, etc.

```
> A := AlgebraicClosure();
> sqrt2 := Sqrt(A ! 2);
> cube3 := Root(A!3, 3);
> A;
Algebraically closed field with 2 variables
Defining relations:
[
    r2^3 - 3,
    r1^2 - 2
]
> sqrt2^2;
2
> cube3^3;
3
```

Example H40E2

The n-th Swinnerton-Dyer polynomial is defined to be

$$\prod(x \pm \sqrt{2} \pm \sqrt{3} \pm \sqrt{5} \pm \cdots \pm \sqrt{p_n}),$$

where p_i is the i-th prime and the product runs over all 2^n possible combinations of $+$ and $-$ signs. Such polynomials lie in $\mathbf{Z}[x]$ and are irreducible over $\mathbf{Z}$. It is very easy to compute them using algebraically closed fields. We simply construct the square roots we need and multiply out the expression, coercing the resulting polynomial to $\mathbf{Z}[x]$.

```
> Z := IntegerRing();
> function SwinnertonDyer(n)
>     P := [2];
>     for i := 2 to n do
>         Append(~P, NextPrime(P[#P]));
>     end for;
>     A := AlgebraicClosure();
>     S := [Sqrt(A ! p): p in P];
>     P<z> := PolynomialRing(A);
>     f := &*[z + &+[t[i]*S[i]: i in [1..n]]: t in CartesianPower({-1, 1}, n)];
>     return PolynomialRing(Z) ! f;
> end function;
> P<x> := PolynomialRing(Z);
> [SwinnertonDyer(i): i in [1..5]];
[
    x^2 - 2,
    x^4 - 10*x^2 + 1,
    x^8 - 40*x^6 + 352*x^4 - 960*x^2 + 576,
    x^16 - 136*x^14 + 6476*x^12 - 141912*x^10 + 1513334*x^8 -
        7453176*x^6 + 13950764*x^4 - 5596840*x^2 + 46225,
    x^32 - 448*x^30 + 84864*x^28 - 9028096*x^26 + 602397952*x^24 -
        26625650688*x^22 + 801918722048*x^20 - 16665641517056*x^18 +
        239210760462336*x^16 - 2349014746136576*x^14 +
        15459151516270592*x^12 - 65892492886671360*x^10 +
        172580952324702208*x^8 - 255690851718529024*x^6 +
        183876928237731840*x^4 - 44660812492570624*x^2 +
        2000989041197056
]
```

The Swinnerton-Dyer polynomials yield worse-case inputs for the Berlekamp-Zassenhaus factorization algorithm for polynomials over $\mathbf{Z}$, but they are no longer difficult to factor using van Hoeij's new algorithm (see Example H23E6).

We can even define a simple extension of the Swinnerton-Dyer polynomials. Let $Q = \{q_1, \ldots, q_n\}$ be a set of n distinct primes or negatives of primes. Define:

$$\mathrm{GSD}_Q := \prod(x \pm \sqrt{q_1} \pm \sqrt{q_2} \pm \cdots \pm \sqrt{q_n}),$$

where the product runs over all 2^n possible combinations of + and − signs. Then $\mathrm{GSD}_Q \in \mathbf{Z}[x]$, is irreducible over $\mathbf{Z}$, has degree 2^n, and has at least 2^{n-1} factors mod any prime. A function to compute these polynomials is only a slight variation on the previous function.

```
> function GSD(Q)
>     n := #Q;
>     A := AlgebraicClosure();
>     S := [Sqrt(A ! x): x in Q];
>     z := PolynomialRing(A).1;
>     f := &*[z + &+[t[i]*S[i]: i in [1..n]]: t in CartesianPower({-1, 1}, n)];
>     return PolynomialRing(Z) ! f;
> end function;
```

One can multiply GSD_Q for various Q to construct more reducible polynomials with many modular factors. We first note the effects of changing the sign of the input primes.

```
> GSD([2, 3, 5]);
x^8 - 40*x^6 + 352*x^4 - 960*x^2 + 576
> GSD([-2, -3, -5]);
x^8 + 40*x^6 + 352*x^4 + 960*x^2 + 576
> GSD([-2, 3, 5]);
x^8 - 24*x^6 + 224*x^4 + 960*x^2 + 1600
> GSD([2, -3, 5]);
x^8 - 16*x^6 + 184*x^4 + 960*x^2 + 3600
> GSD([2, 3, -5]);
x^8 + 152*x^4 + 1920*x^2 + 5776
```

We now form a polynomial f which is the product of two degree-64 irreducible polynomials. f has at least 64 factors modulo any prime, but is not difficult to factor using van Hoeij's algorithm.

```
> f := GSD([2, 3, 5, 7, 11, 13])*GSD([-2, -3, -5, -7, -11, -13]);
> Degree(f);
128
> Max([Abs(x): x in Coefficients(f)]);
74356932844713201802276382813294219572861455394629943303351262856515487990904 17
> time L:=Factorization(f);
Time: 9.850
> [Degree(t[1]): t in L];
[ 64, 64 ]
> Max([Abs(x): x in Coefficients(L[1,1])]);
17710807204306291616851589788921525994 56 11
```

Example H40E3

This example shows how one can compute Puiseux expansions over an algebraic closure. The `PuiseuxExpansion` function calls the `Roots` function internally as it needs to.

```
> A := AlgebraicClosure();
> S<y> := PuiseuxSeriesRing(A);
> P<x> := PolynomialRing(S);
```

```
> f := (x^2 - y^2 - 1)^5 + x*y + 1;
> time S := PuiseuxExpansion(f, 3);
Time: 0.210
> S;
[
    r1*y + (102/2525*r1 - 2/505)*y^3 + O(y^4),
    r2*y + (102/2525*r2 - 2/505)*y^3 + O(y^4),
    r3 + (1/10*r3^2 - 1/10)*y + (-101/1000*r3^7 + 101/200*r3^5 -
        209/200*r3^3 + 26/25*r3)*y^2 + O(y^3),
    r4 + (1/10*r4^2 - 1/10)*y + (-101/1000*r4^7 + 101/200*r4^5 -
        209/200*r4^3 + 26/25*r4)*y^2 + O(y^3),
    r5 + (1/10*r5^2 - 1/10)*y + (-101/1000*r5^7 + 101/200*r5^5 -
        209/200*r5^3 + 26/25*r5)*y^2 + O(y^3),
    r6 + (1/10*r6^2 - 1/10)*y + (-101/1000*r6^7 + 101/200*r6^5 -
        209/200*r6^3 + 26/25*r6)*y^2 + O(y^3),
    r7 + (1/10*r7^2 - 1/10)*y + (-101/1000*r7^7 + 101/200*r7^5 -
        209/200*r7^3 + 26/25*r7)*y^2 + O(y^3),
    r8 + (1/10*r8^2 - 1/10)*y + (-101/1000*r8^7 + 101/200*r8^5 -
        209/200*r8^3 + 26/25*r8)*y^2 + O(y^3),
    r9 + (1/10*r9^2 - 1/10)*y + (-101/1000*r9^7 + 101/200*r9^5 -
        209/200*r9^3 + 26/25*r9)*y^2 + O(y^3),
    r10 + (1/10*r10^2 - 1/10)*y + (-101/1000*r10^7 + 101/200*r10^5 -
        209/200*r10^3 + 26/25*r10)*y^2 + O(y^3)
]
> A;

```

40.5 Related Structures

`Category(A)` `Parent(A)` `Centre(A)`
`PrimeRing(A)` `PrimeField(A)`
`FieldOfFractions(A)`

40.6 Properties

`BaseField(A)`

Return the base field over which A is defined.

`Rank(A)`

Return the current rank of A, that is, the number of variables which currently define A. This can increase by the construction of new roots, or decrease by pruning (see `Roots` and `Prune` respectively below), so the return value of this function is *variable*.

`Degree(A, v)`

Given an algebraically closed field A of rank r and an integer v in the range $1 \leq v \leq r$, return the current degree of the defining polynomial for variable v. The return value of this function is *variable*, as A may be simplified between invocations, making the defining polynomial for v have smaller degree.

`Degree(A)`

Return the current absolute degree of A, that is, the degree over its base field. This necessitates the simplification of A (see `Simplify` below), so may be very time consuming. The return value varies only when new roots of polynomials over the field are computed, but until then, the return value is invariable (as the field will remain simplified, even if `Prune` or `Absolutize` is called – see below).

AffineAlgebra(A)

QuotientRing(A)

Return the affine algebra (or multivariate quotient ring) R which currently represents A. The quotient relations of R consist of the defining polynomials A, and one may coerce between A and R, but note that the variable numbers are inverted. The reason for this is that for the system to work, the first root $A.1$ must be the smallest variable with respect to the lexicographical order in the corresponding affine algebra R, so that reductions modulo the Gröbner basis of relations are in the correct form.

Note also that if A changes in any way (whether from simplification or by pruning), then the affine algebra R of course stays the same and will not be comparable with the new form of A if A has a different number of variables than before.

Ideal(A)

Return the ideal of defining polynomials currently defining A. This is simply equivalent to `DivisorIdeal(AffineAlgebra(A))`. See the relevant comments for the function AffineAlgebra.

Characteristic(A)

40.8 Element Operations

40.8.1 Arithmetic Operators

This section lists the basic arithmetic operations available for elements of an algebraically closed field. Elements are always kept in normal form with respect to the defining relations of the field. Computing the inverse of an element may cause a simplification of the field to be performed.

```
+ a
- a
a + b
a - b
a * b
a / b
a ^ k
a +:= b
a -:= b
a *:= b
```

40.8.2 Equality and Membership

40.8.3 Parent and Category

```
Parent(a)
Category(a)
```

40.8.4 Predicates on Ring Elements

```
IsZero(a)
```

Return whether a is the zero element of its field. This is the most difficult of all arithmetic functions for algebraically closed fields! To determine whether a is zero, MAGMA computes the recursive GCD of a, considered as a polynomial in its highest variable, and the appropriate defining polynomial, to determine the result. If the GCD is non-trivial, then this forces a splitting of the defining polynomial, all elements of the field are reduced, and the original element may now be deemed to be zero (it may not be zero because the cofactor of the GCD may be used to perform the simplification). Despite the fact that simplifications may occur, the return value of this function is *invariable*, and this fact is the most important feature of the whole system, enabling the illusion of a true field to be achieved!

```
IsOne(a)
```

Return whether a is one in its field, which is determined by testing whether $(a-1)$ is zero. Consequently, a simplification of the field may occur, but the return value is invariable.

```
IsMinusOne(a)
```

Return whether a is minus one in its field, which is determined by testing whether $(a+1)$ is zero. Consequently, a simplification of the field may occur, but the return value is invariable.

`a eq b`

Return whether $a = b$, which is determined by testing whether $(a - b)$ is zero. Consequently, a simplification of the field may occur, but the return value is invariable.

`a ne b`

`a in A` `a notin A`

`IsNilpotent(a)` `IsIdempotent(a)`

`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`

`IsIrreducible(a)` `IsPrime(a)`

40.8.5 Minimal Polynomial, Norm and Trace

`MinimalPolynomial(a)`

Return the minimal polynomial of the element a of the field A, relative to the base field of A. This is the unique minimal-degree *irreducible* monic polynomial with coefficients in the base field, having a as a root.

This function works as follows. First the minimal polynomial M of a in the affine algebra corresponding to A is computed. M may be reducible in general, so M is factored, and for each irreducible factor F of M, $F(a)$ is evaluated and it is tested whether this evaluation is zero (using the `IsZero` algorithm). If M is not irreducible, some of these evaluations will cause simplifications of the field, but exactly one of the evaluations will be zero and the corresponding irreducible F is the minimal polynomial of a. Consequently, after F is returned, $F(a)$ will be identically zero so the return value of this function *is invariable*.

Thus the illusion of a true field is sustained by forcing the minimal polynomial of a to be irreducible, by first performing whatever simplifications of A are necessary for this. (In fact, computing minimal polynomials in this way is one method of achieving simplifications.)

`Norm(a)`

Given an element a from an algebraically closed field A, return the absolute norm of a to the base field of A. This is simply computed as $(-1)^{\text{Degree}(M)}$ times the constant coefficient of M, where M is the irreducible minimal polynomial of a returned by `MinimalPolynomial`(a). Consequently, a simplification of the field may occur, but the return value is invariable.

`Trace(a)`

Given an element a from an algebraically closed field A, return the absolute trace of a to the base field of A. This is simply computed as the negation of the coefficient of x^{n-2} in M, where M is the irreducible minimal polynomial of a returned by `MinimalPolynomial`(a). Consequently, a simplification of the field may occur, but the return value is invariable.

`Conjugates(a)`

Given an element a from an algebraically closed field A, return the conjugates of a as a sequence of elements. The conjugates of a are defined to be the roots in A of the minimal polynomial of a, and a is always included. This function is thus simply equivalent to:

```
[t[1] :  t in Roots(MinimalPolynomial(a), A)].
```

(No multiplicities are returned as in the `Roots` function since the minimal polynomial is always squarefree, of course.) As this function first computes the minimal polynomials of a, a simplification of the field may occur, but the return value is invariable.

Example H40E4

We create two elements of an algebraically closed field and note that they are conjugate.

```
> A := AlgebraicClosure();
> x := Sqrt(A!2) + Sqrt(A!-3);
> y := Sqrt(A ! (-1 + 2*Sqrt(A!-6)));
> A;
Algebraically closed field with 4 variables
Defining relations:
[
    r4^2 - 2*r3 + 1,
    r3^2 + 6,
    r2^2 + 3,
    r1^2 - 2
]
> x;
r2 + r1
> y;
r4
> x eq y;
false
> Conjugates(x);
[
    r4,
    -r4,
    r5,
    r6
]
> y in Conjugates(x);
true
```

Of course, x and y are conjugate if and only if they have the same minimal polynomial, which is the case here:

```
> P<z> := PolynomialRing(RationalField());
```

```
> MinimalPolynomial(x);
z^4 + 2*z^2 + 25
> MinimalPolynomial(y);
z^4 + 2*z^2 + 25
```

40.9 Simplification

The following procedures allow one to simplify an algebraically closed field so that it is a true field.

`Simplify(A)`

`Partial` BoolElt *Default :* `false`

(Procedure.) Simplify the algebraically closed field A so that the affine algebra which represents it is a true field, modifying A in place. Equivalently, simplify A so that the multivariate polynomial ideal corresponding to the defining polynomials A is maximal.

The procedure first partially simplifies A by calling `MinimalPolynomial` on all variables and sums of two variables of A. This will usually cause many simplifications, since this forces the corresponding minimal polynomials to be irreducible (see `MinimalPolynomial`). The procedure then performs all other necessary simplifications by successively computing absolute representations and factorizing the absolute polynomials which arise. This may be very expensive (in particular, if the final absolute degree is greater than 20), so is only practical for fairly small degrees.

If the parameter `Partial` is set to `true`, then only the partial simplification is performed, which is usually rather fast, and may be sufficient.

`Prune(A)`

Prune the algebraically closed field A by removing useless variables, modifying A in place. That is, for each variable v of A such that its defining polynomial is a linear polynomial, remove v and the corresponding defining polynomial from A, and shift variables higher than v appropriately.

Note that elements of A are kept reduced to normal form with respect to the defining polynomials of A (at least according the user's perception), so for each such v having a linear relation, v cannot occur in any element of A, so the removal of v from A is possible.

40.10 Absolute Field

One may construct an absolute field isomorphic to the current subfield represented by an algebraically closed field. The construction of the absolute field may be very expensive, as it involves factoring polynomials over successive subfields. In fact, it is often the case that the degree of the absolute field is an extremely large integer, so that an absolute field is not practically representable, yet the system may allow one to compute effectively with the original non-absolute presentation.

`AbsoluteAffineAlgebra(A)`

`AbsoluteQuotientRing(A)`

Simplify the algebraically closed field A fully (see `Simplify(A)` above) and then return an absolute field as a univariate affine algebra R which is isomorphic to the current (true) algebraic field represented by A, and also return the isomorphism $f : A \to R$.

`AbsolutePolynomial(A)`

Simplify the algebraically closed field A fully (see `Simplify(A)` above) and then compute an absolute field isomorphic to the current (true) algebraic field represented by A and return the defining polynomial of the absolute field. That is, return a polynomial f such that $K[x]/ < f >$ is isomorphic to A in its current state.

`Absolutize(A)`

Modify the algebraically closed field A in place so that has an absolute presentation. That is, compute an isomorphic absolute field and absolute polynomial f as in `AbsolutePolynomial` and modify A and its elements in place so that A now only has one variable v and corresponding defining polynomial $f(v)$ and the elements of A correspond via the isomorphism to their old representation.

Example H40E5

We show how one can easily compute the number field over which the complete variety of the Cyclic-6 ideal can be defined.
We first create the ideal I over $\mathbf{Q}$ and compute its variety over A, the algebraic closure of $\mathbf{Q}$.

```
> P<a,b,c,d,e,f> := PolynomialRing(RationalField(), 6);
> B := [
>     a + b + c + d + e + f,
>     a*b + b*c + c*d + d*e + e*f + f*a,
>     a*b*c + b*c*d + c*d*e + d*e*f + e*f*a + f*a*b,
>     a*b*c*d + b*c*d*e + c*d*e*f + d*e*f*a + e*f*a*b + f*a*b*c,
>     a*b*c*d*e + b*c*d*e*f + c*d*e*f*a + d*e*f*a*b +
>         e*f*a*b*c + f*a*b*c*d,
>     a*b*c*d*e*f - 1];
> I := ideal<P | B>;
> time Groebner(I);
Time: 1.459
```

```
> A := AlgebraicClosure();
> time V := Variety(I, A);
Time: 4.219
> #V;
156
```

We now notice that there are 28 variables in A and we check that all elements of V satisfy the original polynomials.

```
> Rank(A);
28
> V[1];
<-1, -1, -1, -1, r1 + 4, -r1>
> V[156];
<r28^3 + 2*r28^2*r9 - 2*r9, -r28^3 - 2*r28^2*r9 + 2*r9, r9, -r28, r28, -r9>
> {Evaluate(f, v): v in V, f in B};
{
    0
}
```

We now simplify A to ensure that it represents a true field, and prune away useless variables now having linear defining polynomials.

```
> time Simplify(A);
Time: 3.330
> Prune(A);
> A;
Algebraically closed field with 3 variables
Defining relations:
[
    r3^2 - 1/3*r3*r2*r1 - 5/3*r3*r2 + 2/3*r3*r1 - 2/3*r3 + r2*r1 + 4*r2 + 1,
    r2^2 - r2*r1 - 4*r1 - 1,
    r1^2 + 4*r1 + 1
]
> V[1];
<-1, -1, -1, -1, r1 + 4, -r1>
> V[156];
<2/3*r3*r2*r1 + 7/3*r3*r2 - 1/3*r3*r1 - 2/3*r3 + 5/3*r2*r1 +
    19/3*r2 + 2/3*r1 + 4/3, -2/3*r3*r2*r1 - 7/3*r3*r2 + 1/3*r3*r1
    + 2/3*r3 - 5/3*r2*r1 - 19/3*r2 - 2/3*r1 - 4/3, -4/3*r2*r1 -
    14/3*r2 - 1/3*r1 - 2/3, 2/3*r3*r2*r1 + 7/3*r3*r2 - 1/3*r3*r1
    - 2/3*r3 - 5/3*r2*r1 - 19/3*r2 + 1/3*r1 - 1/3, -2/3*r3*r2*r1
    - 7/3*r3*r2 + 1/3*r3*r1 + 2/3*r3 + 5/3*r2*r1 + 19/3*r2 -
    1/3*r1 + 1/3, 4/3*r2*r1 + 14/3*r2 + 1/3*r1 + 2/3>
```

Finally we compute an absolute polynomial for A, and then modify A in place using `Absolutize` to make A be defined by one polynomial of degree 8.

```
> time AbsolutePolynomial(A);
x^8 + 4*x^6 - 6*x^4 + 4*x^2 + 1
Time: 0.080
```

```
> time Absolutize(A);
Time: 0.259
> A;
Algebraically closed field with 1 variables
Defining relations:
[
    r1^8 + 4*r1^6 - 6*r1^4 + 4*r1^2 + 1
]
> V[1];
<-1, -1, -1, -1, 1/2*r1^6 + 2*r1^4 - 7/2*r1^2 + 3, -1/2*r1^6 -
    2*r1^4 + 7/2*r1^2 + 1>
> V[156];
<r1^7 + 4*r1^5 - 6*r1^3 + 4*r1, -r1^7 - 4*r1^5 + 6*r1^3 - 4*r1,
    -1/4*r1^7 - 3/4*r1^5 + 11/4*r1^3 - 7/4*r1, -r1, r1, 1/4*r1^7
    + 3/4*r1^5 - 11/4*r1^3 + 7/4*r1>
> {Evaluate(f, v): v in V, f in B};
{
    0
}
```

Example H40E6

In this example we compute the splitting field of a certain polynomial of degree 8.
We first set f to a degree-8 polynomial using the database of polynomials with given Galois group. The Galois group has order 16, so we know that the splitting field will have absolute degree 16.

```
> P<x> := PolynomialRing(IntegerRing());
> load galpols;
Loading "/home/magma/libs/galpols/galpols"
> PolynomialWithGaloisGroup(8, 6);
x^8 - 2*x^7 - 9*x^6 + 10*x^5 + 22*x^4 - 14*x^3 - 15*x^2 + 2*x + 1
> f := $1;
> #GaloisGroup(f);
16
```

We next create an algebraic closure A and compute the roots of f over A.

```
> A := AlgebraicClosure();
> r := Roots(f, A);
> #r;
8
> A;
Algebraically closed field with 8 variables
Defining relations:
[
    r8^8 - 2*r8^7 - 9*r8^6 + 10*r8^5 + 22*r8^4 - 14*r8^3 - 15*r8^2 + 2*r8 + 1,
    r7^8 - 2*r7^7 - 9*r7^6 + 10*r7^5 + 22*r7^4 - 14*r7^3 - 15*r7^2 + 2*r7 + 1,
    r6^8 - 2*r6^7 - 9*r6^6 + 10*r6^5 + 22*r6^4 - 14*r6^3 - 15*r6^2 + 2*r6 + 1,
    r5^8 - 2*r5^7 - 9*r5^6 + 10*r5^5 + 22*r5^4 - 14*r5^3 - 15*r5^2 + 2*r5 + 1,
```

```
    r4^8 - 2*r4^7 - 9*r4^6 + 10*r4^5 + 22*r4^4 - 14*r4^3 - 15*r4^2 + 2*r4 + 1,
    r3^8 - 2*r3^7 - 9*r3^6 + 10*r3^5 + 22*r3^4 - 14*r3^3 - 15*r3^2 + 2*r3 + 1,
    r2^8 - 2*r2^7 - 9*r2^6 + 10*r2^5 + 22*r2^4 - 14*r2^3 - 15*r2^2 + 2*r2 + 1,
    r1^8 - 2*r1^7 - 9*r1^6 + 10*r1^5 + 22*r1^4 - 14*r1^3 - 15*r1^2 + 2*r1 + 1
]
```

Finally we simplify A. There are defining polynomials of degrees 2 and 8 in the simplified field. The absolute polynomial of degree 16 defines the splitting field of f.

```
> time Simplify(A);
Time: 2.870
> A;
Algebraically closed field with 8 variables
Defining relations:
[
    r8 + 1/2*r3*r1^6 - 2*r3*r1^5 - r3*r1^4 + 8*r3*r1^3 - 2*r3*r1^2 -
        5*r3*r1 - 1/2*r3 + r1^7 - 3/2*r1^6 - 9*r1^5 + 4*r1^4 + 19*r1^3
        - r1^2 - 9*r1 - 5/2,
    r7 - 1/2*r3*r1^6 + 2*r3*r1^5 + r3*r1^4 - 8*r3*r1^3 + 2*r3*r1^2 +
        5*r3*r1 + 1/2*r3,
    r6 + r3 - 3/2*r1^7 + 2*r1^6 + 14*r1^5 - 5*r1^4 - 28*r1^3 + 3*r1^2
        + 19/2*r1,
    r5 - 1/2*r3*r1^6 + 2*r3*r1^5 + r3*r1^4 - 8*r3*r1^3 + 2*r3*r1^2 +
        4*r3*r1 + 1/2*r3 + r1^6 - r1^5 - 9*r1^4 - r1^3 + 14*r1^2 +
        6*r1,
    r4 + 1/2*r3*r1^6 - 2*r3*r1^5 - r3*r1^4 + 8*r3*r1^3 - 2*r3*r1^2 -
        4*r3*r1 - 1/2*r3 - 1,
    r3^2 - 3/2*r3*r1^7 + 2*r3*r1^6 + 14*r3*r1^5 - 5*r3*r1^4 -
        28*r3*r1^3 + 3*r3*r1^2 + 19/2*r3*r1 + 3/2*r1^6 - r1^5 -
        15*r1^4 - 4*r1^3 + 27*r1^2 + 11*r1 - 9/2,
    r2 + 1/2*r1^7 - 3/2*r1^6 - 4*r1^5 + 10*r1^4 + 10*r1^3 - 16*r1^2 -
        11/2*r1 + 3/2,
    r1^8 - 2*r1^7 - 9*r1^6 + 10*r1^5 + 22*r1^4 - 14*r1^3 - 15*r1^2 +
        2*r1 + 1
]
> AbsolutePolynomial(A);
x^16 - 36*x^14 + 488*x^12 - 3186*x^10 + 10920*x^8 - 19804*x^6 + 17801*x^4 -
    6264*x^2 + 64
```

41 RATIONAL FUNCTION FIELDS

Chapter 41
RATIONAL FUNCTION FIELDS

41.1 Introduction

Given a ring R such that there is a greatest-common-divisor algorithm for polynomials over R, MAGMA allows the construction of a rational function field K in any number of indeterminates over R. Such function fields are objects of type `FldFunRat` with elements of type `FldFunRatElt`. The elements of K are fractions whose numerators and denominators lie in the corresponding polynomial ring over R. As for polynomial rings, the different univariate and multivariate cases are distinguished, since the fractions just use the different representations given by the different cases of polynomial rings.

A fraction f lying in a function field K is always *reduced*; this means that the numerator and denominator of f are coprime and the denominator of f is *normalized* (monic over fields and positive over $\mathbf{Z}$). Note that R itself need not be a field. Thus it is possible, for example, to create the rational function field $K = \mathbf{Z}(t)$ which is mathematically equal to $\mathbf{Q}(t)$ of course, but will be represented slightly differently. A fraction in $\mathbf{Q}(t)$ will have a monic denominator (and the coefficients of both the numerator and denominator may be non-integral), while a fraction in $\mathbf{Z}(t)$ will have a positive denominator (and the coefficients of both the numerator and denominator will be integral). Thus the fractions $(3t+2)/(4t-2) \in \mathbf{Z}(t)$ and $((3/4)t+1/2)/(t-1/2) \in \mathbf{Q}(t)$ are equal and are both reduced in their respective fields. It is generally much better to use the domain of integers instead of the field of fractions for the coefficient ring R (so it is better to use $\mathbf{Z}(t)$ instead of $\mathbf{Q}(t)$) since arithmetic is much faster, but the use of a field of fractions for the coefficient ring may be more desirable for output purposes.

41.2 Creation Functions

41.2.1 Creation of Structures

`FunctionField(R)`

`RationalFunctionField(R)`

`Global` BOOLELT *Default :* `true`

Create the field $\mathbf{F}$ of rational functions in 1 indeterminate (consisting of quotients of univariate polynomials) over the integral domain R. The angle bracket notation may be used to assign names to the indeterminates, just as in the case of polynomial rings, e.g.: `K<t> := FunctionField(IntegerRing());`.

By default, the unique *global* univariate function field over R will be returned; if the parameter `Global` is set to `false`, then a non-global univariate function field over R will be returned (to which a separate name for the indeterminate can be assigned).

`FunctionField(R, r)`

`RationalFunctionField(R, r)`

`Global` BoolElt *Default :* `false`

Create the field **F** of rational functions in r indeterminates over the integral domain R. may be used to assign names to the indeterminates, just as in the case of polynomial rings, e.g.: `K<a,b,c> := FunctionField(IntegerRing(), 3);`.

By default, a *non-global* function field will be returned; if the parameter `Global` is set to `true`, then the unique global function field over R with n variables will be returned. This may be useful in some contexts, but a non-global result is returned by default since one often wishes to have several function fields with the same numbers of variables but with different variable names (and create mappings between them, for example). Explicit coercion is always allowed between function fields having the same number of variables (and suitable base rings), whether they are global or not, and the coercion maps the i-variable of one function field to the i-th variable of the other function field.

`FieldOfFractions(P)`

Given a polynomial ring P, return its field of fractions F, consisting of quotients f/g, with $f, g \in P$. The angle bracket notation may be used to assign names to the indeterminates, just as in the case of polynomial rings: `K<t> := FieldOfFractions(P);`. If this function is called more than once for a fixed P, then the identical function field will be returned each time.

41.2.2 Names

`AssignNames(~F, s)`

Procedure to change the name of the indeterminates of a function field F. The i-th indeterminate will be given the name of the i-th element of the sequence of strings s (for $1 \leq i \leq \#s$); the sequence may have length less than the number of indeterminates of F, in which case the remaining indeterminate names remain unchanged.

This procedure only changes the name used in printing the elements of F. It does *not* assign to identifiers corresponding to the strings the indeterminates in F; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies F, it is necessary to have a reference `~F` to F in the call to this function.

`Name(F, i)`

Given a function field F, return the i-th indeterminate of F (as an element of F).

41.2.3 Creation of Elements

`F ! [a, b]`

`elt< F | a, b >`

Given the rational function field F (which is the field of fractions of the polynomial ring R), and polynomials a, b in R (with $b \neq 0$), construct the rational function a/b.

`F ! a`

Given the rational function field F as a field of fractions of R, and a polynomial $a \in R$, create the rational function $a = a/1$ in F.

`K . i`

The i-th generator for the field of fractions K of R over the coefficient ring of R.

`One(F)` `Identity(F)`

`Zero(F)` `Representative(F)`

Example H41E1

We create the field of rational functions over the integers in a single variable w.

```
> R<x> := PolynomialRing(Integers());
> F<w> := FieldOfFractions(R);
> F ! x+3;
w + 3
> F ! [ x, x-1 ];
w/(w - 1)
```

41.3 Structure Operations

41.3.1 Related Structures

`IntegerRing(F)`

`RingOfIntegers(F)`

Given the rational function field F this returns the polynomial ring from which F was constructed as its field of fractions.

`BaseRing(F)`

`CoefficientRing(F)`

The coefficient ring of the (ring of integers of) the rational function field F.

`Rank(F)`

The rank (number of indeterminates) of the rational function field F.

`ValuationRing(F)`

Given the rational function field F for which the coefficients come from a field, this returns the valuation ring of F with respect to the valuation given by the degree. This valuation ring consists of those rational functions g/h for which the degree of h is greater than or equal to that of g.

`ValuationRing(F, f)`

Given the rational function field F for which the coefficients come from a field, and an irreducible polynomial f in the ring of integers of F, this returns the valuation ring of F with respect to the valuation associated with f. This valuation ring consists of those rational functions g/h for which f divides g but not h.

`Category(R)` `Parent(R)` `PrimeRing(R)`

41.3.2 Invariants

`Characteristic(F)`

41.3.3 Ring Predicates and Booleans

`IsCommutative(F)` `IsUnitary(F)`
`IsFinite(F)` `IsOrdered(F)`
`IsField(F)` `IsEuclideanDomain(F)`
`IsPID(F)` `IsUFD(F)`
`IsDivisionRing(F)` `IsEuclideanRing(F)`
`IsPrincipalIdealRing(F)` `IsDomain(F)`
`F eq G` `F ne G`

41.3.4 Homomorphisms

In its general form a ring homomorphism taking a function field $R(x_1, \ldots, x_n)$ as domain requires $n + 1$ pieces of information, namely, a map (homomorphism) telling how to map the coefficient ring R together with the images of the n indeterminates.

`hom< P -> S | f, y1, ..., yn >`

`hom< P -> S | y1, ..., yn >`

Given a function field $F = R(x_1, \ldots, x_n)$, a ring S, a map $f : F \to S$ and n elements $y_1, \ldots, y_n \in S$, create the homomorphism $g : F \to S$ by applying the rules of $g(rx_1^{a_1} \cdots x_n^{a_n}) = f(r)y_1^{a_1} \cdots y_n^{a_n}$ for monomials, linearity for polynomials, i.e., $g(M + N) = g(M) + g(N)$, and division for fractions, i.e., $g(n/d) = g(n)/g(d)$.

The coefficient ring map may be omitted, in which case the coefficients are mapped into S by the unitary homomorphism sending 1_R to 1_S. Also, the images y_i are allowed to be from a structure that allows automatic coercion into S.

Example H41E2

In this example we map $\mathbf{Q}(x, y)$ into the number field $\mathbf{Q}(\sqrt[3]{2}, \sqrt{5})$ by sending x to $\sqrt[3]{2}$ and y to $\sqrt{5}$ and the identity map on the coefficients (which we omit).

```
> Q := RationalField();
> F<x, y> := FunctionField(Q, 2);
> A<a> := PolynomialRing(IntegerRing());
> N<z, w> := NumberField([a^3-2, a^2+5]);
> h := hom< F -> N | z, w >;
> h(x^11*y^3-x+4/5*y-13/4);
-40*w*z^2 - z + 4/5*w - 13/4
> h(x/3);
1/3*z
> h(1/x);
1/2*z^2
> 1/z;
1/2*z^2
```

41.4 Element Operations

41.4.1 Arithmetic

`+ a` `- a`

`a + b` `a - b` `a * b` `a / b` `a ^ k`

41.4.2 Equality and Membership

`a eq b` `a ne b`

`a in F` `a notin F`

41.4.3 Numerator, Denominator and Degree

`Numerator(f)`

Given a rational function $f \in K$, the field of fractions of R, return the numerator P of $f = P/Q$ as an element of the polynomial ring R.

`Denominator(f)`

Given a rational function $f \in K$, the field of fractions of R, return the denominator Q of $f = P/Q$ as an element of the polynomial ring R.

`Degree(f)`

Given a rational function f in a univariate function field, return the degree of f as an integer (the maximum of the degree of the numerator of f and the degree of the denominator of f).

`TotalDegree(f)`

Given a rational function f in a multivariate function field, return the total degree of f as an integer (the total degree of the numerator of f minus the total degree of the denominator of f).

`WeightedDegree(f)`

Given a rational function f in a multivariate function field, return the weighted degree of f as an integer (the weighted degree of the numerator of f minus the weighted degree of the denominator of f).

41.4.4 Predicates on Ring Elements

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`

`IsNilpotent(a)` `IsIdempotent(a)`

`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`

41.4.5 Evaluation

`Evaluate(f, r)`

Given a univariate rational function f in F, return the rational function in F obtained by evaluating the indeterminate in r, which must be from (or coercible into) the coefficient ring of the integers of F.

`Evaluate(f, v, r)`

Given a multivariate rational function f in F, return the rational function in F obtained by evaluating the v-th variable in r, which must be from (or coercible into) the coefficient ring of the integers of F.

41.4.6 Derivative

`Derivative(f)`

Given a univariate rational function f, return the first derivative of f with respect to its variable.

`Derivative(f, k)`

Given a univariate rational function f, return the k-th derivative of f with respect to its variable. k must be non-negative.

`Derivative(f, v)`

Given a multivariate rational function f, return the first derivative of f with respect to variable number v.

`Derivative(f, v, k)`

Given a multivariate rational function f, return the k-th derivative of f with respect to variable number v. k must be non-negative.

41.4.7 Partial Fraction Decomposition

`PartialFractionDecomposition(f)`

Given a univariate rational function f in $F = K(x)$, return the (unique) complete partial fraction decomposition of f. The decomposition is returned as a (sorted) sequence Q consisting of triples, each of which is of the form $< d, k, n >$ where d is the denominator, k is the multiplicity of the denominator, and n is the corresponding numerator, and also d is irreducible and the degree of n is strictly less than the degree of d. Thus f equals the sum of the ${n_t}/{d_t}^{k_t}$, where t ranges over the triples contained in Q. If f is improper (the degree of its numerator is greater than or equal to the degree of its denominator), then the first triple of Q will be of the form $< 1, 1, q >$ where q is the quotient of the numerator of f by the denominator of f.

`SquarefreePartialFractionDecomposition(f)`

Given a univariate rational function f in $F = K(x)$, return the (unique) complete squarefree partial fraction decomposition of f. The decomposition is returned as a (sorted) sequence Q consisting of triples, each of which is of the form $< d, k, n >$ where d is the denominator, k is the multiplicity of the denominator, and n is the corresponding numerator, and also d is squarefree and the degree of n is strictly less than the degree of d. Thus f equals the sum of the ${n_t}/{d_t}^{k_t}$, where t ranges over the triples contained in Q. If f is improper (the degree of its numerator is greater than or equal to the degree of its denominator), then the first triple of Q will be of the form $< 1, 1, q >$ where q is the quotient of the numerator of f by the denominator of f.

Example H41E3

We compute the squarefree and complete (irreducible) partial fraction decompositions of a fraction in $Q(t)$.

```
> F<t> := FunctionField(RationalField());
> P<x> := IntegerRing(F);
> f := ((t + 1)^8 - 1) / ((t^3 - 1)*(t + 1)^2*(t^2 - 4)^2);
> SD := SquarefreePartialFractionDecomposition(f);
> SD;
[
    <x^4 + 2*x^3 - x - 2, 1, 467/196*x^3 + 1371/196*x^2 +
        1391/196*x + 234/49>,
    <x^2 - x - 2, 1, -271/196*x + 505/98>,
    <x^2 - x - 2, 2, 271/14*x + 139/7>
]
> // Check appropriate sum equals f:
> &+[F!t[3] / F!t[1]^t[2]: t in SD] eq f;
> D := PartialFractionDecomposition(f);
> D;
[
    <x - 2, 1, -3683/2646>,
    <x - 2, 2, 410/63>,
    <x - 1, 1, 85/36>,
    <x + 1, 1, 1/108>,
    <x + 1, 2, 1/18>,
    <x + 2, 1, 1/18>,
    <x^2 + x + 1, 1, -5/147*x - 8/147>
]
> // Check appropriate sum equals f:
> &+[F!t[3] / F!t[1]^t[2]: t in D] eq f;
true
```

Note that doing the same operation in the function field $Z(t)$ must modify the numerators and denominators to be integral but the result is otherwise the same.

```
> F<t> := FunctionField(IntegerRing());
> P<x> := IntegerRing(F);
> f := ((t + 1)^8 - 1) / ((t^3 - 1)*(t + 1)^2*(t^2 - 4)^2);
> D := PartialFractionDecomposition(f);
> D;
[
    <2646*x - 5292, 1, -3683>,
    <63*x - 126, 2, 25830>,
    <36*x - 36, 1, 85>,
    <108*x + 108, 1, 1>,
    <18*x + 18, 2, 18>,
    <18*x + 36, 1, 1>,
    <147*x^2 + 147*x + 147, 1, -5*x - 8>
]
```

```
> // Check appropriate sum equals f:
> &+[F!t[3] / F!t[1]^t[2]: t in D] eq f;
true
```

Finally, we compute the partial fraction decomposition of a fraction in a function field whose coefficient ring is a multivariate function field.

```
> R<a, b> := FunctionField(IntegerRing(), 2);
> F<t> := FunctionField(R);
> P<x> := IntegerRing(F);
> f := 1 / ((t^2 - a)^2*(t + b)^2*t^3);
> SD := SquarefreePartialFractionDecomposition(f);
> SD;
[
    <x^3 + b*x^2 - a*x - a*b, 1, (-3*a - 2*b^2)/(a^3*b^4)*x^2 +
        (-a - 2*b^2)/(a^3*b^3)*x + (3*a + 3*b^2)/(a^2*b^4)>,
    <x^3 + b*x^2 - a*x - a*b, 2, (a + b^2)/(a^2*b^3)*x^2 +
        1/a^2*x + (-a - b^2)/(a*b^3)>,
    <x, 1, (3*a + 2*b^2)/(a^3*b^4)>,
    <x, 2, -2/(a^2*b^3)>,
    <x, 3, 1/(a^2*b^2)>
]
> // Check appropriate sum equals f:
> &+[F!t[3] / F!t[1]^t[2]: t in SD] eq f;
true
> D := PartialFractionDecomposition(f);
> D;
[
    <x, 1, (3*a + 2*b^2)/(a^3*b^4)>,
    <x, 2, -2/(a^2*b^3)>,
    <x, 3, 1/(a^2*b^2)>,
    <x + b, 1, (-3*a + 7*b^2)/(a^3*b^4 - 3*a^2*b^6 + 3*a*b^8 -
        b^10)>,
    <x + b, 2, -1/(a^2*b^3 - 2*a*b^5 + b^7)>,
    <x^2 - a, 1, (-3*a^2 - 3*a*b^2 + 2*b^4)/(a^6 - 3*a^5*b^2 +
        3*a^4*b^4 - a^3*b^6)*x + (6*a*b - 2*b^3)/(a^5 - 3*a^4*b^2
        + 3*a^3*b^4 - a^2*b^6)>,
    <x^2 - a, 2, (a + b^2)/(a^4 - 2*a^3*b^2 + a^2*b^4)*x -
        2*b/(a^3 - 2*a^2*b^2 + a*b^4)>
]
> // Check appropriate sum equals f:
> &+[F!t[3] / F!t[1]^t[2]: t in D] eq f;
true
```

41.5 Padé-Hermite Approximants

41.5.1 Introduction

A given rational function $F(z) \in k(z)$ over a field k can be written as a power series $f(z)$ in the completion $k((z))$ of $k(z)$ at the place (z). It thus is a good approximation of $f(z)$ in the sense that $F(z)$ is equal to $f(z)$ up to infinite order.

Padé-Hermite approximants deal with the converse. Given a (formal) power series $f(z) \in k[[z]]$ and some non- negative integers n_P and n_Q, find polynomials $P(z), Q(z) \in k[z]$ of degrees at most n_P and n_Q, respectively, such that $P(z)*f(z)-Q(z) = O(z^{n_P+n_Q+1})$ holds. In other words, $P/Q(z)$ is an approximation for $f(z)$ for polynomials P and Q of limited degree in z. In this notation the pair $[P, Q]$ is known as the Padé-Hermite approximant for the power series tuple $(f, -1)$.

The idea of approximating one power series by two polynomials can be extended to approximating several power series at the same time as follows. Consider the vector $\underline{f}^T := (f_1, f_2, \ldots, f_m)^T$ in the m-dimensional vector space $k((z))^m$ over a power series ring. Let $\underline{n} = (n_1, n_2, \ldots, n_m)$ be an m-tuple of non-negative integers. A *Padé-Hermite approximant* of $\underline{f}^T(z)$ of type $\underline{n}$ is a non-zero vector of polynomials $\underline{P} = (P_1, P_2, \ldots, P_m)$ in $k[z]^m$ such that $\underline{P} \cdot \underline{f}^T = O(z^N)$, $N = n_1 + n_2 + \cdots + n_m + m - 1$, is satisfied. A non-trivial Padé-Hermite approximant always exists. The approximant is contained in the sub-space $V_{\underline{f},N} = \{\underline{Q} \in k[z]^m : \underline{Q} \cdot \underline{f}^T = O(z^N)\}$.

The implementation of Padé-Hermite approximants is based on [Der94] and [BL94]. They are implemented in MAGMA as sequences rather than vectors.

41.5.2 Ordering of Sequences

A Padé-Hermite approximant to some sequence of power series does not have to be unique. They can be ordered according to their maximum degree and their type of sequence. A sequence $\underline{P} = [P_1, P_2, ..., P_m]$ is of degree i if the maximum of the weak degrees of $P_1, P_2, \ldots, P_m$ is i. An extension of the definition maximum degree is when a distortion of non-negative integers $\underline{d} = [d_1, d_2, \ldots, d_m]$ on the degrees is allowed. In this case the maximum degree is defined as the maximum of $\deg P_i - d_i$. The type of $\underline{P}$ identifies the last P_i in $\underline{P}$ whose weak degree equals the maximum degree of $\underline{P}$. Again a distortion on the degrees is allowed.

`MaximumDegree(f)`

`Distortion` SEQENUM *Default :* []

MaximumDegree returns the degree of a sequence of polynomials or power series, defined as the maximum of the degrees of $f[i] - d[i]$, where d is the distortion. The value -infinity is returned in the case that f is weakly equal to the zero-sequence.

Example H41E4

```
> S<u> := PowerSeriesRing(Rationals());
> f := [u+u^2, 2+u^2+u^3,0];
```

```
> MaximumDegree(f);
3
> MaximumDegree(f:Distortion:=[]);
3
> MaximumDegree(f:Distortion:=[0,2,1]);
2
> MaximumDegree([S|0,0]);
-Infinity
> MaximumDegree([O(u)]);
-Infinity
```

`TypeOfSequence(f)`

`Distortion` SEQENUM *Default :* []

Returns the highest index i for those $f[i]$ whose (distorted) degree is weakly equal to the maximum of the degrees of all entries. The second integer returned is the maximum degree of the sequence.

Example H41E5

```
> S<u> := PowerSeriesRing(Rationals());
> f := [u+u^2, 2+u^2+u^3,0];
> TypeOfSequence(f);
2 3
> TypeOfSequence(f:Distortion:=[]);
2 3
> TypeOfSequence(f:Distortion:=[0,2,1]);
1 2
> TypeOfSequence([S|0,0]);
2 -Infinity
```

The Padé-Hermite approximant of $\underline{f}$ can be seen as an element of the free module $k[z]^m$ of rank m, or as an element of the sub-space $V_{\underline{f},N}$.

A free sub-model $V \subset k[z]^m$ is generated by m polynomial vectors $\underline{Q}_i$, $1 = 1, 2, \ldots, m$, such that $\underline{Q}_1(z), \underline{Q}_2(z), \ldots, \underline{Q}_m(z)$ form a minimal vector sequence of V. Such a sequence is defined as a sequence S of m vectors in V, such that $S[i]$ is a non-trivial polynomial vector in V of minimal degree of type i, for $i = 1, 2, \ldots, m$. A minimal vector sequence is not unique.

Two variations on a minimal vector sequence are implemented. The first allows a distortion as an attribute. The sequence is the based on the distorted maximal degree. The second attribute sets the positive power p of z in each of the $\underline{Q}_i$ as follows. Instead of considering $\underline{Q}_i(z)$ for each i, one considers $\underline{Q}_i(z^p)$.

`MinimalVectorSequence(f,n)`

`Distortion`	SeqEnum	*Default :* []
`Power`	RngIntElt	*Default :* 1

A minimal sequence of vectors $\underline{Q}_1, \underline{Q}_2, \ldots, \underline{Q}_m$ with respect to the sequence f of length m whose entries are polynomials or power series. The order of $\underline{Q}_i \cdot f$ is at least m.

Example H41E6

```
> S<u> := PowerSeriesRing(Rationals());
> f := [u+u^2, 2+u^2+u^3];
> seq := MinimalVectorSequence(f, 2);
> seq;
[
    (u 0),
    (   -1 1/2*u)
]
> sums := [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
> sums;
[
    u^2 + u^3,
    -u^2 + 1/2*u^3 + 1/2*u^4
]
> seq := MinimalVectorSequence(f,3);
> #seq eq 2,  seq[1], seq[2];
true (u^2   0)
(-1 + u  1/2*u)
```

Example H41E7

```
> L<x> := PolynomialRing(Rationals());
> f := [1+x, 3-x^2, 5+x+x^3-x^5];
> seq := MinimalVectorSequence(f, 10);
> seq[1];
(-2*x^2 + 6   -2*x - 2          0)
> sums := [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
> sums;
[
    0,
    0,
    x^10
]
```

Example H41E8

```
> S<u> := PowerSeriesRing(Rationals());
> f := [2*u^4,2+u^3+u^6];
> seq := MinimalVectorSequence(f, 10);
> seq;
[
    (1/2*u^6       0),
    (-1/2 - 1/4*u^3        1/2*u^4)
]
> sums := [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
> sums;
[
    u^10,
    1/2*u^10
]
```

Example H41E9

```
> S<u> := PowerSeriesRing(Rationals());
> f :=  [1+u-7*u^2, 6-3*u+1/2*u^2-u^3, 5-u+u^2];
> seq := MinimalVectorSequence(f, 5);
>  [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
[
    0,
    u^5,
    0
]
> seq := MinimalVectorSequence(f, 5:Distortion:=[2,0,1]);
> [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
[
    -7/2*u^5,
    u^5,
    0
]
> p:=2;
> seq := MinimalVectorSequence(f, 5:Distortion:=[2,0,1], Power:=p);
> sums := [&+([Q[i]*f[i]: i in [1..#f]]) : Q in seq];
> sums;
> mp:= map<S->S|  x :-> (IsWeaklyZero(x) select 0
>     else  &+([Coefficient(x,i)*(S.1)^(p*i) :  i in Exponents(x)]))
>       + (ISA(Type(v),RngIntElt) select O((S.1)^(p*v))
>   else S!0 where v := AbsolutePrecision(x))>;
> sums := [&+([mp(Q[i])*f[i]: i in [1..#f]]) : Q in seq];
> sums;
[
    u^6 + u^7 - 7*u^8,
```

```
    u^5 - 23/3*u^6,
    -5/3*u^5 + 35/3*u^6
]
```

41.5.3 Approximants

The Padé-Hermite approximant of type $\underline{d} = [d_1, d_2, \ldots, d_m]$ with respect to the tuple $\underline{f}^T \in k((z))^m$ is an element of the space $V_{\underline{f},N} = \{\underline{Q} \in k[z]^m : \underline{Q} \cdot \underline{f}^T = O(z^N)\}$ for N equal to $d_1 + d_2 + \cdots + d_m + m - 1$. This space is generated by the vectors in the minimal vector sequence with respect to $\underline{f}$ with distortion $\underline{d}$. The routine PadeHermiteApproximant returns one that is smallest with respect to the degree on sequences. The input sequence $\underline{f}$ must be a sequence of polynomial ring elements, or be a power series sequence. While the Padé Hermite approximants theoretically are polynomials, MAGMA returns them as elements of the same ring the entries of $\underline{f}$ are contained in.

`PadeHermiteApproximant(f,d)`

`Power` RNGINTELT *Default :* 1

Returns a Padé-Hermite form $\underline{P}$ of f with distortion d, smallest with respect to the degree on sequences, and the corresponding minimal vector sequence. The third argument returned is the order in the order term of $\underline{P} \cdot f$.

Example H41E10

This example can be found on page 813 in [BL94].

```
> S<u> := PowerSeriesRing(Rationals());
> f := [1,u,u/(1-u^4)+u^10+O(u^16),u/(1+u^4)+u^12+O(u^16)];
> pade, padebasis, ord := PadeHermiteApproximant(f,[2,2,2,2]);
> pade, ord;
( u -1  0  0)
11
> BaseRing(Parent(pade)) eq S;
true
> MinimalVectorSequence(f,10);
[
    ( u -1  0  0),
    (   0  u^4 -1/2  1/2),
    (         0    1 - u^4 -1/2 + u^4       -1/2),
    (    0    -u 1/2*u 1/2*u)
]
>
> p := 2;
> seq := MinimalVectorSequence(f,10: Distortion :=[2,2,2,2],Power := p);
> seq;
[
    (u^5   0   0   0),
```

```
    (   0  u^2 -1/2  1/2),
    (         0    1 - u^2 -1/2 + u^2       -1/2),
    (    0    -u 1/2*u 1/2*u)
]
> mp:= map<S->S|  x :-> (IsWeaklyZero(x) select 0
>     else  &+([Coefficient(x,i)*(S.1)^(p*i) :  i in Exponents(x)]))
>       + (ISA(Type(v),RngIntElt) select O((S.1)^(p*v))
>   else S!0 where v := AbsolutePrecision(x))>;
> sums := [&+([mp(Q[i])*f[i]: i in [1..#f]]) : Q in seq];
> [Valuation(v) : v in sums];
[ 10, 10, 10, 11 ]
> sums;
[
    u^10,
    -1/2*u^10 + 1/2*u^12 - u^13 + O(u^16),
    -1/2*u^10 - 1/2*u^12 + u^13 + u^14 + O(u^16),
    u^11 + 1/2*u^12 + 1/2*u^14 + O(u^18)
]
```

Example H41E11

This example covers the example on page 815 in [BL94].

```
> S<u> := PowerSeriesRing(Rationals());
> f := [1,u, -1-u^4-2*u^8+u^10+u^11-u^12+O(u^16),-u-u^5-u^9-u^14-u^15+O(u^16)];
> dist:=[2,2,3,3];
> seq := MinimalVectorSequence(f,13:Distortion:=dist);
> pade, padebasis, ord :=  PadeHermiteApproximant(f,dist);
> pade, ord;
(-u  1  0  0)
13
> padebasis;
[
    (-u  1  0  0),
    (1/2*u -1/2*u^4 1/2*u + 1/2*u^3 + 1/2*u^4 -1/2*u^2 - 1/2*u^3 - u^4),
    (-1/2 1/2*u^3 -1/2 - 1/2*u^2 - 1/2*u^3 - u^4 1/2*u + 1/2*u^2 + 2*u^3),
    (      -u        0        0 -1 + u^4)
]
> padebasis eq seq;
true
> [[Valuation(w[i]): i in [1..Degree(w)]] : w in seq];
[
    [ 1, 0, Infinity, Infinity ],
    [ 1, 4, 1, 2 ],
    [ 0, 3, 0, 1 ],
    [ 1, Infinity, Infinity, 0 ]
]
> [[MaximumDegree([w[i]])-dist[i]: i in [1..Degree(w)] ] : w in seq];
```

```
[
    [ -1, -2, -Infinity, -Infinity ],
    [ -1, 2, 1, 1 ],
    [ -2, 1, 1, 0 ],
    [ -1, -Infinity, -Infinity, 1 ]
]
> p:=2;
> seq := MinimalVectorSequence(f,12:Distortion:=dist,Power:=p);
> seq;
[
    (  u - u^3         0 u - 2*u^3         0),
    (-1 - u + u^2 -u^3 -1 - u + 2*u^2 + u^3 -u^3),
    (u + u^2 - u^3 0 u + u^2 - 2*u^3 - u^4 0),
    (      0       1       0 1 - u^2)
]
> seq[1]-seq[3];
(      -u^2          0 -u^2 + u^4          0)
> mp:= map<S->S|  x :-> (IsWeaklyZero(x) select 0
>     else  &+([Coefficient(x,i)*(S.1)^(p*i) :  i in Exponents(x)]))
>       + (ISA(Type(v),RngIntElt) select O((S.1)^(p*v))
>   else S!0 where v := AbsolutePrecision(x))>;
>  [Valuation(&+([mp(Q[i])*f[i]: i in [1..#f]])) : Q in seq];
[ 12, 12, 13, 13 ]
```

Example H41E12

This example considers the example on page 816 in [BL94].

```
> S<u> := PowerSeriesRing(Rationals());
> f := [1,u,-1-u^4-2*u^8+u^10+O(u^12),-u-u^5-u^9+u^10+O(u^12)];
> dist := [2,2,3,3];
> seq := MinimalVectorSequence(f,12: Distortion := dist);
> [[MaximumDegree([w[i]])-dist[i]: i in [1..Degree(w)] ] : w in seq];
[
    [ -1, -2, -Infinity, -Infinity ],
    [ -2, 1, 0, 0 ],
    [ -Infinity, -Infinity, 1, 0 ],
    [ -1, -Infinity, 0, 1 ]
]
> [Valuation(&+([(Q[i])*f[i]: i in [1..#f]]) ) : Q in seq];
[ Infinity, 12, 12, 12 ]
> [MaximumDegree([ &+([(Q[i])*f[i]: i in [1..#f]]) ]) : Q in seq];
[ -Infinity, -Infinity, 14, -Infinity ]
> PadeHermiteApproximant(f,[2,2,3,3]);
> p := 2;
> seq := MinimalVectorSequence(f,12:Distortion:=[2,2,3,3],Power:=p);
> seq;
[
```

```
    (  1 - u^2        -1 1 - 2*u^2  -1 + u^2),
    (   0 -u^4    0 -u^4),
    (      -u       -1 -u + u^3 -1 + u^2),
    (      0       u       0 u - u^3)
]
> [[MaximumDegree([w[i]])-dist[i]: i in [1..Degree(w)] ] : w in seq];
[
    [ 0, -2, -1, -1 ],
    [ -Infinity, 2, -Infinity, 1 ],
    [ -1, -2, 0, -1 ],
    [ -Infinity, -1, -Infinity, 0 ]
]
> mp:= map<S->S|  x :-> (IsWeaklyZero(x) select 0
>     else  &+([Coefficient(x,i)*(S.1)^(p*i) :  i in Exponents(x)]))
>       + (ISA(Type(v),RngIntElt) select O((S.1)^(p*v))
>   else S!0 where v := AbsolutePrecision(x))>;
>
> [Valuation(&+([mp(Q[i])*f[i]: i in [1..#f]])) : Q in seq];
[ 12, 13, 12, 12 ]
```

A variant of the Padé-Hermite approximant is when the exponent in the order term is set rather that the type of the sequence. It is also possible to let $\underline{f}$ be a sequence such that its entries themselves are vectors of polynomials or power series.

`PadeHermiteApproximant(f,m)`

`Power` RngIntElt *Default :* 1

Returns a Padé-Hermite form of minimal degree in the corresponding minimal vector sequence, such that its inproduct with f has order at least m. The second argument returned is the corresponding minimal vector sequence.

Example H41E13

This example can be found on page 813 in [BL94].

```
> S<u> := PowerSeriesRing(Rationals());
> f := [Vector([1]), Vector([u])];
> pade, seq := PadeHermiteApproximant(f,3);
Calculating the Pade'-Hermite approximant for the sequence [
    1,
    u
]
with order term 3 and power 1 .
> pade;
( u -1)
> seq;
[
```

```
    ( u -1),
    (  0 u^2)
]
> mat := Matrix([Eltseq(v): v in f]);
> pade*mat;
(0)
> PadeHermiteApproximant([1,u],5);
( u -1)
[
    ( u -1),
    (  0 u^4)
]
> PadeHermiteApproximant(f,3:Power:=2);
> g:= [Vector([1,0,0]), Vector([0,1,0]), Vector([1+u,2+u^2,u^3])];
> pade := PadeHermiteApproximant(g,5);
Calculating the Pade'-Hermite approximant for the sequence [
    1,
    u,
    1 + 2*u + u^3 + u^7 + u^11
]
with order term 15 and power 3 .
> pade;
(-u^3 - u^4     -2*u^3        u^3)
> pade*Matrix([Eltseq(v): v in g]);
(  0 u^5 u^6)
```

Example H41E14

This example considers Padé-Hermite approximants for some series that have non-trivial power series expansions.

```
> S<u> := PowerSeriesRing(Rationals());
> f := [Sin(u), Cos(u), Exp(u)];
> [Valuation(f[i]) : i in [1..#f]], [Degree(f[i]) : i in [1..#f]];
[ 1, 0, 0 ]
[ 19, 20, 20 ]
> [AbsolutePrecision(f[i]) : i in [1..#f]];
[ 21, 22, 21 ]
> dist := [3,2,5];
> pade, seq, ord := PadeHermiteApproximant(f,dist);
> 1/420*pade;
(-1275 - 255*u + 45*u^2 + 5*u^3 120 + 495*u + 75*u^2 -120 + 900*u - 600*u^2 +
    160*u^3 - 20*u^4 + u^5)
> ord eq &+(dist)+#f-1, ord;
true 12
> [Degree(pade[i]) : i in [1..Degree(pade)]];
[ 3, 2, 5 ]
> g:= [Cos(2*u)*(u+1)+3,Cos(u)^2+u*Cos(u)+1,Cos(2*u)+1,Cos(u)];
```

```
> pade, basis := PadeHermiteApproximant(g,20);
> 131/75880*pade;
(          2    -4 + 2*u        -3*u 4*u - 2*u^2)
> h := [ 1+u^2-u^7+u^12, Sin(u), Exp(u) ];
> dist:=[3,1,2];
> seq := MinimalVectorSequence(h,8:Distortion := dist);
> sums := [&+([Q[i]*h[i]: i in [1..#f]]) : Q in seq];
> [Valuation(s) : s in sums];
[ 8, 8, 8 ]
> [[MaximumDegree([w[i]]): i in [1..Degree(w)] ] : w in seq];
[
    [ 4, 1, 2 ],
    [ 4, 2, 2 ],
    [ 3, 1, 2 ]
]
>  [[MaximumDegree([w[i]])-dist[i]: i in [1..Degree(w)] ] : w in seq];
[
    [ 1, 0, 0 ],
    [ 1, 1, 0 ],
    [ 0, 0, 0 ]
]
```

42 ALGEBRAIC FUNCTION FIELDS

Chapter 42
ALGEBRAIC FUNCTION FIELDS

42.1 Introduction

This version of MAGMA is based on the KANT Version 4 system for algebraic function field computations. Special functions for rational function fields are described in Chapter FldFunRat.

An algebraic function field F/k (in one variable) over a field k is a field extension F of k such that F is a finite field extension of $k(x)$ for an element $x \in F$ which is transcendental over k. As a MAGMA object it is of type `FldFun` with elements of type `FldFunElt`. For perfect k it is always possible to choose $x \in F$ so that $F/k(x)$ is also separable. For such x there exists a primitive element $\alpha \in F$ with $F = k(x, \alpha)$ where α is a root of an irreducible, separable polynomial in $k(x)[y]$.

42.1.1 Representations of Fields

All function fields in MAGMA can be represented as described above, i.e. as $k(x, \alpha)$ where x is transcendental and α is algebraic. This is the representation which has the most functionality.

Alternatively, one may wish to consider a function field as a combined transcendental and algebraic extension of its constant field, more like a curve. Such a field would be a quotient of $k[x, y]$. Fields in this representation do not have orders.

Algebraic function fields may be extended to create relative finite extensions of $k(x)$ like $F = k(x, \alpha_1, \ldots, \alpha_n)$. The functionality described in this chapter which is not available for these relative extensions is that involving series rings, galois groups and subfields.

It is also possible to make non–simple extensions where more than one root of a polynomial is added at each step by extending by several polynomials. These extensions have the same functionality as the relative finite extensions, except that primitive elements and some functions involving differentials are not available.

Function fields represented as finite extensions may have orders. Some orders will have a basis different to that of their function fields. Orders may have a field of fractions. A field of fractions of an order is isomorphic to the function field of the order, however its elements are represented with respect to the basis of the order. So there are 3 different types of rings covered in this chapter, function fields (`FldFun`), orders of function fields (`RngFunOrd`) and fields of fractions of orders of function fields (`FldFunOrd`). Each ring type has its own corresponding element type.

42.2 Creation of Algebraic Function Fields and their Orders

42.2.1 Creation of Algebraic Function Fields

`ext< K | f >`

`FunctionField(f :`*parameters*`)`

`Check`	BoolElt	*Default :* `true`
`Global`	BoolElt	*Default :* `true`

Let k be a field and $K = k(x)$ or $K = k(x, \alpha_1, \ldots, \alpha_r)$ some finite extension of $k(x)$. Given an irreducible and separable polynomial $f \in K[y]$ of degree greater than zero with coefficients within K, create the algebraic function field $F = K[y]/\langle f \rangle = k(x, \alpha_1, \ldots, \alpha_r, \alpha)$ obtained by adjoining a root α of f to K. F will be viewed as a (finite) extension of K. The polynomial f is also allowed to be $\in k[x][y]$.

The optional parameter `Check` may be used to prevent some conditions from being tested. The default is `Check := true`, so that f is verified to be irreducible and separable. The optional parameter `Global` may be used to allow another copy of the field to be returned if it is set to `false`, otherwise if a field has already been constructed using f over K and has not been deleted then the existing field will be returned.

The angle bracket notation may be used to assign the root α to an identifier: `F<a> := FunctionField(f)`.

`FunctionField(f :`*parameters*`)`

`Check`	BoolElt	*Default :* `true`
`Global`	BoolElt	*Default :* `true`

Let k be a field. Given an irreducible polynomial $f \in k[x, y]$ of degree greater than zero, create the algebraic function field F which is the field of fractions of $k[x, y]/\langle f \rangle$. The polynomial f must be separable in at least one variable. F will be viewed as (infinite) extension of k.

The optional parameter `Check` may be used to prevent some conditions from being tested. The default is `Check := true`, so that f is verified to be irreducible and separable in at least one variable. The optional parameter `Global` may be used to allow another copy of the field to be returned if it is set to `false`, otherwise if a field has already been constructed using f over K and has not been deleted then the existing field will be returned.

The angle bracket notation may be used to assign the images of x, y in F to identifiers: `F<a, b> := FunctionField(f)`.

`FunctionField(S)`

`Check`	BoolElt	*Default :* `true`

Return the function field F whose defining polynomials are the polynomials in the sequence S. If `Check` is set to `false` then it will not be checked the polynomials actually define a field.

`FunctionField(S)`

Return the function field F whose defining polynomials are the polynomials in the sequence S. This field F will be represented as an infinite degree extension of the coefficient field of the polynomials in S.

`HermitianFunctionField(p, d)`

`HermitianFunctionField(q)`

Create the Hermitian function field $F = \mathbf{F}_{q^2}(x, \alpha)$ defined by $\alpha^q + \alpha = x^{q+1}$, where q is the d-th power of the prime number p.

`sub< F | S >`

`sub< F |` $s_1, \ldots, s_r$ `>`

The subfield of the function field F containing the elements in the sequence S or the elements s_i.

`AssignNames(~F, s)`

`AssignNames(~a, s)`

Procedure to change the name of the generating element(s) in the function field F (a in F) to the contents of the sequence of strings s, which must have length 1 or 2 in this case.

This procedure only changes the name(s) used in printing the elements of F. It does *not* assign to any identifier(s) the value(s) of the generator(s) in F; to do this, use an assignment statement, or use angle brackets when creating the field.

Note that since this is a procedure that modifies F, it is necessary to have a reference `~F` to F (or a) in the call to this function.

`FunctionField(R)`

`Global`	BoolElt	*Default :* `true`
`Type`	Cat	*Default :* `FldFunRat`

Return the rational function field over R in one variable. If `Global` is `false` then create a new copy of the field, otherwise reuse any globally created field which already exists. If `Type` is `FldFun` create the field as an algebraic function field, otherwise create as a rational function field.

Example H42E1

Let $\mathbf{F}_5$ be the finite field of five elements. To create the function field extension $\mathbf{F}_5(x, \alpha)/\mathbf{F}_5(x)$, where α satisfies

$$\alpha^2 = 1/x,$$

one may proceed in the following, equivalent ways:

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> F<alpha> := FunctionField(y^2 - 1/x);
> F;
Algebraic function field defined over Univariate rational function field over
GF(5)
Variables: x by
y^2 + 4/x
```

or

```
> R<x> := PolynomialRing(GF(5));
> P<y> := PolynomialRing(R);
> F<alpha> := FunctionField(x*y^2 - 1);
> F;
Algebraic function field defined over Univariate rational function field over
GF(5)
Variables: x by
x*y^2 + 4
```

or

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> F<alpha> := ext< R | y^2 - 1/x >;
> F;
Algebraic function field defined over Univariate rational function field over
GF(5)
Variables: x by
y^2 + 4/x
```

Example H42E2

An extension of F may be created as follows.

```
> R<y> := PolynomialRing(F);
> FF<beta> := FunctionField(y^3 - x/alpha : Check := false);
> FF;
Algebraic function field defined over F by
y^3 + 4*x^2*alpha
```

Example H42E3

To create a non–simple extension:

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> FF<alpha, beta> := FunctionField([y^2 - 1/x, y^3 + x]);
> FF;
Algebraic function field defined over Univariate rational function field over
GF(5) by
y^2 + 4/x
y^3 + x
```

or

```
> P<y> := PolynomialRing(F);
> FF<beta, gamma> := FunctionField([y^2 - x/alpha, y^3 + x]);
> FF;
Algebraic function field defined over F by
y^2 + 4*x^2*alpha
y^3 + x
```

Example H42E4

The creation of an Hermitian function field:

```
> F := HermitianFunctionField(9);
> F;
Algebraic function field defined over GF(3^4) by
y^9 + y + 2*x^10
```

42.2.2 Creation of Orders of Algebraic Function Fields

Equation orders, maximal orders and other orders of algebraic function fields can be created.

`EquationOrderFinite(F)`

Create the 'finite' equation order of the function field $F/k(x, \alpha_1, \ldots, \alpha_r)$, i.e. $k[x, d_1\alpha_1, \ldots, d_r\alpha_r, d\alpha]$ where $d_j, d \in k[x]$ is chosen such that $d_j\alpha_j, d\alpha$ are integral over $k[x]$.

`MaximalOrderFinite(F)`

Create the 'finite' maximal order of the function field $F/k(x, \alpha_1, \ldots, \alpha_r)$. This is the integral closure of $k[x, d_1\alpha_1, \ldots, d_r\alpha_r]$ in F.

`EquationOrderInfinite(F)`

Create the 'infinite' equation order of the function field $F/k(x, \alpha_1, \ldots, \alpha_r)$, i.e. $o_\infty[\alpha_1, \ldots, \alpha_r, \beta]$ where o_∞ denotes the valuation ring of the degree valuation in $k(x)$ and β is a primitive element of $F/k(x, \alpha_1, \ldots, \alpha_r)$ which is integral over o_∞.

`MaximalOrderInfinite(F)`

Create the 'infinite' maximal order of the function field $F/k(x, \alpha_1, \ldots, \alpha_r)$. This is the integral closure of o_∞ in F.

`IntegralClosure(R, F)`

The integral closure of the subring R of the function field F in itself.

`EquationOrder(O)`

The equation order of the order O. An order whose basis is a transformation of that of O and is a power basis.

`MaximalOrder(O)`

`Discriminant`	ANY	*Default :*
`Ramification`	SEQENUM	*Default :*
`Al`	MONSTGELT	*Default :* "*Auto*"
Verbose	`MaximalOrder`	*Maximum :* 5

The maximal order of the order O of an algebraic function field.

If O is a radical (pure) extension then specific code is used to calculate each p-maximal order, rather than the Round 2 method. In this case we can compute a pseudo basis for the p-maximal orders knowing only the valuation of the constant coefficient of the defining polynomial at p [Sut12].

If O is an Artin–Schreier extension then the maximal order can be computed directly without computing the p-maximal orders. The proof of Proposition III.7.8 of [Sti93] gives us a start on some elements which are a basis for the maximal order [Sut13].

If the `Discriminant` or `Ramification` parameters are supplied an algorithm ([Bj94], Theorems 1.2 and 7.6) which can compute the maximal order given the discriminant of the maximal order will be used. `Discriminant` must be an element of the coefficient ring of O if O is a non relative order and must be an ideal of O if O is a relative order. `Ramification` must contain elements of the coefficient ring if O is a non relative order and must contain ideals of O if O is a relative order. The ramification sequence is taken to contain prime factors of the discriminant. Only one of these parameters can be specified and if one of them is then `Al` cannot be specified. Otherwise `Al` may be set to `"Round2"` to avoid using the algorithms for the special cases above.

`SetOrderMaximal(O, b)`

Set the order O of a function field to be maximal if b is `true` and to be non–maximal if b is `false`.

`ext< O | f >`

`Check` BOOL *Default :* `true`

The order O with a root of f adjoined.

Example H42E5

Creation of orders is shown below.

```
> PR<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(PR);
> FR1<a> := FunctionField(y^3 - x*y^2 + y + x^4);
> P<y> := PolynomialRing(FR1);
> FR2<c> := FunctionField(y^2 + y - a/x^5);
> EFR1F := EquationOrderFinite(FR1);
> MFR1F := MaximalOrderFinite(FR1);
> EFR1I := EquationOrderInfinite(FR1);
> MFR1I := MaximalOrderInfinite(FR1);
> EFR2F := EquationOrderFinite(FR2);
> MFR2F := MaximalOrderFinite(FR2);
> EFR2I := EquationOrderInfinite(FR2);
> MFR2I := MaximalOrderInfinite(FR2);
>  MaximalOrder(EFR2I);
>> MaximalOrder(EFR2I);
               ^
Runtime error in 'MaximalOrder': Order must be defined over a maximal order
> MFR2I;
Maximal Order of FR2 over MFR1I
> P<y> := PolynomialRing(FR1);
> MaximalOrder(ext<MFR1F | y^2 + y - a*x^5>); MFR2F;
Maximal Equation Order of Algebraic function field defined over FR1 by
y^2 + y - x^5*a over EFR1F
Maximal Order of FR2 over EFR1F
> MaximalOrder(ext<MFR1I | y^2 - 1/a>);
Maximal Order of Algebraic function field defined over FR1 by
y^2 + 1/x^4*a^2 - 1/x^3*a + 1/x^4 over MFR1I
```

Example H42E6

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> f := y^3 + (4*x^3 + 4*x^2 + 2*x + 2)*y^2 + (3*x + 3)*y + 2;
> F<alpha> := FunctionField(f);
> IntegralClosure(R, F);
```

```
Algebraic function field defined over GF(5) by
y^3 + (4*x^3 + 4*x^2 + 2*x + 2)*y^2 + (3*x + 3)*y + 2
> IntegralClosure(PolynomialRing(GF(5)), F);
Maximal Order of F over Univariate Polynomial Ring in x over GF(5)
> IntegralClosure(ValuationRing(R), F);
Maximal Order of F over Valuation ring of Rational function field of
rank 1 over GF(5)
Variables: x with generator 1/x
```

`Order(O, T, d)`

`Check` BoolElt *Default :* `true`

Create the order whose basis is that of the order O multiplied by the matrix T over the coefficient ring of O divided by the scalar d. If the parameter `Check` is set to `false` then it will not be checked that the result is actually an order (potentially expensive).

`Order(O, M)`

`Check` BoolElt *Default :* `true`

Create the order whose basis is that of the order O multiplied by the dedekind module M. If the parameter `Check` is set to `false` then it will not be checked that the result is actually an order (potentially expensive).

`Order(O, S)`

`Verify` BoolElt *Default :* `true`

`Order` BoolElt *Default :* `false`

Given a sequence S of elements in an algebraic function field F create the minimal order R of F which contains all elements of S.

The order O may be an order of F which will be used as the suborder of R, in which case its coefficient ring should be maximal, or O may be a maximal order of the coefficient field of F.

If `Verify` is `true`, it is verified that the elements of S are integral algebraic numbers. This can be a lengthy process if the field is of large degree.

Setting `Order` to `true`, when the order is large will avoid verifying that the module generated by the elements of S is closed under multiplication. By default, products of the generators will be added until the module is closed under multiplication.

`Simplify(O)`

Return the order O as a direct transformation of its equation order, instead of a composition of transformations.

`O1 + O2`

The smallest common over order of $O1$ and $O2$ where $O1$ and $O2$ have the same equation order.

`O1 meet O2`

The intersection of orders $O1$ and $O2$ which must have the same equation order.

`AsExtensionOf(O1, O2)`

Return the order $O1$ as an transformation of the order $O2$ where $O1$ and $O2$ have the same coefficient ring.

Example H42E7

Some of the above order creations are shown below.

```
> P<x> := PolynomialRing(GF(5));
> P<y> := PolynomialRing(P);
> F<a> := FunctionField(y^3 - x^4);
> O := Order(EquationOrderFinite(F), MatrixAlgebra(Parent(x), 3)!1, Parent(x)!3);
> O;
Order of F over Univariate Polynomial Ring in x over GF(5)
> Basis(O);
[
    2,
    2*a,
    2*a^2
]
> P<y> := PolynomialRing(O);
> EO := ext<MaximalOrder(O) | y^2 + O!(2*a)>;
> V := KModule(F, 2);
> M := Module([V | [1, 0], [4, 3], [9, 2]]);
> M;

Transformation Matrix:
[[ 1, 0, 0 ] [ 0, 0, 0 ]]
[[ 0, 0, 0 ] [ 1, 0, 0 ]]
```

```
> Basis(O2);
[ 1, $.1 ]
```

42.2.3 Orders and Ideals

Orders may be created using ideals of other orders. Ideals are discussed in Section 42.12.

`MultiplicatorRing(I)`

Returns the multiplicator ring of the ideal I of the order O, that is, the subring of elements of the field of fractions of O that multiply I into itself.

`pMaximalOrder(O, p)`

The p-maximal over order of O where p is a prime polynomial or ideal of the coefficient ring of O or an element of valuation 1 of the valuation ring.

If O is a Kummer extension then specific code is used to calculate each p-maximal order, rather than the Round 2 method. In this case we know 1 or 2 elements which generate the p-maximal order and can write the order down.

If O is an Artin–Schreier extension then we can also write down a basis for the p-maximal order and avoid the Round 2 algorithm. We use [Sti93] Proposition III.7.8 to get a start on computing these elements.

`pRadical(O, p)`

Returns the p-radical of an order O for a prime p (polynomial or ideal of the coefficient ring or element of valuation 1 of the valuation ring), defined as the ideal consisting of elements of O for which some power lies in the ideal pO.

It is possible to call this function even if p is not prime. In this case the p-trace-radical will be computed, i.e.

$$\{x \in F \mid \mathrm{Tr}(xO) \subseteq C\}$$

for F the field of fractions of O and C the order of p (if p is an ideal) or the parent of p otherwise. If p is square free and all divisors are larger than the field degree, this is the intersection of the radicals for all l dividing p.

42.3 Related Structures

42.3.1 Parent and Category

Function fields form the MAGMA category `FldFun` and function field orders form the MAGMA category `RngFunOrd`. The notional power structures exist as parents of function fields and their orders but allow no operations.

`Category(F)` `Category(O)`

`Parent(F)` `Parent(O)`

42.3.2 Other Related Structures

More interesting related structures (than above) are listed below.

`PrimeRing(F)`
`PrimeField(F)`
`PrimeRing(O)`

The prime field of the function field F or the order O (prime ring of the constant field).

`ConstantField(F)`
`DefiningConstantField(F)`

The constant field k, where $F = k(x, \alpha)$.

`ExactConstantField(F)`

The exact constant field of the algebraic function field F/k, i.e. the algebraic closure in F of the constant field k of F, together with the inclusion map.

`BaseRing(F)`
`BaseField(F)`
`CoefficientRing(F)`
`CoefficientField(F)`

The rational function field $k(x)$ if the function field F is an extension of $k(x)$ and k if F is an extension of k. If F is an extension of another algebraic function field then this field will be returned.

`ISABaseField(F,G)`

Applies to more general fields within MAGMA than function fields. Returns whether G is amongst the recursively defined base fields of F.

`BaseRing(O)`

`CoefficientRing(O)`

The polynomial algebra $k[x]$ if the order O is finite or the degree valuation ring if O is infinite. If O is an extension of another order of an algebraic function field this order will be returned.

`BaseRing(FF)`

`BaseField(FF)`

`CoefficientRing(FF)`

`CoefficientField(FF)`

Given a field of fractions FF of an order O return the field of fractions of the coefficient ring of O.

`SubOrder(O)`

For a non equation order O returns the order which O was created as a transformation of. This order is one transformation closer to the equation order.

`FunctionField(O)`

The function field which O is an order of.

`FieldOfFractions(O)`

`FieldOfFractions(FF)`

`FieldOfFractions(F)`

Given an order O, this function returns the field of fractions, a field with the same basis as O. On a function field or a field of fractions this function is trivial.

`Order(FF)`

Given a field of fractions FF return the order O which is the ring of integers of FF.

`RationalExtensionRepresentation(F)`

The function field F represented as an extension of a rational function field. This function gives the representation of function fields F/k as finite extensions.

`AbsoluteOrder(O)`

The order O as an extension of its bottom coefficient ring, (i.e. the order of the `RationalExtensionRepresentation` of the field of fractions of O corresponding to O).

`AbsoluteFunctionField(F)`

The function field F expressed as an extension of its constant field.

`UnderlyingRing(F)`

`UnderlyingField(F)`

`UnderlyingRing(F, R)`

`UnderlyingField(F, R)`

Return the underlying ring of the function field F over R. This is F expressed as an extension of R. If R is not given then it is taken to be the coefficient field of the coefficient field of F. The field R must appear in the tower of coefficient fields under F.

`Embed(F, L, a)`

`Embed(F, L, s)`

Install the embedding of F into L with the image(s) of the primitive element(s) of F being the element a in L or the images in s in L.

`Places(F)`

The set of places of the algebraic function field F/k.

`DivisorGroup(F)`

The group of divisors of the algebraic function field F/k.

`DifferentialSpace(F)`

The space of differentials of the algebraic function field F/k.

Example H42E8

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> f := y^3 + (4*x^3 + 4*x^2 + 2*x + 2)*y^2 + (3*x + 3)*y + 2;
> F<alpha> := FunctionField(f);
> ConstantField(F);
Finite field of size 5
> CoefficientField(F);

GF(5)
Variables: x by
y^3 + (4*x^3 + 4*x^2 + 2*x + 2)*y^2 + (3*x + 3)*y + 2
> Order(IntegralClosure(ValuationRing(R), F),
>     MatrixAlgebra(CoefficientRing(MaximalOrderInfinite(F)), 3)!4,
>     CoefficientRing(MaximalOrderInfinite(F))!1);
```

```
Maximal Order of F over Valuation ring of Univariate rational function field
over GF(5) with generator 1/x
> SubOrder($1);
Maximal Order of F over Valuation ring of Univariate rational function field
over GF(5) with generator 1/x
> $1 eq $2;
false
> Places(F);
Set of places of F
> DivisorGroup(F);
Divisor group of F
```

Example H42E9

Output from `UnderlyingRing` is shown.

```
> PF<x> := PolynomialRing(GF(31, 3));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x^3 + 1>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b*x*y - 1>;
> RationalExtensionRepresentation(FF2);
Algebraic function field defined over Univariate rational function field over
GF(31^3) by
y^6 + 29*y^3 + (30*x^5 + x^2)*y^2 + 1
> UnderlyingRing(FF2);
Algebraic function field defined over Univariate rational function field over
GF(31^3) by

```

`WeilRestriction(E, n)`

`Reduction`	BoolElt	*Default :* `true`
Verbose	`WeilRes`	*Maximum :* 1

A hyperelliptic function field in the Weil restriction over $\mathbf{F}_q$ of the elliptic function field E: $y^2+xy+x^3+ax^2+b$ defined over $\mathbf{F}_{q^n}$ where q is a power of 2. Also returns a function which can be used to map a place (not a pole or zero of x) of F into a divisor of the result. See [Gau00]. `Reduction` indicates whether a (possibly quite expensive) reduction step is performed at the end of the computation. It defaults to `true`.

`ConstantFieldExtension(F, E)`

Return the function field with constant field E which contains the function field F. The ring E must cover the constant field of F. If E is contained in the exact constant field of F then F and the new field will be isomorphic.

Example H42E10

Changing the constant field to the exact constant field is shown below.

```
> P<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(P);
> F<c> := FunctionField(y^6 + y + 2);
> E<a> := ExactConstantField(F);
> C, r := ConstantFieldExtension(F, E);
> r(c);
1/16*(a^5 + 4*a^4 + 6*a^3 + 4*a^2 + a)
> $1 @@ r;
c
> e := Random(C, 2);
> e @@ r;
1/2*x*c^5 - 3*x*c^4 + (-12*x + 8)*c^3 + (-16*x + 24)*c^2 + (-8*x + 16)*c - 1
> r($1);
1/2*(-a^5 - a^2 + a)*$.1 + a^5 + a^4 - a^3 - a^2 - 1
```

`Reduce(O)`

Given an order O belonging to a function field F, this function returns the order obtained by applying size-reduction to the basis of O.

42.4 General Structure Invariants

`Characteristic(F)`

`Characteristic(O)`

The characteristic of the function field F/k or one of its orders O.

`IsPerfect(F)`

Applies to any field in MAGMA. Returns whether F is perfect.

`Degree(F)`

`Degree(F, G)`

`Degree(O)`

The degree $[F : G]$ of the field extension F/G where G is the base field of F unless specified. For an order O, this function returns the rank of O as a module over its coefficient ring. Note that this rank is equal to the degree $[F : G]$ where F and G are the field of fractions of O and the coefficient ring of O respectively.

`AbsoluteDegree(F)`

`AbsoluteDegree(O)`

The degree of the function field F or the order O as a finite extension of $k(x)$ or $k[x]$ or as an infinite extension of k.

`DefiningPolynomial(F)`

`DefiningPolynomial(O)`

The defining polynomial of the function field F over its coefficient ring. For an order O belonging to a function field F, this function returns the defining polynomial of O, which may be different from that of $F/k(x, \alpha_1, \ldots, \alpha_r)$.

`DefiningPolynomials(F)`

`DefiningPolynomials(O)`

Return the defining polynomials of the function field F or the order O as a sequence of polynomials over the coefficient ring.

`Basis(F)`

`Basis(O)`

`Basis(O, R)`

The basis $1, \alpha, \ldots, \alpha^{n-1}$ of the function field $F[\alpha]$ over the coefficient field.

Given an order O belonging to a function field F, this function returns the basis of O in the form of function field elements.

Given an additional ring R, return the basis of O as elements of R.

`TransformationMatrix(O1, O2)`

Return the matrix M and a denominator d which transforms elements of the order $O1$ into elements of the order $O2$.

`CoefficientIdeals(O)`

The coefficient ideals of the order O of a relative extension. These are the ideals $\{A_i\}$ of the coefficient ring of O such that for every element e of O, $e = \sum_i a_i * b_i$ where $\{b_i\}$ is the basis returned for O and each $a_i \in A_i$.

`BasisMatrix(O)`

Given an order O in a function field F of degree n, this returns an $n \times n$ matrix whose i-th row contains the coefficients for the i-th basis element of O with respect to the power basis of F. Thus, if b_i is the i-th basis element of O,

$$b_i = \sum_{j=1}^{n} M_{ij} \alpha^{j-1}$$

where M is the matrix and α is the generator of F.

`PrimitiveElement(O)`

A root of the defining polynomial of the order O.

`Discriminant(O)`

The discriminant of the order O, up to a unit in its coefficient ring.

`AbsoluteDiscriminant(O)`

The discriminant of the order O of an algebraic function field F over the bottom coefficient ring of O, (the subring of the rational function field F extends).

`DimensionOfExactConstantField(F)`

`DegreeOfExactConstantField(F)`

The dimension of the exact constant field of the function field F/k over k. The exact constant field is the algebraic closure of k in F.

`Genus(F)`

The genus of the function field F/k.

Example H42E11

```
> PF<x> := PolynomialRing(GF(31, 3));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x^3 + 1>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b*x*y - 1>;
> Characteristic(FF2);
31
> EFF2I := EquationOrderInfinite(FF2);
> MFF2I := MaximalOrderInfinite(FF2);
> Degree(MFF2I) eq 3;
true
> AbsoluteDegree(EFF2I);
6
> Genus(FF2);

[0 0 0 0 1 0]
[0 0 0 0 0 1]
x
```

`GapNumbers(F)`

`SeparatingElement` FldFunGElt *Default :*

The sequence of global gap numbers of the function field F/k (in characteristic zero this is always $[1, \ldots, g]$). A separating element used internally for the computation can be specified, it defaults to `SeparatingElement(F)`. See the description of `GapNumbers` on page 1167.

`GapNumbers(F, P)`

The sequence of gap numbers of the function field F/k at P where P must be a place of degree one. See the description of `GapNumbers` on page 1167.

`SeparatingElement(F)`

Returns a separating element of the function field F/k.

`RamificationDivisor(F)`

`SeparatingElement` FldFunGElt *Default :*

The ramification divisor of the function field F/k. The semantics of calling `RamificationDivisor()` with F or the zero divisor of F are identical. For further details see the description of `RamificationDivisor` on page 1169.

`WeierstrassPlaces(F)`

`SeparatingElement` FldFunGElt *Default :*

The Weierstrass places of the function field F/k. The semantics of calling `WeierstrassPlaces` with F or the zero divisor of F are identical. See the description of `WeierstrassPlaces` on page 1170.

`WronskianOrders(F)`

`SeparatingElement` FldFunGElt *Default :*

The Wronskian orders of the function field F/k. The semantics of calling `WronskianOrders` with F or the zero divisor of F are identical. See the description of `WronskianOrders` on page 1170.

`Different(O)`

The different of the maximal order O.

`Index(O, S)`

The index of S in O where S is a suborder of O and O and S have the same equation order.

42.5 Galois Groups

Finding Galois groups (of normal closures) of polynomials over rational function fields over $k \in \{\mathbf{Q}, \mathbf{F}_q\}$, where $\mathbf{F}_q$ denotes the finite field of characteristic p with $q = p^r$, $r \in \mathbf{Z}_{>0}$ is a hard problem, in general. All practical algorithms used the classification of transitive groups, which is known up to degree 31 [CHM98]. These algorithms fall into two groups: The absolute resolvent method [SM85] and the method of Stauduhar [Sta73].

The MAGMA implementation is based on an extension of the method of Stauduhar by Klüners, Geißler [Gei03, GK00] and, more recently, Fieker [FK12] and Sutherland [Sut]. There is no longer any limit on the degree of the polynomials or fields as this algorithm does not use the classification of transitive groups. In contrast to the absolute resolvent method, it also provides the explicit action on the roots of the polynomial f which generates the function field. The algorithm strongly depends on the fact that the corresponding problem is implemented for the residue class field.

Roughly speaking, the method of Stauduhar traverses the subgroup lattice of transitive permutation groups of degree n from the symmetric group to the actual Galois group. This is done by using so-called relative resolvents. Resolvents are polynomials whose splitting fields are subfields of the splitting field of the given polynomial which are computed using approximations of the roots of the polynomial f.

If the field (or the field defined by a polynomial) has subfields (i.e. the Galois group is imprimitive) the current implementation changes the starting point of the algorithm in the subgroup lattice, to get as close as possible to the actual Galois group. This is done via computation of subfields of a stem field of f, that is the field extension of $k(t)$ which we get by adjoining a root of f to $k(t)$. The Galois group is found as a subgroup of the intersection of suitable wreath products (using the knowledge of the subfields) which may be easily computed.

If the field (or the field defined by a polynomial) does not have subfields (i.e. the Galois group is primitive) we use a combination of the method of Stauduhar and the absolute resolvent method. The Frobenius automorphism of the underlying field already determines a subgroup of the Galois group, which is used to speed up computations in the primitive case.

The algorithms used here are similar to those use for number fields. See also Chapter 38. In addition to the intrinsics described here, some of the intrinsics described in Section 38.2 apply to polynomials over function fields also.

`GaloisGroup(f)`

`Prime`	RngElt	*Default :*
`NextPrime`	UserProgram	*Default :*
`ProofEffort`	RngIntElt	*Default :* 10
`Ring`	GaloisData	*Default :*
`ShortOK`	BoolElt	*Default :* `false`
`Old`	BoolElt	*Default :* `false`
Verbose	`GaloisGroup`	*Maximum :* 5

Given a separable, (irreducible if k is $\mathbf{Q}$) polynomial $f(t, x)$ of degree n over the rational function field $k(t)$, $k \in \{\mathbf{Q}, \mathbf{F}_q\}$, or an extension K thereof (if $k = \mathbf{F}_q$) this function returns a permutation group that forms the Galois group of a splitting field for f in some algebraic closure of K. The permutation group acts on the points $1, 2, \ldots, n$. The roots of f are calculated in the process, expressed as power series and returned as the second argument: For a prime polynomial $p(t) \in k(t)$ denote by $\bar{N}$ the splitting field of the polynomial $f(t, x)$ mod $p(t)$. It is well known that the roots of the polynomial $f(t, x)$ can be expressed as power series in $\bar{N}[[t]]$. We embed $\bar{N}$ in an unramified p-adic extension. The third return value is a structure containing information about the computation that can be used to compute the roots of f to arbitrary precision. This can be used for example in `GaloisSubgroup` on page 979 to compute arbitrary subfields of the splitting field.

The required precision increases linearly with the index of the subgroups, which are passed traversing the subgroup lattice. Therefore computations may slow down considerably for higher degrees and large indices.

The default version employs series computations over either unramified p-adic fields ($k = \mathbf{Q}$) or finite fields ($k = \mathbf{F}_q$). The prime polynomial is determined during a Galois group computation in such a way that f is squarefree modulo p.

The prime to use for splitting field computations can be given via the parameter `Prime`. The method of choosing primes for splitting field computations can be given by the parameter `NextPrime`. An indication of how much effort the computation should make to prove the results can be provided by altering the parameter `ProofEffort`, it should be increased if more effort should be made.

If `Old` is set to `true`, then the old version is called if available. Since the return values of the new version differ substantially from the old one, this may be used in old applications.

`GaloisGroup(F)`

`Prime`	RngElt	*Default :*
`NextPrime`	UserProgram	*Default :*
`ProofEffort`	RngIntElt	*Default :* 10
`Ring`	GaloisData	*Default :*
`ShortOK`	BoolElt	*Default :* `false`

Given a function field F defined as an extension of either a rational function field or a global algebraic function field by one polynomial compute the Galois group of a normal closure of F.

The prime to use for splitting field computations can be given via the parameter `Prime`. The method of choosing primes for splitting field computations can be given by the parameter `NextPrime`. An indication of how much effort the computation should make to prove the results can be provided by altering the parameter `ProofEffort`, it should be increased if more effort should be made.

Example H42E13

A Galois group computation is shown below.

```
> k<t>:= FunctionField(Rationals());
> R<x>:= PolynomialRing(k);
> f:= x^15 + (-1875*t^2 - 125)*x^3 + (4500*t^2 + 300)*x^2 +
>     (-3600*t^2 - 240)*x + 960*t^2+ 64;
> G, r, S:= GaloisGroup(f);

42.6 Subfields

For finite extensions L of $\mathbf{Q}(t)$, $\mathbf{F}_q(t)$ or extensions K of $\mathbf{F}_q(t)$ MAGMA can compute all fields between L and $\mathbf{Q}(t)$, $\mathbf{F}_q(t)$ or K. It should be noted that the computation of subfields does not depend on the Galois groups. The implementation over $\mathbf{Q}(t)$ uses the algorithm of Klüners [Klü02]. The implementation over $\mathbf{F}_q(t)$ and extensions thereof follows the newer ideas of Klüners and van Hoeij [vHKN11].

`Subfields(F)`

All algebraic function fields G with $k(x) \subset G \subseteq F$ or $K \subset G \subseteq F$ where K is an extension of $\mathbf{F}_q(x)$ and the coefficient field of F.

Example H42E15

A subfield computation is shown below.

```
> k<x>:= FunctionField(Rationals());
> R<y>:= PolynomialRing(k);
> f:= y^14 - 3234*y^12 + (8*x + 123480)*y^11 + (-696*x - 1152480)*y^10 +

42.7 Automorphism Group

Let K be a finite extension of the rational function field over a finite field, the rationals or a number field. In contrast to the number field situation, there are two different natural notions of automorphisms here: we distinguish between automorphisms that fix the base field and arbitrary automorphisms that can also induce non-trivial maps of the constant field.

The first case, automorphisms fixing the base field of K, is analogous to the number field case and was implemented by Jürgen Klüners.

The second case of more general automorphisms has been implemented by Florian Heß along the lines of his paper [Heß04]. Here the constant field of K can, in fact, be any exact perfect field in Magma with a few provisos.

42.7.1 Automorphisms over the Base Field

`Automorphisms(K, k)`

Computes all $\mathbf{Q}(t)$ automorphisms of the absolute finite extension K that fix k. The field k has to be $\mathbf{Q}(t)$ for this function.

`AutomorphismGroup(K, k)`

Return the group of k-automorphisms of the algebraic function field K together with the map from the group to the sequence of automorphisms of K. The field k has to be $\mathbf{Q}(t)$.

Example H42E16

We define an extension of degree 7 over $\mathbf{Q}(t)$ and compute the automorphisms.

```
> Q:=Rationals();
> Qt<t>:=PolynomialRing(Q);
> Qtx<x>:=PolynomialRing(Qt);
> f := x^7 + (t^3 + 2*t^2 - t + 13)*x^6 + (3*t^5 - 3*t^4
>     + 9*t^3 + 24*t^2 - 21*t + 54)*x^5 + (3*t^7 -
>     9*t^6 + 27*t^5 - 22*t^4 + 6*t^3 + 84*t^2 -
>     121*t + 75)*x^4 + (t^9 - 6*t^8 + 22*t^7 -
>     57*t^6 + 82*t^5 - 70*t^4 - 87*t^3 + 140*t^2 -
>     225*t - 2)*x^3 + (-t^10 + 5*t^9 - 25*t^8 +
>     61*t^7 - 126*t^6 + 117*t^5 - 58*t^4 - 155*t^3
>     + 168*t^2 - 80*t - 44)*x^2 + (-t^10 + 8*t^9 -
>     30*t^8 + 75*t^7 - 102*t^6 + 89*t^5 + 34*t^4 -
>     56*t^3 + 113*t^2 + 42*t - 17)*x + t^9 - 7*t^8
>     + 23*t^7 - 42*t^6 + 28*t^5 + 19*t^4 - 60*t^3 -
>     2*t^2 + 16*t - 1;
> K:=FunctionField(f);
> A:=Automorphisms(K, BaseField(K));
> #A;
7
```

Now we transform this list into a group to see that it is really cyclic. We pass in special functions for equality testing and multiplication to speed the algorithm up.

```
> G := GenericGroup(A: Eq := func<a,b | a`Images eq b`Images>,
>                      Mult := func<a,b | hom<K -> K | a`Images @ b>>);
> G;
Finitely presented group G on 2 generators
Relations
    G.1 = Id(G)
    G.1 * G.2 = G.2 * G.1
    G.1 * G.2^2 = G.2^2 * G.1
    G.1 * G.2^3 = G.2^3 * G.1
    G.1 * G.2^4 = G.2^4 * G.1
    G.1 * G.2^5 = G.2^5 * G.1
```

```
    G.1 * G.2^6 = G.2^6 * G.1
    G.1 = G.2^7
```

Finally, we verify that this gives the same result as `AutomorphismGroup`.

```
> AutomorphismGroup(K, BaseField(K));
Finitely presented group on 2 generators
Relations
    $.1 = Id($)
    $.1 * $.2 = $.2 * $.1
    $.1 * $.2^2 = $.2^2 * $.1
    $.1 * $.2^3 = $.2^3 * $.1
    $.1 * $.2^4 = $.2^4 * $.1
    $.1 * $.2^5 = $.2^5 * $.1
    $.1 * $.2^6 = $.2^6 * $.1
    $.1 = $.2^7
Mapping from: GrpFP to [
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K,
    Mapping from: FldFun: K to FldFun: K
] given by a rule
```

`IsSubfield(K, L)`

Given two absolute finite extensions K and L of $\mathbf{Q}(t)$, decide if L is an extension of K. If this is the case, return an embedding map from K into L.

`IsIsomorphicOverQt(K, L)`

Given two absolute finite extensions K and L of $\mathbf{Q}(t)$, decide if L is $\mathbf{Q}(t)$-isomorphic to K. If this is the case, return a map from K onto L.

Example H42E17

`Subfields` and `IsIsomorphic` are illustrated below.

```
> Q:=Rationals();
> Qt<t>:=PolynomialRing(Q);
> Qtx<x>:=PolynomialRing(Qt);
> K:=FunctionField(x^4-t^3);
> L:=Subfields(K);
> #L;
2
> L:=L[2][1]; L;
Algebraic function field defined over Univariate
```

```
rational function field over Rational Field
Variables: t by
x^2 - t^3
```

Now we will check if L is indeed a subfield of K:

```
> IsSubfield(L,K);
true Mapping from: FldFun: L to FldFun: K
```

Obviously, L can be defined using a simpler polynomial:

```
> LL:=FunctionField(x^2-t);
> IsIsomorphicOverQt(LL,L);
true Mapping from: FldFun: LL to FldFun: L
```

42.7.2 General Automorphisms

`Isomorphisms(K, E)`

`BaseMorphism`	MAP	*Default :* `false`
`Bound`	RNGINTELT	*Default :* ∞
`Strategy`	MONSTGELT	*Default :* "*None*"

Given two function fields K and E, this function computes a list of at most `Bound` field isomorphisms from K to E.

If `BaseMorphism` is given it should be an isomorphism f between the constant fields of K and E. In this case only isomorphisms extending f are considered.

The default behaviour is for all isomorphisms from K to E which extend SOME isomorphism of the constant field of K to that of E considered. In this case (no base morphism is specified), the constant fields must be finite, the rationals or a number field. If the base morphism f is specified then the constant fields can be any exact perfect fields (finite or characteristic 0).

If the base morphism f is specified, it can be defined in the natural way for most constant field types. For example, for finite fields and number fields, the usual `hom<k->l|x>`, where `x` gives the image of $k.1$, can be used. A common situation is where the constant fields of K and E are equal to k and f is the identity. This can be defined very simply for any k by `IdentityFieldMorphism(k)` . Several more intrinsics related to field morphisms are described in the following subsection.

The possible choices of `Strategy` are `"None"`, `"Weierstrass"` or `"DegOne"`. If `Strategy` is different to `"None"`, this determines the places that are used as the basis of the construction of the maps. In all cases, a finite set of places of E and K which must correspond under any isomorphism are used. All isomorphisms are found between the canonical affine models (as defined by Heß) obtained by omitting one of these places from each of E and K.

`DegOne` can only be used with finite constant fields. In this case, isomorphisms are determined which map a fixed degree one place of K to any one of the finite

number of degree one places of E. This function can fail in rare situations if the constant field of K is too small and no degree one place exists. In this case an appropriate error message is displayed.

`Weierstrass` uses the Weierstrass places of the fields. Isomorphisms are determined which map a fixed Weierstrass place of K to any of those of E with the same degree and Riemann-Roch data. This strategy can be very fast if the residue field and Riemann-Roch data of a particular place of K match those of only a few (or no!) Weierstrass places of E.

In case of fields of genus < 2, the constant field must be finite.

`IsIsomorphic(K, E)`

`BaseMorphism`	MAP	*Default :* `false`
`Strategy`	MONSTGELT	*Default :* "*None*"

As above, except the function only computes a single isomorphism if one exists.

`Automorphisms(K)`

`BaseMorphism`	MAP	*Default :* `false`
`Bound`	RNGINTELT	*Default :* ∞
`Strategy`	MONSTGELT	*Default :* "*None*"

This function computes a list of at most `Bound` automorphisms of the function field K. This is an abbreviation for `Isomorphisms(K, K)` and the parameters are as described above.

An important difference is that the BaseMorphism, if specified, must be of field morphism type. `IdentityFieldMorphism` may be used, but basic constrictors for non-trivial constant field maps f will usually cause an error if used directly. The way around this is to use the conversion `f := FieldMorphism(f)` (see the following subsection).

`Isomorphisms(K,E,p1,p2)`

`Automorphisms(K,p1,p2)`

`Bound`	RNGINTELT	*Default :* ∞

As above except that the constant field morphism is taken as the identity and only iso/automorphisms which take function field place $p1$ to $p2$ are computed.

`AutomorphismGroup(K)`

`BaseMorphism`	MAP	*Default :* `false`
`Strategy`	MONSTGELT	*Default :* "*None*"

Given a function field K, this function computes that group of automorphisms satisfying the conditions specified by the parameters and returns it as a finitely-presented group. The map also returned is invertible and takes a group element to the function field isomorphism that it represents.

`AutomorphismGroup(K,f)`

`Strategy` MonStgElt *Default : "None"*

In this variation, the automorphism group of the function field K is computed in its permutation representation on a set of places or divisors or in its linear representation on a space of differentials or subspace of K.

The return values consist of the representing group G, a map (with inverse) from G to the maps of K giving the actual isomorphisms, and a sequence of isomorphisms of K which consist of the kernel of the representation.

Only automorphisms fixing the constant field are considered here. If the set/space on which the representation is to be defined is not invariant by the automorphism group, a run-time error will result.

The argument f should be a map defining the representation.

Its domain must be an enumerated sequence for a permutation representation or a vector space for a linear representation.

Its codomain should be K or a space or enumerated sequence of elements of K, places of K, divisors of K or differentials of K. The examples below show some common ways of producing f by using functions like `DifferentialSpace` and `RiemannRochSpace`.

42.7.3 Field Morphisms

The isomorphisms returned by the functions in the last subsection are of general `Map` type but contain some extra internal structure. The same is true of the maps used to specify `BaseMorphism`. These objects come in two flavours: *field morphisms*, that represent maps between general fields, and the more specialised *function field morphisms*, representing maps between algebraic function fields. This subsection contains several related functions that are very useful when working with (function) field morphisms.

`IsMorphism(f)`

Returns `true`, if the map is a field or function field morphism; `false` otherwise.

`FieldMorphism(f)`

Converts a homomorphism between fields into a field morphism.

`IdentityFieldMorphism(F)`

Returns the identity automorphism of field F as a field morphism.

`IsIdentity(f)`

Returns `true` if f is the identity morphism; `false` otherwise.

`Equality(f, g)`

Returns `true`, if the two maps are both field morphisms or function field morphisms and are equal; `false` otherwise.

`HasInverse(f)`

Either returns "true" and the inverse morphism for (function) field morphism f, or "false" if inverse does not exist, or "unknown" if it cannot be computed.

`Composition(f, g)`

The composition of the field morphisms f and g.

Example H42E18

We illustrate the use of the general isomorphism functions with some examples. In the first, we have a rational function field of characteristic 5:

```
> k<w> := GF(5);
> kxf<x> := RationalFunctionField(k);
> kxfy<y> := PolynomialRing(kxf);
> F<a> := FunctionField(x^2+y^2-1);
> L := Isomorphisms(kxf, F);
> #L eq #PGL(2, k);
```

In the next example we consider the function field of a hyperelliptic curve defined over $\mathbf{Q}(i)$ $[i^2 = -1]$ and a Galois twist of it. The fields are not isomorphic over $\mathbf{Q}(i)$ but they are over $\mathbf{Q}$:

```
> k<i> := QuadraticField(-1);
> kxf<x> := RationalFunctionField(k);
> kxfy<y> := PolynomialRing(kxf);
> F1<a> := FunctionField(y^2-x^5-x^2-i);
> F2<b> := FunctionField(i*y^2-x^5-i*x^2+1);
> c := IdentityFieldMorphism(k);
> IsIsomorphic(F1,F2 : BaseMorphism := c);
false
> IsIsomorphic(F1,F2);
true Mapping from: FldFun: F1 to FldFun: F2 given by a rule
> L := Isomorphisms(F1, F2);
> [<f(a), f(x), f(i)> : f in L];
[
    <-i*b, i*x, -i>,
    <i*b, i*x, -i>
]
```

In the next example we consider the function field of the genus 3 plane curve $x^3*y+y^3*z+z^3*x = 0$, which has full automorphism group $PGL_2(\mathbf{F}_7)$. We compute automorphisms over different finite fields and also compute the automorphisms group as an FP group.

```
> k := GF(11);
> kxf<x> := RationalFunctionField(k);
> kxfy<y> := PolynomialRing(kxf);
> K<y> := FunctionField(x^3*y+y^3+x);
> L := Automorphisms(K);
> #L;
3
```

```
> // Extend base field to get all autos
> k := GF(11^3);
> kxf<x> := RationalFunctionField(k);
> kxfy<y> := PolynomialRing(kxf);
> K<y> := FunctionField(x^3*y+y^3+x);
> L := Automorphisms(K);
> #L;
504
> // restrict to just "geometric" autos, which fix the base
> c := IdentityFieldMorphism(k);
> L := Automorphisms(K : BaseMorphism := c);
> #L;
168
> // get the automorphism group instead as an FP group
> G,mp := AutomorphismGroup(K : BaseMorphism := c);
> G;
Finitely presented group G on 2 generators
Relations
    G.2^3 = Id(G)
    (G.1^-1 * G.2)^3 = Id(G)
    G.1^7 = Id(G)
    (G.2^-1 * G.1^-3)^2 = Id(G)
    (G.2^-1 * G.1^-1)^4 = Id(G)
> #G;
168
> IdentifyGroup(G); // find in small group database
<168, 42>
```

Finally, we give an example of a genus 1 function field over $\mathbf{F}_5$ where the group of automorphisms is computed acting on various spaces of functions and differentials.

```
> k<w> := GF(5);
> kxf<x> := RationalFunctionField(k);
> kxfy<y> := PolynomialRing(kxf);
> f := x^3 + y^3 + 1;
> F<a> := FunctionField(f);
> f := Numeration(Set(Places(F, 1)));
> G, h, K := AutomorphismGroup(F, f);
> #G; Type(G);
12
GrpPerm
> V, f := SpaceOfDifferentialsFirstKind(F);
> G, h, K := AutomorphismGroup(F, f);
> #G; Type(G);
2
GrpMat
> D := &+ Places(F, 1);
> V, f := DifferentialSpace( -D );
> G, h := AutomorphismGroup(F, f);
```

```
> #G;
12
> V, f := RiemannRochSpace( D );
> G, h, ker := AutomorphismGroup(F, f);
> #G; #ker;
12
1
```

42.8 Global Function Fields

F/k denotes a global function field in this section.

42.8.1 Functions relative to the Exact Constant Field

`NumberOfPlacesOfDegreeOverExactConstantField(F, m)`

`NumberOfPlacesDegECF(F, m)`

The number of places of degree m of the global function field F/k. Contrary to the `Degree` function the degree is here taken over the respective exact constant fields.

`NumberOfPlacesOfDegreeOneOverExactConstantField(F)`

`NumberOfPlacesOfDegreeOneECF(F)`

The number of places of degree one in the global function field F/k. Contrary to the `Degree()` function the degree is here taken over the exact constant field.

`NumberOfPlacesOfDegreeOneOverExactConstantField(F, m)`

`NumberOfPlacesOfDegreeOneECF(F, m)`

The number of places of degree one in the constant field extension of degree m of the global function field F/k. Contrary to the `Degree()` function the degree is here taken over the respective exact constant fields.

`SerreBound(F)`

`SerreBound(F, m)`

`SerreBound(q, g)`

The Serre bound on the number of places of degree one in a global function field of genus g over the exact constant field of q elements (of the global function field F, of the constant field extension of degree m of F). Contrary to the `Degree()` function the degree is here taken over the respective exact constant fields.

`IharaBound(F)`

`IharaBound(F, m)`

`IharaBound(q, g)`

The Ihara bound on the number of places of degree one in a global function field F/k of genus g over the exact constant field of q elements (of the global function field F, of the constant field extension of degree m of F). Contrary to the `Degree` function the degree is here taken over the respective exact constant fields.

`NumberOfPlacesOfDegreeOneECFBound(F)`

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(F)`

`NumberOfPlacesOfDegreeOneECFBound(F, m)`

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(F, m)`

`NumberOfPlacesOfDegreeOneECFBound(q, g)`

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(q, g)`

The minimum of the Serre and Ihara bound. Contrary to the `Degree` function the degree is here taken over the respective exact constant fields.

`LPolynomial(F)`

The L-polynomial of the global function field F/k (with respect to the exact constant field).

`LPolynomial(F, m)`

The L-polynomial of the constant field extension of degree m of the global function field F/k (with respect to the exact constant field).

`ZetaFunction(F)`

The Zeta function of the global function field F/k (with respect to the exact constant field).

`ZetaFunction(F, m)`

The Zeta function of the constant field extension of degree m of the global function field F/k (with respect to the exact constant field).

42.8.2 Functions Relative to the Constant Field

`Places(F, m)`

A sequence containing the places of degree m of the global function field F/k.

`HasPlace(F, m)`

Returns `true` and a place of degree m if and only if there exists such a place in the global function field; `false` otherwise.

`HasRandomPlace(F, m)`

Returns `true` and a random place of degree m in the global function field (`false` if there are none).

`RandomPlace(F, m)`

Returns a random place of degree m in the global function field or throws an error if there is none.

Example H42E19

```
> Y<t> := PolynomialRing(Integers());
> R<x> := FunctionField(GF(9));
> P<y> := PolynomialRing(R);
> f := y^3 + y + x^5 + x + 1;
> F<alpha> := FunctionField(f);
> Genus(F);
4
> NumberOfPlacesDegECF(F, 1);
22
> NumberOfPlacesOfDegreeOneECFBound(F);
32
> HasRandomPlace(F, 2);
true (x^2 + $.1*x + 2, alpha + $.1^2*x + $.1^5)
> LPolynomial(F);
6561*t^8 + 8748*t^7 + 7290*t^6 + 3888*t^5 + 1539*t^4 + 432*t^3 + 90*t^2
    + 12*t + 1
```

Example H42E20

Some of the above functions are demonstrated for a global relative field.

```
> PF<x> := PolynomialRing(GF(13, 2));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b>;
> RER_FF2 := RationalExtensionRepresentation(FF2);
> NumberOfPlacesOfDegreeOneECF(FF2) eq NumberOfPlacesOfDegreeOneECF(RER_FF2);
```

```
true
> SerreBound(FF2);
170
> NumberOfPlacesDegECF(FF2, 1);
170
> _, P := HasPlace(FF2, 1);
> P;
(x, (($.1^44*x + $.1^100)*b + ($.1^82*x + $.1^10))*d^2 + (($.1^85*x + $.1^67)*b
    + ($.1^107*x + $.1^130))*d + ($.1^26*x + $.1^69)*b + $.1^149*x)
> Degree(P) eq 1;
true
> LPolynomial(FF2, 2) eq LPolynomial(RER_FF2, 2);
true
```

42.8.3 Functions related to Class Group

`UnitRank(O)`

Given a maximal 'finite' order O in a global function field, return the unit rank of O.

`UnitGroup(O)`

The unit group of a 'finite' maximal order O as an Abelian group and the map from the unit group into O. Also see IsUnitWithPreimage on page 1133.

`Regulator(O)`

The regulator of the unit group of the 'finite' maximal order O.

`PrincipalIdealMap(O)`

The map from the multiplicative group of the field of fractions of O to the group of fractional ideals of O where O is a 'finite' maximal order.

Example H42E21

Following on from the last example,

```
> EFF2F := EquationOrderFinite(FF2);
> G, m := UnitGroup(EFF2F);
> G;
Abelian Group isomorphic to Z/168
Defined on 1 generator
Relations:
    168*G.1 = 0
> m(Random(G));
[ [ $.1^120, 0 ], [ 0, 0 ], [ 0, 0 ] ]
> IsUnit($1);
true
```

```
> Regulator(EFF2F);
1
```

`ClassGroup(F :parameters)`

`DegreeBound`	RngIntElt	*Default :*
`SizeBound`	RngIntElt	*Default :*
`ReductionDivisor`	DivFunElt	*Default :*
`Proof`	BoolElt	*Default :*

The divisor class group of F/k as an Abelian group, a map of representatives from the class group to the divisor group and the homomorphism from the divisor group onto the divisor class group. For a detailed description see `ClassGroup` on page 1172.

`ClassGroup(O)`

The ideal class group of the 'finite' maximal order O as an Abelian group, a map of representatives from the ideal class group to the group of fractional ideals and the homomorphism from the group of fractional ideals onto the ideal class group.

`ClassGroupExactSequence(O)`

Returns the maps in the center of the exact sequence

$$0 \to U \to F^\times \to Id \to Cl \to 0$$

where U is the unit group of O, $F^\times$ is the multiplicative group of the field of fractions of O, Id is the group of fractional ideals of O and Cl is the class group of O for a 'finite' maximal order O.

`ClassGroupAbelianInvariants(F :parameters)`

`DegreeBound`	RngIntElt	*Default :*
`SizeBound`	RngIntElt	*Default :*
`ReductionDivisor`	DivFunElt	*Default :*
`Proof`	BoolElt	*Default :*

Computes a sequence of integers containing the Abelian invariants of the divisor class group of F/k. For a detailed description see `ClassGroupAbelianInvariants` on page 1172.

`ClassGroupAbelianInvariants(O)`

Computes a sequence of integers containing the Abelian invariants of the ideal class group of the 'finite' maximal order O.

`ClassNumber(F)`

The order of the group of divisor classes of degree zero of F/k.

`ClassNumber(O)`

The order of the ideal class group of the 'finite' maximal order O.

Example H42E22

An example of class groups of relative fields is shown.

```
> PF<x> := PolynomialRing(GF(13, 2));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b : Check := false>;
> MFF2I := MaximalOrderInfinite(FF2);
> G, m, mi := ClassGroup(FF2);
> m(Random(G));
Divisor in reduced representation:
Divisor in ideal representation:
Fractional ideal of Maximal Equation Order of FF2 over Maximal Equation Order of
FF1 over Univariate Polynomial Ring in x over GF(13^2)
Generators:
1
($.1^60/x*b + $.1^57/x)*d^2 + ($.1^141/x*b + $.1^4/x)*d + $.1^80/x*b, Ideal of
MFF2I
Generators:
1
1,
-2,
6*(1/x, (($.1^132*x^2 + $.1^164*x + 12)/x^3*b + ($.1^85*x^2 + $.1^155*x +
    12)/x^3)*d^2 + (($.1^75*x^2 + $.1^81*x + 12)/x^3*b + ($.1^29*x^2 + $.1^155*x
    + 12)/x^3)*d + ($.1^163*x^2 + $.1^29*x + 12)/x^3*b + ($.1^141*x + 12)/x^2),
    (x)^2 * (1/x)^2
> mi(&+[Divisor(Random(FF2, 3)) : i in [1 .. 3]]);
0
> ClassNumber(FF2);
1
```

`GlobalUnitGroup(F)`

The group of global units of F/k, i. e. the multiplicative group of the exact constant field, as an Abelian group, together with the map into F. Also see `IsGlobalUnit` on page 1133 and `IsGlobalUnitWithPreimage` on page 1133.

`ClassGroupPRank(F)`

Compute the p-rank of the class group of F/k where p is the characteristic of F/k. For a detailed description see ClassGroupPRank on page 1175.

`HasseWittInvariant(F)`

Return the Hasse–Witt invariant of F/k. See HasseWittInvariant on page 1175 for a detailed description.

`IndependentUnits(O)`

A sequence of independent units of the 'finite' maximal order O.

`FundamentalUnits(O)`

A sequence of fundamental units of the 'finite' maximal order O.

Example H42E23

```
> R<x> := FunctionField(GF(3));
> P<y> := PolynomialRing(R);
> f := y^4 + x*y + x^4 + x + 1;
> F<a> := FunctionField(f);
> O := MaximalOrderFinite(F);
> Basis(O);
[ 1, a, a^2, a^3 ]
> Discriminant(O);
x^12 + x^3 + 1
> UnitRank(O);
1
> U := FundamentalUnits(O);
> U;
[ [ x^33 + x^31 + 2*x^30 + 2*x^28 + 2*x^27 + x^25 + 2*x^24 + x^22 + 2*x^19 +
    2*x^15 + x^10 + 2*x^9 + 2*x^7 + x^6 + 2*x + 2, x^32 + 2*x^30 + x^29 + 2*x^28
    + 2*x^27 + 2*x^26 + x^22 + x^21 + 2*x^19 + x^18 + x^17 + x^16 + x^13 + x^11
    + 2*x^10 + 2*x^9 + 2*x^3 + 1, x^29 + x^27 + 2*x^25 + 2*x^23 + x^22 + 2*x^21
    + x^20 + x^18 + 2*x^17 + x^16 + x^15 + 2*x^14 + x^11 + 2*x^10 + 2*x^4 + x,
    x^30 + 2*x^27 + x^24 + x^21 + 2*x^18 + x^9 + 2*x^6 + 2 ] ]
> Norm(U[1]);
1
> Regulator(O);
33
```

42.9 Structure Predicates

`IsField(R)` `IsEuclideanDomain(R)`
`IsPID(R)` `IsUFD(R)`
`IsDivisionRing(R)` `IsEuclideanRing(R)`
`IsPrincipalIdealRing(R)` `IsDomain(R)`
`F eq G` `F ne G` `O1 eq O2` `O1 ne O2`

`O1 subset O2`

Return whether $O1$ is a subset of $O2$.

`IsGlobal(F)`

Returns `true` if and only if the algebraic function field F/k is global, i.e. the constant field is a finite field; `false` otherwise.

`IsRationalFunctionField(F)`

Return `true` if the function field F is isomorphic to a rational function field, (i.e. F is only trivially algebraic).

`IsFiniteOrder(O)`

Given an order O of a function field, return `true` if and only if the bottom coefficient ring of O is a polynomial ring.

`IsEquationOrder(O)`

Given an order O of a function field, return `true` if and only if the order O is an equation order (i.e. it has been defined by a polynomial and so has a power basis).

`IsAbsoluteOrder(O)`

Return `false` if the order O is an extension of another order, otherwise `true`.

`IsMaximal(O)`

Given an order O of a function field, return `true` if and only if the order O is maximal in its field of fractions.

`IsTamelyRamified(O)`

Return whether the order O is tamely ramified, i.e. no prime ideal of O has residue field with characteristic dividing its ramification index.

`IsTotallyRamified(O)`

Return whether there is an ideal of the order O which is totally ramified, i.e. its ramification index is equal to the degree of O over its coefficient ring.

`IsUnramified(O)`

Return whether a finite order O is unramified at the finite places and whether an infinite order O is unramified at the infinite places.

`IsWildlyRamified(O)`

Return whether there is a prime ideal of the order O which is wildly ramified, i.e. its ramification index is divisible by the characteristic of its residue class field.

`IsInKummerRepresentation(K)`

Tests if the global function field K is, in its current representation, a Kummer extension. More specific, this function tests if the defining polynomial is of the form $x^r - a$ for some r coprime to the characteristic and if r divides the order of the multipicative group of the constant field, ie. if the coefficient ring of K contains a primitive r-th root of unity. In case K is in Kummer representation, the element a is returned as a second return value.

`IsInArtinSchreierRepresentation(K)`

Tests if a global function field K is, in its current representation, a Artin-Schreier extension, ie. if the defining polynomial of K is of the form $x^p - x - a$ where p is the characteristic of K. In this case, the element a is returned as a second return value.

42.10 Homomorphisms

`hom< F -> R | g >`

`hom< F -> R | cf, g >`

The homomorphism from the function field F to any ring R where g is the image of the generator of F in R and cf is a map from the coefficient field of F into R.

`hom< O -> R | g >`

`hom< O -> R | cf, g >`

Create the map from the order O of an algebraic function field to R using g as the image of the primitive element of O. If the map cf is given it should be from the coefficient ring of O into R, otherwise the coefficient ring of O should be automatically coercible into R.

`IsRingHomomorphism(m)`

Return whether the vector space homomorphism m is a homomorphism of rings.

Example H42E24

A simple use of homomorphisms is shown.

```
> PR<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(PR);
> FR1<a> := FunctionField(y^3 - x*y + 1);
> P<y> := PolynomialRing(FR1);
> FR2<c> := FunctionField(y^2 - a^5*x^3*y + 1);
> EFR2F := EquationOrderFinite(FR2);
> cf := hom<FR1 -> EFR2F | a + 1>;
> h := hom<FR2 -> EFR2F | cf, c + 1>;
> h(c) eq c + 1;
true
> h(a*c) eq a*c + a + c + 1;
true
```

`hom< O -> R | `$b_1, ..., b_n$` >`

`hom< O -> R | m, `$b_1, ..., b_n$` >`

Return the map from the order O of an algebraic function field into the ring R which maps the basis elements of O to $b_1, ..., b_n$. The map m, if given, should be from the coefficient ring of O into R and will be used to map the coefficients of the basis elements. If not given, the coefficient ring of O should automatically coerce into R.

42.11 Elements

The function field $F = k(x, \alpha_1, \ldots, \alpha_r, \alpha)$ may be viewed as n-dimensional vector space over $k(x, \alpha_1, \ldots, \alpha_r)$, where n is the degree of the field extension $F/k(x, \alpha_1, \ldots, \alpha_r)$. Note that F is spanned by the powers $1, \alpha, \ldots, \alpha^{n-1}$. Within MAGMA, function field elements are printed as linear combinations of these powers of α over the coefficient field.

An order can be viewed as a free R-module of rank n where R is its coefficient ring (a polynomial ring or the degree valuation ring of $k(x)$ or an order which is a lesser degree extension of $k[x]$) and n equals the degree $F/k(x, \alpha_1, \ldots, \alpha_r)$. It has a basis consisting of n elements. Within MAGMA, function field order elements are printed as a sequence of coefficients of the R-linear combination of such a basis.

Elements can also be represented as a product of other function field or order elements. This is referred to as the product representation. Product representations can be useful for large elements, however, it is expensive to put such elements in a set or to test them for equality as this involves finding coefficients for the element.

42.11.1 Creation of Elements

```
F . 1
F . 2
```

(i) Return the generator for the function field F over $k(x, \alpha_1, \ldots, \alpha_r)$, that is, $\alpha \in F$ such that $F = k(x, \alpha_1, \ldots, \alpha_r, \alpha)$.

(ii) Return the first and second generators for the function field F over k, that is, $\alpha \in F$ and $x \in F$ such that $F = k(x, \alpha)$.

```
Name(F, i)
```

Given a function field F, return the i-th generator, i.e. return the element `F.1` or `F.2` of F.

```
O . i
FF . i
```

Return the ith basis element of the order O or its field of fractions FF.

```
F ! a
elt< F | a >
```

Create the element of the function field F specified by a; here a is allowed to be an element coercible into F, which means that a may be:

(i) an element of F,

(ii) an element of the coefficient field of F,

(iii) an element of another representation of F.

For F an extension of $k(x)$ we additionally have

(iv) an element of an order of F,

(v) an element being coercible into $k(x)$,

(vi) a sequence of elements being coercible into the coefficient field of F of length equal to the degree of F over its coefficient field. In this case the element $a_0 + a_1\alpha + \ldots + a_{n-1}\alpha^{n-1}$ is created, where $a = [a_0, \ldots, a_{n-1}]$ and α is the generator `F.1` of F over its coefficient field.

```
O ! a
elt< O | a >
```

Create the element of the order O specified by a; here a is allowed to be an element coercible into O, which means that mathematically $a \in O$ and that a may be any of:

(i) an element of the function field F,

(ii) an element of an order of the function field F,

(iii) an element that can be coerced into $k(x)$,

(iv) an element that can be coerced into its coefficient field,

(v) a sequence of elements being coercible into the coefficient field of O of length equal to the rank of O over its coefficient field. In this case the element $a_1\omega_1 + a_2\omega_2 + \ldots + a_n\omega_n$ is created, where $a = [a_1, \ldots, a_n]$ and $\omega_1, \omega_2, \ldots, \omega_n$ is the basis of O as returned by `Basis(O)`.

`FF ! a`
`elt< FF | a >`

Create the element of the field of fractions FF of an order O specified by a, where a may be any of the above such that $d * a$ is mathematically in O for some $d \in O$.

`elt< F | a0, a1, ..., an-1 >`

Create the element $a_0 + a_1\alpha + \ldots + a_{n-1}\alpha^{n-1}$ where $a_0, \ldots, a_{n-1}$ are coercible into the coefficient field of the function field F, n equals the degree of F over its coefficient field and α is the generator `F.1` of F over $k(x)$.

`elt< O | a1, a2, ..., an >`
`elt< FF | a1, a2, ..., an >`

Create the element $a_1\omega_1 + a_2\omega_2 + \ldots + a_n\omega_n$ where $a_1, \ldots, a_n$ are coercible into the coefficient ring of the order O, n equals the rank of O over its coefficient ring and $\omega_1, \omega_2, \ldots, \omega_n$ is the basis of O as returned by `Basis(O)`, (where O is the ring of integers of the field of fractions FF).

`One(F)` `One(O)`
`Identity(F)` `Identity(O)`
`Zero(F)` `Zero(O)`
`Representative(F)` `Representative(O)`

These generic functions (cf. Chapter 17) create 1, 1, 0, and 0 respectively in the function field F or order O.

`Random(F, m)`
`Random(O, m)`

A "random" element of the global function field F or one of its orders O. The size of the coefficients of the element are determined by m.

42.11.2 Parent and Category

`Parent(a)` `Category(a)`

42.11.3 Sequence Conversions

The sequence conversions refer to the function field F as a vector space of dimension n over the coefficient field of F where F is a finite degree extension (degree n) of its coefficient field.

`ElementToSequence(a)`

`Eltseq(a)`

The sequence $[a_1, \ldots, a_n]$ of elements of the coefficient field of the parent of the function field or order element a such that $a = a_1\omega_1 + a_2\omega_2 + \ldots + a_n\omega_n$ where $\omega_1, \omega_2, \ldots, \omega_n$ is a basis of the parent of a.

`Eltseq(a, R)`

A sequence of coefficients of the function field element a in the coefficient field R.

`Flat(a)`

A sequence of coefficients of the function field element a in the bottom coefficient field of the parent of a.

`F ! [ a0, a1, ..., an-1 ]`

The element $a = a_0 + a_1\alpha + \ldots + a_{n-1}\alpha^{n-1}$ where the function field $F = k(x, \alpha_1, \ldots, \alpha_r, \alpha)$ and the a_i may be coerced into $k(x, \alpha_1, \ldots, \alpha_r)$.

`O ! [ a1, a2, ..., an ]`

The element $a = a_1\omega_1 + a_2\omega_2 + \ldots + a_n\omega_n$ where $\omega_1, \omega_2, \ldots, \omega_n$ is a basis of the order O and the a_i are coercible into the coefficient ring of O.

Example H42E25

```
> R<x> := FunctionField(GF(5));
> P<y> := PolynomialRing(R);
> f := y^3 + (4*x^3 + 4*x^2 + 2*x + 2)*y^2 + (3*x + 3)*y + 2;
> F<alpha> := FunctionField(f);
> Evaluate(f, alpha);
0
> F.1;
alpha
> b := x + alpha + 1/x*alpha^2;
> b;
1/x*alpha^2 + alpha + x
> b eq F ! [x, 1, 1/x];
true
```

42.11.4 Arithmetic Operators

The following binary arithmetic operations can also be performed in the case where one operand is an element of the function field F or an order O and the other operand is a ring element which can naturally be mapped into F or O.

`+ a` `- a`

`a + b` `a - b` `a * b` `a div b` `a / b` `a ^ k`

`Modexp(a, k, m)`

Return $a^k \ mod \ m$ where m is an element of $k[x]$ or o_∞ according to whether the parent of a is a finite or infinite order.

`a mod I`

Return the element a belonging to the order O as an element of O/I.

`Modinv(a, m)`

Return the inverse of the element a of an order of a function field modulo m where m is an element of $k[x]$ or o_∞ according to whether the order of a is a finite or infinite order or an ideal of the order of a.

42.11.5 Equality and Membership

The following binary arithmetic operations can also be performed in the case where one operand is an element of the function field F or an order O and the other operand is a ring element which can naturally be mapped into F or O.

`a eq b` `a ne b`

`a in F` `a in O` `a in FF`

`a notin F` `a notin O` `a notin FF`

42.11.6 Predicates on Elements

The functions in this section list the general ring element predicates that apply to function fields and orders of a function field.

`IsDivisibleBy(a, b)`

Given elements a and b belonging to a function field F or an order O, returns `true` if there exists $c \in F$ or $c \in O$ such that $a = bc$ and returns c as well, provided that $b \neq 0$.

`IsZero(a)` `IsOne(a)` `IsMinusOne(a)`

`IsNilpotent(a)` `IsIdempotent(a)`

`IsUnit(a)` `IsZeroDivisor(a)` `IsRegular(a)`
`IsIrreducible(a)` `IsPrime(a)`

`IsSeparating(a)`

Returns `true` if the function field element a is a separating element (has a non zero differential).

`IsConstant(a)`

Whether the algebraic function a is constant; if so it is returned as an element of the exact constant field.

`IsGlobalUnit(a)`

Whether the function field element a is a global unit, i.e. a constant (equivalent to `IsConstant`)

`IsGlobalUnitWithPreimage(a)`

Returns `true` and the preimage of the function field element a in the global unit group, `false` otherwise. The function field must be global.

`IsUnitWithPreimage(a)`

Returns `true` and the preimage of the order element a in the unit group of O if a is a unit, `false` otherwise. The function field has to be global.

42.11.7 Functions related to Norm and Trace

Multiplication by $a \in F$ or $a \in O$ defines a linear map of the vector space F over its coefficient field where F is a finite extension of its coefficient field. The following functions work with respect to this mapping.

`Trace(a)` `Norm(a)`
`MinimalPolynomial(a)`
`CharacteristicPolynomial(a)`

`RepresentationMatrix(a)`

Returns the matrix $M \in R^{n \times n}$ such that $a\,(\omega_1, \omega_2, \ldots, \omega_n) = (\omega_1, \omega_2, \ldots, \omega_n)\,M$, where $\omega_1, \omega_2, \ldots, \omega_n$ is a R-basis of the parent of the function field or order element a and R is the coefficient ring of the parent of a.

`Trace(a, R)`

The trace of the function field or order element a over R, a coefficient ring or field of the parent of a.

`Norm(a, R)`

The norm of the order or algebraic function field element a over R, a coefficient ring or field of the parent of a.

`CharacteristicPolynomial(a, R)`

The characteristic polynomial of the order or algebraic function field element a over R, a coefficient ring or field of the parent of a.

`MinimalPolynomial(a, R)`

The minimal polynomial of the order or algebraic function field element a over R, a coefficient ring or field of the parent of a.

`AbsoluteMinimalPolynomial(a)`

The minimal polynomial of the function field element a over the rational function field.

`RepresentationMatrix(a, R)`

Returns the matrix $M \in R^{n\times n}$ such that $a\,(\omega_1, \omega_2, \ldots, \omega_n) = (\omega_1, \omega_2, \ldots, \omega_n)\,M$, where $\omega_1, \omega_2, \ldots, \omega_n$ is a R-basis of the parent of the function field or order element a and R is a coefficient ring of the parent of a.

Example H42E26

```
> P<x> := PolynomialRing(Integers());
> N<n> := NumberField(x^6 - 6);
> P<x> := PolynomialRing(N);
> P<y> := PolynomialRing(P);
> F<c> := FunctionField(y^8 - x^3*N.1^5);
> P<y> := PolynomialRing(F);
> F2<d> := FunctionField(y^3 + N.1*F!x - c);
> d^10;
(c^3 - 3*n*x*c^2 + 3*n^2*x^2*c - n^3*x^3)*d
> Norm(d^10);
-120*n^3*x^3*c^7 + 210*n^4*x^4*c^6 - 252*n^5*x^5*c^5 + 1260*x^6*c^4 -
    720*n*x^7*c^3 + (270*n^2*x^8 + n^5*x^3)*c^2 + (-60*n^3*x^9 - 60*x^4)*c +
    6*n^4*x^10 + 270*n*x^5
> Norm(d^10, CoefficientField(F));
13060694016*n^2*x^80 - 21767823360*n^5*x^75 + 97955205120*n^2*x^70 -

42.11.8 Functions related to Orders and Integrality

`IntegralSplit(a, O)`

Split the element function field or order element a into a numerator and denominator with respect to the order O.

`Numerator(a, O)`

The numerator of the function field element a with respect to the order O.

`Numerator(a)`

Given an element a in a field of fractions of an order O return the numerator of a with respect to O.

`Numerator(a, O)`

Given an element a in a field of fractions of an order and an order O of a function field return the numerator of a with respect to O.

`Denominator(a, O)`

The denominator of the function field element a with respect to the order O.

`Denominator(a)`

Given an element a in a field of fractions of an order O return the denominator of a with respect to O.

`Denominator(a, O)`

Given an element a in a field of fractions of an order and an order O of a function field return the denominator of a with respect to O.

`Min(a, O)`
`Minimum(a, O)`

A generator of the ideal $R \cap (d \times a \times O)$ where R is the coefficient ring of the order O and d is the denominator of the function field or order element a wrt O (d is the second return value).

42.11.9 Functions related to Places and Divisors

`Evaluate(a, P)`

Evaluate the algebraic function a at the place P. If it is not defined at P, infinity is returned.

`Lift(a, P)`

Lift the element a of the residue class field of the place P (including infinity) to an algebraic function.

`Valuation(a, P)`

The valuation of the function field or order element a at the place P.

`Expand(a, P)`

`RelPrec`	RngIntElt	*Default :* 10
`AbsPrec`	RngIntElt	*Default :*

Expand the algebraic function a to a series of given precision at the place P and return the local parameter.

`Divisor(a)`
`PrincipalDivisor(a)`

The (principal) divisor (a) of the function field or order element a.

`Zeros(a)`
`Zeroes(a)`

A sequence containing the zeros of the algebraic function a.

`Zeros(F, a)`
`Zeroes(F, a)`

The zeros of the function field element a in the function field F.

`Poles(a)`

A sequence containing the poles of the algebraic function a.

`Poles(F, a)`

A sequence containing the poles of the function field element a in the function field F.

`Degree(a)`

The degree of the algebraic function a, being defined as the degree of the pole (or zero) divisor of a.

`CommonZeros(L)`

Return the common zeros of the function field elements in the sequence L.

`CommonZeros(F, L)`

Return the common zeros in the function field F of the function field elements in the sequence L.

Example H42E27

```
> R<x> := FunctionField(GF(9));
> P<y> := PolynomialRing(R);
> f := y^3 + y + x^5 + x + 1;
> F<a> := FunctionField(f);
> MinimalPolynomial(a);
y^3 + y + x^5 + x + 1
> RepresentationMatrix(a);
[                  0                   1                   0]
[                  0                   0                   1]
[    2*x^5 + 2*x + 2                   2                   0]
> O := IntegralClosure(ValuationRing(R), F);
> Denominator(a, O);
1/x^2
> O := IntegralClosure(PolynomialRing(GF(9)), F);
> Denominator(a, O);
1
> Zeros(a);
[ (x + 2, a), (x^3 + 2*x^2 + 1, a + x^3 + 2*x^2 + 1) ]
> Degree(a);
5
> P := RandomPlace(F, 2);
> P;
(x^2 + $.1^2*x + $.1^6, a + x^2 + $.1^5*x + 1)
> b := Evaluate(a, P);
> b;
$.1^3*$.1 + $.1^3
> c := Lift(b, P);
> c;
$.1^3*x + $.1^3
> Valuation(a, P);
0
> Valuation(a-c, P);
1
```

`Module(L, R)`

`IsBasis`	BoolElt	*Default :* `false`
`PreImages`	BoolElt	*Default :* `false`

The R-module generated by the function field elements in the sequence L as an abstract module, together with the map into the algebraic function field. The resulting modules can be used for intersection and inner sum computations.

If the optional parameter `IsBasis` is set `true` the function assumes that the given elements form a basis of the module to be computed.

If the optional parameter `PreImages` is set `true` then the preimages of the given elements under the map are returned as the third return value.

Both optional parameters are mainly used to save computation time.

`Relations(L, R)`

`Relations(L, R, m)`

The module of R-linear relations between the function field elements of the sequence L. The argument m is used for the following: Let the elements of L be $a_1, \ldots, a_n$, V be the relation module $\subseteq R^n$ and define $M := \{ \sum_{i=1}^{m} v_i a_i \,|\, v = (v_i)_i \in V \}$. The function tries to compute a generating system of V such that the corresponding generating system of M consists of "small" elements.

`Roots(f, D)`

Compute the roots of the polynomial f which lie in the Riemann-Roch space of the divisor D.

Example H42E28

This example shows the capability of `Module` and `Relations` with relative function fields.

```
> PR<x> := PolynomialRing(Rationals());
> P<y> := PolynomialRing(PR);
> FR1<a> := FunctionField(y^3 - x);
> P<y> := PolynomialRing(FR1);
> FR2<c> := FunctionField(y^2 - a);
> MFR1F := MaximalOrderFinite(FR1);
> m, f := Module([c, c + a], MFR1F);
> f(m.1);
1
> f(m.2);
c
> m, f := Module([c, c + a], FR1);
> f(m.1);
c
> f(m.2);
1
> m;
KModule m of dimension 2 over FR1
```

```
> Relations([c, c + a], FR1, 1);
Vector space of degree 2, dimension 0 over FR1
User basis:
Matrix with 0 rows and 2 columns
```

42.11.10 Other Operations on Elements

`ProductRepresentation(a)`

Return a product representation for the function field or order element a.

`ProductRepresentation(Q, S)`

`PowerProduct(Q, S)`

Return the element given by the product representation of function field elements in the sequence Q and exponents in the sequence S. It is expensive to put large elements in product representation into sets or to test for them for equality.

`RationalFunction(a)`

`RationalFunction(a, R)`

Return the algebraic function a as a rational function in free variables with respect to the defining polynomial over the coefficient field.

If the ring R is provided it must appear in the tower of coefficient fields of the parent of a and the result is a polynomial over R with respect to all the defining polynomials of the extensions in between.

`Differentiation(x, a)`

The first differentiation resp. derivative of the function field element a with respect to the separating element x.

`Differentiation(x, n, a)`

The nth differentiation of the function field element a with respect to the separating element x. In characteristic zero the nth differentiation equals the nth derivative times $1/n!$.

`DifferentiationSequence(x, n, a)`

The 0-th up to the n-th differentiation of the function field element a with respect to the separating element x.

`PrimePowerRepresentation(x, k, a)`

Return the coefficients of the representation of the function field element a as a linear combination of k-th prime powers and powers of the function field element x. More precisely, let $p > 0$ be the characteristic of F. Then F^{p^k} is a subfield of F of index p^k and F can be viewed as a F^{p^k}-vector space. A basis is given by $1, x, \ldots, x^{p^k-1}$ for x a separating element. The function returns $\lambda_1, \ldots, \lambda_{p^k-1} \in F^{p^k}$ such that $a = \sum_i \lambda_i x^i$.

`Different(a)`

The different of the element a of an order of an algebraic function field.

`RationalReconstruction(e, f)`

For an element e of some some function field K with integral coefficients $e = \sum e_i \alpha^i$, $e_i \in k[x]$ and some polynomial $f \in k[x]$ find the (essentially) unique $E = \sum E_i \alpha_i$ with $E_i \in k(x)$ and $E_i = e_i \bmod f$, where the numerator and denominator of the E_i have degree bounded by half the degree of f. If such E_i exists they are unique, the corresponding element $\sum E_i \alpha^i$ for the function field will be returned as a second return value, the first being `true` to indicate success. If no such element exists, `false` will be returned.

`CoefficientHeight(a)`

`CoefficientHeight(a)`

The (naive) height of the element as defined as the largest degree of any coefficient or denominator polynomial occurring in the coefficients of a.

`CoefficientLength(a)`

`CoefficientLength(a)`

The (naive) length or size of the element, defined as the sum of the degrees of all polynomials occurring as coefficients or denominators in the coefficient representation of a.

Example H42E29

```
> F<z> := GF(13, 3);
> PF<x> := PolynomialRing(F);
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - ConstantField(FF1).1>;
> ProductRepresentation([Random(FF2, 2) : i in [1 .. 3]], [2, 3, 2]);

42.12 Ideals

Ideals for function field orders O are O-modules $I \subseteq F$ for which there is a $d \in F$ such that $dI \subseteq O$ is a non-zero ideal of O, that is they are fractional ideals of O. Over the coefficient ring of O they are also free modules of rank n, where n equals the degree $[F : k(x, \alpha_1, \ldots, \alpha_r)]$.

42.12.1 Creation of Ideals

`ideal< O | a1, a2, ... , am >`

Given an order O, as well as elements $a_1, a_2, \ldots, a_m$ coercible into the field of fractions F of O, create the fractional ideal of O generated by these elements.

Note that, contrary to the general case for the constructors, the right hand side elements are not necessarily contained in the left hand side.

`ideal< O | T, d >`

The ideal of the order O of an algebraic function field whose basis is the matrix or dedekind module T over the coefficient ring of O divided by the element d of the denominator ring of O.

`ideal< O | T, S >`

`ideal< O | T, I1,...,In >`

The ideal of the order O of an algebraic function field whose basis is the matrix T over the coefficient ring of O along with the coefficient ideals $I_1, ..., I_n$ or those in S.

`x * O`

`O * x`

Create the ideal $x * O$ where x is coercible into the function field of the order O.

`Ideal(P)`

Create a prime ideal corresponding to the place P.

`Ideals(D)`

Create two ideals of the 'finite' and 'infinite' maximal order respectively corresponding to the divisor D.

`O !! I`

Return the ideal I as an ideal of the order O.

42.12.2 Parent and Category

`Parent(I)` `Category(I)`

42.12.3 Arithmetic Operators

`I + J` `I * J`
`I / J` `I ^ k`

The ideal J is required to be invertible. The ideal I is required to be invertible for negative k.

`c * I` `I * c` `I / c`

`c / I`

The principal ideal generated by the ring element c divided by the ideal I.

`IdealQuotient(I, J)`
`ColonIdeal(I, J)`

The colon ideal $[I : J]$ of elements which multiply all elements of the ideal J into the ideal I.

`ChineseRemainderTheorem(I1, I2, e1, e2)`
`CRT(I1, I2, e1, e2)`

Returns an element e of the order O such that $(e_1 - e)$ is in the ideal I_1 of O and $(e_2 - e)$ is in the ideal I_2.

42.12.4 Roots of Ideals

`IsPower(I, n)`

Return whether the ideal I has an nth root and if so return an nth root.

`Root(I, n)`

Return the nth root of the ideal I.

`IsSquare(I)`

Return whether the ideal I is a square and if so return a square root.

`SquareRoot(I)`
`Sqrt(I)`

Return a square root of the ideal I.

Example H42E30

A simple creation of an ideal and the use of `IsSquare` is shown below.

```
> P<x> := PolynomialRing(GF(79));
> P<y> := PolynomialRing(P);
> Fa<a> := FunctionField(y^2 - x);
> P<y> := PolynomialRing(Fa);
> Fb<b> := FunctionField(y^2 - a);
> P<y> := PolynomialRing(Fb);
> Fc<c> := FunctionField(y^2 + a*b);
> I := a*b*c*MaximalOrderInfinite(Fc);
> IsSquare(I^2);

```

42.12.5 Equality and Membership

`I eq J` `I ne J` `I in S` `I notin S`

42.12.6 Predicates on Ideals

`IsZero(I)`

Returns `true` if and only if the ideal I is the zero ideal of the order O.

`IsOne(I)`

Returns `true` if and only if the ideal I is the identity ideal of the order O, i.e. $I = O$.

`IsIntegral(I)`

Returns `true` if and only if the ideal I is integral (a true ideal of its order).

`IsPrime(I)`

Returns `true` if and only if the ideal I is prime.

`IsPrincipal(I)`

Returns `true` and a generator if the fractional ideal I is principal, `false` otherwise. The function field has to be global.

42.12.6.1 Predicates on Prime Ideals

`IsInert(P)`

Return `true` if the inertia degree of the prime ideal P is the degree of its order.

`IsInert(P, O)`

Return `true` if there is an inert ideal in the order O above the prime ideal P.

`IsRamified(P)`

Return `true` if the ramification index of the prime ideal P is not 1.

`IsRamified(P, O)`

Return `true` if there is a ramified ideal in the order O above the prime ideal P.

`IsSplit(P)`

Return `true` if the prime ideal P is not the only ideal lying above the prime ideal it lies above.

`IsSplit(P, O)`

Return `true` if there are at least 2 distinct ideals which lie in the order O above the prime ideal P.

`IsTamelyRamified(P)`

Return whether the prime ideal P is not wildly ramified.

`IsTamelyRamified(P, O)`

Return whether the prime ideal P is not wildly ramified in the order O.

`IsTotallyRamified(P)`

Return whether the ramification index of the prime ideal P is the same as the degree of its order over its coefficient order.

`IsTotallyRamified(P, O)`

Return whether there are any totally ramified ideals in the order O lying above the prime ideal P.

`IsTotallySplit(P)`

Return whether there are as many ideals as the degree of the order of the prime ideal P lying over the prime P lies over.

`IsTotallySplit(P, O)`

Return whether there are as many ideals of the order O which lie above the prime ideal P as the degree of O.

`IsUnramified(P)`

Return whether the ramification index of the prime ideal P is 1.

`IsUnramified(P, O)`

Return whether all the ideals of the order O which lie above the prime ideal P are unramified.

`IsWildlyRamified(P)`

Return whether the ramfication index of the prime ideal P is a multiple of the characteristic of the residue field of P.

`IsWildlyRamified(P, O)`

Return whether any of the ideals of the order O which lie above the prime ideal P are wildly ramified.

42.12.7 Further Ideal Operations

`I meet J`

The intersection of the ideals I and J.

`Gcd(I, J)`

Given invertible ideals of an order O, returns the greatest common divisor of the ideals I and J.

`Lcm(I, J)`

Given invertible ideals of an order O, returns the least common multiple of the ideals I and J.

`Factorization(I)`
`Factorisation(I)`

Factorization of the ideal I (as sequence of prime ideal, exponent pairs). The order must be maximal.

`Decomposition(O, p)`

A sequence containing all prime ideals of the order O lying above the prime element or ideal p of the coefficient ring of O.

`Decomposition(O)`

A sequence containing all prime ideals of the 'infinite' maximal order O.

`DecompositionType(O, p)`

Sequence of tuples of residue degrees and ramification indices of the prime ideals of the order O lying over p, a prime polynomial or ideal or element of valuation ring of valuation 1.

`DecompositionType(O)`

Sequence of tuples of residue degrees and ramification indices of the prime ideals of the 'infinite' maximal order O.

`MultiplicatorRing(I)`

Returns the multiplicator ring of the ideal I of the order O, that is, the subring of elements of the field of fractions of O that multiply I into itself.

`pMaximalOrder(O, p)`

The p-maximal over order of the order O where p is a prime ideal of the coefficient ring of O. See also the description in Section 42.2.3.

`pRadical(O, p)`

Returns the p-radical of an order O for a prime ideal p of the coefficient ring of O, defined as the ideal consisting of elements of O for which some power lies in the ideal pO.

It is possible to call this function even if p is not prime. In this case the p-trace-radical will be computed, i.e.

$$\{x \in F \mid \mathrm{Tr}(xO) \subseteq C\}$$

for F the field of fractions of O and C the order of p (if p is an ideal) or the parent of p otherwise. If p is square free and all divisors are larger than the field degree, this is the intersection of the radicals for all l dividing p.

`Valuation(a, P)`

`Valuation(I, P)`

The valuation of a or the ideal I at the prime ideal P. The element a must be coercible into the field of fractions of P's order.

`Order(I)`

The order of the ideal I.

`Denominator(I)`

The "smallest" element d of the coefficient ring of the order O of the ideal I such that $dI \subseteq O$.

`Minimum(I)`

A generator m of the ideal $R \cap dI$ where R is the coefficient ring of the ideal's order and d is the denominator of the ideal I (d is the second return value).

`I meet R`

The intersection of the ideal I with a coefficient ring R of its order.

`IntegralSplit(I)`

The integral ideal dI and d, where d is the denominator of the ideal I.

`Norm(I)`

The norm of the ideal I, as element of the coefficient field of the algebraic function field to which I belongs.

`TwoElement(I)`

Given an ideal I with function field F as the function field of its order O, returns two elements $a, b \in F$ such that $I = aO + bO$.

`Generators(I)`

Given a (fractional) ideal I of the order O, return a sequence of elements of the function field F that generate I as an ideal.

`Basis(I)`

`Basis(I, R)`

A basis of the ideal I as a free module over the coefficient ring of its order, coerced into the ring R if given.

`BasisMatrix(I)`

Let $(b_1, \ldots, b_n)$ be the basis of the ideal I and let $(\omega_1, \ldots, \omega_n)$ be the basis of the order O. A matrix B with coefficients in the rational function field is returned such that $(b_1, \ldots, b_n) = (\omega_1, \ldots, \omega_n)B^t$.

`TransformationMatrix(I)`

Let $(b_1, \ldots, b_n)$ be the basis of the ideal I and let $(\omega_1, \ldots, \omega_n)$ be the basis of the order O. A matrix T with coefficients in the coefficient ring of O and a denominator d are returned such that $(b_1, \ldots, b_n) = (\omega_1, \ldots, \omega_n)T^t/d$.

`CoefficientIdeals(I)`

The coefficient ideals of the ideal I in a relative extension. These are the ideals $\{A_i\}$ of the coefficient ring of the order of I such that for every element $e \in I$, $e = \sum_i a_i * b_i$ where $\{b_i\}$ is the basis returned for I and each $a_i \in A_i$.

`Different(I)`

The different of the (possibly fractional) ideal I of an order of an algebraic function field.

`Codifferent(I)`

The codifferent of the ideal I. This will be the inverse of the different of I if I is an ideal of a maximal order.

`Divisor(I)`

The divisor corresponding to the ideal factorization of the ideal I.

`Divisor(I, J)`

The divisor corresponding to the ideal factorization of the ideals I and J belonging to the 'finite' and 'infinite' maximal order.

Example H42E31

```
> PR<x> := FunctionField(Rationals());
> P<y> := PolynomialRing(PR);
> FR1<a> := FunctionField(y^3 - x + 1/x^3);

42.12.7.1 Functions on Prime Ideals

`RamificationIndex(I)`

`RamificationDegree(I)`

The ramification index of the prime ideal I over the corresponding prime of its coefficient ring.

`Degree(I)`

`InertiaDegree(I)`

`ResidueClassDegree(I)`

The residue class degree (inertia degree) of the prime ideal I over the corresponding prime of its coefficient ring.

`ResidueClassField(I)`

The residue class field of the prime ideal I and the residue class mapping.

`Place(I)`

The place corresponding to the prime ideal I, where I is defined over the 'finite' or 'infinite' maximal order.

`SafeUniformizer(P)`

For an ideal I of a maximal order in a function field, this returns an element which has valuation 1 at the given prime and which has valuation 0 at all other primes lying over the same prime of the underlying rational function field. See also `LocalUniformizer` (for places) below.

Example H42E32

```
> R<x> := FunctionField(GF(3));
> P<y> := PolynomialRing(R);
> f := y^4 + x*y + x^4 + x + 1;
> F<a> := FunctionField(f);
> O := MaximalOrderFinite(F);
> x*O;
Ideal of O
Generator:
x
> L := Factorization(x*O);
> L;
[ <Ideal of O
Generators:
```

```
x
a^2 + a + 2, 1>, <Ideal of O
Generators:
x
a^2 + 2*a + 2, 1> ]
> P1 := L[1][1];
> P2 := L[2][1];
> BasisMatrix(P1);
[x 0 0 0]
[0 x 0 0]
[2 1 1 0]
[1 1 0 1]
> P1 meet P2 eq x*O;
true
> IsPrime(P1);
true
> Place(P1);
(x, a^2 + a + 2)
```

42.13 Places

42.13.1 Creation of Structures

`Places(F)`

The set of places of the algebraic function field F/k.

42.13.2 Creation of Elements

42.13.2.1 General Function Field Places

`Decomposition(F, P)`

A sequence containing all places of F/k lying above the place P of the coefficient field $k(x)$ of F. The function field F must be a finite extension of $k(x)$.

`DecompositionType(F, P)`

Sequence of tuples of residue degrees and ramification indices of the places of F/k lying over the place P of the coefficient field $k(x)$ of F. The function field F must be a finite extension of $k(x)$.

`Zeros(a)`

A sequence containing all zeros of the algebraic function a.

`Poles(a)`

A sequence containing all poles of the algebraic function a.

`S ! I`
`Place(I)`

The place corresponding to the prime ideal I, where I is defined over the 'finite' or 'infinite' maximal order and S is the set of places of a function field.

`Support(D)`

Sequences containing the places and exponents occurring in the divisor D.

`AssignNames(~P, s)`

Change the print name employed when displaying P to be the first element in the sequence of strings s which must have length 1.

`InfinitePlaces(F)`

The infinite places of the function field F.

42.13.2.2 Global Function Field Places

F/k denotes a global function field in this section.

`HasPlace(F, m)`

Returns `true` and a place of degree m if and only if there exists such in the function field F/k; `false` otherwise.

`HasRandomPlace(F, m)`

Returns `true` and a random place of degree m in the function field F/k or (`false` if there are none).

`RandomPlace(F, m)`

Returns a random place of degree m in the function field F/k or throws an error if there is none.

`Places(F, m)`

A sequence containing the places of degree m of the function field F/k.

Example H42E33

Some creation of places is illustrated below.

```
> P<t> := PolynomialRing(Integers());
> N := NumberField(t^2 + 2);
> P<x> := PolynomialRing(N);
> P<y> := PolynomialRing(P);
> F<c> := FunctionField(y^4 + x^5 - N.1^7);
> F;
Algebraic function field defined over Univariate rational function field over N
by
y^4 + x^5 + 8*N.1
> Zeros(c);
[ (x^5 + 8*N.1, c + x^5 + 8*N.1) ]
> P<y> := PolynomialRing(F);
> F2<d> := FunctionField(y^2 + F!N.1);
> Decomposition(F2, $1[1]);
[ (x^5 + 8*N.1, c + 2*x^5 + 16*N.1) ]
> DecompositionType(F2, $2[1]);
[ <2, 1> ]
> Places(F2)!$3[1];
(x^5 + 8*N.1, c + 2*x^5 + 16*N.1)
```

42.13.3 Related Structures

42.13.3.1 Parent and Category

The sets of function field places form the MAGMA category `PlcFun`. The notional power structure exists as parent but allows no operations.

`FunctionField(S)`

The corresponding function field of the set of places S.

`DivisorGroup(F)`

The group of divisors of the algebraic function field F/k, which is the free abelian group generated by the elements of the set of places of F/k.

42.13.4 Structure Invariants

42.13.4.1 General function fields

`WeierstrassPlaces(F)`

`SeparatingElement` FLDFUNGELT *Default :*

The Weierstrass places of the function field F/k. The semantics of calling `WeierstrassPlaces()` with F/k or the zero divisor of F/k are identical. See the description of `WeierstrassPlaces` on page 1170.

42.13.4.2 Global Function Fields

F/k denotes a global function field in this section.

`NumberOfPlacesOfDegreeOneOverExactConstantField(F, m)`

`NumberOfPlacesOfDegreeOneECF(F, m)`

The number of places of degree one in the constant field extension of degree m of the function field F/k. Contrary to the `Degree()` function the degree is here taken over the respective exact constant fields.

`NumberOfPlacesOfDegreeOneOverExactConstantFieldBound(F, m)`

`NumberOfPlacesOfDegreeOneECFBound(F, m)`

The minimum of the Serre and Ihara bound on the number of places of degree one in the constant field extension of degree m of the function field F/k. Contrary to the `Degree()` function the degree is here taken over the respective exact constant fields.

`NumberOfPlacesOfDegreeOverExactConstantField(F, m)`

`NumberOfPlacesDegECF(F, m)`

The number of places of degree m of the function field F/k. Contrary to the `Degree()` function the degree is here taken over the respective exact constant fields.

42.13.5 Structure Predicates

`S1 eq S2` `S1 ne S2`

42.13.6 Element Operations

42.13.6.1 Parent and Category

`Parent(P)` `Category(P)`

42.13.6.2 Arithmetic Operators

`- P`

`P1 + P2` `P1 - P2` `k * P` `P div k` `P mod k`

`Quotrem(P, k)`

Returns divisors D_1, D_2 such that the place $P = kD_1 + D_2$ and the exponents in D_2 are of absolute value less than $|k|$. The operations `div` and `mod` yield D_1 resp. D_2.

42.13.6.3 Equality and Membership

`P1 eq P2` `P1 ne P2` `P in S` `P notin S`

42.13.6.4 Predicates on Elements

`IsFinite(P)`

Returns `true` if the place P is a 'finite' place.

`IsWeierstrassPlace(P)`

Whether the degree one place P is a Weierstraß place of its function field F. See the description of `WeierstrassPlaces` on page 1170.

42.13.6.5 Other Element Operations

`FunctionField(P)`

The function field that corresponds to the place P.

`Degree(P)`

The degree of the place P over the constant field of definition k.

`RamificationIndex(P)`
`RamificationDegree(P)`

The ramification index of the place P over its subplace of the rational function field $k(x)$ (the function field of P must be a finite extension of $k(x)$).

`InertiaDegree(P)`
`ResidueClassDegree(P)`

The degree of inertia (or residue class degree) of a place P over the corresponding subplace of the rational function field (the function field of P must be a finite extension of $k(x)$)

`Minimum(P)`

A monic prime polynomial in $k[x]$ or $1/x$ or an ideal, corresponding to the place of the coefficient field of the function field of the place P which P lies above (the function field of P must be a finite extension of $k(x)$).

`ResidueClassField(P)`

The residue class field of the place P and the map from the order of the place into the field.

`Evaluate(a, P)`

Evaluate the algebraic function a at the place P. If it is not defined at P, infinity is returned.

`Lift(a, P)`

Lift the element a of the residue class field of the place P (including infinity) to an algebraic function.

`TwoGenerators(P)`

Two algebraic functions having the place P as their unique common zero.

`LocalUniformizer(P)`

`UniformizingElement(P)`

A local uniformizing parameter at the place P.

`SafeUniformizer(P)`

The valuation of the element a at the place P.

`Ideal(P)`

Create a prime ideal corresponding to the place P.

`Norm(P)`

The divisor of the norm of the ideal of the place P.

Example H42E34

```
> R<x> := FunctionField(GF(9));
> P<y> := PolynomialRing(R);
> f := y^4 + (2*x^5 + x^4 + 2*x^3 + x^2)*y^2 + x^8
>      + 2*x^6 + x^5 +x^4 + x^3 + x^2;
> F<a> := FunctionField(f);
> Genus(F);
7
> NumberOfPlacesDegECF(F, 2);
28
> P := RandomPlace(F, 2);
> P;
(x^2 + $.1^2*x + $.1^7, a + $.1^5*x + $.1^5)
> LocalUniformizer(P);
x^2 + $.1^2*x + $.1^7
> TwoGenerators(P);
x^2 + $.1^2*x + $.1^7 a + $.1^5*x + $.1^5
> ResidueClassField(P);
Finite field of size 3^4
> Evaluate(1/LocalUniformizer(P), P);
Infinity
> Valuation(1/LocalUniformizer(P), P);
-1
```

42.13.7 Completion at Places

```
Completion(F, p)
Completion(O, p)
```

`Precision` RngIntElt *Default :* 20

The completion of the algebraic function field F or an order O of such at the place p of F or the function field of O. The map from F or O into the series ring is returned also.

The series ring returned is an infinite precision ring whose default precision for elements is given by the `Precision` parameter.

42.14 Divisors

42.14.1 Creation of Structures

```
DivisorGroup(F)
```

Create the group of divisors of the algebraic function field F/k.

42.14.2 Creation of Elements

```
Divisor(P)
Div ! P
1 * P
```

Given a place P in a function field, return the prime divisor $1 * P$.

```
Div ! a
Divisor(a)
```

Given an algebraic function a, return the principal divisor (a).

```
Div ! I
Divisor(I)
```

The divisor corresponding to the factorization of the ideal I.

```
Divisor(I, J)
```

The divisor corresponding to the ideal factorization of the ideals I and J belonging to the 'finite' and 'infinite' maximal order.

```
Identity(G)
Id(G)
```

Given the group G of divisors of a function field, return the zero divisor.

`CanonicalDivisor(F)`

A canonical divisor of the function field F/k.

`DifferentDivisor(F)`

The different divisor of the underlying extension of the function field $F/k(x)$.

`AssignNames(~D, s)`

Change the print name employed when displaying D to be the contents of s which must have length 1 in this case.

42.14.3 Related Structures

42.14.3.1 Parent and Category

The group of divisors form the MAGMA category `DivFun`. The notional power structure exists as parent but allows no operations.

`FunctionField(G)`

Given the group G of divisors of a function field F/k, return F.

`Places(F)`

The set of places of the algebraic function field F/k.

42.14.4 Structure Invariants

`NumberOfSmoothDivisors(n, m, P)`

The number of effective divisors of degree less equal n who consist of places of degree less equal m only. The sequence element $P[i]$ contains the (generic) number of places of degree $1 \leq i \leq \min\{n, m\}$. The formula used is described in [Heß99].

`DivisorOfDegreeOne(F)`

A divisor of degree one over the exact constant field of the global function field F/k.

42.14.5 Structure Predicates

`Div1 eq Div2` `Div1 ne Div2`

42.14.6 Element Operations

42.14.6.1 Arithmetic Operators

`- D`

`D1 + D2` `D1 - D2` `k * D` `D div k` `D mod k`

`P + D` `D + P` `D - P` `P - D`

`Quotrem(D, k)`

Returns divisors D_1, D_2 such that the divisor $D = kD_1 + D_2$ and the exponents in D_2 are of absolute value less than $|k|$. The operations `div` and `mod` yield D_1 resp. D_2.

`GCD(D1, D2)`
`Gcd(D1, D2)`
`GreatestCommonDivisor(D1, D2)`

The greatest common divisor of the divisors $D1$ and $D2$.

`LCM(D1, D2)`
`Lcm(D1, D2)`
`LeastCommonMultiple(D1, D2)`

The least common multiple of the divisors $D1$ and $D2$.

42.14.6.2 Equality, Comparison and Membership

`D1 eq D2` `D1 ne D2`

`D1 le D2` `D1 lt D2` `D1 ge D2` `D1 gt D2`

`D in Div` `D notin Div`

42.14.6.3 Predicates on Elements

`IsZero(D)`

`IsEffective(D)` `IsPositive(D)`

`IsSpecial(D)` `IsPrincipal(D)`

`IsCanonical(D)`

Returns `true` iff the divisor D is canonical and a differential having D as its divisor.

Example H42E35

We show some simple creations and operations on divisors.

```
> PF<x> := PolynomialRing(GF(13, 2));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;

42.14.6.4 Other Element Operations

`FunctionField(D)`

Given a divisor D, return the function field.

`Degree(D)`

The degree of the divisor D over k, the constant field of definition.

`Support(D)`

A sequence containing the places occurring in the divisor D.

`Numerator(D)`

`ZeroDivisor(D)`

The numerator of the divisor D.

`Denominator(D)`
`PoleDivisor(D)`

The denominator of the divisor D.

`Ideals(D)`

Create two ideals of the 'finite' and 'infinite' maximal order respectively corresponding to the divisor D.

`Norm(D)`

The divisor of the norms of the ideals of the divisor D.

`FiniteSplit(D)`
`FiniteDivisor(D)`
`InfiniteDivisor(D)`

Split the divisor D into its finite and infinite part, returning either 2 divisors which are the sum of the finite places in D and the sum of the infinite places in D or the appropriate one of these.

`Dimension(D)`

The dimension of the Riemann-Roch space $\mathcal{L}(D)$ of the divisor D over k, the constant field of definition.

`IndexOfSpeciality(D)`

The index of speciality of the divisor D, which equals the dimension of $\mathcal{L}(W - D)$ where W is a canonical divisor.

`ShortBasis(D :`*parameters*`)`

`Reduction`	BoolElt	*Default :* `true`
`Simplification`	MonStgElt	*Default :* "*Full*"

Compute a basis for the Riemann-Roch space of D in short form:

Let $F = k(x, y)$ be an algebraic function field defined by $f(x, y) = 0$ over k. Given a divisor D of F/k this function returns a basis of the k-vector space

$$\mathcal{L}(D) = \{a \in F^\times \mid (a) \geq -D\} \cup \{0\}$$

in the short form

$$B = [\, b_1 \ldots, b_n \,],\ [\, d_1, \ldots, d_n \,]$$

with $b_i \in F^\times$ and $d_i \in \mathbf{Z}$ for all $1 \leq i \leq n$, where n denotes the degree in y of the defining equation f of F, such that

$$\mathcal{L}(D) = \left\{ \sum_{i=1}^{n} \lambda_i b_i \mid \lambda_i \in k[x] \text{ with } \deg \lambda_i \leq d_i \text{ for } 1 \leq i \leq n \right\}.$$

The optional argument `Reduction` controls whether to use divisor reduction internally or not; it defaults to `true`. For small divisors this is sometimes faster.

The optional argument `Simplification` controls whether the resulting basis is simplified or not; it defaults to `"Full"`. Simplification sometimes is not insignificantly expensive and can be avoided by setting the parameter to `"None"`.

The algorithm is described in [Heß99].

`Basis(D :parameters)`

`Reduction`	BoolElt	*Default :* `true`
`Simplification`	MonStgElt	*Default :* "*Full*"

A sequence containing a basis of the Riemann-Roch space $\mathcal{L}(D)$, for the divisor D.

The optional argument `Reduction` controls whether to use divisor reduction internally or not; it defaults to `true`. For small divisors this is sometimes faster.

The optional argument `Simplification` controls whether the resulting basis is simplified or not; it defaults to `"Full"`. Simplification sometimes is not insignificantly expensive and can be avoided by setting the parameter to `"None"`.

`RiemannRochSpace(D)`

Given a function field F/k and a divisor D belonging to F/k, return a vector space V and a k-linear mapping $h : V \longrightarrow F$ such that V is isomorphic to the Riemann-Roch space $\mathcal{L}(D) \subset F$ under h.

`Valuation(D, P)`

The exponent of the place P in the divisor D.

`Reduction(D)`

`Reduction(D, A)`

Let D be a divisor. Denote the result of both functions by $\tilde{D}$, r, A and a (for the second function the input A always equals the output A). The divisor A has (must have) positive degree and the following holds:

(i) $D = \tilde{D} + rA - (a)$,

(ii) $\tilde{D} \geq 0$ and $\deg(\tilde{D}) < g + \deg(A)$ (over the exact constant field),

(iii) $\tilde{D}$ has minimal degree among all such divisors satisfying (i), (ii).

`GapNumbers(D, P)`

The sequence of gap numbers of the divisor D at P where P must be a place of degree one:

Let F/k be an algebraic function field, D a divisor and P a place of degree one. An integer $m \geq 1$ is a gap number of D at P if $\dim\big(D+(m-1)P\big) = \dim(D+mP)$ holds. The gap numbers m of D satisfy $1 \leq m \leq 2g-1-\deg(D)$ and their cardinality equals the index of speciality $i(D)$. `GapNumbers(D, P)` returns such a particular sequence. The sequences of gap numbers of D at various P are independent of constant field extensions for perfect k and are the same for all but a finite number of places P of degree one (consider e.g. k algebraically closed). If P is omitted in the function call, this uniform sequence is returned by `GapNumbers(D)`. The places P where D has different sequences of gap numbers are called Weierstraß places of D and are returned by `WeierstrassPlaces(D)`. In the above mentioned functions it is equivalent to replace D by either F or the zero divisor.

`GapNumbers(D)`

`SeparatingElement` FLDFUNGELT *Default :*

The sequence of global gap numbers of the divisor D. A separating element used internally for the computation can be specified, it defaults to `SeparatingElement(F)`. See the description of GapNumbers on page 1167.

Example H42E36

Consider the function field F defined by the curve of genus 7 defined by

$$y^4 + (2*x^5 + x^4 + 2*x^3 + x^2)*y^2 + x^8 + 2*x^6 + x^5 + x^4 + x^3 + x^2$$

We construct the function field $F/\mathbf{F}_9$ and compute the Riemann-Roch space corresponding to a certain divisor.

```
> k<w> := GF(9);
> R<x> := FunctionField(k);
> P<y> := PolynomialRing(R);
> f := y^4 + (2*x^5 + x^4 + 2*x^3 + x^2)*y^2 + x^8
>      + 2*x^6 + x^5 +x^4 + x^3 + x^2;
> F<a> := FunctionField(f);
> Genus(F);
7
> P1 := RandomPlace(F, 1);
> P2 := RandomPlace(F, 1);
> D := P1 - P2;
> D;
(1/x, w^7/x^7*a^3 + w^5/x^5*a^2 + w^3/x^2*a + w) - (x, 2/(x^4 + x^2 + 2*x)*a^3 +
    w^3/x*a^2 + (w^5*x^3 + w^3*x + w^7)/(x^3 + x + 2)*a + w^5)
> IsPrincipal(336*D);
true
> infty := Poles(F!x)[1];
```

```
> V, h := RiemannRochSpace(11*infty);
> V;
KModule V of dimension 5 over GF(3^2)
> h;
Mapping from: ModFld: V to FldFun: F
> B := h(Basis(V));
> B;
[
    x/(x^3 + x + 2)*a^3 + (2*x^4 + 2*x^3 + x)/(x^3 + x + 2)*a,
    1/(x^3 + x + 2)*a^3 + (2*x^3 + 2*x^2 + 1)/(x^3 + x + 2)*a,
    a^2 + 2*x^3 + 2*x^2,
    1/x*a^2 + 2*x^2 + 2*x,
    1
]
> (B[2] + 2*B[3])@@h;
(    0     1     2     0     0)
```

Example H42E37

As a trivial but illustrative example we consider the algebraic function field generated by $\sin(x)$ and $\cos(x)$ over Q and construct a single function $a(x)$ such that $\sin(x)$ and $\cos(x)$ can be expressed in terms of $a(x)$:

```
> Qc<c> := PolynomialRing(RationalField());
> Qcs<s> := PolynomialRing(Qc);
> F<s> := FunctionField(s^2 + c^2 - 1);
> c := F!c;
> Genus(F);
0
> Zeros(s);
[ (c - 1, s), (c + 1, s) ]
> Zeros(c-1);
[ (c - 1, s) ]
> P := Zeros(c-1)[1];
> Degree(P);
1
> Dimension(1*P);
2
> Basis(1*P);
[ 1/(c - 1)*s, 1 ]
> a := Basis(1*P)[1];
> Degree(a);
1
> MinimalPolynomial(a);
$.1^2 + (c + 1)/(c - 1)
> (a^2 - 1)/(a^2 + 1);
c
> a * ((a^2 - 1)/(a^2 + 1) - 1);
```

```
s
```

Example H42E38

Over $Q(i)$ the familiar identities

$$\cos(x) = (\exp(ix) + \exp(-ix))/2$$

$$\sin(x) = (\exp(ix) - \exp(-ix))/(2i).$$

hold. In MAGMA one can proceed as follows:

```
> Qx<x> := PolynomialRing(RationalField());
> k<i> := NumberField(x^2 + 1);
> kc<c> := PolynomialRing(k);
> kcs<s> := PolynomialRing(kc);
> F<s> := FunctionField(s^2 + c^2 - 1);
> c := F!c;
> Genus(F);
0
> e := c + i*s;
> ebar := c - i*s;
> Degree(e);
1
> c eq (e + ebar) / 2;
true
> s eq (e - ebar) / (2*i);
true
```

`RamificationDivisor(D)`

`SeparatingElement` FLDFUNGELT *Default :*

The ramification divisor of the divisor D (using `SeparatingElement` for the computation which defaults to `SeparatingElement(F)` for F/k the function field of D):

Let F/k be an algebraic function field, x a separating variable and D a divisor. The ramification divisor of D is defined to be

$$i(D)\,(W - D) + \big(W_x(D)\big) + \nu\,(dx),$$

where W is a canonical divisor of F/k, $W_x(D)$ is the determinant of the Wronksian matrix of D with respect to x and ν is the sum of the Wronskian orders of D with respect to x. It is effective and consists of the Weierstraß places of D. The constant field k is required to be exact.

`WeierstrassPlaces(D)`

`SeparatingElement` FldFunGElt *Default :*

The Weierstrass places of the divisor D (using `SeparatingElement` for the computation which defaults to `SeparatingElement(F)` for F/k the function field of D):

Let F/k be an algebraic function field, D a divisor and P a place of degree one. An integer $m \geq 1$ is a gap number of D at P if $\dim\big(D+(m-1)P\big) = \dim(D+mP)$ holds. The gap numbers m of D at P satisfy $1 \leq m \leq 2g-1-\deg(D)$ and their cardinality equals the index of speciality $i(D)$. The sequences of gap numbers of D are independent of constant field extensions for perfect k and are the same for all but a finite number of places P of degree one (consider e.g. k algebraically closed). The places P of degree one at which D has different sequences of gap numbers are called Weierstraß places of D.

This function returns a list of all places of F/k (having not necessarily degree one) which are lying below Weierstraß places of D viewed in $F\bar{k}/\bar{k}$ (k perfect). The constant field k is required to be exact. Note that if the characteristic of F is positive this function is currently quite slow for large genus because of `Differentiation()`.

`IsWeierstrassPlace(D, P)`

Given a divisor D and a degree 1 place P of a function field, return whether P is a weierstrass place of D.

`WronskianOrders(D)`

`SeparatingElement` FldFunGElt *Default :*

Let D be a divisor of an algebraic function field F/k with separating element x and let $v_1, \ldots v_l$ be a basis of $\mathcal{L}(D)$. For the differentiation D_x with respect to x consider the successively smallest $\nu_1 \leq \ldots \leq \nu_l \in \mathbf{Z}^{\geq 0}$ such that the rows $D_x^{(\nu_i)}(v_1), \ldots, D_x^{(\nu_i)}(v_l)$, $1 \leq i \leq l$ are F-linearly independent. The numbers $\nu_1, \ldots, \nu_l$ are the Wronskian orders of D with respect to x and are returned. If D has dimension zero, the empty list is returned. The constant field k is required to be exact.

The separating element can be given by setting the `SeparatingElement` parameter appropriately.

`ComplementaryDivisor(D)`

Return the complementary divisor $D^{\#}$ of the divisor D. The function field F/k of D must be a finite extension of a rational function field $k(x)$. The divisor $D^{\#}$ equals $\mathrm{Diff}(F/k(x)) - D$ for F the function field of D and $\mathrm{Diff}(F/k(x))$ the different divisor of $F/k(x)$.

`DifferentialBasis(D)`

A basis of the space of differentials of the divisor D. See `DifferentialBasis` on page 1177 for details.

`DifferentialSpace(D)`

A vector space and the isomorphism from this space to the differential space of the divisor D.

`Parametrization(F, D)`

An element x in F which is a non constant element of the basis of the divisor D having degree one and a sequence of elements L in the rational function field are returned such that x generates the function field F over the constant field and L contains the images of the generators of F over its constant field in the rational function field.

42.14.7 Functions related to Divisor Class Groups of Global Function Fields

Let F/k be a global function field. The group of divisor classes is isomorphic to the product of a copy of $\mathbf{Z}$ and the group of divisors classes of degree zero which is a finite abelian group. MAGMA features an algorithm to compute the divisor class group by computing an abelian group G in the form $\mathbf{Z}/c_1\mathbf{Z} \times \ldots \times \mathbf{Z}/c_{2g}\mathbf{Z} \times \mathbf{Z}$ with integers $c_1|\ldots|c_{2g}$ and a surjective homomorphism $f : Div(F) \to G$ from the divisor group to G whose kernel consists precisely of the principal divisors.

The algorithm employed is a randomized index calculus style method of expected subexponential running time for "small" constant field size and "large" genus. A description of this and other algorithms of this section can be found in [Heß99].

Elements in product representation may result from applying the maps returned by some of the computations below. It can be expensive to put these elements into sets and to test them for equality.

`ClassGroupGenerationBound(q, g)`

A bound B such that the places of degree (over the exact constant field) less than or equal to B, taken together with the places of a divisor of degree one, generate the whole divisor class group of any global function field of genus g over the exact constant field of q elements.

`ClassGroupGenerationBound(F)`

A bound B such that all places of degree (over the exact constant field) less than or equal to B, taken together with the places of a divisor of degree one, generate the whole divisor class group of the function field F. Particular properties of the function field are taken into account.

`ClassNumberApproximation(F, e)`

An approximation of the class number of the global function field F/k with multiplicative error less than $1 + e$ for $e > 0$. The formula

$$\left| \log\big(h \,/\, q^g\big) - \sum_{r=1}^{b} q^{-r}/r\big(N_r - (q^r + 1)\big) \right| \;\le\; 2gq^{-b/2}/\big((q^{1/2} - 1)(b + 1)\big)$$

is used where N_r denotes the number of places of degree one in the constant field extension of degree r of F/k.

`ClassNumberApproximationBound(q, g, e)`

Returns an integer B such that all places of degree less than or equal to B of a global function field of genus g over the exact constant field of q elements have to be considered in order to approximate the class number with multiplicative error less than $1 + e$ for $e > 0$.

`ClassGroup(F :`*parameters*`)`

`DegreeBound`	RngIntElt	*Default :*
`SizeBound`	RngIntElt	*Default :*
`ReductionDivisor`	DivFunElt	*Default :*
`Proof`	BoolElt	*Default :*

The divisor class group of the function field F/k as an abelian group, a map of representatives from the class group to the divisor group and the homomorphism from the divisor group onto the divisor class group.

The optional parameter `DegreeBound` allows to control the size of the factor basis which consists of all places of degree less equal `DegreeBound` (plus a small additional amount; the degree is taken over the exact constant field). If not provided the algorithm tries to choose an appropriate value.

The optional parameter `SizeBound` bounds the size of the factor basis to not exceed `SizeBound` places. Every time the factor basis has to be enlarged during the computation it will be by no more than `SizeBound` additional places. If not provided there is no bound on the size of the factor basis. Every enlargement of the factor basis will append all places of the next degree.

The optional parameter `ReductionDivisor` contains the reduction divisor used in the relation search stage. Reasonable choices are divisors of small positive degree. If not provided the algorithm tries to choose an appropriate reduction divisor.

The optional parameter `Proof` indicates whether the computed result should be proven in a proof step. If a small degree bound for the factor basis is used and the divisor class group happens to be a product of a large number of cyclic groups the proof step can be very time consuming and `Proof := false` might be helpful. Once a value is given for `Proof` it remains the default value until set differently. The initial value of `Proof` for every function field is `true`.

`ClassGroupAbelianInvariants(F :`*parameters*`)`

`DegreeBound`	RngIntElt	*Default :*
`SizeBound`	RngIntElt	*Default :*
`ReductionDivisor`	DivFunElt	*Default :*
`Proof`	BoolElt	*Default :*

Computes a sequence of integers containing the Abelian invariants of the divisor class group of the function field F/k.

The optional parameters are the same as for `ClassGroup`.

`ClassNumber(F)`

The order of the group of divisor classes of degree zero of the function field F/k.

Example H42E39

Some class group calculations :

```
> Y<t> := PolynomialRing(Integers());
> R<x> := FunctionField(GF(9));
> P<y> := PolynomialRing(R);
> f := y^3 + y + x^5 + x + 1;
> F<alpha> := FunctionField(f);
> ClassNumberApproximation(F, 1.3);
24890.25505701632912193514

```

`GlobalUnitGroup(F)`

The group of global units of the function field F/k, i. e. the multiplicative group of the exact constant field, as an Abelian group, together with the map into F.

`IsGlobalUnit(a)`

Whether the function field element a is a global unit, i.e. a constant (equivalent to `IsConstant`).

`IsGlobalUnitWithPreimage(a)`

Returns `true` and the preimage of the function field element a in the global unit group, `false` otherwise.

`PrincipalDivisorMap(F)`

The map from the multiplicative group of the function field to the group of divisors.

`ClassGroupExactSequence(F)`

Returns the three maps in the center of the exact sequence

$$0 \to k^\times \to F^\times \to Div \to Cl \to 0$$

where $k^\times$ is the global unit group of the function field, $F^\times$ is the multiplicative group of the function field, Div is the divisor group and Cl is the divisor class group.

`SUnitGroup(S)`

The group of S-units as an Abelian group and the map into the function field, where S is a sequence of places of a function field.

`IsSUnit(a, S)`

Returns `true` if the function field element a is an S-unit for the sequence of places S, `false` otherwise.

`IsSUnitWithPreimage(a, S)`

Returns `true` and the preimage of the function field element a in the S-unit group if a is an S-unit for the sequence of places S, `false` otherwise.

`SRegulator(S)`

The S-Regulator for the sequence of places S.

`SPrincipalDivisorMap(S)`

The map from the multiplicative group of the function field to the group of divisors (mod places in the sequence S).

`IsSPrincipal(D, S)`

Returns `true` and a generator if the divisor D is principal modulo places in the sequence S, `false` otherwise

`SClassGroup(S)`

The S-class group for the sequence of places S as an Abelian group, a map of representatives from the S-class group to the group of divisors (mod places in S) and the homomorphism from the group of divisors (mod places in S) onto the S-class group.

`SClassGroupExactSequence(S)`

Returns the three maps in the center of the exact sequence

$$0 \to U(S) \to F^\times \to Div(S) \to Cl(S) \to 0$$

where $U(S)$ is the S-unit group, $F^\times$ is the multiplicative group of the function field, $Div(S)$ is the group of divisors (mod places in the sequence S) and $Cl(S)$ is the S-class group.

`SClassGroupAbelianInvariants(S)`

Computes a sequence of integers containing the Abelian invariants of the S-class group for the sequence of places S.

`SClassNumber(S)`

The order of the torsion part of the S-class group for the sequence of places S.

`ClassGroupPRank(F)`

Compute the p-rank of the class group of F/k where p is the characteristic of F/k. More precisely: Let F/k be a function field of characteristic p. Consider the subgroup $Cl^0(F/k)[p]$ of p-torsion elements of the group of divisor classes of degree zero. This function returns its dimension as an $\mathbf{F}_p$-vector space. Possible values range from 0 to g, where g is the genus of F/k. The field k is currently required to be a finite field.

`HasseWittInvariant(F)`

Return the Hasse–Witt invariant of F/k. More precisely: Let F/k be a function field of characteristic p. Let $F\bar{k}/\bar{k}$ be the constant field extension by the algebraic closure $\bar{k}$ of k within an algebraic closure $\bar{F}$ of F/k. Consider the subgroup $Cl^0(F\bar{k}/\bar{k})[p]$ of p-torsion elements of the group of divisor classes of degree zero. This function returns its dimension as an $\mathbf{F}_p$-vector space. Possible values range from 0 to g, where g is the genus of F/k. k is required to be perfect.

`TateLichtenbaumPairing(D1, D2, m)`

The Tate–Lichtenbaum pairing $Cl_0[m] \times Cl_0/mCl_0 \to k$ for coprime divisors $D1$ and $D2$.

Example H42E40

```
> k<w> := GF(9);
> R<x> := FunctionField(k);
> P<y> := PolynomialRing(R);
> f := y^4 + (2*x^5 + x^4 + 2*x^3 + x^2)*y^2 +
>             x^8 + 2*x^6 + x^5 + x^4 + x^3 + x^2;
> F<a> := FunctionField(f);
> D1 := Zeros(a)[1] - Poles(F!x)[1];
> D2 := Zeros(a)[4] - Poles(F!x)[2];
> G,mapfromG,maptoG:=ClassGroup(F : Proof:=false);
> Order(maptoG(D1));
48
> Order(maptoG(D2));
336
> TateLichtenbaumPairing(D1,D2,48);
w^7
> TateLichtenbaumPairing(D2,D1,336);
w^3
```

42.15 Differentials

Spaces of differentials of function fields can be created and the differentials belonging to them manipulated. Divisors can be created from differentials and modules generated by a collection of differentials can be formed.

42.15.1 Creation of Structures

`DifferentialSpace(F)`

The space of differentials of the algebraic function field F/k.

42.15.2 Creation of Elements

The simplest ways of creating a differential are given below.

`Differential(a)`

Create the differential $d(a)$ of the function field or order element a.

`Identity(D)`

The identity differential of the space of differentials D.

`IsCanonical(D)`

Returns `true` iff the divisor D is canonical and a differential having D as its divisor.

42.15.3 Related Structures

`FunctionField(D)`

The function field of the differentials in the space D.

`FunctionField(d)`

The function field of the differential d.

42.15.4 Subspaces

`SpaceOfDifferentialsFirstKind(F)`

`SpaceOfHolomorphicDifferentials(F)`

A vector space and the isomorphism from this space to the space of differentials of the first kind (holomorphic differentials) of the function field F/k.

`BasisOfDifferentialsFirstKind(F)`

`BasisOfHolomorphicDifferentials(F)`

A basis of the space of differentials of the first kind (holomorphic differentials) of the function field F/k.

`DifferentialBasis(D)`

Computes a basis for the space of differentials

$$\Omega(D) := \{ \omega \in \Omega(F/k) \mid (\omega) \geq D \}$$

for a divisor D of an algebraic function field F/k.

`DifferentialSpace(D)`

A vector space and the isomorphism from this space to the differential space of the divisor D.

Example H42E41

This example illustrates the differential space of a divisor and some of the operations that can be done with it.

```
> Q := Rationals();
> Qx<x> := PolynomialRing(Q);
> Qxy<y> := PolynomialRing(Qx);
> f1 := y^2 - (x-1)*(x-2)*(x-3)*(x-5)*(x-6);
> F := FunctionField(f1);
> d := Divisor(F.1) + Divisor(F!BaseRing(F).1);
> V1 := DifferentialSpace(d);
> d := 2*Divisor(F.1) - Divisor(F!BaseRing(F).1);
> V2 := DifferentialSpace(d);
> V1;
```

```
KModule V1 of dimension 2 over Rational Field
> V2;
KModule V2 of dimension 2 over Rational Field
> V1 meet V2;
KModule of dimension 0 over Rational Field
> D := DifferentialSpace(F);
> v := V1 ! [2/9, 4/9]; v;
V1: (2/9 4/9)
> D!v;
(2/9*x^2 + 4/9*x) d(x)
> V1!$1;
V1: (2/9 4/9)
> BasisOfDifferentialsFirstKind(F);
[ (x/(x^5 - 17*x^4 + 107*x^3 - 307*x^2 + 396*x - 180)*F.1) d(x), (1/(x^5 -
    17*x^4 + 107*x^3 - 307*x^2 + 396*x - 180)*F.1) d(x) ]
```

42.15.5 Structure Predicates

`D1 eq D2`

Return `true` if the spaces of differentials $D1$ and $D2$ are the same.

42.15.6 Operations on Elements

A number of general operations for elements are also provided for differentials as well as a number of specific functions for differentials.

42.15.6.1 Arithmetic Operators

`r * x`
`x * r`
`x + y`
`-x`
`x - y`
`x / y`
`x / r`

The operations on differentials are inherited from the vector space structure of the space of differentials. Additionally, this space is one–dimensional as a vector space over the function field itself. The quotient x/y of two differentials x and y then gives the unique $r \in F$ such that $x = ry$.

42.15.6.2 Equality and Membership

`x eq y`

Returns `true` if x and y are the same differential.

`x in D`

Returns `true` if x is in the space of differentials D.

42.15.6.3 Predicates on Elements

`IsExact(d)`

Return whether d is known to be an exact differential. If `true` additionally return a generator. If d is not already known to be exact then no attempts to determine whether d is exact or not are currently undertaken.

`IsZero(d)`

Return `true` if d is the zero differential.

42.15.6.4 Functions on Elements

`Valuation(d, P)`

The valuation of the differential d at the place P.

`Divisor(d)`

The divisor (d) of the differential d.

`Residue(d, P)`

The residue of the differential d at the place P, where P must (currently) have degree one.

Example H42E42

```
> PF<x> := PolynomialRing(GF(31, 3));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b : Check := false>;
> Differential(d);
(26/x*d) d(x)
> I := Random(FF2, 2)*MaximalOrderInfinite(FF2);
> P := Place(Factorization(I)[1][1]);
> Valuation(Differential(d), P);
-2
> IsExact(Differential(Random(FF2, 2)));
true
```

`Module(L, R)`

`IsBasis`	BoolElt	*Default :* `false`
`PreImages`	BoolElt	*Default :* `false`

The R-module generated by the differentials in the sequence L as an abstract module, together with the map into the space of differentials. The resulting modules can be used for intersection and inner sum computations.

If the optional parameter `IsBasis` is set `true` the function assumes that the given elements form a basis of the module to be computed.

If the optional parameter `PreImages` is set `true` then the preimages of the given elements under the map are returned as the third return value.

Both optional parameters are mainly used to save computation time.

`Relations(L, R)`

`Relations(L, R, m)`

The module of R-linear relations between the differentials of the sequence L. The argument m is used for the following: Let the elements of L be $a_1, \ldots, a_n$, V be the relation module $\subseteq R^n$ and define $M := \{ \sum_{i=1}^{m} v_i a_i \mid v = (v_i)_i \in V \}$. The function tries to compute a generating system of V such that the corresponding generating system of M consists of "small" elements.

Example H42E43

This example shows some of the conversions and operations possible with the results of `Module`.

```
> Q := Rationals();
> Qx<x> := PolynomialRing(Q);
> Qxy<y> := PolynomialRing(Qx);
> f1 := y^2 - (x-1)*(x-2)*(x-3)*(x-5)*(x-6);
> F := FunctionField(f1);
> D := DifferentialSpace(F);
> M7 := Module([Differential(3*F.1)], FieldOfFractions(Qx));
> M8 := Module([Differential(F.1), Differential(F!BaseRing(F).1)],
> FieldOfFractions(Qx));
> M12 := M7 meet M8;
> M16 := M7 + M8;
> assert M12 subset M7;
> assert M12 subset M8;
> assert M12 subset M16;
> r := M7![&+[Random([-100, 100])/Random([1, 100])*x^i : i in [1 .. 5]]/
> &+[Random([-100, 100])/Random([1,
> 100])*x^i : i in [1 .. 5]] : j in [1 .. Dimension(M7)]];
> assert M7!D!r eq r;
> r;
M7: ((1/100*x^4 + x^3 - x^2 + 1/100*x - 1/100)/(x^4 - 1/100*x^3 - 1/100*x^2 +
    1/100*x - 1/100))
> D!r;
```

```
((3/40*x^8 + 162/25*x^7 - 20937/200*x^6 + 114873/200*x^5 - 279531/200*x^4 +
    304167/200*x^3 - 24321/40*x^2 + 303/20*x - 297/50)/(x^9 - 1701/100*x^8 +
    2679/25*x^7 - 30789/100*x^6 + 19891/50*x^5 - 3593/20*x^4 - 63/10*x^3 +
    883/100*x^2 - 144/25*x + 9/5)*F.1) d(x)
```

`Cartier(b)`

`Cartier(b, r)`

The result of applying the Cartier operator r times to b. More precisely, let F/k be a function field over the perfect field k, $x \in F$ be a separating variable and $b = g\,dx \in \Omega(F/k)$ with $g \in F$ be a differential. The Cartier operator is defined by

$$C(b) = \left(-d^{p-1}g/dx^{p-1}\right)^{1/p} dx.$$

This function computes the r-th iterated application of C to b.

42.15.6.5 Other

`CartierRepresentation(F)`

`CartierRepresentation(F, r)`

Compute a row representation matrix of the Cartier operator on a basis of the space of holomorphic differentials of F/k (applied r times). More precisely, let F/k be a function field over the perfect field k, $\omega_1, \ldots, \omega_g \in \Omega(F/k)$ be a basis for the holomorphic differentials and $r \in \mathbf{Z}^{\geq 1}$. Let $M = (\lambda_{i,j})_{i,j} \in k^{g \times g}$ be the matrix such that

$$C^r(\omega_i) = \sum_{m=1}^{g} \lambda_{i,m}\omega_m$$

for all $1 \leq i \leq g$. This function returns M and $(\omega_1, \ldots, \omega_g)$.

Example H42E44

An example of a trivial cartier action.

```
> PF<x> := PolynomialRing(GF(31, 3));
> P<y> := PolynomialRing(PF);
> FF1<b> := ext<FieldOfFractions(PF) | y^2 - x>;
> P<y> := PolynomialRing(FF1);
> FF2<d> := ext<FF1 | y^3 - b : Check := false>;
> Cartier(Differential(d), 4);
(0) d(x)
> CartierRepresentation(FF2, 3);
Matrix with 0 rows and 0 columns
[]
```

42.16 Weil Descent

Weil Descent is a technique that can be applied to cryptosystem attacks amongst other things. The general idea is as follows. If C is a curve defined over field L and K is a subfield of L, the group of points of the Jacobian of C, $Jac(C)$, over L is isomorphic to the group of points of a higher-dimensional abelian variety, the *Weil restriction* of $Jac(C)$, over K. If a curve D over K can be found along with an algebraic homomorphism defined over K from $Jac(D)$ to this Weil restriction, it is usually possible to transfer problems about $Jac(C)(L)$ (like discrete log problems) to $Jac(D)(K)$. D will have larger genus than C, but we have descended to a smaller field. The advantage is that techniques like Index calculus, where the time complexity depends more strongly on the field size than the genus, can now be applied.

An important special case is where C is an ordinary elliptic curve over a finite field of characteristic 2. In this case, Artin-Schreier theory gives a very concrete algorithm for computing a suitable D. This is the GHS attack (see [Gau00] or the chapter by F. Heß in [Bla05]). There is a corresponding function `WeilDescent` in the Elliptic Curve chapter that works with curves rather than function fields.

The functions below implement the GHS Weil Descent in a more general characteristic p setting.

`WeilDescent(E,k)`

The main function. E must be an "Artin-Schreier" function field over finite field K, an extension of k, of the following form. If p is the characteristic of K, then the base field of E is a rational function field $K(x)$ and $E.1$, the generator of E over $K(x)$ has minimal polynomial of the form $y^p - y = c/x + a + b * x$ for $a, b, c \in K$. These parameters must satisfy $b, c \neq 0$ and at least one of the following conditions
i) $Trace_{K/k}(b) \neq 0$
ii) $Trace_{K/k}(c) \neq 0$
iii) $Trace_{K/\mathbf{F}_p}(a) = 0$

Then, if E_1 is the Galois closure of the separable field extension E/k and $[K : k] = n$, there is an extension of the Frobenius generator of $G(K/k)$ to an automorphism of E_1 which fixes x and is also of order n. If F is the fixed field of this extension, then it has exact constant field k and so it is the function field of a (geometrically irreducible) curve over k. This is the WeilDescent curve. It's algebraic function field F is the first return value.

Note that when $p = 2$, E is the function field of an ordinary elliptic curve in characteristic 2 (multiply the defining equation by x^2 and take xy as the new y variable) and conversely, any such elliptic curve can be put into this form in multiple ways.

The second return value is a map from the divisors of E to the divisors of F which represents the homomorphism $Jac(Curve(E))(K) \to Jac(Curve(F))(k)$. This map, however does not attempt any divisor reduction. For the characteristic 2 `WeilDescent` function on elliptic curves mentioned in the introduction, if F is hyperelliptic, the divisor map returned is the actual homomorphism from the elliptic

curve (with function field E) to the Jacobian of the hyperelliptic curve with function field F. This may be more convenient for the user.

There are functions below that may be called to return the genus and other attributes of F before actually going through with its construction.

One important special case, worth noting here, is that when $p = 2$ and b or c is in k, then the degree of F is also 2 and so the descent curve is a hyperelliptic curve.

`ArtinSchreierExtension(c,a,b)`

A convenience function to generate the function field which is an extension of $K(x)$ by the (irreducible) polynomial $y^p - y - c/x - a - bx$ where K is a finite field which is the parent of a, b, c and p is the characteristic of K.

`WeilDescentDegree(E,k)`

With E and k as in the main `WeilDescent` function, returns the degree of the descended function field F over its rational base field $k(x)$. The computation only involves the Frobenius action on a, b, c and the descent isn't actually performed.

`WeilDescentGenus(E,k)`

With E and k as in the main `WeilDescent` function, returns the genus of the descended function field F over its rational base field $k(x)$. The computation only involves the Frobenius action on a, b, c and the descent isn't actually performed.

`MultiplyFrobenius(b,f,F)`

This is a simple convenience function, useful for generating elements of K on which the Frobenius has a given minimal polynomial when considered as an $\mathbf{F}_p$-linear map (see the example below).

The argument b should be an element of a ring R, f a polynomial over ring R_0, which is naturally a subring of R and F a map from R to itself.

If $f = a_0 + a_1 x + \ldots$ then the function returns $f(F)(b)$ which is $a_0 + a_1 F(b) + a_2 F(F(b)) + \ldots$.

Example H42E45

We demonstrate with an example of descent over a degree 31 extension in characteristic 2, which results in a genus 31 hyperelliptic function field, and a small characteristic 3 example.

```
> SetSeed(1);
> k<u> := GF(2^5);
> K<w> := GF(2^155);
> Embed(k, K);
> k2<t> := PolynomialRing(GF(2));
> h := (t^31-1) div (t^5 + t^2 + 1);
> frob := map< K -> K | x :-> x^#k >;
> b := MultiplyFrobenius(K.1,h,frob);
> E := ArtinSchreierExtension(K!1, K!0, b);
> WeilDescentGenus(E, k);
```

```
31
> WeilDescentDegree(E,k);
2
> C,div_map := WeilDescent(E, k);
> C;
Algebraic function field defined over Univariate rational function field over
GF(2^5) by
y^2 + u*y + u^18/($.1^32 + u^29*$.1^16 + u^14*$.1^8 + u^2*$.1^4 + $.1^2 +
    u^9*$.1 + u^5)
> // get the image of the place representing a K-rational point
> pl := Zeroes(E!(BaseField(E).1)-w)[1];
> D := div_map(pl);
> Degree(D); //31*32
992
> k := GF(3);
> K<w> := GF(3,4);
> a := w+1;
> c := w;
> b := c^3+c;
> E := ArtinSchreierExtension(c, a, b);
> WeilDescentDegree(E,k);
27
> WeilDescentGenus(E,k);
78
> C := WeilDescent(E, k);
> C;
Algebraic function field defined over Univariate rational function field over
GF(3) by
y^27 + 2*y^9 + y^3 + 2*y + (2*$.1^18 + 2*$.1^12 + 2*$.1^9 + 2)/($.1^9 + $.1^3 +
    1)
```

42.17 Function Field Database

An optional database of function fields may be downloaded from the MAGMA website. This section defines the interface to that database. Each database is associated to a given finite field and extension degree. The supported combinations are:

- $\mathbf{F}_2$: degrees 2, 3
- $\mathbf{F}_3$: degree 2
- $\mathbf{F}_4$: degrees 2, 3, 5
- $\mathbf{F}_5$: degrees 2, 3, 4, 8
- $\mathbf{F}_7$: degree 9
- $\mathbf{F}_{11}$: degree 3
- $\mathbf{F}_{13}$: degree 3

For each function field in the database, the following information is stored and may be used to limit the function fields of interest via the sub constructor: The genus; the number of degree one places; the class number; and the class group.

42.17.1 Creation

`FunctionFieldDatabase(q, d)`

Returns a database object for the function fields of degree d over $\mathbf{F}_q$.

`sub< D | : parameters >`

`Genus` RngIntElt *Default :*

`NumberOfDegreeOnePlaces`

RngIntElt *Default :*

Returns a sub-database of D, restricting (or further restricting, if D is already a sub-database of the full database) the contents to those function fields satisfying the specified conditions. Note that it is not possible to "undo" restrictions with this constructor — the results are always at least as limited as D is.

The parameter `Genus` may be used to restrict the search to fields with the specified genus.

The parameter `NumberOfDegreeOnePlaces` may be used to restrict the search to only those fields with the specified number of places of degree one.

42.17.2 Access

`BaseField(D)`

`CoefficientField(D)`

Returns the finite field underlying each function field in the database.

`Degree(D)`

Returns the degree of each function field in the database.

`#D`

`NumberOfFields(D)`

Returns the number of function fields stored in the database.

`FunctionFields(D)`

Returns the sequence of function fields stored in the database.

Example H42E46

The genus of a degree four function field is at most 6. We can see the distribution in a database by counting the size of appropriate sub-databases:

```
> D := FunctionFieldDatabase(5, 4);
> #D;
196380
> [ #sub<D |: Genus := g> : g in [0..6] ];
[ 60, 480, 960, 12960, 35040, 63120, 83760 ]
```

43 CLASS FIELD THEORY FOR GLOBAL FUNCTION FIELDS

Chapter 43
CLASS FIELD THEORY FOR GLOBAL FUNCTION FIELDS

Global function fields admit a class field theory in the same way as number fields do (Chapter 39). From a computational point of view the main difference is the use of divisors rather than ideals and the availability in general of analytical methods; see Section 43.6.

Class field theory deals with the abelian extensions of a given field. In the number field case, all abelian extensions can be parameterized using more general class groups, in the case of global function fields, the same will be achieved using the divisor class group and extensions of it.

43.1 Ray Class Groups

The ray divisor class group Cl_m modulo a divisor m of a global function field K is defined via the following exact sequence:

$$1 \to k^\times \to O_m^\times \to \mathrm{Cl}_m \to \mathrm{Cl} \to 1$$

where O_m^* is the group of units in the "residue ring" mod m, k is the exact constant field of K and Cl is the divisor class group of K. This follows the methods outlined in [HPP97].

`RayResidueRing(D)`

Let $D = \sum n_i P_i$ be an effective divisor for some places P_i (so $n_i > 0$). The ray residue ring R is the product of the unit groups of the local rings:

$$R = O_m^\times := \prod (O_{P_i}/P_i^{n^i})^\times$$

where O_{P_i} is the valuation ring of P_i.

The map returned as the second return value is from the ray residue ring R into the function field and admits a pointwise inverse for the computation of discrete logarithms.

`RayClassGroup(D)`

Let D be an effective (positive) divisor. The ray class group modulo D is a quotient of the group of divisors that are coprime to D modulo certain principal divisors. It may be computed using the exact sequence:

$$1 \to k^\times \to O_m^\times \to \mathrm{Cl}_m \to \mathrm{Cl} \to 1$$

Note that in contrast to the number field case, the ray class group of a function field is infinite.

The map returned as the second return value is the map from the ray class group into the group of divisors and admits a pointwise inverse for the computation of discrete logarithms.

Since this function uses the class group of the function field in an essential way, it may be necessary for large examples to precompute the class group. Using ClassGroup directly gives access to options that may be necessary for complicated fields.

RayClassGroupDiscLog(y, D)

RayClassGroupDiscLog(y, D)

Return the discrete log of the place or divisor y in the ray class group modulo the divisor D. This is a version of the pointwise inverse of the map returned by RayClassGroup. The main difference is that using the intrinsics the values are cached, ie. if the same place (or divisor) is decomposed twice, the second time will be instantaneous.

A disadvantage is that in situations where a great number of discrete logarithms is computed for pairwise different divisors, a great amount of memory is wasted.

Example H43E1

We will demonstrate the creation of some ray class and ray residue groups. First we have to create a function field:

```
> k<w> := GF(4);
> kt<t> := PolynomialRing(k);
> ktx<x> := PolynomialRing(kt);
> K := FunctionField(x^3-w*t*x^2+x+t);
```

Now, to create some divisors:

```
> lp := Places(K, 2);
> D1 := 4*lp[2]+2*lp[6];
> D2 := &+Support(D1);
```

And now the groups:

```
> G1, mG1 := RayResidueRing(D1); G1;
Abelian Group isomorphic to Z/2 + Z/2 + Z/2 + Z/2 + Z/2 + Z/2 +
Z/2 + Z/4 + Z/60 + Z/60
Defined on 10 generators
Relations:
    2*G1.1 = 0
    2*G1.2 = 0
    2*G1.3 = 0
    2*G1.4 = 0
    2*G1.5 = 0
    2*G1.6 = 0
```

```
    2*G1.7 = 0
    4*G1.8 = 0
    60*G1.9 = 0
    60*G1.10 = 0
> G2, mG2 := RayResidueRing(D2); G2;
Abelian Group isomorphic to Z/15 + Z/15
Defined on 2 generators
Relations:
    15*G2.1 = 0
    15*G2.2 = 0
```

$G_1 = O_{D_1}^{\times}$ should surject onto $D_2 = O_{D_2}^{\times}$ since $D_2 | D_1$:

```
> h := hom<G1 -> G2 | [G1.i@mG1@@mG2 : i in [1..Ngens(G1)]]>;
> Image(h) eq G2;
true
> [ h(G1.i) : i in [1..Ngens(G1)]];
[
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    G2.2,
    G2.1
]
```

Ray class groups are similar and can be mapped in the same way:

```
> R1, mR1 := RayClassGroup(D1);
> R2, mR2 := RayClassGroup(D2); R2;
Abelian Group isomorphic to Z/5 + Z/15 + Z
Defined on 3 generators
Relations:
    5*R2.1 = 0
    15*R2.2 = 0
> hR := hom<R1 -> R2 | [R1.i@mR1@@mR2 : i in [1..Ngens(R1)]]>;
> Image(hR);
Abelian Group isomorphic to Z/5 + Z/15 + Z
Defined on 3 generators in supergroup R2:
    $.1 = R2.1
    $.2 = R2.2
    $.3 = R2.3
Relations:
    5*$.1 = 0
    15*$.2 = 0
> $1 eq R2;
```

```
true
```

Note that the missing C_3 part in comparing G_2 and R_2 corresponds to factoring by $k^\times$. The free factor comes from the class group.
Now, let us investigate the defining exact sequence for R_2:

```
> C, mC := ClassGroup(K);
> h1 := map<K -> G2 | x :-> (K!x)@@mG2>;
> h2 := hom<G2 -> R2 | [ G2.i@mG2@@mR2 : i in [1..Ngens(G2)]]>;
> h3 := hom<R2 -> C | [ R2.i@mR2@@mC : i in [1..Ngens(R2)]]>;
> sub<G2 | [h1(x) : x in k | x ne 0]> eq Kernel(h2);
> Image(h2) eq Kernel(h3);
> Image(h3) eq C;
```

So indeed, the exact sequence property holds.

43.2 Creation of Class Fields

Since the beginning of class field theory one of the core problems has been to find defining equations for the fields. Although most of the original proofs are essentially constructive, they rely on complicated and involved computations and thus were not suited for hand computations.

The method used here to compute defining equations is essentially the same as the one used for number fields. The main differences are due to the problem of p-extensions in characteristic p where Artin-Schreier-Witt theory is used, and the fact that the divisor class group is infinite.

`AbelianExtension(D, U)`

Given an effective divisor D and a subgroup U of the ray class group, (see RayClassGroup), Cl_D of D such that the quotient Cl_D/U is finite, create the extension defined by this data. Note that, at this point, no defining equations are computed.

`MaximalAbelianSubfield(K)`

For a relative extension K/k of global function fields, compute the maximal abelian subfield $K/A/k$ of K/k as an abelian extension of k. In particular, this function compute the norm group of K/k as a subgroup of a suitable ray class group.

`HilbertClassField(K, p)`

For a global function field K and a place p of K, compute the (a) Hilbert class field of K as an abelian extension of K. This field is characterised by being the maximal abelian unramified extension of K where p is totally split.

`FunctionField(A)`

`WithAut`	BoolElt	*Default :* `false`
Verbose	`ClassField`	*Maximum :* 3

Given an abelian extension of function fields as created by `AbelianExtension`, compute defining equations for the corresponding (ray) class field.

More precisely: Let $\mathrm{Cl}/U = \prod \mathrm{Cl}/U_i$ be a decomposition of the norm group of A such that the Cl/U_i are cyclic of prime power order. Then for each U_i the function will compute a defining equation, thus A is represented by the compositum.

If `WithAut` is `true`, the second sequence returned contains a generating automorphism for each of the fields returned as the first return value. If `WithAut` is `false`, the first (and only) return value is a function field in non-simple representation.

`MaximalOrderFinite(A)`

`MaximalOrderInfinite(A)`

Compute a finite or an infinite maximal order of the function field of the abelian extension A.

Example H43E2

First we have to create a function field, a divisor and a ray class group:

```
> k<w> := GF(4);
> kt<t> := PolynomialRing(k);
> ktx<x> := PolynomialRing(kt);
> K := FunctionField(x^3-w*t*x^2+x+t);
> lp := Places(K, 2);
> D := 4*lp[2]+2*lp[6];
> R, mR := RayClassGroup(D);
```

Let us compute the maximal extension of exponent 5 such that the infinite place is totally split. This means that we

- have to create a subgroup of R containing the image of the infinite place
- compute the fifth power of R
- combine the two groups

and use this as input to the class field computation:

```
> inf := InfinitePlaces(K);
> U1 := sub<R | [x@@ mR : x in inf]>;
> U2 := sub<R | [5*R.i : i in [1..Ngens(R)]]>;
> U3 := sub<R | U1, U2>;
> A := AbelianExtension(D, U3);
> A;
Abelian extension of type [ 5 ]
Defined modulo 4*(t^2 + t + w, $.1 + w^2*t + 1) +
2*(t^2 + w^2*t + w^2, $.1 + w*t + w)
over Algebraic function field defined over
```

```
Univariate rational function field over GF(2^2) by
x^3 + w*t*x^2 + x + t
> FunctionField(A);
Algebraic function field defined over K by
$.1^5 + (w*K.1^2 + (w*t + w^2)*K.1 + (w^2*t^2 + t
    + w^2))*$.1^3 + ((t^2 + 1)*K.1^2 + w*t*K.1 +
    (w*t^4 + w))*$.1 + (t^3 + w*t^2 + w^2*t)*K.1^2
    + (w*t^4 + w^2*t^2 + w^2)*K.1 + t^4 + w^2*t^3
    + w^2*t + w
> E := $1;
>  #InfinitePlaces(E);
10
```

Which shows that all the places in `inf` split completely.
Now, suppose we still want the infinite places to split, but now we are looking for degree 4 extensions such that the quotient of genus by number of rational places is maximal:

```
> q, mq := quo<R | U1>;
> l4 := [ x`subgroup : x in Subgroups(q : Quot := [4])];
> #l4;
768
> A := [AbelianExtension(D, x@@mq) : x in l4];
> s4 := [<Genus(a), NumberOfPlacesOfDegreeOne(a), a>
>                             : a in A];
> Maximum([x[2]/x[1] : x in s4]);
16/5 15
> E := FunctionField(s4[15][3]);
>  l22 := [ x`subgroup : x in Subgroups(q : Quot := [2,2])];
>  #l22;
43435
```

Since this is quite a lot, we won't investigate them here further.

43.3 Properties of Class Fields

Let D be an effective divisor and U be a subgroup of the ray class group Cl_D. The main existence theorem of class field theory asserts that there is exactly one function field corresponding to the quotient Cl_D/U whose Galois group is isomorphic to Cl_D/U in a canonical way.

Since the field is uniquely defined this way so are its invariants. Some of the invariants can easily be read off the groups involved. Therfore none of the functions listed here will compute a set of defining equations. They can therefore be used on very large fields.

`Conductor(m)`

Let m be an effective divisor. This function computes the conductor of Cl_m which is the smallest divisor f such that the projection $\mathrm{Cl}_m \to \mathrm{Cl}_f$ is surjective.

`Conductor(m, U)`

Let m be an effective divisor and U be a subgroup of the ray class group of m. This function computes the conductor of Cl_m/U which is the smallest divisor f such that the projection $\pi : \mathrm{Cl}_m/U \to \mathrm{Cl}_f/\pi(U)$ is an isomorphism.

`Conductor(A)`

For an abelian extension A of global function fields, compute its conductor, ie. the conductor of the norm group of A.

`DiscriminantDivisor(m, U)`

Let m be an effective divisor and U a subgroup of ray class group such that Cl_m/U is finite. The discriminant divisor is defined as the norm of the different divisor.

`DiscriminantDivisor(A)`

For an abelian extension A of a global function field, compute its discriminant divisor, ie. the norm of the different divisor. Note that the discriminant divisor can be computed from the norm group, thus no defining equation is derived.

`DegreeOfExactConstantField(m)`

Let m be an effective divisor. Since the ray class field modulo m is always an infinite field extension containing the algebraic closure of the constant field, this returns ∞.

`DegreeOfExactConstantField(m, U)`

Let m be an effective divisor and U be a subgroup of the ray class group, (see `RayClassGroup`), modulo m. This function computes the degree of the algebraic closure of the constant field in the class field corresponding to Cl_m/U. This can be infinite.

`DegreeOfExactConstantField(A)`

The degree of the exact constant field of the abelian extension A of a global function field. This is the degree of the algebraic closure of the constant field of the base field of A in A. The degree of this field can be computed from the norm group, thus no defining equation is derived.

`Genus(m, U)`

Let m be an effective divisor and U be a subgroup of the ray class group, (see `RayClassGroup`), modulo m. This function computes the genus of the class field corresponding to Cl_m/U.

`Genus(A)`

The genus of the abelian extension A of a global function field.

`DecompositionType(m, U, p)`

Let m be an effective divisor and U be a subgroup of the ray class group, (see RayClassGroup), modulo m such that the quotient Cl_m/U is finite. For a place p this function will determine the decomposition type of the place in the extension defined by Cl_m/U, i.e. it will return a sequence of pairs $\langle f, e\rangle$ containing the inertia degree and ramification index for all places above p.

`DecompositionType(A, p)`

For an abelian extension A of a global function field k and a place p of k, compute the degree and ramification index of all places P lying above p.

`NumberOfPlacesOfDegreeOne(m, U)`

Let m be an effective divisor and U be a subgroup of the ray class group, (see RayClassGroup), modulo m such that the quotient Cl_m/U is finite. This function will compute the number of places of degree 1 that the class field corresponding to Cl_m/U has.

`NumberOfPlacesOfDegreeOne(A)`

For an abelian extension A of global function fields, compute the number of places of A that are of degree one over the constant field of the base field of A.

`Degree(A)`

For an abelian extension A of global function fields, return the degree of A over its base ring.

`BaseField(A)`

For an abelian extension A of global function fields, return the base field, ie, the global field k over which A was created as an extension.

`A eq B`

For two abelian extensions of the same base field, decide if they describe the same field, ie if the norm groups pulled back into a common over group, agree.

`A subset B`

For two abelian extensions of the same base field, test if the first is contained in the second. This is done by comparing the norm groups in a common over group, thus defining equations are not computed.

`A meet B`

Compute the intersection of two abelian extensions of the same base field as an abelian extension.

`A * B`

Compute the compositum of two abelian extensions of the same base field as an abelian extension. Since both fields are normal, the compositum is well defined and can be computed from the norm groups alone.

43.4 The Ring of Witt Vectors of Finite Length

The ring of Witt vectors of length n (type `RngWitt`) over a global function field K parametrizes the cyclic extensions of K of degree p^n where p is the characteristic of K. Witt vectors (type `RngWittElt`) can be defined over any ring with positive characteristic p. The ring of Witt vectors of length n will always be of characteristic p^n. In the case of Witt vectors over finite fields, they can be seen as isomorphic to finite quotients of unramified p-adic rings.

The functionality offered here is mainly motivated by the class field theory which deals with vectors of short length only.

The Witt rings are based on code developed by David Kohel.

`WittRing(F, n)`

Creates the ring of Witt vectors of length n where F must be a field of positive characteristic.

`W ! a`

Witt vectors of the Witt ring W can be constructed from a where a is

- an element of the same ring
- an integer
- an element of the base ring
- a sequence of length `Length(W)` whose universe can be changed to the base ring of W.

`BaseRing(W)`

`BaseField(W)`

The field of coefficients of the Witt ring W.

`Length(W)`

The length (dimension) of the elements of the Witt ring W.

`Eltseq(a)`

The list of coefficients of the Witt vector a.

`Unity(W)`

`Zero(W)`

The one resp. zero in the Witt ring W.

`W . 1`

The first non-trivial basis element of the Witt ring.

`x in W` `a eq b` `a - b` `- a` `a + b` `a * b` `a ^ n`

`FrobeniusMap(W)`

The Frobenius map on the Witt ring W which is defined to be the map sending vectors to vectors where every coefficient is raised to the pth power.

`FrobeniusImage(e)`

Computes the image of the Witt vector e under the Frobenius map.

`VerschiebungMap(W)`

The verschiebungs map of the Witt ring W, i.e. shift all coefficients one position to the right and pad with a zero in front.

`VerschiebungImage(e)`

Computes the image of the Witt vector e under the verschiebung map.

`Random(W)`

For finite Witt rings, i.e. Witt rings defined over finite fields, return a random element.

`Random(W, n)`

For Witt rings where the base field admits a random function with size restriction n.

`TeichmuellerSystem(R)`

A Techmüller system for the local ring R, ie. a system of representatives for the residue class field of R that is closed under multiplication.

`LocalRing(W)`

Any ring W of Witt vectors of finite length over a finite field is isomorphic to some unramified local ring. This intrinsic will create the corresponding local ring and the embedding into it.

`ArtinSchreierMap(W)`

Returns the map $x \mapsto F(x) - x$ where F is the Frobenius map of the Witt ring W.

`ArtinSchreierImage(e)`

This function computes the image of the Witt vector e under the Artin-Schreier map.

`FunctionField(e)`

`WithAut`	BoolElt	*Default :* `true`
`Check`	BoolElt	*Default :* `false`
`Abs`	BoolElt	*Default :* `false`

A Witt vector $e = (e_1, \ldots, e_n)$ of length n over k where e_1 is not in the image of the Artin-Schreier map $e_1 \notin \{x^p - x : x \in k\}$ defines a cyclic extension K/k of degree p^n. This function will compute K.

If `WithAut` is `true` in addition to K it will compute a generating automorphism and return it as second return value.

If `Abs` is `true`, the function will compute a K as a single step extension of k, otherwise, K will be constructed as a series of n Artin-Schreier extensions.

If `Check` is `true`, it will be verified that the extension is of degree p^n. In particular the restrictions on e_1 are tested.

43.5 The Ring of Twisted Polynomials

The ring of twisted polynomials plays a core role in the analytic side of class field theory of global function fields. Twisted polynomials can be viewed as additive polynomials where the multiplication is the composition of two polynomials. Alternatively, they are the ring of polynomials in the Frobenius automorphism of the base field as indeterminate and multiplication defined in terms of application of the corresponding endomorphism. Thus Twisted polynomials have two natural polynomial representations:

- as (arbitrary) polynomials in F, the Frobenius automorphism
- as additive polynomials, ie. as polynomials where the only terms are T^{q^i}.

In Magma the first representation is used (as the degrees are lower), but the second can always be obtained by converting to a polynomial.

Since every endomorphism in positive characteristic can be represented by an additive polynomial (or an additive power series), this section can also be viewed as making the endomorphism ring accessible.

In Magma the ring of twisted polynomials is of type `RngUPolTwst` and individual elements are of type `RngUPolTwstElt`. Twisted polynomial rings can be created over any ring of characteristic $p > 0$. They are left euclidean and therefore left PIR.

43.5.1 Creation of Twisted Polynomial Rings

`TwistedPolynomials(R)`

`q`	RngIntElt	*Default :* `false`

Given a ring R of characteristic $p > 0$, create the ring of twisted polynomials over R. If `q` is given it has to be a power of the characteristic p, it defaults to $q := p$. The multiplication in this ring $R < F >$ is defined by $rF = Fr^q$ for all $r \in R$. Elements if $R < F >$ are represented as polynomials in F.

43.5.2 Operations with the Ring of Twisted Polynomials

`Unity(R)`

For a ring R of twisted polynomials return the polynomial representing 1.

`Zero(R)`

For a ring R of twisted polynomials return the polynomial representing 0.

`R eq S`

For two rings of twisted polynomials R and S test if they are equal, that is if the underlying polynomial ring is considered equal by MAGMA. Generically that means to test if the base rings of R and S coincide.

`BaseRing(R)`

The coefficient ring of the ring R of twisted polynomials.

`R . i`

For a ring of twisted polynomials R and an integer i which should be 1, return the transcendental element of R.

43.5.3 Creation of Twisted Polynomials

Apart from creation from polynomials directly, twisted polynomial can also be created by specifying some finite $\mathbf{F}_q$-vector space where the corresponding additive polynomial will have its roots.

`AdditivePolynomialFromRoots(x, P)`

`InfBound`	RNGINTELT	*Default :* 5
`Map`	MAP	*Default :* id
`Class`	DIVFUNELT	*Default :* 0
`Limit`	RNGINTELT	*Default :* ∞
`Scale`	RNGELT	*Default :* `false`

An additive polynomial is characterized by the fact that its set of zeros forms an $\mathbf{F}_q$ vector space. Conversely, given an $\mathbf{F}_p$-vector space M in R there is essentially one additive polynomial that has M as its set of roots. Given a place P and a ring element x, this function computes the additive polynomial with roots $L(\texttt{InfBound}P)$, evaluated at x, ie. the module M is a Riemann-Roch space. By choosing x to be for example a transcendental element in a polynomial ring, the actual additive polynomial can be computed. If the parameter `Map` is given, the elements of the Riemann-Roch space are first mapped by this map before the polynomial is computed, thus allowing the creation of polynomials over the completion of a function field. If the parameter `Limit` is given, the polynomial is reduced modulo $x^{\mathbf{Limit}}$. If `Class` is set to a non-zero divisor, instead of $L(nP)$, the Riemann-Roch space $L(nP+\texttt{Class})$ is used. If "tt Scale is set to a ring element that is either compatible with elements of the Riemann-Roch space or with elements in the codomain of the map, the module is scaled as well, thus allowing for normalization.

`Random(F, n)`

For F the ring of twisted polynomials over a finite ring (ie. a ring that supports the generation of random elements, this function will return a polynomial of degree $n-1$ with randomly chosen coefficients.

Example H43E3

```
> Fq<w> := GF(4);
> k<t> := RationalFunctionField(Fq);
> R := TwistedPolynomials(k:q := 4);
> R![1,1];
T_4 + 1
> R![w*t, 1];
T_4 + w*t
> $2 * $1;
T_4^2 + (w*t^4 + 1)*T_4 + w*t
> $2 * $3;
T_4^2 + (w*t + 1)*T_4 + w*t

43.5.4 Operations with Twisted Polynomials

`A + B` `A - B` `- A` `A * B` `A ^ n`

`A eq B` `IsZero(A)`

`LeadingCoefficient(F)`

For a twisted polynomial F, return the leading coefficient as an element of the coefficient ring.

`ConstantCoefficient(F)`

For a twisted polynomial F, return the constant coefficient as an element of the coefficient ring.

`Degree(F)`

For a twisted polynomial F, return its degree. The degree of the underlying additive polynomial is q times the degree of the twisted polynomial.

`Quotrem(F, G)`

For twisted polynomials F and G in the same ring, perform a right division with remainder: This function computes Q and R such that $F = Q * G + R$ and the degree of R is less than the degree of G. In general, unless the coefficient ring is algebraically closed or perfect, there is no left quotient, so the ring of twisted polynomials is a left-PID, but no right-PID.

`GCD(F, G)`

For twisted polynomials F and G in the same ring, compute the creates common right divisor of F and G, ie a twisted polynomial H such that $F = f_1 H$ and $G = f_2 H$ for some twisted polynomials f_1 and f_2 and such that H is monic of maximal degree.

`BaseRing(F)`

For a twisted polynomial F, return the coefficient ring of F, ie. the ring where all the coefficients of F are from.

`Polynomial(G)`

For a twisted polynomial G, return the corresponding additive polynomial by replacing the transcendental element F by T^q and in general F^i by T^{q^i} for $i = 0, \ldots,$ degree of G.

`SpecialEvaluate(F, x)`

For a twisted polynomial F, return the result of the evaluation of the corresponding additive polynomial at the point x.

`SpecialEvaluate(F, x)`

For a univariate polynomial F, return the evaluation of F at x. This function in particular is optimized for sparse polynomials (for example additive polynomials) and imprecise coefficients. In the general case, a call to `Evaluate` will be faster.

`Eltseq(F)`

For a twisted polynomial F, return a sequence containing its coefficients.

43.6 Analytic Theory

Probably the most significant difference between the class field theories for number fields and function fields is the fact that function fields allow an analytic description of abelian extensions in general where number fields (currently) only admit the analytical view for extensions of the rationals (cyclotomic fields) and imaginary quadratic fields (CM-theory).

The analytic description is based on Drinfeld-modules of rank 1 (or in the case of the rational function field the Carlitz-module). Informally, a Drinfeld module is a representation of some (infinite) maximal order of a function field into the ring of additive polynomials over some appropriate ring containing the original field. Similar to CM-theory, abelian extensions are then generated by adjoining torsion points under this action.

`CarlitzModule(R, x)`

For a rational function field $k = \mathbf{F}_q(t)$ and a polynomial f in $k[t]$, compute the image of f under the Carlitz module as an element in the ring of twisted polynomials R. Specifically, the Carlitz module is the representation induced by sending t to $F + t$ where F is the transcendental element of R, the Frobenius of k. As $\mathbf{F}_q[t]$ is freely generated by t, this defines a homomorphism (a representation) of $\mathbf{F}_q[t]$ into the twisted polynomials over k.

Example H43E4

We demonstrate how the Carlitz-module can be used to define abelian extensions of the rational function field.

```
> Fq<w> := GF(4);
> k<t> := RationalFunctionField(Fq);
> R<T> := TwistedPolynomials(k:q := 4);
```

Suppose we want to create the Ray-class field modulo $p := t^2 + t + w$, ie we want to find an abelian extension unramified outside p and the infinite place.

```
> p := t^2+t+w;
> P := CarlitzModule(R, p);
> F := Polynomial(P);
```

```
> Factorisation(F);
[
    <T, 1>,
    <T^15 + (t^4 + t + 1)*T^3 + t^2 + t + w, 1>
]
> K := FunctionField($1[2][1]);
> a := Support(DifferentDivisor(K));
> a[1];
(t^2 + t + w, K.1)
> [ IsFinite(x) : x in a];
[ true, false, false, false, false, false ]
> RamificationIndex(a[1]);
15
```

So, this shows that the field has the ramification bahaviour we wanted. However, the Carlitz-module will give us more information: We will demonstrate that the automorphism group of K is isomorphic to the unit group of $\mathbf{F}_q[t]/p$ under this module.

```
> q, mq := quo<Integers(k)|p>;
> au := func<X|Evaluate(Polynomial(CarlitzModule(R, X)), K.1)>;
> [ <IsUnit(x), Evaluate(DefiningPolynomial(K), au(x@@mq)) eq 0>
>                     : x in q];
[ <true, true>, <true, true>, <true, true>, <true, true>, <true,
true>, <true, true>, <true, true>, <true, true>, <true, true>, <true,
true>, <true, true>, <true, true>, <true, true>, <true, true>, <true,
true>, <false, false> ]
```

Now we try to create the same field using the algebraic class field machinery:

```
> D, U := NormGroup(K);
> Conductor(D, U);
($.1^2 + $.1 + w) + (1/$.1)
```

So this also shows that K is ramified exactly at p and the infinite places and, since the multiplicity is one, tamely ramified at both places.

```
> A := AbelianExtension(D, U);
> F := FunctionField(A);
> F;
Algebraic function field defined over Algebraic function field defined
over GF(2^2) by
$.2 + 1 by
$.1^3 + ($.1^2 + $.1 + w)^2
$.1^5 + w^2*$.1^3 + w*$.1 + (w^2*$.1^4 + w^2*$.1^2 + 1)/($.1^6 + $.1^5
    + w^2*$.1^4 + $.1^3 + $.1^2 + w^2*$.1 + 1)
> HasRoot(Polynomial(K, DefiningPolynomials(F)[1]));
true K.1^10 + (t^2 + t + w)*K.1^4 + (t^2 + t + w)*K.1
> HasRoot(Polynomial(K, DefiningPolynomials(F)[2]));
true w/(t^2 + t + w)*K.1^12 + (w*t^2 + w*t + 1)/(t^2 + t + w)*K.1^6 +
    w*K.1^3
```

`AnalyticDrinfeldModule(F, p)`

For F a global function field and p a place, compute an algebraic description of "the" Drinfeld modudule of rank 1 defined for the ring of functions integral outside p. More precisely, let R be the ring of functions integral outside p, ie. functions havinf their only poles at R. In MAGMA this is represented by changing the representation of the function field so that p is the only infinite place. Then R becomes simply the finite maximal order. Futhermore, let C be the completion of F at p and $\tilde{C}$ be the closure of the algebraic closure of C, thus D will play the role of the complex numbers in this theory, while C is closely related to the reals. By means of mapping R to its image in $D \subset C$, we obtain a lattice Λ of rank 1. Related to this lattice are certain exponential functions (analytic functions where the set of zeros is Λ). The transformation behaviour of such functions can be used to define a map from R to the endomorphisms of C, represented as additive (twisted) polynomials. In particular, under suitable normalisation, the lattice Λ as defined above, the transformation behaviour can be realised over the Hilbert-class field of F. Since a Drinfeld module is uniquely defined by specifying a single image of a non-constant element of R, this function returns a non-constant (as first return value) and the image as a twisted polynomial over the Hilbert-class field as a second. In case the place is of degree one, the Drinfeld module will also be sign-normalized.

`Extend(D, x, p)`

Given D, the image of a non-constant element under a Drinfeld module for the ring R of functions integral outside p, an element x in R, compute the image of x.

Example H43E5

Although the code is not restricted to genus 1 (or 2) and even though hyperelliptic function fields can be handled in a more direct fashion, we will demonstrate the computation of a Drinfeld module on an elliptic curve.
We begin by defining a curve.

```
> k<w> := GF(4);
> kt<t> := PolynomialRing(k);
> kty<y> := PolynomialRing(kt);
> F := FunctionField(y^3+w*t^5+w*t);
> Genus(F);
1
> ClassNumber(F);
3
```

Now, to define a Drinfeld module, we need to single out an "infinite" place:

```
> p := InfinitePlaces(F)[1];
> Degree(p);
1
```

Since the place p is of degree 1, our Drinfeld module will be sign-normalised.

```
> A, D := AnalyticDrinfeldModule(F, p);
```

```
> H<h> := CoefficientRing(D);
> A;
w^2/(x + 1)*F.1
> D;
T_4^2 + ((w*x^5 + 1)/(x^5 + x)*$.1^2*h^2 + (w^2*x^5 + w^2*x^4 + w^2*x
+ 1)/(x^4 + x^3 + x^2 + x)*F.1^2*h + (x^4 + x^2 + w)/(x^2 +
1)*$.1^2)*T_4 + w^2/(x + 1)*F.1
```

So, the Drinfeld module is uniquely determined by the image of a single non-constant (A) which is chosen to have maximal valuation at p and sign 1.
The values of the Drinfeld module are defined over H which is the Hilbert-class field of F, ie. the maximal abelian unramified extension where p is completely split.

```
> Sign(A, p);
1
> Valuation(A, p);
-2
```

To compute the value of "the" Drinfeld module of a different element we use `Extend`:

```
> b := F!t;
> Extend(D, b, p);
w*T_4^3 + ((w*x^20 + w*x^19 + w*x^18 + w*x^17 + w*x^16 + w*x^15 +
w*x^14 + w*x^13 + w*x^12 + w*x^11 + w*x^10 + w*x^9 + w*x^8 + w*x^7 +
w*x^6 + w*x^5 + w*x^4 + w*x^3 + w*x^2 + w*x + w)/(x^4 + x^3 + x^2 +
x)*$.1^2*h^2 + (w^2*x^20 + w^2*x^19 + w^2*x^16 + w^2*x^15 + w^2*x^4 +
w^2*x^3 + w^2)/(x^3 + x^2 + x + 1)*$.1^2*h + (x^20 + x^18 + x^12 +
x^10 + w*x^4 + w*x^2 + w^2)/(x^2 + 1)*$.1^2)*T_4^2 + ((w*x^5 + w^2*x^3
+ w^2*x^2 + x + w)/(x^2 + 1)*$.1*h^2 + (w^2*x^5 + w^2*x^4 + x^3 +
w)/(x + 1)*$.1*h + (x^5 + w^2*x^3 + w*x^2 + w^2*x)*$.1)*T_4 + x
```

To compute a "Ray-class field" from here we can use the following:

```
> P := Places(F, 2)[1];
> a,b := TwoGenerators(P);
> GCD(Extend(D, a, p), Extend(D, b, p));
T_4^2 + ((w*x^5 + 1)/(x^5 + x)*$.1^2*h^2 + (w^2*x^5 + w^2*x^4 + w^2*x
+ 1)/(x^4 + x^3 + x^2 + x)*$.1^2*h + (x^4 + x^2 + w)/(x^2 +
1)*$.1^2)*T_4 + w^2/(x + 1)*$.1 + w^2
> Polynomial($1);
T_4^16 + ((w*x^5 + 1)/(x^5 + x)*F.1^2*h^2 + (w^2*x^5 + w^2*x^4 + w^2*x
    + 1)/(x^4 + x^3 + x^2 + x)*F.1^2*h + (x^4 + x^2 + w)/(x^2 +
    1)*F.1^2)*T_4^4 + (w^2/(x + 1)*F.1 + w^2)*T_4
> R := FunctionField($1 div Parent($1).1);
> R;
Algebraic function field defined over H by
T_4^15 + ((w*x^5 + 1)/(x^5 + x)*F.1^2*h^2 + (w^2*x^5 + w^2*x^4 + w^2*x
    + 1)/(x^4 + x^3 + x^2 + x)*F.1^2*h + (x^4 + x^2 + w)/(x^2 +
```

```
    1)*F.1^2)*T_4^3 + w^2/(x + 1)*F.1 + w^2
```

This should be an abelian extension over F, ramified only at p and P. So let's try to verify that:

```
> f := MinimalPolynomial(R.1, F);
> Degree(f);
45
> Ra := FunctionField(f:Check := false);
> NormGroup(Ra:Cond := 1*p+P);
(1/x, 1/x^2*F.1) + (x^2 + x + w^2, F.1 + x + 1)
Abelian Group isomorphic to Z
Defined on 1 generator in supergroup:
    $.1 = 2*$.1 + 3*$.2 + $.3 (free)
> D, sub_group := $1;
> W := AbelianExtension(D, sub_group);
> W;
Abelian extension of type [ 3, 15 ]
Defined modulo (1/x, 1/x^2*$.1) + (x^2 + x + w^2, $.1 + x + 1)
over Algebraic function field defined over Univariate rational
function field over GF(2^2) by
y^3 + w*t^5 + w*t
> FunctionField(W);
Algebraic function field defined over F by
$.1^3 + (x + 1)^-2 * (x^2 + x + w^2)^-1 * (F.1 + w*x + w) * (F.1 +
    w^2*x + w^2)
$.1^3 + (x) * (x + 1)^-4 * (F.1 + x + 1)^2 * (x^2 + x + w^2)^-1 * (F.1
    + w*x + w) * (F.1 + w^2*x + w^2)
$.1^5 + (1/(x^2 + 1)*F.1^2 + w^2/(x + 1)*F.1 + (x^2 + x + 1))*$.1^3 +
    (w/(x^2 + 1)*F.1^2 + w*x*F.1 + (x^4 + x^2 + 1))*$.1 + (x^2 + x +
    1)/(x^2 + 1)*F.1^2 + w^2*x*F.1 + x^4 + w^2*x^2 + w*x + w^2
> WW := $1;
>  [HasRoot(Polynomial(Ra, x)) : x in DefiningPolynomials(WW)];
[ true, true, true]
```

`Exp(x,p)`

`InfBound`	RngIntElt	*Default :* 5
`Map`	Map	*Default :* id
`Class`	DivFunElt	*Default :* 0
`Limit`	RngIntElt	*Default :* ∞
`Scale`	RngElt	*Default :* `false`

In Drinfeld's theory of elliptic modules, one associates an exponential function to a lattice. The transformation of this function under scaling of the lattice gives then rise to the "Drinfeld-module". This function computes an approximation to the exponential of the "standard-lattice". More precisely: let R be the ring of functions integral outside the place p and let C be the completion of the function field at p.

Considered as a subset of C, R is a 1-dimensional lattice Λ in Drinfelds sense. The exponential associated to this lattice is the function

$$\exp : z \to z \prod{}'(1 - z/l)$$

where the product is taken over all non-zero lattice points l. This function can be seen to be an additive analytic function.

For $n > 0$, let now $L(np)$ be the Riemann-Roch spaces and

$$f_n : z \to z \prod{}'(1 - z/l)$$

(the product is over the non-zero elements of $L(np)$). It can be seen that $f_n \to \exp$ as $n \to \infty$. This intrinsic computes f_n for n equal the value of `InfBound`. If `Limit` is given then the twised polynomial representing f_n is truncated at that term. If `Class` is given and contains the divisor d, then instead of $L(np)$ we use $L(np + d)$ which will approximate a (in general) non-isomorphic exponential coming from the lattice from the ideal representing the finite part of d.

If `Map` is given, then the map is applied to each element in $L(np)$ first, thus allowing to compute analytic approximations instead of alegebraic ones. Additionally, if `Scale` is given, the elements of $L(np)$ are multiplied by this value before the functions are formed, corresponding to a scaling of the lattice.

The exponential is evaluated at x, the first argument. Typically, x will be the transcendental element of a polynomial ring, a twisted polynomial ring or a power series ring.

`AnalyticModule(x, p)`

`InfBound`	RngIntElt	*Default :* 5
`Map`	Map	*Default :* id
`Class`	DivFunElt	*Default :* 0
`Limit`	RngIntElt	*Default :* ∞
`Scale`	RngElt	*Default :* `false`

Let Λ be the lattice as described for `Exp` above. By Drinfeld's theory, the exponential functions of Λ and $x\Lambda$ are related through some polynomial. This function computed the polynomial for x, which is "the" image of x under the Drinfeld module defined by Λ. The use of the parameters is as for `Exp` above.

`CanNormalize(F)`

Let F be a twisted polynomial, typically over a completion. This function tries to conjugate F so that the coefficients are integral with small valuations. On success, `true`, the new polynomial and the element used to normalise F is returned.

`CanSignNormalize(F)`

Let F be a twisted polynomial, typically over a completion. This function tries to conjugate F so that the highest coefficient is an element in the residue class field. On success, `true`, the new polynomial and the element used to normalise F is returned.

`AlgebraicToAnalytic(F, p)`

Given a non-trivial image F under a Drinfeld module with the "infinite place" p, compute a basis for a submodule of the lattice underlying F. The parameter `RelPrec` is used to limit the number of coefficients of the exponential that are reconstructed, thus it also limits the dimenstion of the submodule.

43.7 Related Functions

This section list some related functions that are either useful in the context of class fields for function fields or are necessary for their computation. They will most certainly change their appearance.

`StrongApproximation(m, S)`

`Strict`	BoolElt	*Default :* `false`
`Exception`	DivFunElt	*Default :* `false`
`Raw`	BoolElt	*Default :* `false`

Given an effective divisor m and a sequence S of pairs (Q_i, e_i) of places and elements, find an element a and a place Q_0 such that

$$v_{Q_i}(a - e_i) \geq v_{Q_i}(m),$$

and a is integral everywhere outside Q_i $(0 \leq i \leq n)$.

If `Exception` is not `false`, it has to be a place that will be used for Q_0.

If `Strict` is `true`, the element a will be chosen such

$$v_{Q_i}(a - e_i) = v_{Q_i}(m)$$

If `Raw` is `true`, different rather technical return values are computed that are used internally.

Example H43E6

We first have to define a function field and some places:

```
> k<w> := GF(4);
> kt<t> := PolynomialRing(k);
> ktx<x> := PolynomialRing(kt);
> K := FunctionField(x^3-w*t*x^2+x+t);
```

```
> lp := Places(K, 2);
```

We will now try to find an element x in K such that $v_{p_i}(x - e_i) \geq m_i$ for $p_i =$`lp[i]`, $m_i = i$ and random elements e_i:

```
> e := [Random(K, 3) : i in lp];
> m := [i : i in [1..#lp]];
> D := &+ [ m[i]*lp[i] : i in [1..#lp]];
> x := StrongApproximation(D, [<lp[i], e[i]> : i in [1..#lp]]);
> [Valuation(x-e[i], lp[i]) : i in [1..#lp]];
[ 1, 2, 3, 4, 5, 6 ]
```

Note, that we only required $\geq$ for the valuations, to enforce $=$ we would need to pass the `Strict` option. This will double the running time.

`NonSpecialDivisor(m)`

`Exception`	DivFunElt	*Default :*

Given an effective divisor m, find a place P coprime to m and an integer $r \geq 0$ such that $rP - m$ is a non special divisor and return r and P.

If `Exception` is specified, it must be an effective divisor n coprime to m. In this case the function finds $r > 0$ such that $rn - m$ is non special and returns r and n.

`NormGroup(F)`

`Cond`	DivFunElt	*Default :*
`AS`	RngWittElt	*Default :*
`Extra`	RngIntElt	*Default :* 5

Given a global function field, try to compute its norm group. The norm group is defined to be the group generated by norms of unramified divisors. This group can be related to a subgroup of some ray class group.

Provided F is abelian, this function will compute a divisor m and a sub group U of the ray class group modulo m such that F is isomorphic to the ray class field thus defined.

This function uses a heuristic algorithm. It will terminate after the size of the quotient by the norm group is less or equal than the degree for `Extra` many places.

If `Cond` is given, it must be an effective divisor that will be used as the potential conductor of F. Note: if `Cond` is too small, ie. a proper divisor of the true conductor, the result of this function will be wrong. However, if the conductor is not passed in, the discriminant divisor is used as a starting point. As this is in general far too large, the function will be much quicker if a better (smaller) starting point is passed in.

If `AS` is given, it must be a Witt vector e of appropriate length and F should be the corresponding function field. This allows a much better initial guess for the conductor than using the discriminant.

`Sign(a, p)`

Given a function a in some global function field and a place p such that a is integral at p (has non-negative valuation) return the sign of a, ie. the first non-zero coefficient if the expansion of a at p. The sign function is not unique. MAGMA choses a sign function when creating the residue class field map.

`ChangeModel(F, p)`

Given a global function field F and a place p, return a new function field G that is $\mathbf{F}_q$-isomorphic to F and has p as the only infinite place.

43.8 Enumeration of Places

In several situations one needs to loop over the places of a function field until either the one finds a place with special properties or until they generate a certain group. The functions listed here support this.

`PlaceEnumInit(K)`

`Coprime`	ANY	*Default :*
`All`	BOOLELT	*Default :* `false`

Initialises an enumeration process for places of the function field K. The enumeration process will loop over all irreducible polynomials of the underlying finite field and for each polynomial over all primes lying above it.

If `Coprime` is given, it should be either a set of places that should be ignored in the process or a divisor. In case a divisor is passed in only places coprime to the divisor will be returned.

If `All` is `false`, the infinite places won't be considered.

`PlaceEnumInit(P)`

`Coprime`	ANY	*Default :*

Constructs an enumeration process for places starting at the place P.

If `Coprime` is given, it should be either a set of places that should be ignored in the process or a divisor. In case a divisor is passed in only places coprime to the divisor will be returned.

`PlaceEnumInit(K, Pos)`

`Coprime`	ANY	*Default :*

Constructs an enumeration environment that starts at the place of the function field K indexed by Pos as returned from `PlaceEnumPosition`.

`PlaceEnumCopy(R)`

Copies the environment and the current state of the enumeration process for places R.

`PlaceEnumPosition(R)`

Returns a list of integers that acts as an index to the places as enumerated by the environment R.

`PlaceEnumNext(R)`

Returns the "next" place of the process R.

`PlaceEnumCurrent(R)`

Returns the current place pointed to by the environment R, i.e. the last place returned by `PlaceEnumNext`.

44 ARTIN REPRESENTATIONS

Chapter 44
ARTIN REPRESENTATIONS

44.1 Overview

An *Artin representation* is a complex representation of $\mathrm{Gal}(\bar{\mathbf{Q}}/\mathbf{Q})$ that factors through some finite quotient $\mathrm{Gal}(F/\mathbf{Q})$. In MAGMA, Artin representations are represented as characters of $\mathrm{Gal}(F/\mathbf{Q})$, not the actual modules. They are allowed to be virtual, except in the L-function machinery (see Chapter 127).

44.2 Constructing Artin Representations

`ArtinRepresentations(K)`

`f`	RngUPolElt	*Default :*
`Ramification`	BoolElt	*Default :* `false`
`FactorDiscriminant`	BoolElt	*Default :* `false`
`p0`	RngIntElt	*Default :*

Compute all irreducible Artin representations that factor through the normal closure F of the number field K.

The Galois group $G = \mathrm{Gal}(F/K)$ whose representations are constructed is represented as a permutation group on the roots of `f`, which must be a monic irreducible polynomial with integer coefficients that defines K. By default this is the defining polynomial of K represented as an extension of $\mathbf{Q}$. (It is possible to specify any monic integral polynomial whose splitting field is F, even a reducible one, but `PermutationCharacter(K)` and the Dedekind ζ-function of K will not work correctly.)

The `Ramification` parameter specifies whether to pre-compute the inertia groups at all ramified primes and the conductors of all representations.

The parameter `FactorDiscriminant` determines whether to factorize the discriminant of `f` completely, even if it appears to contain large prime factors. The factorization is used to determine which primes ramify in F/K, which is necessary to compute the conductors. If the factorization is incomplete, MAGMA assumes that the primes in the unfactored part of the discriminant are unramified. One may specify `FactorDiscriminant:=`

`<TrialLimit,PollardRhoLimit,ECMLimit,MPQSLimit,Proof>` and these 5 parameters are passed to the `Factorization` function; the default behaviour (`false`) is the same as `<10000,65535,10,0,false>`. When the factorization is incomplete, MAGMA will print "(?)" following the conductor values, when asked to print an Artin representation.

Finally, p0 specifies which p-adic field to use for the roots of f, in particular in Galois group computations. It must be chosen so that GaloisGroup(f:Prime:=p0) is successful. By default it is chosen by the Galois group computation.

```
K !! ch
```

Writing F for the normal closure of $K/\mathbf{Q}$, this function converts an abstract group character of $\mathrm{Gal}(F/\mathbf{Q})$ or the sequence of its trace values into an Artin representation.

```
PermutationCharacter(K)
```

Construct the permutation representation A of the absolute Galois group of $\mathbf{Q}$ on the embeddings of K into $\mathbf{C}$. This is an Artin representation of $\mathrm{Gal}(F/\mathbf{Q})$ of dimension $[K:\mathbf{Q}]$, where F is the normal closure of K, and it is the same as the permutation representation of $\mathrm{Gal}(F/\mathbf{Q})$ on the cosets of $\mathrm{Gal}(F/K)$.

```
Determinant(A)
```

Construct the determinant of a given Artin representation. The result is given as a 1-dimensional Artin representation attached to the same field.

```
ChangeField(A,K)
```

```
K !! A
```

MinPrimes RngIntElt *Default :* 20

Given an Artin representation (attached to some number field) that is known to factor through the Galois closure of K, attempts to recognize it as such. Returns "the resulting Artin representation attached to K", true if successful, and 0, false if it proves that there is no such representation. The parameter MinPrimes specifies the number of additional primes for which to compare traces of Frobenius elements.

Example H44E1

A quadratic field K has two irreducible Artin representations the factor through $\mathrm{Gal}(K/\mathbf{Q})$, the trivial one and the quadratic character of K:

```
> K<i> := QuadraticField(-1);
> triv, sign := Explode(ArtinRepresentations(K));
> sign;
Artin representation of Quadratic Field with defining polynomial x^2 + 1
over the Rational Field with character ( 1, -1 )
```

An alternative way to define them is directly by their character:

```
> triv,sign:Magma;
QuadraticField(-1) !! [1,1]
QuadraticField(-1) !! [1,-1]
```

The regular representation of $\mathrm{Gal}(K/\mathbf{Q})$ is their sum:

```
> PermutationCharacter(K);
```

```
Artin representation of Quadratic Field with defining polynomial z^2 + 1
over the Rational Field with character ( 2, 0 )
> $1 eq triv+sign;
true
```

Next, let $L = K(\sqrt{-2-i})$. Then L has normal closure F with $\mathrm{Gal}(F/\mathbf{Q}) = D_4$, the dihedral group of order 8:

```
> L := ext<K|Polynomial([2+i,0,1])>;
> G := GaloisGroup(AbsoluteField(L));
> IsIsomorphic(G,DihedralGroup(4));
true
> [Dimension(A): A in ArtinRepresentations(L)];
[1, 1, 1, 1, 2 ]
```

We use `ChangeField` to lift Artin representations from $\mathrm{Gal}(K/\mathbf{Q})$ to $\mathrm{Gal}(F/\mathbf{Q})$, and check that it is still the same as an Artin representation.

```
> A := ChangeField(sign,L);
> A;
Artin representation of Number Field with defining polynomial $.1^2 + i + 2
over its ground field with character ( 1, 1, -1, 1, -1 )
> A eq sign;
true;
```

44.3 Basic Invariants

`Field(A)`

Number field K such that A factors through the Galois group of the normal closure of K.

`Degree(A)`

Degree (=dimension) of an Artin representation A.

`Group(A)`

The Galois group of the field through which A factors.

`Character(A)`

Character of an Artin representation A, represented as a complex-valued character of `Group(A)`.

`Conductor(A)`

Conductor of an Artin representation A (which must be a true representation, i.e. its character is not allowed to be a generalized character). Computes all the necessary local information if Artin representations were defined with `Ramification:=false`, so the first call to this function might take some time.

`Decomposition(A)`

Decompose an Artin representation A into irreducible constituents. Returns a sequence of tuples `[...<`A_i`,`n_i`>...]` with A_i irreducible and n_i its exponent in A (nonzero but possibly negative).

`DefiningPolynomial(A)`

Returns the polynomial whose roots `Group(A)` permutes.

`Minimize(A)`

`Optimize` BoolElt *Default :* `true`

Returns A attached to the smallest number field K such that A factors through its Galois closure. If `Optimize := true`, attempts to minimize the defining polynomial of K using `OptimizedRepresentation`.

`Kernel(A)`

Smallest Galois extension K of the rationals through which A factors. Note that this field may be enormous and incomputable.

Example H44E2

We take an S_4-extension of $\mathbf{Q}$ and compute its Artin representations.

```
> R<x> := PolynomialRing(Rationals());
> K := NumberField(x^4+9*x-2);
> A := ArtinRepresentations(K);
> [Dimension(a): a in A];
[ 1, 1, 2, 3, 3 ]
```

Then we minimize the 2-dimensional one, which factors through an S_3-quotient.

```
> B := Minimize(A[3]); B;
Artin Representation of Number Field with defining polynomial x^3 + 8*x - 81
over the Rational Field with character ( 2, 0, -1 )
> Kernel(B);
Number Field with defining polynomial x^6 + 48*x^4 + 576*x^2 + 179195 over the
Rational Field
```

`IsIrreducible(A)`

Return `true` iff a given Artin representation is irreducible as a complex representation.

`IsRamified(A, p)`

Return `true` iff a given Artin representation is ramified at p.

`IsWildlyRamified(A, p)`

Return `true` iff a given Artin representation is wildly ramified at p.

`EulerFactor(A, p)`

`R` FLD *Default :* `ComplexField()`

The local polynomial (Euler factor) of an Artin representation A at the prime p. It is a polynomial with coefficients in the field R, which is complex numbers by default, and it is the inverse characteristic polynomial of (arithmetic) Frobenius at p on the inertia invariant subspace of A.

Example H44E3

Here are the invariants of Artin representations that factor through the splitting field of $x^4 - 3$, a D_4-extension of $\mathbf{Q}$.

```
> R<x> := PolynomialRing(Rationals());
> K := NumberField(x^4-3);
> A := ArtinRepresentations(K);
> Degree(Field(A[1]),Rationals());
8
> [Dimension(a): a in A];
[ 1, 1, 1, 1, 2 ]
> Character(A[5]);
( 2, -2, 0, 0, 0 )
> [Conductor(a): a in A];
[ 1, 3, 4, 12, 576 ]
> [IsRamified(a,3): a in A];
[ false, true, false, true, true ]
> [IsWildlyRamified(a,3): a in A];
[ false, false, false, false, false ]
> EulerFactor(A[5],5);
$.1^2 + 1.00000000000000000000000000000
```

`DirichletCharacter(A)`

Convert a one-dimensional Artin representation to a Dirichlet character.

`ArtinRepresentation(ch)`

`field` FLDNUM *Default :*

Convert a Dirichlet character `ch` to a one-dimensional Artin representation A. To avoid recomputation, the minimal field through which A factors may be supplied by the `field` parameter. This now uses class field theory (thanks to C. Fieker).

Example H44E4

An example that goes back and forth between the Dirichlet character and the Artin representation.

```
> load galpols;
> f := PolynomialWithGaloisGroup(8,46); // order 576
> K := NumberField(f); // octic field
> A := ArtinRepresentations(K);
> [Degree(a) : a in A];
[ 1, 1, 1, 1, 4, 4, 6, 6, 9, 9, 9, 9, 12 ]
> [Order(Character(Determinant(a))) : a in A];
[ 1, 2, 4, 4, 2, 2, 1, 2, 2, 1, 4, 4, 2 ]
> chi := DirichletCharacter(A[3]); // order 4
> Conductor(chi), Conductor(chi^2);
215 5
> Minimize(ArtinRepresentation(chi)); // disc = N(chi)^2*N(chi^2)
Artin representation of Number Field with defining polynomial
 x^4 - x^3 - 54*x^2 + 54*x + 551 with character ( 1, -1, I, -I )
> Factorization(Discriminant(Integers(Field($1))));
[ <5, 3>, <43, 2> ]
```

44.4 Arithmetic

`A1 + A2`

Direct sum of two Artin representations

`A1 - A2`

Direct difference of two Artin representations

`A1 * A2`

Tensor product of two Artin representations

`A1 eq A2`

Returns `true` iff the two Artin representations are equal

`A1 ne A2`

Returns `true` iff the two Artin representations are not equal

Example H44E5

For Artin representations constructed from the same number field, their arithmetic is just arithmetic of characters:

```
> P<x> := PolynomialRing(Rationals());
> K := NumberField(x^3-2);
> A := ArtinRepresentations(K: Ramification:=true);
> triv, sign, rho := Explode(A);
> triv;
Artin representation of Number Field with defining polynomial
x^3 - 2 over the Rational Field with character ( 1, 1, 1 )
and conductor 1
> rho;
Artin representation of Number Field with defining polynomial
x^3 - 2 over the Rational Field with character ( 2, 0, -1 )
and conductor 108
> triv+rho;
Artin representation of Number Field with defining polynomial
x^3 - 2 over the Rational Field with character ( 3, 1, 0 )
and conductor 108
> sign*rho eq rho;
true
```

Example H44E6

When Artin representations factor through different fields, their arithmetic involves the compositum of the fields:

```
> K1 := QuadraticField(2);
> triv1, sign1 := Explode(ArtinRepresentations(K1));
> K2 := QuadraticField(3);
> triv2, sign2 := Explode(ArtinRepresentations(K2));
> twist := sign1*sign2;
> Field(twist);
Number Field with defining polynomial $.1^4 - 10*$.1^2 + 1
over the Rational Field
> sign3 := Minimize(twist);
> sign3;
Artin representation of Number Field with defining polynomial
$.1^2 - 6 over the Rational Field with character ( 1, -1 )
> sign1*sign2*sign3 eq triv1;
true
```

44.5 Implementation Notes

The algorithms for recognizing Frobenius elements in Galois groups are described in [DD10]. They rely on the cycle type identification, Serre's trick for alternating groups and the general machinery from [DD10]. MAGMA is usually able to handle Galois groups of size < 10000 acting on a small number of points easily, and much larger special groups such as A_n and S_n.

PART VII
LOCAL ARITHMETIC FIELDS

45 VALUATION RINGS

Chapter 45
VALUATION RINGS

45.1 Introduction

MAGMA currently supports basic operations in valuation rings obtained either from the rational field $\mathbf{Q}$ (and a finite prime p), or from a field of rational functions over a field (and an irreducible polynomial, or the infinite prime).

45.2 Creation Functions

45.2.1 Creation of Structures

`ValuationRing(Q, p)`

Given the rational field Q and a rational prime number p, create the valuation ring R corresponding to the discrete non-Archimedean valuation v_p, consisting of rational numbers r such that $v_p(r) \geq 0$, that is, $r = \frac{x}{y} \in \mathbf{Q}$ such that $p \not| y$.

`ValuationRing(F, f)`

Given the rational function field F as a field of fractions of the univariate polynomial ring $K[x]$ over a field K, as well as a monic irreducible polynomial $f \in K[x]$, create the valuation ring R corresponding to the discrete non-Archimedean valuation v_f. Thus R consists of rational functions $\frac{g}{h} \in F$ with $v_f(g/h) \geq 0$, that is, with $f \not| h$.

`ValuationRing(F)`

Given the rational function field F as a field of fractions of the univariate polynomial ring $K[x]$ over a field K, create the valuation ring R corresponding to v_∞, consisting of $\frac{g}{h} \in F$ such that $\deg(h) \geq \deg(g)$.

45.2.2 Creation of Elements

`V ! r`

Given a valuation ring V and an element of the field of fractions F of V (from which V was created), coerce the element r into V. This is only possible for elements $r \in F$ for which the valuation on V is non-negative, an error occurs if this is not the case.

45.3 Structure Operations

45.3.1 Related Structures

`Category(V)` `Parent(V)` `PrimeRing(V)` `Center(V)`

`FieldOfFractions(V)`

Return field of fractions of the valuation ring V, which is the rational field or the function field from which V was created.

45.3.2 Numerical Invariants

`Characteristic(V)`

45.4 Element Operations

45.4.1 Arithmetic Operations

`+ v` `- v`

`v + w` `v - w` `v * w` `v ^ k` `v / w`

`v +:= w` `v -:= w` `v *:= w`

`v div w`

The quotient q of the division with remainder $v = qw + r$ of the valuation ring elements v and w, where the remainder will have valuation less than that of w; if the valuation of v is greater than or equal than that of w, this simply returns the quotient v/w, if the valuation of w exceeds that of v it returns 0.

45.4.2 Equality and Membership

`v eq w` `v ne w`

`v in V` `v notin V`

45.4.3 Parent and Category

`Parent(v)` `Category(v)`

45.4.4 Predicates on Ring Elements

`IsZero(n)` `IsOne(n)` `IsMinusOne(n)`
`IsNilpotent(n)` `IsIdempotent(n)`
`IsUnit(n)` `IsZeroDivisor(n)` `IsRegular(n)`

45.4.5 Other Element Functions

`EuclideanNorm(v)`
`Valuation(v)`

Given an element v of a valuation ring V, return the valuation (associated with V) of v.

`Quotrem(v, w)`

Given two elements v, w of a valuation ring V with associated valuation ϕ, return a quotient and remainder q and r in V such that $v = qw + r$ and $0 \leq \phi(r) < \phi(w)$. If $\phi(v) < \phi(w)$ this simply returns $q = 0$ and $r = v$, and if $\phi(v) \geq \phi(w)$ then it returns $q = v/w$ and $r = 0$.

`GreatestCommonDivisor(v, w)`
`Gcd(v, w)`

This function returns a greatest common divisor of two elements v, w in a valuation ring V. This will return u^m, where $m = \min(\phi(v), \phi(w))$ is the minimum of the valuations of v and w $m = \min(\phi(v), \phi(w))$ and u is the uniformizing element of V (with valuation $\phi(u) = 1$).

`ExtendedGreatestCommonDivisor(v, w)`
`Xgcd(v, w)`
`XGCD(v, w)`

This function returns a greatest common divisor $z \in V$ of two elements v, w in a valuation ring V as well as multipliers $x, y \in V$ such that $xv + yw = z$. The principal return value will be $z = u^m$, where $m = \min(\phi(v), \phi(w))$ is the minimum of the valuations of v and w $m = \min(\phi(v), \phi(w))$ and u is the uniformizing element of V (with valuation $\phi(u) = 1$).

46 NEWTON POLYGONS

Chapter 46
NEWTON POLYGONS

46.1 Introduction

This chapter introduces functions which allow the creation and simple study of Newton polygons. It allows data from a number of different contexts to be used to construct the polygons. It also covers different interpretations of Newton polygons, and translation among these interpretations. Recall that a Newton polygon is the intersection of finitely many rational half spaces in the rational plane. An advantage of this definition is that it emphasizes that Newton polygons are often thought of as being noncompact. However, they are not implemented here in this way. Instead polygons are interpreted as the convex hull of finitely many points of the plane (possibly including some points at $+\infty$ along the axes).

Any Newton polygon is contained in some virtual cartesian product of the rational field with itself (virtual since this plane is not a structure that is intended to be accessible to the user or which is characteristic of the polygon). The first and second coordinate functions of this plane are referred to as the x and y coordinates respectively. Points of the plane will always be written $\langle a, b\rangle$ while faces of polygons will be written $\langle a, b, c\rangle$. Geometrically, a face $\langle a, b, c\rangle$ is a one-dimensional boundary intersection of N with the line $ax + by = c$.

The *standard Newton polygon* of a polynomial $f = f(u, v)$ is, by definition, the convex hull of the points $\langle a, b\rangle$, so-called *Newton points*, ranging over monomials $u^a v^b$ having nonzero coefficient in f together with the points $+\infty$ on the two axes. The infinite points, however, are not listed among the vertices of the polygon; they are simply a convenient way of hiding all Newton points other than those on the 'lower lefthand' faces of the hull of those points. A similar definition applies to polynomials $f(y)$ whose coefficients lie in some field of fractional power series, or *Puiseux field*, $k\langle\langle x\rangle\rangle$. Newton Polygons can also be created for polynomials over local rings (and fields). The defining points are computed as $\langle i, v(a_i)\rangle$ where a_i is the coefficient of the i-th power of the generator and v denotes the valuation function on the ring. Infinite points arise only as the valuation of zero coefficients.

The main intended application of Newton polygons is to the Newton–Puiseux analysis of singular points of plane curves, or put another way, the factorization of polynomials defined over Puiseux fields.

The examples below should be thought of as running consecutively in a single MAGMA session.

```
> R<x,y> := PolynomialRing(Rationals(),2);
> f := x^5 + x^2*y + x^2*y^3 + y^4 + x^3*y^5 + y^2*x^7;
> N := NewtonPolygon(f);
> N;
Newton Polygon of x^7*y^2 + x^5 + x^3*y^5 + x^2*y^3 + x^2*y + y^4 over
```

```
Rational Field
> Faces(N);
[ <3, 2, 8>, <1, 3, 5> ]
> Vertices(N);
[ <0, 4>, <2, 1>, <5, 0> ]
```

This is the standard Newton polygon associated with the polynomial f. Only those vertices and faces of the convex hull of points which correspond to the monomials appearing in f which 'face' the origin are considered to be vertices and faces of the polygon. As already mentioned, one interpretation of this is to think of the points $+\infty$ on each axis as being included among the defining points of N, and then N is the convex hull of its defining points.

To consider N as the compact convex hull of only the monomials of f simply use alternative vertex and face functions.

```
> AllVertices(N);
[ <0, 4>, <2, 1>, <5, 0>, <7, 2>, <3, 5> ]
> AllFaces(N);
[ <3, 2, 8>, <1, 3, 5>, <-1, 1, -5>, <-3, -4, -29>, <1, -3, -12> ]
```

However, where there is a choice of interpretation, MAGMA always interprets N in the way it was defined. So for example, the functions which test for faces and vertices compare a given value with the sequence returned by the functions `Faces(N)` or `Vertices(N)`, which are fixed the first time they are calculated, rather than with any other collections of faces or vertices.

```
> IsFace(N,<3/4,3/6,2>);
true <3, 2, 8>
> IsFace(N,<-3,-4,-29>);
false
```

Notice that faces are reduced to normal integral form and that the correct form is returned as the second return value of the test function.

When a polygon is created using a polynomial, the restriction of the polynomial to faces is important characteristic data.

```
> FaceFunction(Faces(N)[1]);
x^2*y + y^4
```

The face function is simply the sum of those monomial terms of f (they keep their coefficients) whose corresponding Newton point lies on the given face.

46.2 Newton Polygons

All polygons are determined by a finite collection of points in the rational plane. For MAGMA, these points are the most basic attribute of any Newton polygon. They are always determined and recorded on creation of a polygon. Throughout this chapter, for a Newton polygon N, these points are denoted by P_N. As seen in the introduction, the main class of polygons is that comprising polygons in the first quadrant of the plane and including the points $+\infty$ on the two axes. But there are other useful types, especially when calculating factorizations of univariate polynomials over series rings. The data distinguishing the different flavours of Newton polygon is the collection of lines and points that are considered to be faces and vertices.

46.2.1 Creation of Newton Polygons

These are the functions available for constructing Newton polygons and retrieving the points which describe them.

`NewtonPolygon(f)`

`Faces`	MONSTGELT	*Default :* "*Inner*"

The standard Newton polygon of a polynomial f in two variables. This is the hull of the Newton points of the polynomial together with the points $+\infty$ on each axis. The horizontal and vertical 'end' faces are not listed among the faces of the polygon; the points at infinity are not listed among the vertices of the polygon.

The parameter `Faces` can have the value `"Inner"`, `"Lower"` or `"All"`. This determines which faces are returned by the intrinsic `Faces`.

`NewtonPolygon(f)`

`SwapAxes`	BOOLELT	*Default :* `false`
`Faces`	MONSTGELT	*Default :*

The standard Newton polygon of a polynomial in one variable defined over a series ring or a local ring or field. A value of `true` for `SwapAxes` is only valid if the polynomial is over a series ring. If `SwapAxes` is set to `true` then the exponents of the series variable will be plotted on the horizontal axis and the exponents of the polynomial on the vertical axis.

For a polynomial over a series ring, the hull includes the points $+\infty$ on each axis. For a polynomial over a local ring, the infinite points are not included.

The parameter `Faces` can have the value `"All"`, `"Inner"` or `"Lower"`. This determines which faces are returned by the intrinsic `Faces`. The default for series rings is `"Inner"` and for local rings is `"Lower"`.

`NewtonPolygon(f, p)`

`Faces`	MONSTGELT	*Default :* "*Inner*"

The newton polygon of f where p is a prime used for valuations of the coefficients of f. The polynomial f may be over the integers or rationals or a number field or

algebraic function field or an order thereof. The prime p may be an integer or a prime ideal. The newton polygon will have points (i, v_i) where i is the exponent of a term of f and v_i is the valuation of the coefficient of the ith term. The points at $+\infty$ on each axis are included.

The parameter `Faces` can have the value `"Inner"`, `"Lower"` or `"All"`. This determines which faces are returned by the intrinsic `Faces`.

`NewtonPolygon(f, p)`

`Faces` MonStgElt *Default : "Inner"*

The newton polygon of the polynomial f where the place p of an algebraic function field is the prime used for determining the valuations of the coefficients of f. The points at $+\infty$ on each axis are included.

The parameter `Faces` can have the value `"Inner"`, `"Lower"` or `"All"`. This determines which faces are returned by the intrinsic `Faces`.

`NewtonPolygon(C)`

The standard Newton polygon of the defining polynomial of the curve C.

`NewtonPolygon(V)`

`Faces` MonStgElt *Default : "All"*

The Newton polygon that is the compact convex hull of the set or sequence V of points of the form $\langle a, b\rangle$ where a, b are integers or rational numbers.

The parameter `Faces` can have the value `"All"`, `"Lower"` or `"Inner"`. This determines which faces are returned by the intrinsic `Faces`.

`DefiningPoints(N)`

The points of the rational plane used in the initial creation of N. Applying this function to two polygons allows their defining points to be compared. No explicit function is provided for testing whether defining points of two polygons are equal.

Example H46E1

Some ways of creating Newton Polygons from polynomials are shown below.

```
> P<y> := PuiseuxSeriesRing(Rationals());
> R<x> := PolynomialRing(P);
> f := 3*x^4 + (5*y^3 + 4*y^(1/4))*x^3 + (7*y^2 + 1/2*y^(1/3))*x^2 + 6*x + y^(
> 4/5);
> N := NewtonPolygon(f);
> N;
Newton Polygon of 3*x^4 + (4*y^(1/4) + 5*y^3)*x^3 + (1/2*y^(1/3) + 7*y^2)*x^2 +
6*x + y^(4/5) over Puiseux series field in y over Rational Field
> P<x> := PolynomialRing(Integers());
> L := ext<ext<pAdicRing(5, 100) | 3> | x^2 + 5>;
> R<x> := PolynomialRing(L);
> f := 3*x^4 + 75*x^3 + 78*x^2 + 10*x + 750;
```

```
> NR := NewtonPolygon(f);
> NR;
Newton Polygon of 3*x^4 + 75*x^3 + 78*x^2 + 10*x + 750 over L
```

Newton Polygons can also be created by specifying the defining points that the polygon must enclose.

```
> N2 := NewtonPolygon({<2, 0>, <0, 3>, <4, 1>});
> N2;
Newton Polygon with defining points {(0, 3), (2, 0), (4, 1)}
> N6 := NewtonPolygon({<1, 4>, <1, 6>, <2, 4>, <3, 1>, <6, 1>, <5, 2>, <4, 5>,
> <4, 7>, <6, 6>, <7, 7>, <2, 7>, <5, 9>, <8, 4>, <8, 6>, <8, 8>, <7, 9>});
> N6;
Newton Polygon with defining points {(1, 4), (1, 6), (2, 4), (2, 7), (3, 1), (4,
5), (4, 7), (5, 2), (5, 9), (6, 1), (6, 6), (7, 7), (7, 9), (8, 4), (8, 6), (8,
8)}
```

These polygons will be referred to in later examples.

46.2.2 Vertices and Faces of Polygons

Both the vertices $\langle a, b\rangle$ and faces $\langle a, b, c\rangle$ (representing $ax + by = c$) of a given polygon N are computed as needed. As seen above, these will be a particular choice of possible faces and vertices determined by the data used to create the polygon. They can be recovered using the `Faces()` and `Vertices()` intrinsics. A different choice of faces and vertices, those faces and vertices of the compact convex hull of the defining points say, can be made using the other intrinsics below.

Recall that P_N denotes the set of points used in the definition of the Newton polygon N whether they arise as the powers of monomials appearing in a polynomial or have been given explicitly as a sequence of pairs.

`Faces(N)`

The sequence of faces $\langle a, b, c\rangle$ (representing $ax + by = c$) of N listed anticlockwise. How this is interpreted in terms of the points used to create N depends on the creation function used (see Section 46.2.1). The faces are listed anticlockwise starting with the face with its left endpoint being the lowest of the leftmost points.

`InnerFaces(N)`

Those faces of the compact convex hull of P_N starting at the lowest of the leftmost points which have strictly negative gradient.

`LowerFaces(N)`
